INTRODUCTION

The personal dosemeter system of IPEN is based on film dosimetry. Personal doses at IPEN are mainly due to X or gamma radiation.

The use of personal photographic dosemeters involves two steps: firstly, data acquisition including their evaluation with respect to the calibration quantity and secondly, the interpretation of the data in terms of effective dose .

The effective dose was calculated using artificial intelligence techniques by means of neural network. The learning of the neural network was performed by taking the readings of optical density as a function of incident energy and exposure from the calibration curve (1). The obtained output in the daily grind is the mean effective energy and the effective dose .

MATERIALS AND METHODS

The photographic dosemeters used at IPEN are made up of two parts:
a) the Personal Monitoring 2/10 film (Agfa - Gevaert), consisting of two emulsions. b) the holder (badge) containing four filters (plastic, lead, copper and cadmium) and an open window. The area of the filters is sufficiently large to avoid edge effects.

The irradiations were performed using a ^{60}Co (1.0 GBq) ,^{137}Cs(53 TBq) and a X-ray machine Stabilipan model 250 Siemens.The quality control was carried out using a ^{14}C plane source.

The measurement of radiographic film density was performed using a transmission densitometer MacBeth TD 904.

The calibration curves (OD x Exposure) were ploted out as a function of the radiation energy for each filter of the badge. In this case , for each lecture **j** , due to a certain filter, it is possible to construct a family of response curves of OD (d_{ij}) as a function of Exposure (X_i) for each energy value (2).

NEURAL NETWORK STRUCTURE

Different structures of neural networks can be used, each one associated with one application. In this work it was used the backpropagation paradigma, were the neuronios are arranjed in layers: input, output and intermediate layers as shown in Fig. 1 In this work it was used the Neural Works Professional II/Plus software (3,4).

All values used for the network training are the average of five lectures.

For the training of the network the data were arranjed as a matrix as shown bellow . The matrix was presented to the network 10^6 times, during 30h in a PC-AT 486. The obtained average square error was less than 0.1%.

Different from the training, the use of the trained network is very fast, only a fraction of seconds (5).

In order to apply the trained network it was developed a software in Visual Basic Language for Windows.

IMPROVEMENT OF A BETA/GAMMA DOSE RATE METER FOR MEASURING $\dot{H}^*(10)$ AND $\dot{H}'(0.07)$

J. Pillath, S. Colak, H. Dederichs, M. Heinzelmann, G. Opladen

Forschungszentrum Jülich GmbH — ASS, Leo-Brandt-Straße, D-52425 Jülich, Germany

The portable dose rate meter DL 1 was developed at the Research Centre Jülich approx. 14 years ago for measuring the area dose rate in mixed β-γ-radiation fields. This instrument with a small ionization chamber is particulary well suited for measurements near contaminated surfaces where the contribution of β-radiation to the dose rate can be very high.
An adaption of the device is required for measuring the new operational quantities $\dot{H}'(0.07)$ and $\dot{H}^*(10)$. Ionization chambers of different configuration were tested. By a suitable choice of the chamber form and wall material it is possible to measure $\dot{H}'(0.07)$ for β-radiation within $\pm$ 20 % for energies from 0.23 to 2.2 MeV and up to angles of incidence of 60°. $\dot{H}^*(10)$ is determined within $\pm$ 20 % for photons with energies > 50 keV. Furthermore, the microphonic effect was reduced.

INTRODUCTION

In handling unsealed radioactive sources, the skin dose due to the β radiation can exceed many times that caused by γ radiation. For measurements in mixed β-γ radiation fields, the portable β-γ dose rate meter DL 1 was developed at the Research Centre Jülich approximately 14 years ago [1]. Its detector is a small (15 cm^3) thin-walled ionization chamber suitable for measuring the dose rate especially near contaminated surfaces. For β radiation the dose rate is determined at 70 μm tissue depth. An additional build-up cap serves to measure the photon dose equivalent rate for γ radiation.
Due to the planned introduction of the new operational quantities *directional dose equivalent* $H'(0.07)$ and *ambient dose equivalent* $H^*(10)$ [2] it is necessary to modify the above dose rate meter. Apart from an energy-independent response with respect to either $\dot{H}'(0.07)$ or $\dot{H}^*(10)$ particular attention was paid to a response independent of the direction of radiation incidence. Whereas in the past an isotropic response was also demanded for β radiation fields, investigations into the new operational quantities revealed a quite pronounced dependence of the dose rate on the angle of incidence [3]. Depending on the energy of β radiation, both higher and lower values can be obtained for the dose rate in the case of inclined radiation incidence relative to vertical incidence (e.g. the response is 15 % higher for an angle of incidence of 60° than of 0° in case of $^{90}Sr/^{90}Y$ β radiation).
Based on the existing measurement system, new chamber configurations were designed according to basic physical and geometrical principles, constructed and subsequently tested in β and γ radiation fields. The response with respect to $\dot{H}'(0.07)$ and $\dot{H}^*(10)$ was optimized by successively improving the configuration.

EXPERIMENTAL

Work was aimed at determining the operational quantity $\dot{H}'(0.07)$ within $\pm$ 20 % for maximum β energies between 0.2 MeV and 2 MeV and for angles of incidence up to 60° [3]. An isotropic response with respect to $\dot{H}^*(10)$ within $\pm$ 20 % was also demanded for photon radiation with energies > 60 keV. Investigations concerning the response with respect to $\dot{H}'(0.07)$ for β radiation were carried out using the β secondary standard [4] with three different β emitters (^{147}Pm, 0.23 MeV; ^{204}Tl, 0.765 MeV; $^{90}Sr/^{90}Y$, 2.2 MeV). $\dot{H}^*(10)$ was measured at an X-ray unit with filtration for radiation quality A [5]. The reference for all data specified is the response to ^{137}Cs γ radiation (662 keV).
Our investigations were based on the existing dose rate meter DL 1, at which the different chamber

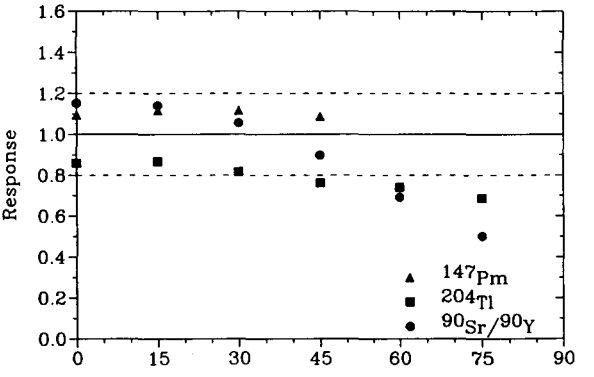

Fig. 2b

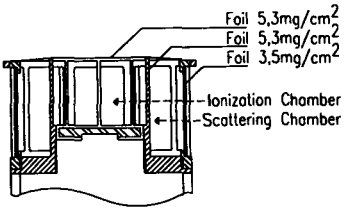

Fig. 3a Final chamber configuration

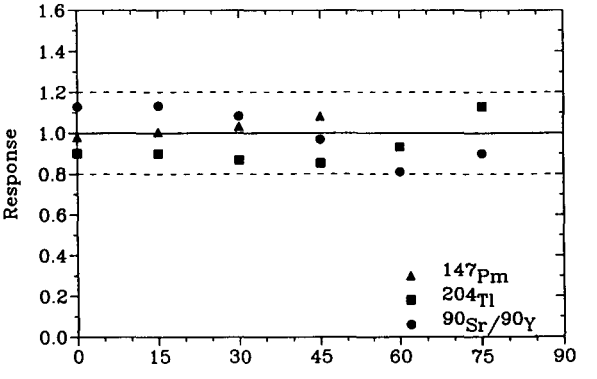

Fig. 3b

Fig. 1-3 Different chamber configurations (a) and related response with respect to Ḣ'(0.07) (b) as a function of radiation incidence

types were tested. The range of the instrument extends from 1 mSv/h (full scale) to 10 Sv/h in five measuring ranges. This also applies to the chamber types described below since the active measuring volume was kept approximately constant.

The original DL 1 ioniziation chamber (Fig. 1a) is formed by an aluminium cage with lateral windows and one end window, which are covered by an electrically conductive plastic foil with a mass/unit area of 7 mg/cm^2. In this chamber, as well as in the other types, the outer wall of the measurement chamber forms the cathode and a graphite disk of 25 mm diameter the collecting anode. The response with respect to $\dot{H}'(0.07)$ of this chamber is shown in Fig. 1b. It displays an inadmissibly strong dependence especially on the angle of incidence. Various experiments with a changed geometry of the measurement chamber as well as variations of the foil thickness did not initially yield any significant improvement.

In order to achieve a better adaptation of the response with respect to $\dot{H}'(0.07)$, it was attempted to adapt the measuring principle to real exposure conditions, where laterally scattered radiation in the upper layer of the skin increases the dose rate in the radiation-sensitive basal layer of the epidermis. On the basis of these considerations, the original chamber was first enclosed in a very large additional scattering chamber (19 cm diameter). The optimum front wall proved to be a plastic foil with a mass/unit area of 7 mg/cm^2. This configuration enabled $\dot{H}'(0.07)$ to be measured within $\pm$ 15 % for β radiation independent of energy up to an angle of incidence of 75°. Due to the size of the scattering chamber, however, this configuration is not suitable for practical application.

In a next step, therefore, the diameter of the scattering chamber was reduced (Fig. 2a). Shading of the bulk lateral walls deteriorated the response for larger angles of incidence (Fig. 2b).

A reduction in height of the lateral walls of the scattering chamber can reduce this shading effect. It proved to be difficult, however, to cover the scattering chamber with a foil, since it was practically impossible to avoid wrinkling.

This problem can be solved by a scattering chamber with high lateral walls with twelve windows that are covered with a plastic foil (Fig. 3a). The energy dependence of the response was optimized for β radiation by varying the individual foil thicknesses (Fig. 3b).

For this chamber configuration, the response to photon radiation as a function of energy was determined using an additional 10 mm thick build-up cap made of PMMA. The required tolerance of $\pm$ 20 % is also maintained here. The dependence on the angle of incidence also shows deviations within $\pm$ 20 % from the target value up to angles of 60°.

As an additional effect, the measurement chamber is protected by the scattering chamber against vibration due to sudden air pressure fluctuations. This leads to a considerable reduction of microphonic effects.

CONCLUSIONS

An additional scattering chamber around the measurement chamber allows the determination of $\dot{H}'(0.07)$ within $\pm$ 20 % for β radiation with energies from 0.23 MeV to 2.2 MeV and for angles of incidence up to 60°. A build-up cap ensures that by measuring $\dot{H}^*(10)$ the response to photon radiation is also constant within $\pm$ 20 % for energies > 50 keV.

SILICON STRIP DETECTORS FOR DETERMINATION OF RADIONUCLIDES IN VARIOUS SUBSTANSES

P.Litovchenko , V.Pugatch, L.Barabash, O.Zinets , Yu.Pavlenko, A.Rosenfeld

Institute for Nuclear Research, Kiev, Ukraine

Abstract. Silicon strip detectors for the coordinate determination of short-range particles can be effectively used for measurements of radionuclide spectra in various substances because of their high energy resolution. In comparison with usual detectors they have much lower noise level at the same value of the sensitive area.

INTRODUCTION

Silicon strip defectors are widely used for the coordinate determination of ionizing particles in high energy physics (1-3). They were also applied for measurements of alpha-particles spectra with high spatial resolution (3-6]). Strip detectors allow to obtain higher energy resolution in comparison with usual large area detectors (for instance , surface barrier detectors) because the capacitance and reverse current of a strip, which determine the energy resolution , are much smaller than those of usual detectors. In the present communication the main attention is paid to measurements of energy spectra of alpha -active nuclides by silicon strip detectors.

DETECTOR FABRICATION

Detectors were fabricated on the base of (111) oriented wafers of high resistivity n-type silicon. The p^+-n junction were made by the ion implantation of boron and rearside n^+ -n junction was obtained by the ion implantation of phosphorus with subsequent aluminium metallization (aluminium layer thickness was 0.3 μm). Passivating SiO_2 layers have thickness 0.15 - 0.20 μm . Some other characteristics of silicon strip detectors are presented in Table 1.

Table 1. Characteristics of fabricated strip detectors.

*)the annular strip detectors.
**)Strip length and capacitance are dependent on the strip radius.

RESULTS AND DISCUSSION

The experimental set up and the measurement technique were described in details in ref .(3). Fabricated detectors were tested with alpha sources ^{226} Ra , ^{241} Am and minimum ionizing particles (m.i.p.) from sources ^{106}Ru and ^{90}Sr + ^{90}Yr .

Fig. 1 shows the result of measurements of charges Q_i and Q_{i+1} collected at two neighboring strips. The total charge collected at the strips $Q = Q_i + Q_{i+1} = const(E)$ represents events from particles of the same fixed energy *E*. Charge generated in the detector by short-range particles (alpha particles of ^{226} Ra and ^{241}Am) was collected at one or two strips. Hence, the capacitance and the reverse current for strip detectors are much smaller than those for usual detectors with the same total sensitive area.Four loci in Fig.1 correspond to the following alpha particle energies 7.69, 6.0 , 5.49 and 4.82 MeV (^{226} Ra source) .

Noise of detectors strongly depends on the capacitance and reverse currents of strips. The strip capacitance C at applied voltage V in the case $V < V_{depl}$ (V_{depl} is the full depletion voltage) is equal to (see ref.(7))

$$C = 1.054\ S/d\ ,\ d = (2\varepsilon\mu_e\rho V)^{1/2}\ ,\ V_{depl} = w^2/(2\varepsilon\mu_e\rho)\ ,$$

where $\varepsilon = 1.054\ 10^{-12}$ F cm^{-1}, μ_e is the electron mobility, ρ -is the silicon resistivity, S is the strip area. d - is the depletion layer thickness. The main contribution to the reverse current of a strip gives the generation- recombination current (7)

$$I_{gen} = qn_i\Omega/(2\tau)\ ,$$

where q is the elementary charge, n is the intrinsic concentration, τ is the lifetime, $\Omega = Sd$ is the volume of the depleted region.

Capacitances and reverse currents in strip detectors are in S_{strip}/S_{total} times smaller than in large area detectors , so one can expect a higher energy resolution for strip detectors. However, a real gain was smaller because a limiting factor was the input capacitance of preamplifiers and observed values of reverse currents were larger than current estimated by expression for I_{gen} . This indicates a significant role of the edge effects and inhomogeniety of original silicon as well as some decrease in lifetime τ during the detector fabrication. The measured energy resolution was ΔE = 25 keV for type 1 detector (E = 5.8 MeV) and ΔE = 15 keV for type 2 detector (E = 5.8 MeV).These values are much better than those obtained with large area detectors (ΔE = 70 keV for a detector with area of 4 cm × 4 cm). The equivalent noise measured by means of m.i.p. Landau distributionwas in the range of 4 keV for different detectors (the signal to noise ratio ≈ 20).

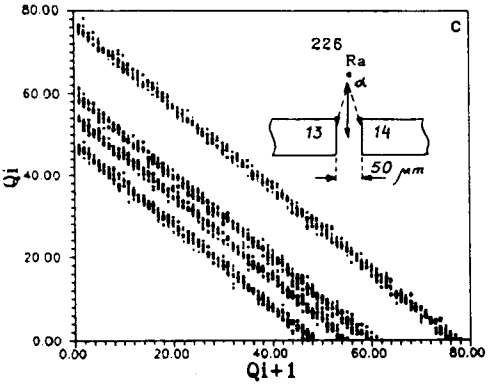

Figure 1. The two-dimensional distribution of charges Q_i and Q_{i+1} collected by neighboring strips (charges are in arbitrary units) .

CONCLUSIONS

Investigated silicon strip detectors have some advantages over usual detectors with the same total area. They have a better signal to noise ratio which is determined by much smaller capactance and reverse current of one strip. Such detectors can be used for determination of the alpha spectra of various substanses. They also can give information on spatial location of alpha sources with high position accuracy.

ACKNOWLEGEMENTS

We express our gratitude to Dr. Frolov and V.Pervertaylo for the fabrication of some strip detectors (the firm " Detector". This research has been partly supported by the International Atomic Energy Agency under research contract No. 7200/R2/RB.

INTRODUCTION

Some types of semiconductors are meant to operate under heavy radiation conditions. It may take place in the destroyed Chernobyl NPP and also in high energy hadron collider experiments. The properties of detectors are mainly determined by electrical characteristics of high purity silicon and also by the peculiarities of technology of their fabrication.

Peculiarities of the volume inhomogeneity distribution of τ and ρ in silicon samples, manufactured by different producers (Wacker, Topsil, ZTMC etc) have earlier been studied (1). Hear an effort was made to establish the correlation between revealed volume inhomogeneities of $\tau-$ and $\rho-$ parameters and the presense of growth sructural microdefects.

The present study has an aim to investigate the peculiarities of electrical properties evolution in high ohmic silicon and detectors manufactured on its base being in high radiation fields of γ-rays.

EXPERIMENTAL PROCEDURE AND RESULTS

The samples cut from float-zoned silicon (FZ-Si) were choosen for investigation. To achieve the above goals the Hall-coefficient measurements have been performed. When studying the evolution of electrical properties, the silicon crystals have been irradiated by the γ-rays at successiv steps with dose ranging from 10^6 to 10^9 rad. After each step the samples were removed to perform the necessery measurements. The effect of γ-irradiation on carrier concentration of high purity n- and p- silicon, produced by Topsil, Wacker and ZTMC (Ukraine) firms are shown at Fig.1.

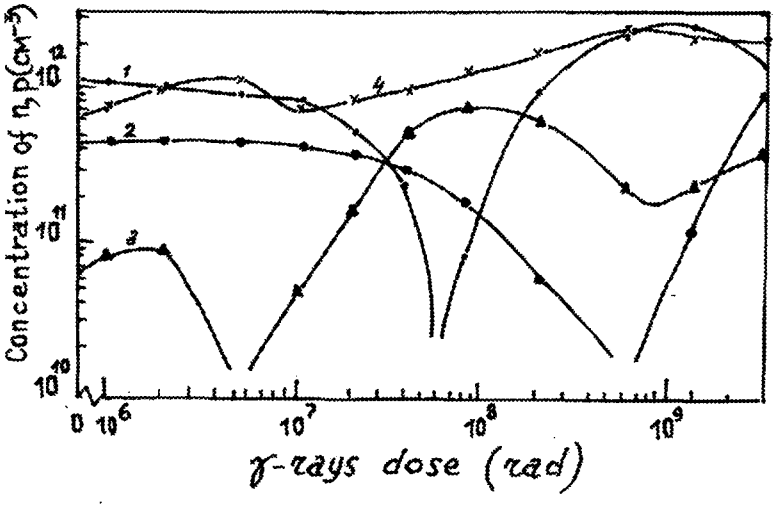

Figure 1. Dependence of carrier concentration on γ-irradiation doses for : 1 - ZTMC, 2 - Wacker, 3 - Topsil (all n - Si), 4 - ZTMC (p - Si).

As evidenced by this figure in n-Si the carrier density decreases with dose increasing, achieves intrinsic value and then invert into p-type conductivity where the hole concentration increases reaching the level of saturation near $2 \cdot 10^{12}$ cm^{-3}. Earlier it was shown that the hole density saturation occurs mainly due to creation of divacancy (2). The value of inverting dose in certain extent

corresponds to the initial carrier concentration in samples. The results of measurements are given in Table 1.

Table 1

Sample	Initial concentration n_0, cm^{-3}	Inverting dose Φ, rad
Topsil	$6 \cdot 10^{10}$	$5 \cdot 10^{6}$
ZTMC	$1 \cdot 10^{12}$	$6 \cdot 10^{7}$
Wacker	$5 \cdot 10^{11}$	$6 \cdot 10^{8}$

It can be seen that the only exception from the above established rule is Wacker n-Si. Comparation of the carrier removal rates $\varepsilon = -\Delta n/\Delta\Phi$ in range $(1 - 2) \cdot 10^7$ rad shows that the Wacker n-Si considerably distinguishes from all other samples. Parameter ε for the Topsil, ZTMC and Wacker crystals equals $4 \cdot 10^{-5}$ cm^{-1}, $2 \cdot 10^{-5}$ cm^{-1} and $3.5 \cdot 10^{-6}$ cm^{-1} respectively. As can be seen the Wacker n-Si has the most radiation hardness among all examined n-type silicon. This phenomenon may be attributed to the presence of electrically nonactive impurities that serve as rather effective drains for the primary radiation-induced defects.

As far as the p-type silicon samples are concerned (Fig. 1, curve 4) the test that were perfomed revealed the ZTMC p-Si (with $p_0 = 10^{12}$ cm^{-3}) as a most radiation-damage resistant material of all examined p- silicon crystals under γ-irradiation.

In order to test the electrical and spectrometrical properties of detectors made on the basis of investigated materials, the detectors with diode struture were fabricated using both surface-barrier and planar technology. As a function of γ-irradiation from ^{60}Co the I-V, C-V and R-V measurements were perfomed. Detectors were exposed at successive steps by γ-irradiation as it was previously done for the silicon materials. All detectors were measured being biased at 50 V. The results achieved show that the both diode reverse current and energy resolution for all examined detectors as a function of irradiation dose were found to be similar in the dose ranging from 10^6 to $1.2 \cdot 10^7$ rad. Besides, there were no evidence of direct connection between the reverse current and energy resolution also as a function of dose.

It should be however noted that at initial range of irradiation there can be seen the improving of detector characteristics, but this effect takes place at different doses for different silicon materials. For Wacker n-Si this effect reveals at dose of 10^6 rad, for ZTMC - $6 \cdot 10^6$ rad (n-Si), $2 \cdot 10^6$ rad (p-Si) and for Topsil n-Si - near 10^6 rad. The effect of characteristics improving is confirmed also by the increasing of carrier concentration deduced from the C-V measurements. This the so-called effect of little doses can be associated with the non-equilibrium states, which are creating in the process of detector fabrication. The γ-irradiation leads to the proceeding of radiation-stimulated reactions with the point defects involved. This reaction brings the diode structures to be well regulated and to the disappearance of non-equilibrium states.

Concernig the technology, it should be noted that for planar detectors fabricated by different producers (Ukraine and Australia) we observed significant increase of the reverse current and deterioration of energy resolution. At dose of 10^7 rad the energy resolution deteriorates by 4 times and reverse current increases by one order while the characteristics of surface-barrier detectors did not change considerebly.

CONCLUSION

1. Wacker n-Si crystals show the most radiation hardness among all examined n- silicon under γ-irradiation.
2. There is no direct connection between the reverse current and energy resolution as a function of γ-irradiation dose for all detectors examined.
3. The radiation hardeness of detectors fabricated by the surface-barrier technology without high temperature treatments is higher than that for planar detectors where such treatments have been applied.

ABSTRACT (See instructions overleaf)

Semiconductor detectors are widely used for radiation dosimetry due to their high sensitivity, small size, and absence of external bias. In previous investigations the authors found that common photodiodes, which have the same junction characteristics of semiconductor detectors, present a linear dose-response relationship. In this paper, the BPW-34, a PIN photodiode manufactured by Siemens, was tested for measuring the central axis depth doses in both photon and electron fields.

Measurements were carried out with the photodiode connected in the photovoltaic mode to the input of an integrating electrometer developed in the Nuclear Energy Department at the Federal University of Pernambuco, Brazil. Depth dose distribution curves were obtained in a slab perspex phanton measuring 30cm x 30cm x 20 cm. The doses were measured in a ^{60}Co gamma beam, in 6-MV and 10-MV X-ray beams, and in a 10-MV electron beam, for field sizes of 5 x 5 cm^2, 10 x 10 cm^2, and 20 x 20 cm^2.

The results of the measurements with the photodiode agree with those obtained with the ionization chamber at the same irradiation conditions within less than 1%. These results show that the BPW-34 photodiode can be used for mapping the depth dose distribution in both photon and electron fields. Its small size makes the BPW-34 photodiode suitable for patient dose measurements during radiotherapic treatments.

IMPROVEMENT OF THE SENSITIVITY OF CdTe SEMICONDUCTOR DETECTOR IN THE HIGH ENERGY REGION

INTRODUCTION

Cadmium Telluride, CdTe, semiconductor detectors have sufficient band gap energy (1.47 eV) to use at room temperature, and their atomic number are so large (48 and 52) that their photon detection efficiency is more excellent than that of Si or Ge. Recently CdTe crystals have become easily available because of improvements in the crystal growth method. It is a useful X-ray detector, because it has good energy resolution and high efficiency at the full energy peak at less than a few hundred keV of incident photon energy. However, if the incident photon energy become higher, the efficiency of the full energy peak become worse, and it is very difficult to distinguish the full energy peak above 1 MeV, because the mobility of charge carriers in the CdTe crystal is much smaller than in Si and Ge and it is difficult to produce a larger volume element.

In order to analyze the energy of several radioisotopes, it is necessary to improve the sensitivity of CdTe detectors in high energy regions. We have previouly suggested a multi-layered structure of CdTe elements.[1] This paper describes a simulation and experiment to improve the efficiency of the full energy peak in the high energy region above 1 MeV.

METHOD OF SENSITIVITY IMPROVEMENT

It is common to increase the detector volume in order to improve the efficiency of the full energy peak in the high energy region. However, the charge carrier mobility of CdTe, particularly in holes, is much smaller than that of Si and Ge.[2,3] Most holes drifting in the CdTe crystal are trapped at trapping centers, for example lattice defects, and their mean free path is shorter than the thickness of the detector. Therefore most holes can not reach the collecting electrode and hence all the energy deposited in the detector by photons does not contribute to the output pulse height.

In order to collect more holes, we suggest a multi-layered structure of CdTe elements as shown in Fig. 1. The output pulse from each layer is superimposed by connecting them in parallel. By this method only one amplifier is needed and therefore minimizing the cost to improve sensitivity. There is only air between each element in order to minimize the photon interaction other than with CdTe elements. The sensitivity in the high energy region is improved, because the collection efficiency of charge carriers become higher and the detector volume is increased.

SIMULATION

The response function of the CdTe detector was predicted by simulation with the Monte-Carlo calculation code, EGS4 (Electron Gamma Shower Ver. 4)[4] to evaluate the degree of sensitivity

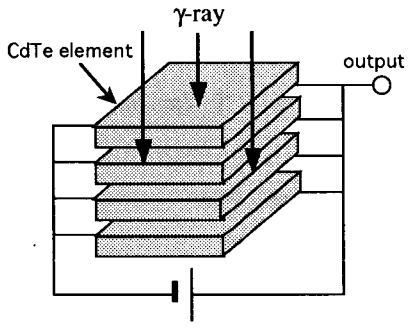

Fig. 1. Multi-layred CdTe detector.

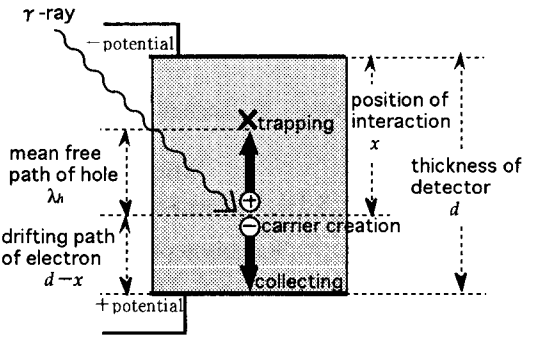

Fig. 2. Simulation model considering the hole trapping in the semiconductor detector.

improvement. In this calculation, the hole trapping in the CdTe crystal was considered. In the case of a planar type detector, the collected charge $Q(t)$ on the electrode is presented as,

$$Q(t) = \frac{q_0}{d}\left(\text{drifting length of electron} + \text{drifting length of hole} \right) \quad (1)$$

where d is the thickness of detector, and t is the time from creation of charge carriers q_0 by photon interaction . In Fig. 2, the charge carriers are created at the interaction position and the distance from this point to the negative electrode is indicated by x . However the holes are trapped as they drift in the CdTe crystal (the mean free path of holes is λ_h), the collected charge $Q(x)$ is presented as,

$$Q(x) = q_0\left[\frac{d-x}{d} + \frac{\lambda_h}{d}\right] \quad (2)$$

When the energy deposition in the CdTe detector was calculated, the energy calculated by EGS4 was multiplied by the weight function, $[(d-x)/d+\lambda_h/d]$. Therefore the energy derived from this model is less than the energy when the hole trapping is not considered. The simulated result with this model was in good agreement with the experimental result of a one-element CdTe detector as shown in Fig. 3 which indicated that the simulation model was correct.

By using this model, we predicted the degree of sensitivity improvement of a multi-layered CdTe detector in the high energy region. Figure 4 shows the energy dependence of the relative sensitivity by the simulation. The relative sensitivity is defined as the ratio of the full energy peak efficiency of four layers to that of one layer. It was predicted by simulation that the relative sensitivity would exceed four in the energy region of more than 1 MeV and therefore the improvement effect would be larger than the simple multiplication of the number of elements.

EXPERIMENT

Figure 5 shows a block diagram of the present experiment. The applied voltage to the superimposed CdTe elements was adjusted so that the measured voltage of 1 layer and that of 4 layers was the same. A check source of ^{60}Co (3.29MBq) was used in this experiment. The distance between detector and source was kept long enough so that the direction of the gamma-rays was parallel and that the dose rate errors at the detector became a minimum. The output pulse height distribution was measured and the full energy peak efficiency was determined by counting the 1.33 MeV peak of ^{60}Co.

The result is shown in Fig. 6. The sensitivity of the 1.33 MeV peak in the case of 4 layers was 4.9 times better than the case of 1 layer. The improvement of the sensitivity is in good agreement with the simulation result as shown in Fig. 4.

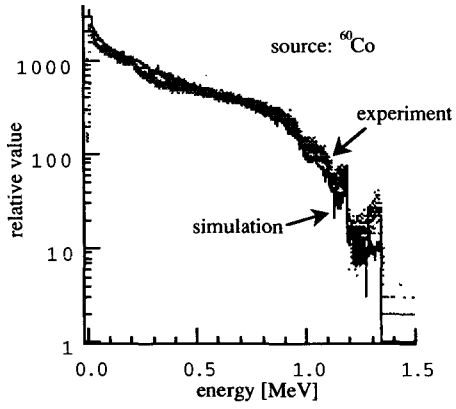

Fig. 3. Simulation results considering the hole trapping for the 1 element detector compared with the experiment.

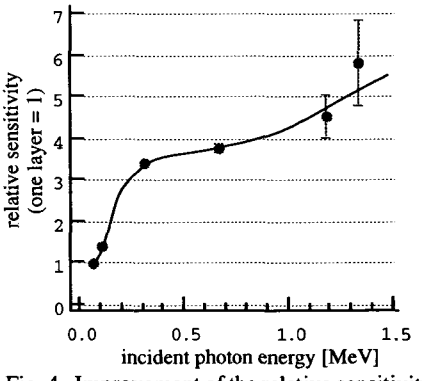

Fig. 4. Improvement of the relative sensitivity for the 4 layered detector predicted by simulation.

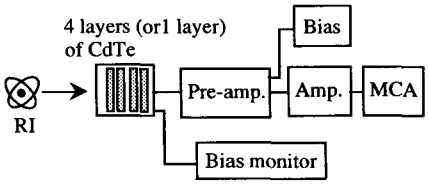

Fig. 5. Block diagram of the experiment.

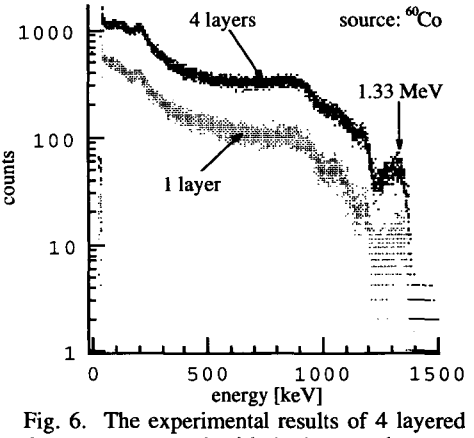

Fig. 6. The experimental results of 4 layered detector compared with 1 element detector.

CONCLUSION

A multi-layered structure of elements was proposed to improve the sensitivity of a CdTe semiconductor detector in high energy regions. The response function of a semiconductor detector whose charge carrier mobility is even as small as CdTe could be simulated, and the degree of sensitivity improvement in the high energy region above 1 MeV was predicted by using this model. The results of both simulation and experiment indicated that the improvement effect of the full energy peak with a multi-layered CdTe detector was larger than the effect of simply multiplying the number of elements.

CALIBRATION OF PORTABLE HPGe SPECTROMETER FOR INDOOR DOSE RATE ESTIMATIONS

A. Clouvas, M. Antonopoulos-Domis and S. Xanthos

Department of Electrical and Computer Engineering,
Aristotle University of Thessaloniki,
GR.-54006 Thessaloniki

INTRODUCTION

In situ gamma spectrometry is a powerful tool to study indoor and outdoor dose rates. A high resolution spectrum allowing analysis of individual photo peaks provides valuable information on the relative contribution of the various nuclides to the total exposure rates. In situ techniques for measuring the dose rate, resulting from the gamma radiation and characterizing its sources, with a gamma ray spectrometer have been used successfully in the outdoor environment (1-4). In principle, the same methods can be applied to indoor radiation measurements. However, due to complex or generally unknown geometry in indoor areas, the methods for outdoor environments can not be applied directly to indoor ones. In the present work we investigate the applicability of the calibration factors derived from field geometry to indoor geometry.

METHODOLOGY

In order to check whether calibration factors for field geometry can be applied to indoor radiation measurements, we applied to our measured indoor and outdoor spectra a geometry independent method, the spectral stripping method (5), (6), for determining the gamma dose rates, which does not require any assumptions concerning the source geometry. The measured indoor and outdoor spectra were performed with a portable coaxial HPGe detector (10% efficiency).

A count registered by the detector can be caused by the full or partial absorption of an incident photon or by the passage of a cosmic ray produced charged particle. In order to convert to gamma dose rate, the spectrum must be stripped of the partial absorption and cosmic-ray events leaving only the events corresponding to the full absorption of a gamma ray. The resulting spectrum, which represents both primary as well as scattered photons, can then be converted to the total incident flux spectrum by applying the full absorption efficiency curve of the detector.

The flux spectrum is then used to calculate the total gamma dose rate which can be compared with the sum of the individual dose rates for each radionuclide (natural and man-made) obtained with the use of the calibration factors for field geometry. When these two values are in agreement, one can assume that the calibration factors being used are correct.

Concerning the cosmic-ray events induced in the detector we followed the methodology given in ref. (5), (6). The cosmic ray count rate in the region below 3 MeV in a typical Ge detector is generally small compared to the gamma count rate. Since there is no natural gamma line present between 3 and 4 MeV, this region is used to estimate the cosmic ray count rate which is then extrapolated back to 0 MeV and subtracted out from the spectrum. Although there may be some variation in the energy distribution, we have assumed as in ref. (5), (6) that the cosmic continuum is flat in this region.

Concerning the partial absorption events induced in the detector we followed the methodology given in ref. (5), (6) and ref. (7).The events corresponding to partial absorption in the detector make up a large fraction of the counts in the spectrum and are not as simple to strip out. For the most part, these events are the result of compton scatter in the crystal itself or the surrounding cryostat. For single scatter events, a continuum of counts will form in the spectrum reaching a maximum energy at the compton edge given by

$$E_c = E_p - \left(\frac{2}{0.511} + \frac{1}{E_p} \right)^{-1} \quad (1)$$

where E_c is the energy of the Compton edge and E_p is the energy of the incident gamma ray.

Okano et al (7) have used a distribution of counts with energy which is essentially a single step function between the low end of the spectra and E_c. An example of the actual distribution of counts in the continuum for normal incident 0.662 MeV photons in our detector is shown in Figure 1. It can be seen that: (a) the energy dependence below Ec can not be described by a constant and (b) there are a number of counts that lie above E_c, which are a result of multiple scatter events within the crystal. Based on this, Miller (5), (6) incorporated into the stripping routine, a multiple step function fit to the continuum. In our method which is simple, quick and acceptable accurate, a two function fit to the continuum was incorporated into the stripping routine. The region below E_c is fitted with a polynomial function of second order and the region between E_c and E_p with the sum of an exponential and linear function. The different parameters of the polynomial and exponential function depend on the incident photon energy and have been obtained assuming a constant Peak to Compton ratio for all energies. For incident photons 0.662 MeV, the polynomial and exponential functions used in the stripping routine are also shown in Figure 1. The correlation coefficients between measured and fitted data for the fist region, (100 keV until E_c) and the second one (E_c until E_p) are 0.76 and 0.99 respectively. It should be noted also, that when we write Peak to Compton ratio, we mean the number of counts at E_p divided by the average number of counts in the channels for the range from $0.99 \cdot E_c$ through E_c, and not the one given by the manufacturer, which is determined as the ratio which is found by dividing the number of counts in the 1.332 MeV peak channel by the average number of counts in the channels for the range from 1.040 through 1.096 MeV. One must have in mind that the number of counts in the peak

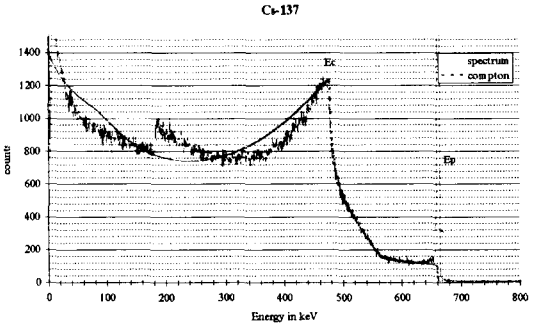

Figure 1. Cs-137 spectrum and compton fit.

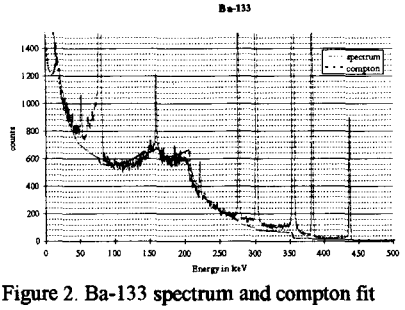

Figure 2. Ba-133 spectrum and compton fit

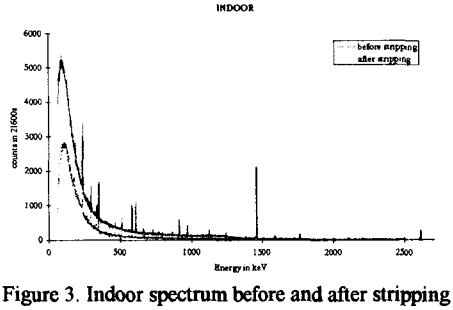

Figure 3. Indoor spectrum before and after stripping

(E_p) are considerably higher that the counts in the Compton edge (E_c).

Using the assumed shapes for the cosmic and partial absorption continua we proceed to a computerized stripping operation which subtracts out from the measured in-situ spectrum those counts that represent cosmic-ray events or partial absorption of gamma rays in the detector. The stripping operation is initiated at the highest energy gamma peak (2.615 MeV) and involves subtracting the assumed continuum of counts which is lower in energy. The operation continues for succeeding lower energies gamma peaks down to 100 keV. In order to check our stripping operation we test it in a spectrum obtained with incident γ rays emitted from a Co-60 and Ba-133 point sources. It can be seen in Figure 2, that the compton distribution deduced from the stripping operation describes successfully the experimental values.

An example of a stripped indoor spectrum as compared to the original spectrum is shown in Figure. 3. Typically about 50% of the counts are removed. These counts are removed from the continuum portion of the spectrum, while the peaks due to the full absorption of primary flux are preserved. The stripped spectrum of Fig. 3 is converted to incident flux by applying the full absorption efficiency of the detector.

Having calculated the flux energy distribution $\varphi(E)$ the absorbed dose rate in air due to the gamma radiation can be easily calculated by

$$\dot{D} = \int_0^{E_{max}} \varphi(E) \cdot E \cdot \mu(E) \cdot dE \qquad (2)$$

where $\mu(E)$ is the mass absorption coefficient for air at energy E and E_{max} is the highest energy gamma line (2.615 MeV).

RESULTS AND DISCUSSION

In order to check the applicability of the field calibration factors to indoor geometry we performed long duration measurements (six hours). Specifically 5 measurements took place in buildings and 6 in outdoor environments, with 3 of them on roads and pavements. For each spectrum we calculated the total external dose rate (nGy/h) using 3 different methods. (a) The field calibration factors assuming equilibrium along the various nuclides in the U and Th series, so that the measurement of any one spectral line yields concentration values for the entire series, although averaging several spectral lines will give a more precise value. For the U-series we used the lines of 0.352 MeV (Pb-214) and 0.609 MeV (Bi-214) and for the Th-series the lines of 0.583 MeV (Tl-208) and 0.911 MeV (Ac-228). We also measured the lines 1.461 MeV (K-40) and 0.662 MeV (Cs-137). (b) The field calibration factors without assuming equilibrium along the various nuclides in the U and Th series, using equation 2 for the unscattered photons and multiplying the resultant dose rate for each energy with the appropriate build up factor (8). (c) The spectral striping method using equation 2. The results are shown in Table 1.

Over Soil	44.9	44.2	44.05	1.02

Table 1. Total external dose rate in air (nGy/h)

The fact that the field factors have been verified for the outdoor environment indicate that the stripping operation used is accurate. This can be seen from the ratio between the dose rates estimated by field factors and the stripping operation for measurements over soil, in Table 1.

One can see, observing mainly the results for buildings and houses, that disequilibrium in the U series due to exhalation of Rn-222, from the soil surface or the building materials, does not affect the total dose rate significantly. Also, it is notable, that the use of field calibration factors for roads and pavements underpredict the dose rate

The generally good agreement between the two dose rate estimates between calibration factors and stripping method, which has been observed also for almost all indoor spectra, used for this test, justify the applicability of field geometry factors to indoor geometry at least in the case of masonry structure which is typical for most of the buildings and houses in Greece.

COMPUTERISED GLOW CURVE DECONVOLUTION:APPLICATION TO THERMOLUMINESCENCE DOSIMETRY

Y.S. Horowitz and D. Yossian
Physics Department, Ben Gurion University of the Negev, Beersheva, Israel

INTRODUCTION

Computerised glow curve fitting methods (CGCD) used to improve the dosimetric applications of thermoluminescence have come of age. A recent monograph (1) outlines the glow curve deconvolution of various TLD materials and then discusses the many and varied applications to dosimetry. These include: dramatic improvements in precision and minimum measureable dose, dose re-estimation using phototransferred thermoluminescence (PTTL), simultaneous estimation of dose and elapsed time following irradiation, estimation of fading and sensitivity corrections, optimal annealing procedures, mixed field beta/gamma and neutron/gamma dosimetry, and various quality control applications at both the growth, material characterization and readout stages. At Ben Gurion University we are currently investigating some of the more recent developments in CGCD concerning quality control and neutron/gamma dosimetry. In addition, we present some preliminary results concerning abnormal glow curves obtained for low energy x-rays and beta rays due to oxygen contamination during 400oC in air annealing. These latter results should be of concern to users involved in superficial dose estimation using LiF-TLD.

CGCD APPLIED TO QUALITY CONTROL

This application, although still in its infancy (2), is potentially one of the most. important applications of CGCD. One can envisage important material-selection improvements in the manufacturing stage of the material, in the manufacturer's quality control of the final product and in the final stage of glow curve readout involving verification of dose data as well as diagnostics of the reader malfunctions. The final stage is especially important since glow curve analysis automatically involves a form of permanent storage of the dose information and completely answers one of the complaints in the use of TLD regarding a permanent record of the dose information. For these reasons many operational dosimetrists have become enthusiastic proponents of glow curve storage in order to be able to test for abnormalities and dose verification. Hoot and Landrum (3) were the first to publish a library of error conditions to be verified by glow curve analysis. Liu et al (4) in their study of the optimization of the readout procedures for the Harshaw 8800 automatic TL dosimetry system, report occasional irregular glow curves of thin TLD-700 dosemeters which were easily identified by the CGCD routine currently operative in the 8800 system. Tan et al (5) are developing computerized programs to screen for abnormal LiF glow curves. Bos et al (6), studied the kinetic trapping parameters of different Harshaw Production batches. This study has a direct relevance to the question of production quality control and the non-universality of dosimetric properties in Harshaw LiF products. Generally, users request uniform sensitivity in batch selection and ignore details of glow curve shape. It is clear that users interested in maintaining dosimetric characteristics over the years in their procurement of dosimetric material should specify not only overall batch sensitivities but also should place specifications on glow curve shapes.

At Ben Gurion University we have studied how to retrieve dosimetric information from distorted glow curves using CGCD (2). Fig.1 illustrates a type of distortion involving distortion over a temperature range of approximately 20^{o}C in the maximum of peak 5 in a "four-glow-peak glow curve".

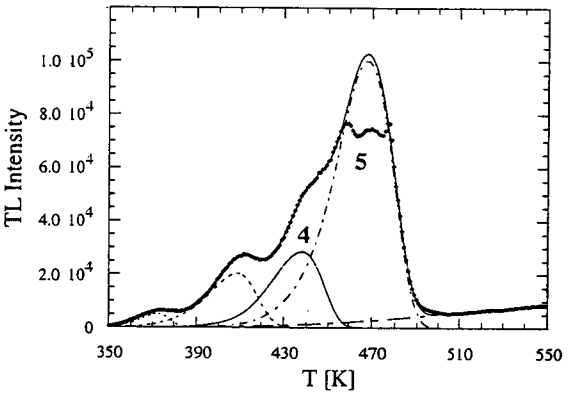

Figure 1. Gamma induced glow Curve of TLD-100 illustrating system malfunction in the central portion of peak 5. (•) experimental

The analysis of the glow curve was carried out by excluding the distorted region from the computerised fitting procedure. In this particular exercize, and for demonstration purposes, this exclusion procedure is carried out by visual inspection. It is no problem to configure the fitting procedure to automatically identify and exclude the distorted regions. The results of the computerised analysis in all the cases studied allowed us to retrieve the dosimetric information to an accuracy of better than 2%.

CGCD APPLIED TO NEUTRON-GAMMA DOSIMETRY

This application has been discussed in detail by Horowitz and Yossian (1). The dominance of TLDs in the personal dosimetry of photons and beta rays suggests that further efforts must be invested in the use of TLDs in fast neutron environments simply because of the increasing availability of automated TL facilities in nuclear, medical and industrial installations where fast neutron dosimetry is a subject of continuing concern. Most previous applications centered on the use of TLDs in albedo dosimetry or in the use of the fast-neutron-sensitive high temperature glow peaks in LiF:Mg,Ti, but these approaches suffer from several disadvantages. At Ben Gurion University we are currently studying the possibility of the application of peak 4/5 ratios in the glow curve of TLD-600 in the separation of gamma and neutron dose. A typical glow curve following fast neutron irradiation is shown in Fig. 2.

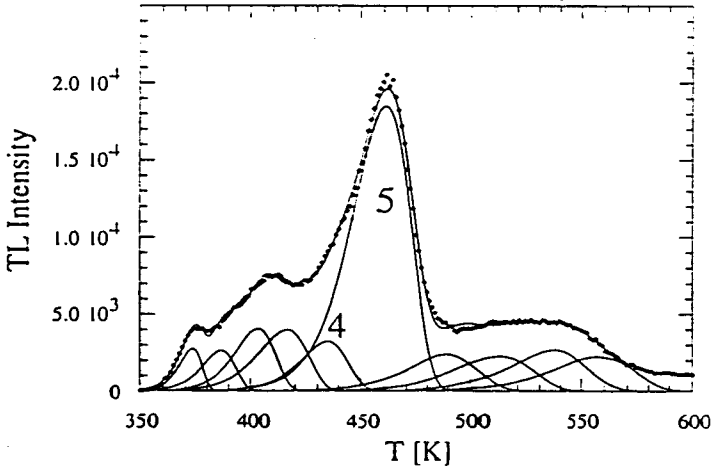

Figure 2. Glow curve of TLD-600 following fast-neutron irradiation

The ratio of peak 4/peak 5 is approximately 15% compared to approximately 30% following gamma irradiation. The success of this technique depends critically on the reproducibility of these 4/5 ratios which is the subject of our current investigations.

CGCD APPLIED TO SURFACE DOSE ESTIMATION

Dosimetric measurements of low energy radiation using LiF-TLD may be subject to difficulties due to surface contamination by OH^- ions during 400°C air-annealing. Differences in the TL efficiency between air and N_2 annealing have been well documented in the literature (7), but not much attention has been given to glow curve analysis. A typical glow curve of TLD-100 following irradiation by ^{63}Ni beta rays (air-annealing) is shown in Fig. 3. The intensity of the low temperature peaks 2-3 is greatly enhanced relative to peak 5, and in addition, new low-temperature peaks appear. Similar glow curves have been obtained following ^3H or alpha-particle irradiation. The effect increases with subsequent air-anneals and is totally absent when the chips are annealed in N_2. Dosimetrists involved in superficial dose estimation of low-energy radiations, should, therefore, pay especial care to the purity of the N_2 atmosphere used in the high temperature annealing procedure and during readout. Changes in sensitivity to low energy-radiation may occur which will not be detected by high energy, volumetric, calibration.

OPTIMIZATION OF MAGNESIUM BORATE THERMOLUMINESCENT MATERIAL FOR RADIATION PROTECTION DOSIMETRY

Mirjana S. Prokić

Institute of Nuclear Sciences, Vinča, 11001 Belgrade, Yugoslavia

Abstract - The dosimetric performances of developed MgB_4O_7:Dy,Na, optimized magnesium borate TL material have been evaluated and the results are presented. Three types of thin active layer TL dosemeters based on new magnesium borate are developed to provide beta and neutron dosimetry.

INTRODUCTION

Valuable features of magnesium borate TL material such as near tissue-equivalency, high sensitivity, and its good performances for X, gamma, beta and neutron dosimetry, were the ground that systematic studies were carried out for further improvement of this material. Previously prepared sensitized magnesium borate thermoluminescent materials activated with rare earth elements, dysprosium or thulium, are highly sensitive phosphors (1). However, these TL materials show remarkable fading, multiple peak structure of the main TL peak and slight chemical instability. These shortcomings of magnesium borate phosphors have been entirely overcome by development of the original preparative procedure and development of MgB_4O_7:Dy,Na - thermoluminescent material with optimal TL characteristics.

Also, three types of thin active layer TL dosemeters based on new magnesium borate are developed to provide beta and neutron dosimetry.

The performances of these TL dosemeters are presented.

MgB_4O_7:Dy,Na - TL performances

TL material, MgB_4O_7:Dy,Na differs considerably in its chemical composition from all types of magnesium borate, TL materials previously synthesized. TL material is nearly tissue equivalent, with an effective atomic number for photoelectric absorption, Zeff = 8.55.

MgB_4O_7:Dy,Na shows single TL peak at about 185°C-190°C, and the sensitivity which is, depending on the reader type used (2) 6-15 times higher than that of LiF:Mg,Ti (TLD-100). The technology developed proved to be efficient for evident modification of the main, multistructure peak which was characteristic for the previously prepared magnesium borate TL materials, with the maximum at about 165°C, to simpler TL peak with the maximum at about 185°C-190°C.

MgB_4O_7:Dy,Na is a complex, composed of two phases, of about 70% of magnesium tetraborate, MgB_4O_7, and of about 30% of magnesium meta borate, MgB_2O_4. The X-ray diffraction analysis shows that a complex comprising the phases, MgB_4O_7 and MgB_2O_4. With increasing of the content of the phase MgB_2O_4, the glow TL peak is shifted to higher temperatures. Consequently, fading for the optimized magnesium borate TL material was found to be only of the order of less than 2-5% for three months, at the ambient temperature of 30°C in dark, compared to 35% for two months fading for previously prepared magnesium borate TLDs. In fact, this very low fading of MgB_4O_7:Dy,Na are comparable to the uncertainties due to the homogenity of the batches and also comparable to this defined for LiF TL phosphors.

The dosemeters are in form of solid sintered pellets with a diameter of 4.5 mm. The measurements were performed on Harshaw Model 2000 TL Analyser and partly on ALNOR Dosacus TLD reader.

Thin layer TL detectors for beta and neutron dosimetry based on MgB_4O_7:Dy,Na

TL Detectors for Beta-Ray Dosimetry

The optimal thermoluminescent dosemeter for beta dosimetry is thin detector of a few mg.cm^{-2} active layer with the detection threshold lower of 20 μGy, nearly tissue equivalent, insensitive to humidity, with low fading, excellent reusability and mechanically rugged.

Graphite mixed MgB_4O_7:Dy TL detectors with 2-3% of graphite were introduced in beta dosimetry by Prokić (3). A general problem with the graphite mixed TL dosemeters is that the TL sensitivity is relatively low. Particularly, the problem of high fading of previously prepared MgB_4O_7:Dy was the reason for development of TL detectors for beta dosimetry based on new, MgB_4O_7:Dy,Na TL material.

Two types of thin active layer TL detectors are developed to provide beta dosimetry: (a) The first type is an active thin TLD layer, difusion bonded onto graphite mixed magnesium borate base, and (b) A type of ultra thin TLD layer infiltrated on the surface of non-thermoluminescent sintered magnesium borate pellets, by their immersion in the activator (Dy) water solution.

The gamma ray sensitivity of the first type of thin layer dosemeters, with the TLD layer thickness of about 5 mg.cm^{-2} are rather high; in fact, relative sensitivity amounts 28, normalized to TLD-700 for which sensitivity to ^{60}Co gamma rays is taken as 100. The second type of TL dosemeters prepared by the variation of the period of immersion of sintered pellets (and by changing the concentration of the activator solution), the active TLD layer is selected to be ultra thin, 1 μm, to about 4 mg.cm^{-2}, or more. After second sintering, the relative TL sensitivity for ultra thin TLD layer, about 4 mg.cm^{-2} to ^{60}Co gamma rays is 16. For comparison, graphite mixed magnesium borate TLDs with the similar effective thickness has relative gamma ray sensitivity of about 6 to 7, with the excellent low beta energy response of 0.70 to 0.83 (4). Beta ray response of the two types of developed thin TLDs for low energy beta radiation of ^{147}Pm (Emax = 0.225 MeV) is 0.68 and 0.77, respectively, i.e. similar to that of graphite mixed magnesium borate TLDs. Beta ray response is given as the ratio of the response of a bare detector to low energy beta radiation (^{147}Pm), to the response to gamma radiation (^{60}Co).

Recent progress in the development of thin layer TL detectors has made it possible to improve the sensitivity without changing (no more than for 10%) the efficiency for beta dose measurements, with a flat beta ray energy response curves for skin dose measurements when applied Mylar foil of corresponding thickness to fit the 0.07 mm tissue for beta ray maximum energies above 0.2 MeV.

TL Detectors for Personal Neutron Dosimetry

At the present, only ^{6}LiF:Mg,Ti, as commonly used TL detector, and also $Mg^{10}B_4O_7$:Dy,Na can be used as a neutron dosemeters. Sintered TL dosemeters based on magnesium borate ^{10}B enriched, along with ^{10}B depleted magnesium borate TLDs can be used successfully for separate measurements of neutron and gamma doses in an albedo type personal neutron dosemeter system (5). In fact, thermal neutrons are absorbed mostly in the first 0.2-0.3 mm layer of neutron sensitive TL dosemeter, while absorbtion of photons is uniform through the detector thickness. Hence, by the application, in principle, the technologies developed for the preparation of thin layer TLDs for weakly penetrating radiation, it was prepared thin neutron sensitive TLD layer, $Mg^{10}B_4O_7$:Dy,Na with the active TLD thickness of about 65 mg.cm^{-2}.

However, the main intention of this project was an attempt to improve the thermal neutron sensitivity of the $Mg^{10}B_4O_7$:Dy,Na, but not only to obtain high ratio of neutron to gamma

response. The neutron highly sensitive TL dosemeter is prepared by infiltration of the thin active layer on the surface of non-thermoluminescent magnesium borate sintered pellet. The isotop separated lithium (^{6}Li) and boron (^{10}B) content is added in the active TLD layer and as a very thin enamel wrapper, over the pellet before the second sintering. With this highly efficient method, neutron sensitivity is enhanced for nearly the factor of even 2 to that of ^{6}LiF:Mg,Ti (TLD-600). This value presents only the preliminary results but it pointed at the correct direction of the method under development.

In the preliminary test, in order to measure the neutron sensitivity, moderated ^{252}Cf source was used. Detectors are placed on the surface of the polyethylene cylinder. Since for moderated ^{252}Cf neutron spectrum, the fluence and neutron dose equivalent were not known, the relative neutron sensitivity is normalized to TLD-600. Further study will be performed by irradiation with the thermal neutrons.

CONCLUSION

Thermoluminescent dosemeter MgB_4O_7:Dy,Na differs considerably in its chemical composition from all types of magnesium borate TL detectors previously synthesized. It presents the optimal TL material based on magnesium borate with negligable fading, which is comparable to that defined for LiF TL phosphors.

MgB_4O_7:Dy,Na as a high sensitive nearly tissue-equivalent TL material are attractive for various dosimetric applications, with TL performances suitable for photon, beta and neutron dosimetry.

Two types of thin active layer TL detectors are developed to provide beta dosimetry with high sensitivity to gamma, and the high response of low energy beta radiation. Also, an unique neutron dosemeter is under development which exhibit a significant improvement in neutron sensitivity.

ABSTRACT (See instructions overleaf)

HARSHAW/BICRON◆NE has developed the capability of producing high sensitivity, copper doped, lithium fluoride (LiF:Mg,Cu,P) material for thermoluminescence dosimetry (TLD). This material has been proven to be about twenty times more sensitive than standard lithium fluoride (LiF:Mg,Ti), and it can be produced with ^{7}Li, ^{6}Li, and natural Li. TL chips made of this high sensitivity lithium fluoride can be mounted in standard four-element cards in either Teflon® or Kapton®. This paper reports the results of the testing done to characterize the dosimetric properties of this material, both as bare elements and in cards. The energy response was found to be relatively flat and fade is negligible. Additional results reported in this paper are detection threshold, reproducibility, batch uniformity, residual signal, linearity, ambient light-induced thermoluminescence and fade, and spectral response. The results of these tests show this high sensitivity material to be an almost perfect material for environmental, personnel, and medical dosimetry applications.

THE INFLUENCE OF THE ANNEALING PROCEDURE ON THE THERMOLUMINESCENCE READER CALIBRATION OF A PERSONAL DOSIMETRY SERVICE

Viviana Klamert

Dipartimento di Ingegneria Nucleare del Politecnico, Via Ponzio 34/3, 20133 Milano, Italy

INTRODUCTION

Personal dosimetry services are required to distribute monthly a large quantity of dosemeters: their handling has thus to be easier and safer so that detectors could be read by an automatic reader. As a solution, badges have been devised containing more plastic encapsulated chips. Alternatively, individual detectors have been sealed into a plastic envelope with an appendix containing the identification bar code. A problem arises when these arrangements are applied to LiF:Mg,Ti (TLD-100) detectors: annealing is impossible because the procedure requires a 400°C heating step, that the plastic envelope cannot withstand.

The need to handle a large quantity of dosemeters has led to shorter set-up times. Thus, the annealing cycle for the unsealed chips has been modified from the "400°C, 1h and 80°C, 24 h" routine to the "400°C, 1h and 100°C, 2 h" one. The theory shows that the latter may worsen the reproducibility of repeated measurements and introduce sensitivity variations between chips of the same batch (1,2).

Objective of this paper is to compare the performances of three detector groups, two of them annealed by the two above-mentioned routines, while the third one is left without annealing.

METHODS

The batch of 90 individually coded TLD-100 chips has been divided in three 30 chip groups, A, B, C, each one further split to prepare a calibration set of six subgroups of five chips each. Five of these subgroups are irradiated with a Co-60 source in the range of kerma in air from 600 μGy to 10 mGy, under secondary particles equilibrium conditions. The sixth subgroup is read without irradiation, to evaluate the system background signal.

The reader is the manual Harshaw B+C type, always kept on. The applied HV to the PM tube is left unchanged. The operator acts carefully to obtain a good readouts reproducibility. The features of the reading cycle are:

- heating rate: 14°C s^{-1}
- initial temperature of the readings: 50°C
- integration interval: 120°C - 250°C
- at least five initialization cycles of heating and cooling with a dummy chip before reading the chips of the calibration sets.

The group A is annealed by the "400°C, 1h and 80°C, 24 h" routine and the group B by the "400°C, 1h and 100°C, 2 h" routine. The group C is not annealed, like the chips encapsulated in plastic.

The thermal features of the two ovens used for the annealing procedures have been investigated (3). They appear reproducibile. Within the heating volume, the temperature varies ±1°C in the 80°C or 100°C oven. It varies between a range of ±3°C for the 400°C oven. The value of the annealing temperature is read with a mini thermocouple fixed on the basis of the ceramic container of the chips.

Before the beginning of the test, the sensitivity S_i of each chip of each of the three groups is evaluated as the ratio of the mean readout of the chips of the group, exposed to the same value of irradiation, and the readout of the single chip.

The groups are then submitted to the same irradiation values and read through the same reading cycle, as already stated. The procedure is iterated 9 times. The sensitivity evaluation is then repeated as before the beginning of the test.

DATA PROCESSING AND RESULTS

Fig. 1 shows the S_i sensitivity values of every group as measured after the test as function of the values before the test for the same chip. The group B shows the minimum spread around the straight line with slope 1, while the unannealed group C shows the widest spread.

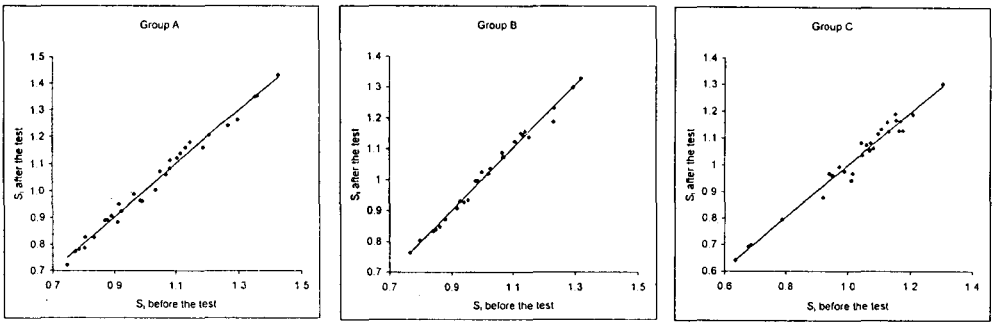

Fig. 1: S_i sensitivity values of the three groups

Fig. 2 shows the best fit obtained through a calibration set. Each dot is the average of subgroup's five detector readouts, sensitivity corrected, minus the average of sensitivity-corrected readouts of the unirradiated subgroup. The calibration factor is the reciprocal of the line' s slope. The calibration factors of the three groups are listed in Table 1 together with the related mean value and standard deviation. The mean value of the calibration factors of the group C unannealed chips is different from the mean values for the two other groups. The standard deviation shows the highest value.

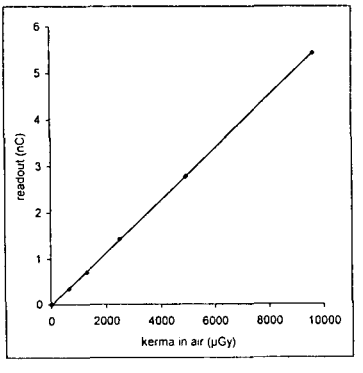

Fig. 2: Best fit of a calibration set

Table 1: Calibration factors (mGy/nC)

N. of test	Group A	Group B	Group C
1	1.80	1.74	1.18
2	1.85	1.88	1.38
3	1.87	1.90	1.39
4	1.91	1.89	1.28
5	1.89	1.90	1.31
6	1.86	1.81	1.31
7	1.91	1.92	1.28
8	1.89	1.89	1.33
9	1.96	1.95	1.52
mean	1.88	1.88	1.33
SD	0.045 (2.4%)	0.067 (3.6%)	0.094 (7.1%)

The mean values of the percent standard deviation (%SD) of each chip over 9 readouts for the same irradiation value are listed in Table 2. The Group B shows the lowest values with a low spread.

Table 2: Mean values of the %SD of each chip over 9 readouts for the same irradiation value

kerma in air (μGy)	Group A	Group B	Group C
9640	7.9	3.9	7.9
4940	3.5	2.6	5.3
2510	3.7	3.3	5.3
1300	3.1	3.3	11.3
690	5.4	3.8	7.3

CONCLUSIONS

The results show that a dosimetry service, adopting one of the two mentioned annealing routines will obtain better results than without anneling, if all other procedures are left unchanged.

Assuming the Table 2 results as an index of the variability of the reader and detector system, the group B evidences better results than group A.

Tests will continue to look for additional proof of such an evidence. Additional tests will also ascertain the reliability of the same detector, with or without annealing, until it lose its features.

ACKNOWLEDGEMENTS

Thanks to Mr. G. Minchillo for this assistance in the measurements.

INTRODUCTION

The increasing use of radioactive sources in medicine, industry and research has led to a growth in the number of persons exposed to some kind of ionizing radiation, therefore the importance of an accurate dosimetry. Thermally Stimulated Exoelectron Emission (TSEE), consisting of low energy electrons that are emitted from surfaces of many insulating solids at temperatures below those at which thermionic emission occurs, is a technique that can be used to measure weakly penetrating radiations, such as alpha and beta particles and low energy X-rays. The principles of exoelectron emission are very similar to those of thermoluminescence. Due to an exposure to ionizing radiation, electron traps in the energy band gap of an insulator are occupied. During the heating, the trapped electrons are released and are emitted from the surface of the crystal, if their energy exceeds the electron affinity (1,2,3). The emitted electrons are called exoelectrons and the curve of this emission as a function of temperature is called TSEE glow curve (1,3). Exoelectron dosimetry differs from thermoluminescent dosimetry in that particles (electrons) rather than photons provide the indication of dose. Due to the short range of exoelectrons, the sensitive layer of the dosemeter is thin enough that emission can be considered as a surface phenomenon (2). Usually, exoelectrons are measured with detectors counters, such as windowless Geiger-Müllers, ionization chambers or proportional counters (4). Sometimes, exoelectrons emission studies have to be performed in high vacuum conditions; in this case an electron multiplier is employed. Normally, this equipment is used preferentially for experimental research than for practical dosimetric purposes. In all devices, the samples are linearly heated up to a certain temperature. In this work the properties of pure $CaSO_4$ sintered pellets and others with 10% of graphite were investigated, using the TSEE technique, in order to verify their usefulness for dosimetric purposes.

MATERIALS AND METHODS

Powdered $CaSO_4$ crystals and chemically pure graphite powder were used to produce sintered pellets of pure $CaSO_4$ and others with 10% of graphite (6mm diameter and 0.8mm thickness). The $CaSO_4$ sintered pellets were tested in X radiation beams of a Rigaku-Denki generator, Model Geigerflex with a Philips tube Model PW/2184/00 (Tungsten target and Beryllium window - 60 kV). Prior to each irradiation, the samples were thermally treated at 300 °C for 15 min. The readout of the samples was made in a 2π windowless proportional counter with hemispherical volume and with P-10 gas flow (10% Methane + 90% Argon). The diameter of the gold anode wire is 50 μm and the operating high voltage is 2.0 kV. The samples are inserted into the counter and are fixed on a heater plate (Monel) ; they are linearly heated at a rate of 5.0 °C/s. The temperature control for linear heating is carried out by a temperature programmer (TP-2000, Theall Engineering Company), that provides rates between 0.1 and 5.0 °C/s, from room temperature up to about 400 °C. The glow curves were recorded in a multichannel scaler (EG&G - Ortec ACE-MCS SN 363 plug-in card).

RESULTS

Figure 1 shows the TSEE glow curve for a $CaSO_4$ sintered pellet irradiated with 10 Gy of X radiation (0.91 mmAl of HVL, 50 kV). The main glow peak appears at about 120 °C. Although the glow curve obtained with $CaSO_4$ + 10% of graphite is not shown, it is similar to that obtained with pure $CaSO_4$. The reproducibility of the TSEE response of the $CaSO_4$ sintered pellets was obtained measuring them 10 times after

repeated standard annealing and irradiation procedure. The standard deviation after ten readout cycles was lower than 5.0% for pure $CaSO_4$ and 11.0% for $CaSO_4$ + 10% of graphite sintered pellets.

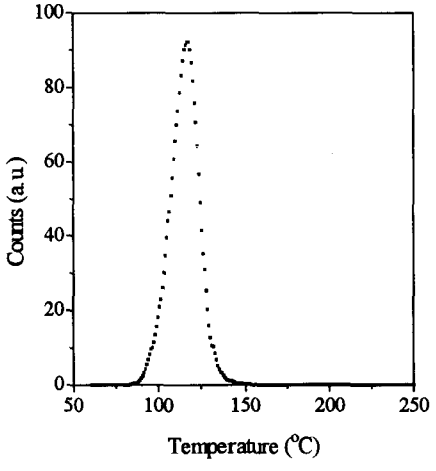

Figure 1. Typical TSEE glow curve for a pure $CaSO_4$ sintered pellet (10Gy).

The TSEE response of both kinds of materials as a function of the absorbed dose of X radiation was measured and the results are shown in Fig.2. The standard deviation of these measurements was always less than 10%. Although the observed sublinear TSEE behavior, the response increment in function of the absorbed dose show that these materials may be used for X radiation dosimetry in the range of 50 mGy up to 100 Gy.

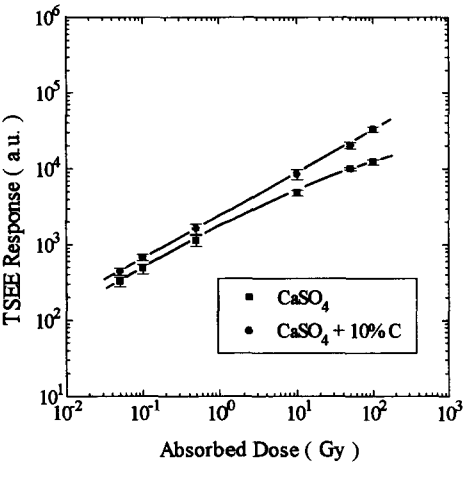

Figure 2 . The TSEE response for $CaSO_4$ sintered pellets.

The lowest detectable value was determined studying the variation of the signal obtained by the reading of non irradiated pellets. It was taken as being equal to three standard deviations from the mean zero dose reading of the pellets. The lowest detectable value was 0.5 mGy. The performance of the $CaSO_4$ and $CaSO_4$ + 10% of graphite sintered pellets was studied in relation to its energy dependence for X-rays. The

TSEE response was measured from samples exposed to 10 Gy in X radiation beams of 25, 30, 40,45 and 50 kV in air. The maximum energy dependence was reached for 19 keV of effective energy, as shown in Fig.3.

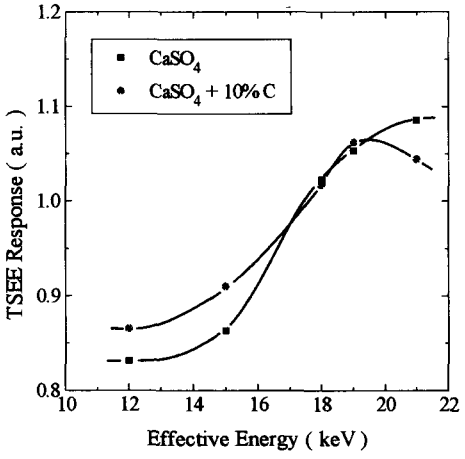

Figure 3. Energy dependence of $CaSO_4$ sintered pelllets.

CONCLUSION

The preliminary results on some dosimetric characteristics as reproducibility, glow curves ,calibration curves and energy dependence of the calcium sulphate sintered pellets studied in this work indicate that these materials may be useful for X radiation dosimetry between 0.5 mGy and 100 Gy.

LIF THERMOLUMINESCENT DOSEMETER - TO MEASURE THE WHOLE GLOW CURVE , PEAK 5 ALONE , OR PEAK (4+5) ?

B. Ben-Shachar

NRC - Negev, P.O.B. 9001, Beer-Sheva, 84190, Israel.

INTRODUCTION

One of the most important characteristics of the integrating thermoluminescent (TL) detectors used as iosining radiation dosemeters is the stability of the stored TL signal. The most glaring disadvantage of the LiF (TLD-100) is its extremely complicated glow curve structure which had led to great difficulty in the arriving of universally accepted characterization of its fading properties (1,2,3,4,5,6). The routine measurement of this phosphor includes its heating to a temperature of 250-300°C. The main glow peak (and the most important for dosimetric applications) is the peak 5, vastly overlaping with peak 4.

One of the possible reasons of the great variability (especially the high fading rates for the short storage intervals) is the inclusion of the rapidly fading peaks 2 and 3 in the TL signal, when the measurement of the signal is performed by integrating the total glow curve (without peak separation). Another reason could be the application of different kind of annealings: pre-irradiation annealing of 400°C/1h and different low temperature pre- and/or post-irradiation annnealins(3). At the other extreme, the comparative low fading rates are presumably based on some combination of the peaks (4+5) or peak 5 alone (the main peaks used for routine dosimetry).

Another important parameter is the change of the sensitivity of peak 4, 5 and/or (4+5) as a function of the glow curve heating rate, as well as the cooling after the pre-irradiation annealing. It has been demonstrated that peaks 4 and 5 grow significantly, while peaks 2 and 3 decay following an intermediate temperature annealing from 150°C to 190°C (7,8).

In the present work I shall present the sensitivities of peaks 4, 5 and (4+5), separated by the computerized glow curve deconvolution (CGCD), as a function of the heating rate (from 100 to 1000°C), as well as the fading of these peaks, irradiated by gammas, alphas and thermal neutrons.

MATERIALS AND METHOD

TLD-100 (Bicron/Harshaw) hot pressed chips (3mm X 3mm X 0.9mm) were used in these investigations. The annealed materials were heated in air to 400°C/1h immediately prior to every irradiation followed by a natural "air cool" at approximately 75°C/min to room temperature. All dosimeters were calibrated individually and the annealed materials were read prior to the irradiation and calibration, so as to standardize their response. The TL glow curves were analysed using a computerized glow curve deconvolution technique (CGCD).

RESULTS AND DISCUSSION

1.Glow curve heating rate.

In table 1 the TL sensitivities of peak 4, 5 and (4+5) are tabulated for both 400°C annealed and unannealed TLD-100 as a function of glow curve heating rate from 100

to 1000°C/min. In these measurements no 100°C pre- or post- irradiation annealing was applied.

TABLE 1 : TL sensitivity as a function of the heating rate.

Heating rate	Annealed			Unannealed		
(°C/min)	4	5	(4+5)	4	5	(4+5)
100	1.78	7.09	8.87	1.92	7.14	9.06
275	2.19	8.38	10.60	2.06	7.20	9.26
430	1.93	7.42	9.35	1.45	7.57	9.02
580	2.53	6.77	9.30	2.69	6.73	9.42
800	2.62	6.43	9.05	2.78	6.43	9.21
1000	2.49	6.13	8.62	3.00	6.59	9.60
Average sens.	2.26	7.04	9.29	2.32	6.94	9.26
S.D. (%)	14	10.4	6.7	24	5.7	2.1

The followings can be concluded:

A. There is no significant difference in the TL sensitivity between the 400°C annealed and unannealed materials.

B. The integrated sensitivity of peaks (4+5) is not a function of the glow curve heating rate.

C. As the heating rate increases above 500°C/min a tendency appears, in both annealed and unannealed materials, for peak 4 to increase and peak 5 to decrease. This indicates that peak 4 and 5 are difficult to resolve accurately and consistently and this difficulty is greatly exacerbated at high heating rates as the two peaks merge more.

2. The fading of peaks 4 and 5.

The individualy calibrated TLD-100 chips were irradiated by Co-60 gamma ray source to a dose of 50 mGy, stored at dark room temperature for a period of 30 days and evaluated. The same chips were irradiated again to the same dose and evaluated immediately. The measurements were performed with annealed and unannealed materials. The same experiments were performed for alpha and thermal neutron irradiation of peaks 4, 5 and (4+5) and the fading of the whole glow curve are presented in table 2.

TABLE 2 : The changing in the sensitivity of different peaks in TLD-100.

Irradiation	Peak 4	Peak 5	Peak (4+5)	Whole glow curve
alpha (anneald)	-23.0	-5.2	-10.0	-19.9
alpha (unanneal)	-38.0	-5.2	-17.0	-27.6
neut. (annealed)	-5.6	-10.9	-9.9	-10.0
neut. (unanneal)	+43.8	-4.9	+3.3	+2.8
gamma (annealed)	+11.3	-3.9	+0.7	-10.8
gamma (unanneal)	+32.0	-2.9	+6.3	-24.5
over all rad. (both types)		-5.5±2.6	-4.4±8.3	-18.8±12.8

From the results of table 2 it can be concluded:

A. We have received a growth of peak 4 after a period of 30 days for irradiation of both annealed and unannealed gamma rays and thermal neutrons for unannealed chips. Similar results were reported by Johnson (9) and Booth (10).

B. The fading of the whole glow curve is very different for different types of irradiation (gamma rays, alphas or thermal neutrons) or different materials (annealed or unannealed).

C. No evidence of LET dependence of the whole glow curve fading was found (for example, for unannealed materials, the results of the fading alpha and gamma rays were similar, and different from the fading of thermal neutrons; for the annealed one, the results of the fading of gamma were almost identical to the fading of thermal neutrons and different from the fading of alpha).

D. A well behaved fading rate (-5.5±2.6) was obtained for the peak 5 after 30 days, for both types of materials and different irradiations.

CONCLUSIONS

In the dosimetric applications involving long storage of irradiation periods (environmental or personnel dosimetry) where fading corrections are important, the use of peak 5 alone (separated from peak 4 by using CGCD) is recomended. In other applications requiring maximum precision (clinical dosimetry), the use of the area of peak (4+5) is optimal, again using CGCD to separate the peaks (4+5) from peaks 2, 3 and 7. In all applications heating rates bellow 500°C/min are recomended to allow adequate separation to peaks 4 and 5 from their high temperature and low temperature satellites. The common practice of integrating the TL signal to include part of peaks 2, 3, 6 and 7 in dosimetric measurements is one of the main reasons underlying the non-universality in many of the reported dosimetric characteristics of TLD-100.

TL DOSIMETRIC METHOD FOR ENERGY DISCRIMINATION IN EXTREMITY IRRADIATION MONITORING

Elisabetta Zucchi, Alberto Pilot

Servizio Fisica Sanitaria, Ospedale S. Martino, Genova, Italia

ABSTRACT

Radioisotopes employing in medical laboratory, nuclear medicine techniques for imaging and therapy, radioscopic investigations in surgery need extremity irradiation monitoring of workers.
Frequently, gamma - emitting radioisotopes differing for energy range are manipolated by the same person.
Extremity dose is therefore due to different radiation contribution.

INTRODUCTION

A TL dosimetric method is presented for EM energy discrimination in extremity irradiation monitoring.
The decision limit and the detection limit are defined.
The response of the dosimeter is indagated for EM energy ranging from E = 31 KeV to E = 1250 KeV, both in single and mixed fields.
The dosimetric system accuracy, tested with standard certificated radiations, is indagated like ratio between measured dose and the corresponding true one.

MATERIALS AND METHODS

The dosimeter consists of a watherproof nylon ring having density of 1.1 gr. cm^{-3} and window of 1 mm. Two detectors of different thickness and a 1 mm. Al foil between them are stacked in the case of the ring.The detectors are LiF chips, the inner having thickness of 0.9 mm., the outer 0.4 mm. The case window, the thin chip and the Al foil form the right buildup for the inner detector, from which measured doses are obtained.
Dosimetric system calibration is carried out with irradiations performed in the ENEA - Bologna secondary standard laboratory for ionizing radiations.
The chacteristic curve, obtained with a Co^{60} collimated source, is determined in the 0.4 - 48 mGy range.
The sensitivity curve is obtained with ISO - X reference raditions for calibrating dosemeters, having the following effective energy: 31 - 58 - 104 - 134 - 169 - 202 KeV. A Cs^{137} irradiation with the same value of air kerma is also used.
Dosimeter response to mixed fields is tested by several combinations of the above radiations.
The decision limit and the detection limit are defined at 95 % level of confidence, like stated by international raccomandations.
The reader is a Harshaw TLD System 4000. It provides the amount of the TL light like nCoulomb quantities.
The light emitted from the thick detector contained in the ring is used to defined the characteristic curve to obtain the dose measurement referred to the reference radiation (Co^{60}).
The ratio between the thin detector reading and the thick detector one is calculated to identify the energy of each investigated radiation field.
The energy correction factor to apply to the dose expression obtained from the characteristic curve, is derived like ratio between the thick detectors readings, the first relating to a stated energy radiation, the second to the reference one, each irradiated with the same dose.

RESULTS

The decision limit, defined as the dose level above which the measured doses with a 95 % probability can be regarded as true doses which do not belong to the background population, is 24 μGy. The detection limit, that is the dose level for which there is only a low risk (5 %) that a true dose will not be detected and that a background dose will be reported as a true dose , is 40 μGy.

To test the dosimetric system accuracy, unknown irradiation with standard certificated radiations are used to verify the condition stated by UNI raccomandations, that is $L_i \leq X_V / X_A \leq L_s$

where $L_i = 0.7 \times (1 - 2 X_o / (X_o - X_A))$, $L_s = 1.5 \times (1 + X_o / (2 X_o + X_A))$, X_V = measured dose, X_A = certified dose by standard laboratory, X_o = lower limit of dose range stated by standard laboratory (5×10^{-4} Gy).

Data analysis from tab. 1 shows a mean value of 0.849 for the ratio between the measured dose and the corresponding certified one (SD = 0.091).

Besides, each measured dose, except for the one referred to dosemeter 28, is included in the stated limits of accuracy.

Perfectly Tissue-equivalent TLD Phosphor $Li_2B_4O_7(Cu,Pb)$

Noboru Soramasu, Yoshitake Yasuno
Matsushita Industrial Equipment Co. Ltd.
3-3-1, Inazu-cho, Toyonaka, Osaka, 561 Japan

The Lithium-Borate TLD phosphor shows a small sub-response below 80 KeV(1), while other commercially available tissue-equivalent phosphors such as Lithium Fluoride or Beryllium Oxide show an over-response. This indicates the possibility of a perfectly tissue-equivalent Lithium Borate by adding the proper amount of high Z elements.

We investigated several high Z materials including Ag,Sn,Zn,Cr and Pb as well as the method to add these materials to commercial $Li_2B_4O_7(Cu)$. Lead Oxide was found to be effective in adjusting the energy response of $Li_2B_4O_7(Cu)$ without damaging its original TL characteristics. In preparing samples, we first obtained $Li_2B_4O_7(Cu)$ by a sintering method(2), then the sintered phosphor was mixed with PbO and the mixture was heat treated for Pb ions to diffuse.

Figure 1 shows the glow curves of obtained $Li_2B_4O_7(Cu,Pb)$. The shape of the glow curve does not change by adding PbO, however the TL intensity gradually decreases as the amount of PbO increases. Figure 2 shows the distribution of Li. Cu and Pb ions on the surface of a $Li_2B_4O_7(Cu,Pb)$ grain observed by the secondary ion mass spectroscopy. The Pb ions distribute similarly as Cu ions, indicating that Pb ions have replaced Cu ions.

Using the new phosphor, we prepared dosimeters of the commercial structure(3). The $Li_2B_4O_7(Cu,Pb)$ grains of approx. 90μm in diameter were fixed on a plastic film to form a single layer. Figure 3 shows the energy response of the dosimeters placed on phantom. The response below 0.1 MeV increases as the amount of Pb added. The dosimeter using $Li_2B_4O_7(Cu)$ + Pb(0.28%) shows an energy response within ± 3% of the 1 cm deep dose equivalent conversion coefficient curve in the energy range 25KeV and 1.25MeV.

The excellent tissue-equivalence of the phosphor promises better accuracy in medical dosimetry as well as in personal dosimetry.

INTRODUCTION

Since 1965, the survey of individual exposure for the people working in the medical field is carried out within the Institute of Hygiene and Public Health, by a central service belonging to the Romanian Ministry of Health. During this period, 6500 persons per month were monitored, using film-badges. The relative low sensitivity of film dosemeters lead to a decrease of confidence in this old system. Furthermore, the film badges do not have appropriate filters for measuring the personal equivalent doses Hp(10) and Hp(0.07), as are the new recommendations of ICRP and IAEA.

These facts made clear there is a necessity of changing this type of monitoring system with another one, having a higher sensitivity and allowing the measurement of personal equivalent doses Hp(10) and Hp(0.07).

The decision was to switch to a TL dosimetry system, namely the Harshaw 6600 System [1]. The performances of this new system have to be checked by the TL Dosimetry Group, at the Institute of Hygiene and Public Health, before being officially accepted as the new individual dosimetry system.

The paper presents the results of some of the test performed on the TLD-100 chips, concerning the influence of the heating rate and pre-heat temperature and duration (the time-temperature profiles) and the fading of the detectors.

MATERIALS AND METHOD

In order to check the performances of the TLD-100 chips, we have used the Harshaw 6600 System, which is the new system meant to be used for individual dosimetry.

The Harshaw 6600 TLD System consists of a TLD reader and a computer system. The reader uses hot nitrogen, or hot dry air to read the TLD cards. The TLD cards we are using (Fig. 1) are bar-coded cards, containing two LiF: Mg, Ti (TLD-100) included in Teflon foil.

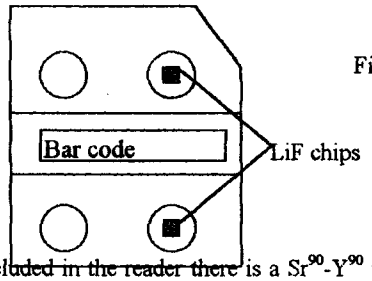

Fig. 1: Schematic of a TLD card used by the Harshaw 6600 System.

Included in the reader there is a Sr^{90}-Y^{90} irradiation source, that we used to irradiate the cards. The source was calibrated at the Secondary Standard Dosimetry Laboratory, within the IISP. A

computer system, with the TLDREMS software (also provided by Harshaw) is used to control the reader. The reproducibility of the working parameters (photomultiplier noise, high voltage, reference light, etc.) is checked at least daily, in this way assuring the reproducibility of the experiment.

The software allows the selection of different time-temperature profiles for every TL chip independently. Selection can be made on the preheat temperature and duration of preheat, on the temperature rate, on the maximum temperature, on the acquire time and on the annealing temperature and duration. Using this option from TLDREMS, we have defined six time-temperature profiles for our experiment.

Table 1: TTPs used in the experiment.

TTP1	TTP2	TTP3	TTP4	TTP5	TTP6
No preheat Temperature rate: 10°C/s Maximum temperature: 300°C Acquisition time: 13 1/3 s No annealing	No preheat Temperature rate: 25°C/s Maximum temperature: 300°C Acquisition time: 36 2/3 s No annealing	No preheat Temperature rate: 30°C/s Maximum temperature: 300°C Acquisition time: 13 1/3 s No annealing	Preheat temperature. 100°C Time of preheat: 30s Temperature rate: 25°C/s Maximum temperature: 300°C Acquisition time: 13 1/3 s No annealing	Preheat temperature: 100°C Time of preheat: 60s Temperature rate: 25°C/s Maximum temperature: 300°C Acquisition time: 13 1/3 s No annealing	Preheat temperature: 100°C Time of preheat: 120s Temperature rate: 25°C/s Maximum temperature: 300°C Acquisition time: 13 1/3 s No annealing

RESULTS AND DISCUSSION

The first three TTPs were use to determine the influence of the temperature rate on the use of the TLD cards as personal dosemeters. In our case, the peaks of interest are peaks number 3, 4, 5. (Fig. 2), the others peaks having a too low temperature to be used in this purpose, which presumes long-term (at least one month) survey.

It is well known that the Randall - Wilkins model predicts a dependence of the peak maximum position by the heating rate given by [2]:

(1) $\beta = (sk/E)T_M^2 \exp(-E/kT_M)$,

where s is the attempt to escape frequency, k is the Botzmann constant, E is the trap activation energy and T_M is the position of the peak maximum. This expression indicates that rather large changes in heating rate result in small changes in peak maximum position. The measurements we have performed indicated that the position of the peak changes with 10% +/- 3% when the heating rate changes from 10°C/s to 25°C/s, and with 5% +/- 1% when the heating rate changes from 25°C/s to 30°C/s. All measurements were performed on a batch of 50 cards.

The next three TTPs were used to determine if we can skip the period of minimum 1 week, that needs to separate the time of irradiation from the time of measurement, when the calibration of the system is performed. This time interval is needed to allow the fading of the low

temperature peak, not useful for personal dosimetry, and to realize calibration conditions as close as possible to actual personal dose measurements. We have used a batch of 50 cards irradiated with the Sr^{90}-Y^{90}, and read out immediately after irradiation. The glow curves were compared with the reading of other 50 TLD cards, performed 2 weeks after irradiation.

The results indicated that, in order to obtain similar readings with the readings performed after 2 weeks, a longer annealing time is needed, than the times we have used on the reader. For example, peak number 2 had an intensity about 5 times smaller when annealed at 100°C, for 120s, than when read out immediately after irradiation. However, the same peak had an intensity about 10 times lower when read out two weeks after irradiation, which means the annealing should be done for about 1 hour, at 100°C.

A batch of 100 cards was irradiated and read out at different times after the irradiation (immediately, one day after, two days, then at two days interval until one month was achieved). The fading of the TL signal is presented in Fig. 2.

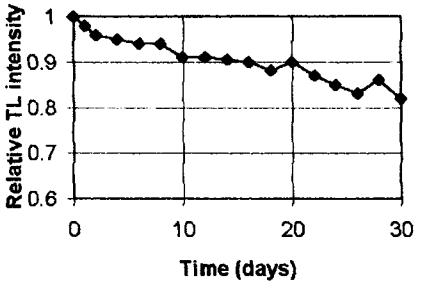

Fig. 2: Fading of TL chips used by Harshaw 6600

The relative intensity was calculated by respect to the read out immediately after the irradiation. As it can be seen, the fading is very low (less than 20% for the total area of the glow curve). Furthermore, the fading of the peaks of interest for personal dosimetry is even less important (only 3% for peaks 3, 4 and 5).

CONCLUSIONS

The measurements presented here allowed us to conclude that Harshaw 6600 is a very reliable system for personnel dosimetry.

INTRODUCTION

Dosimetry of weakly penetrating radiation, beta and photon radiation below 15 keV, has got more attention only during the last 20 years when a variety of methods for skin dosimetry were developed. One of the main difficulty in beta dosimetry is the energy independent dose determination. Dosemeters have been developed may be characterized as: mechanically thin TL detectors, surface sensitive elements, multi-element constructions and application of special evaluation regimes and/or glow curve analysis (1). Surface sensitive dosemeters include: TSEE detectors; reduction of the light transparency of thick detectors by adding graphite or other materials; creating new TL traps near the detector surface by diffusion of boron into LiF or Li_2 or $Li_2B_4O_7$. Good results have been achieved with carbon loaded LiF, $Li_2B_4O_7$ and MgB_4O_7 (2,3,4,5). Detectors loaded with carbon in a range of 11-20 % C have an effective thickness of a few $mg \cdot cm^{-2}$ therefore with an appropriate window thickness, 1-5 $mg \cdot cm^{-2}$, nearly energy independent beta dose measurement is possible even from $E_{\beta eff}$ 70 keV.

Lower sensitivity of thinner effective sensitive layer may be compensated by using high sensitivity TL material such as LiF; MCP (6) Present work presents results on graphite-mixed $CaSO_4$:Dy.

MATERIALS AND METHODS

Sintered $CaSO_4$:Dy pellets were prepared of 63-125 μm grains (7). These detectors have very good dosimetric properties: the main dosimetric peak exhibits at about 220°C, linear dose range is 10 Gy, no need for annealing at low doses, batch uniformity is letter than 2.3 %, reproducibility is better than 2 %. Environmental factors do not affect the detectors, no fading of the main dosimetric peak during a five months period is observed. The wavelengths of emission peaks are 478 nm and 550 nm, the relative TL response normalized to TLD-100 is 12-49 depending on the TL reader used for read-out. Detectors of $CaSO_4$:Dy were produced with different carbon loading, 5-10 % C. TL materials such as LiF:Mg,Cu,P IPN, Krakow, LiF (TLD-100), cold pressed LiF (0.85 % C) IKI, Budapest were used for comparison. BeO, Battelle Institute, Frankfurt and cold pressed LiF (C) were used for TSEE measurements.

Irradiations were carried out with newly designed nearly tissue equivalent beta sources. Beta dose-rates were measured with extrapolation chamber and flat ionization chambers. Irradiations were carried out at a 'contact' geometry, source to detectors distance was 7 mm, and 6.5 $mg \cdot cm^{-2}$ thick Mylar foil covered the detectors.

Irradiated TL detectors were analyzed by a Daybreak TL reader utilizing photon counting and the applied heating rate was $3°C \cdot s^{-1}$. TSEE measurements were carried out with reader developed at Fontenay-aux Roses, France having a multi needle counter.

RESULTS AND DISCUSSION

Detectors type $CaSO_4$ (C) used in measurements were selected from a larger batch and their sensitivities did not differ more than 3 % from the mean value.

Relative TL responses of pure, graphite-mixed $CaSO_4$:Dy detectors are given in Table 1 and in Fig. 1 and for the other TL detectors in Fig. 2.

Table 2. Relative TL responses of $CaSO_4$:Dy (C) detectors normalized to ^{90}Sr-^{90}Y irradiation

Detector	$CaSO_4$ pure	$CaSO_4$ 5 % C	8 % C	10 % C
^{147}Pm	10.5	36	48.5	49.7
^{204}Tl	58.3	69.6	72.5	81.1
^{90}Sr-^{90}Y	100	100	100	100
^{106}Ru-^{106}Rh	140	98	86	86

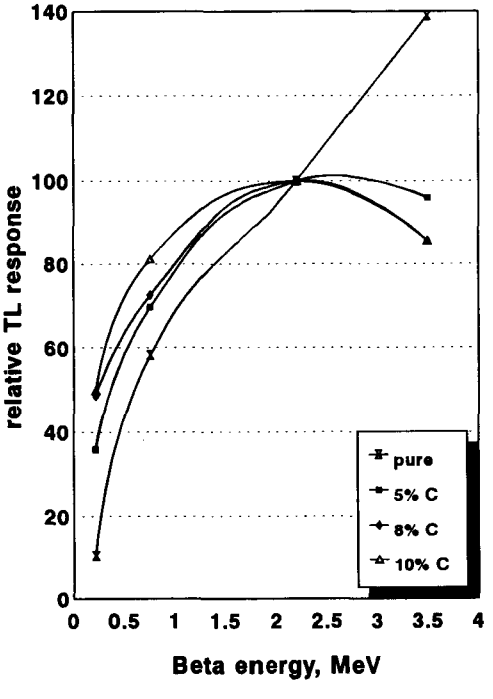

Fig.1. Energy dependence of TL responses of $CaSO_4$:Dy (C) detectors

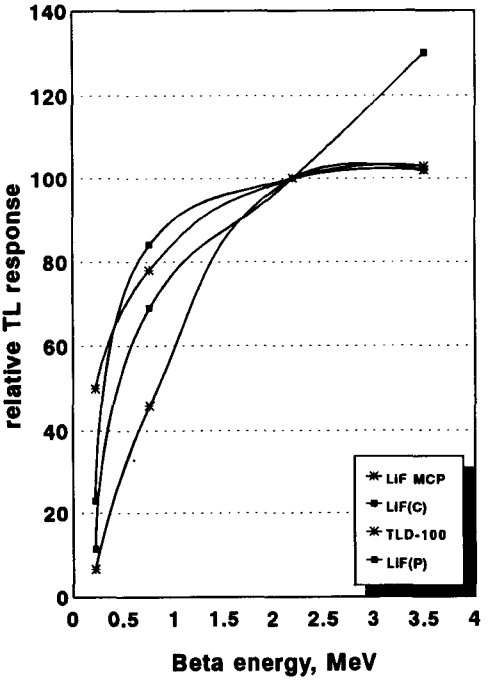

Fig.2. Energy dependence of TL responses of different LiF detectors

Sensitivities of different dosemeters were determined, see Table 2.

Table 2. Sensitivities of TL and TSEE methods using different materials

Method	Dosemeter	Lower detection limit, μSv
TSEE	BeO	2.5
	LiF (0.85 % C)	3000
TL	LiF; Mg,Cu,P	15
	LiF (0.85 % C)	300
	LiF (p) Krakow*	80
	TLD-100*	150
	$CaSO_4$:Dy pure*	10
	$CaSO_4$:Dy (5 % C)	80
	$CaSO_4$:Dy (8 % C)	200
	$CaSO_4$:Dy (10 % C)	250

Lower detection limits is set to 3 σ of the second reading; integration: the main dosimetric peak only.
*Sensitivities are valid only for higher $E_\beta \geq 0.5$ MeV radiations due to strong energy dependence of TL responses.

Results of $CaSO_4$:Dy (C) detector measurements have shown: this detectors are suitable for beta dosimetry, their sensitivity is high enough, energy dependence of TL responses are nearly flat for a wide energy range if an entrance window about 3 $mg \cdot cm^{-2}$ thick is used. The general excellent dosimetric properties of investigated $CaSO_4$:Dy (C) detectors make them a good candidate for beta dosimetry especially for pure beta radiation field measurement where their overresponses for low gamma radiation does not appear.

ABSTRACT (See instructions overleaf)

The Harshaw Model 4500 Manual TLD Reader is a newly designed instrument that is unique in its ability to read all forms of Harshaw thermoluminescent (TL) material: cards, Chipstrates™, chips, rods, microcubes, disks, and powder. The unit uses a sliding, dual-tube PMT Assembly to simultaneously read two positions of a TLD card or two Chipstrates, or to read a single unmounted dosimeter. Mounted dosimeters are heated with a hot gas medium to a maximum of 400°C. Unmounted dosimeters are heated by conduction on a planchet heated by electrical resistance to a maximum of 600°C. In both cases, the temperature is held precisely to a linear time-temperature profile by an electronic, closed loop feedback system. This paper reports the complete characterization of the reader in both heating modes, using IEC standards as a guide. Superior results were achieved and are reported in the following categories: detection threshold, reproducibility, ambient light sensitivity, climatic sensitivity, residual signal, system stability, linearity, test light stability, and power leakage.

A NEW APPROACH TO SCREENING ABNORMAL GLOW CURVES

R. A. Tawil, J. E. Rotunda, K. J. Velbeck, and Y. Tan

BICRON ◆ NE Radiation Measurement Products, Solon, Ohio, 44139

ABSTRACT

A simple computer program specifically developed to electronically screen abnormal LiF:Mg,Ti glow curves in routine dosimetry is presented. The method identifies glow curves with abnormal patterns by examining a few key features from which information about background and thermoluminescent (TL) signals can be extracted. The underlying criteria for glow curve acceptance/rejection are discussed. By analyzing the records of Quality Control (QC) cards that are in the same group as the field cards, the dosimeter- and reader-dictated parameters (such as the peak location) are automatically determined, thus eliminating the need for any prior knowledge of those conditions required for reference determination. The program performance was evaluated by using actual glow curve data provided by users of commercially available readers and dosimeters in routinely high-throughput operations. The initial tests showed a near 100% success rate in identifying abnormal glow curves (no false positive results) and a minimal rate of rejection of normal glow curves. Results have shown that this method is applicable for dose levels down to 50 μSv.

INTRODUCTION

As radiation monitoring and protection becomes an increasingly important issue, the growth in the scale of routine dosimetry is inevitable. A well established and widely employed dosimetry technique is thermoluminescence dosimetry (TLD) using LiF as the host material[1,2]. Dose information is generally extracted from the integral area under the glow curve or part of the glow curve. Errors in such measurements are inevitable due mainly to the existence of background and to the complex nature of the fast-fading glow peaks. Much effort has been devoted to improving the accuracy of dose measurement by subtracting background signal and by eliminating contributions from the fast-fading glow peaks[3-5].

In routine dosimetry where accuracy is not a critical issue, dosimetric information is approximated by the total area under the glow curve. The validity of such practice is ensured by carefully examining each individual glow curve and eliminating spurious readings before they can be used in dose algorithms[6]. Currently glow curve screening is done manually. This is not only time consuming, but the pass/fail decision making is highly subjective. The existing analysis programs cannot help change this situation because many features of these methods are not compatible with the practical requirements of routine dosimetry.

For the now-apparent reasons we have developed a simple program for routine personnel dosimetry to electronically analyze the shape of LiF:Mg,Ti glow curves. Rather than separating individual glow peaks, this method automatically recognizes irregular glow curves by identifying a few key glow curve features and testing them against a set of empirical criteria. Emphasis is placed on complete rejection of faulty glow curves and minimal rejection of good glow curves. Some specific faulty features in glow curve shape are:

1) saturation of readout
2) spikes caused by electrical interference
3) lack of a glow peak
4) glow peak occurs at unexpected temperature
5) distortion caused by non-radiation induced signal
6) high IR tail or high residual signal
7) end of acquisition before completion of glow curve.

GLOW CURVE STANDARDS

The intrinsic glow curve characteristics — the location and width of the main glow peak — are adversely affected by a host of factors such as the chip thickness, electronics of the card-reading instrument, and the heating profile used for readout. If all cards in a group are of the same type and are read in a relatively short time frame (say, one day) by the same reader, we can reasonably expect these glow curves to exhibit close similarity in shape. The established values of these parameters are defined as 'glow curve standards'.

Because the standards are largely determined by factors that are different from user to user, it is impossible to arrive at a universal set of parameters that are applicable to all users. This difficulty, however, can be overcome by utilizing the Quality Control (QC) cards that were interspersed in groups of field cards during card reading. The values of the intrinsic parameters (with reasonable tolerances) for field glow curves

can be predicted from the corresponding aspects of the QC curves. This approach enables the determination of glow curve standards without any prior knowledge of the aforementioned conditions.

GLOW CURVE ASSESSMENT STEPS

The glow curve screening program proceeds through the following logical decision tree to determine which glow curves are likely to have faulty features and need visual inspection.

1. Saturation Test. Check for readout saturation by testing for a flat top in the TL spectrum.

2. Curve smoothing. Outlier points must first be removed from the initial spectrum. An outlier is a discrete point on the curve which, judging from its amplitude, is likely to arise from instrument malfunction rather than from statistical fluctuation. Specifically, an outlier y_i satisfies the condition:

$$\frac{|y_i - y^0{}_i|}{y_{max}} > 0.1$$

where

$$y^0{}_i = 0.5 * (y_{i-1} + y_{i+1})$$

is the corresponding average of the immediate neighboring channels. An outlier is removed by replacing y_i with $y^0{}_i$. The weighted averaging method is used to filter out glow curve noise caused by the dosimeter and by instrument electronics. The weighting factors are chosen such that a respectable smoothing is achieved without altering the original features of the glow curve.

3. Glow curve noise level. The noise level of a glow curve is characterized by the number of outlier points and by the extent of the TL scatter. The latter is estimated by comparing the spectra before and after smoothing. If the estimated noise level exceeds a pre-set threshold, the glow curve is rejected.

4. Peak finding and Peak 5 identification. Peaks are automatically found by searching for local maximum, which is defined as the highest points in a region of ±10 channels from a putative apex. The main dosimetric peak — peak 5 — is identified as the one closest to the expected peak location (as defined by the standard) and lies within a certain tolerance window.

5. Estimate various regions of interest. The glow curve from an irradiated dosimeter upon linear heating can be divided into three regions, where background and dosimetric information can be extracted.

   Region I: Low temperature region (peaks 1 and 2). In routine personnel dosimetry, peaks 1 and 2 are generally invisible due to long fade time. Consequently, this region should be dominated by the photomultiplier tube dark current. Excess signal in this region indicates the possibility of non-radiation induced signal, in which case the glow curve should be rejected.

   Region II: Main dosimetric peak region. This is the region of dosimetric interest and usually includes peaks 3, 4 and 5.

   Region III: High temperature region. This region is dominated by the temperature-dependent background, due mainly to infrared radiation (IR) by hot TL element and detector parts. The relative size of the IR radiation to the actual dosimetric signal is estimated by the ratio of the area under the curve for the last few channels over the area of Region II. An internal upper limit for this ratio has been set to reject those glow curves with high IR tails.

6. Determine the inflection point on the high-temperature side of Peak 5. This point is found either by searching for a local minimum immediately to the right of Peak 5, or by utilizing the curve slope information. If this point cannot be found, the glow curve should be rejected as incomplete.

7. Baseline fitting and background subtraction. For a complete glow curve, the baseline is fitted to an exponential function:

$$y = \exp(a + bx),$$

where x is the channel number, y is the background level at channel x, a and b are parameters to be

extracted from the fit. The sampling points used in the fit are the first N channels with constant background and the points in Region III. Figure 1 shows a smoothed glow curve and a superimposed background curve. The background signal can be calculated by integrating the area under the fitted background curve. If the ratio of background signal to the total signal is greater than the limit pre-specified by the user, the glow curve will be rejected.

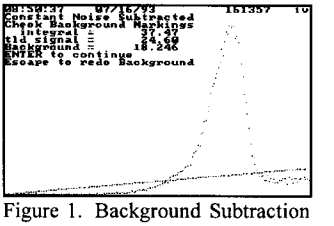

Figure 1. Background Subtraction

8. Estimate the width of the main glow peak. The glow peak width is measured by its full width at half maximum (FWHM) height. A maximum acceptable value of FWHM is determined based on the information obtained from the QC card records in the same group. A very wide glow curve structure usually indicates poor heat transfer and hence should be rejected.

PROGRAM OUTPUT

If a glow curve is rejected by the algorithm as a result of a failure from the evaluation criteria, an online message is displayed stating the dosimeter ID and reason for rejection. Upon completion of the program a summary report is created including the user-specified values of glow curve acceptance criteria, the number of dosimeters processed and a list of all glow curves rejected along with reasons for rejection.

PERFORMANCE EVALUATION

The method described herein has been tested with some 2000 glow curves provided by users of Harshaw/Bicron Model 8800 Automatic TLD Readers. The current algorithms demonstrated a success rate of nearly 100% in rejecting problematic glow curves. While having certain irregularities, a small fraction of the rejected glow curves may be deemed by some users as acceptable for dose evaluation. Figures 2 through 4 show some of the glow curves rejected by this program.

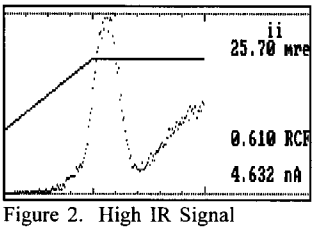

Figure 2. High IR Signal

Naturally this method is more effective for high doses than for low doses. Nonetheless, it is effective down to the level of 50 μSv. Bearing in mind that the purpose of this program is to avoid erroneous evaluation and reporting of radiation received by the dosimeter wearer, the significance of this program is of less concern in analyzing glow curves that reflect only background radiation.

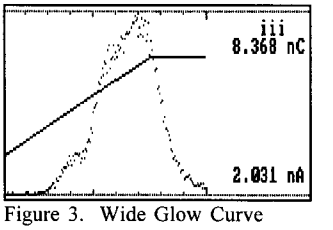

Figure 3. Wide Glow Curve

CONCLUSION

A simple computer program has been developed to screen abnormal LiF:Mg,Ti glow curves in routine dosimetry. Extremely encouraging results were obtained from the initial tests. More careful and extensive tests are suggested to thoroughly evaluate the current algorithms. Continuous efforts are anticipated to improve the program's functionality. It is worth pointing out that although this method was developed specifically for analyzing LiF glow curves, it can be modified with reasonable ease to extend its scope to include glow curves from other types of TL materials.

MAJOR SCIENTIFIC TOPIC NUMBER 3.2 (see page 7)

ABSTRACT (See instructions overleaf)

The expansion of the number of TL materials currently available that exhibit ultra high sensitivity, such as LiF:Mg,Cu,P (GR-200A),$CaSO_4$:Dy (TLD-2000H), $CaSO_4$:Tm (TLD-2001H), and Al_2O_3:C (TLD-500K), make it important to study and compare their individual TL properties under the optimal measurement procedures.

The behaviour of hypersensitive thermoluminescent phosphors in form of solid TL detectors has been studied under two basically types of TL Dosimetry Systems based on different heating methods, planchet , and hot nitrogen gas heating. Also, the different types of TLD systems may differ markedly in their spectral light detection responses, i.e. the spectral response of photomultiplier depends on the composition of the photocathode, on the special transmission of the tube window, as well as on optical filter built in. Since the spectral emission of the various TL materials spans from 300nm to 600nm, the investigation of the influence of the measurement conditions on the main characteristics of the investigated phosphors is also analyzed.

This study shows that the main characteristics of examined TL materials including sensitivity, reproducibility, linearity, minimum detectability repeatibility, residual dose, ambient light sensitivity, stability of glow curve shape, fading, dependence on the heating rate,etc., support the importance of achieving compatibility between the TL material and the type of Thermoluminescence Dosimetry System used.

A new laser thermoluminescence dosimetry system for the determination of the personal dose equivalent $H_p(10)$ and the irradiation conditions

Introduction

For the purpose of radiation protection additional information about the irradiation conditions may be important if a personal dose above a specified threshold is detected. The objective of the development of a new personal dosemeter therefore is to determine the personal dose equivalent with the necessary accuracy and, also, to provide infomation about the irradiation conditions. To fulfil these requirements, a new laser-heated TL dosemeter (TLD) system, commercially available and produced by International Sensor Technology Inc. has been modified. A new algorithm based on linear programming (1, 2) is applied to improve the dose determination. A TL-sheet is inserted into the dosemeter badge to allow information to be obtained about the irradiation conditions.

Laser TLD system

The unique feature of the dosemeter (Figure 1) used in the laser TLD system is a $CaSO_4$:Tm imaging sheet (image area: 9 mm × 15 mm). The sheet determines the direction of incident radiation by the "shadow" projected by two metal plugs (ø: 1,5 mm, length: 3,8 mm, lead alloy), one arranged above and the other below the sheet. Four $CaSO_4$:Tm elements (3,5 mm × 3,5 mm) (3), each with different filtering, are used to calculate the personal dose equivalent $H_p(10)$, including an estimate of the mean energy of the incident photon radiation. The following four filters are used: plastic material 1,17 mm and 3,30 mm thick, tin 1,40 mm thick and stainless steel 0,25 mm thick.

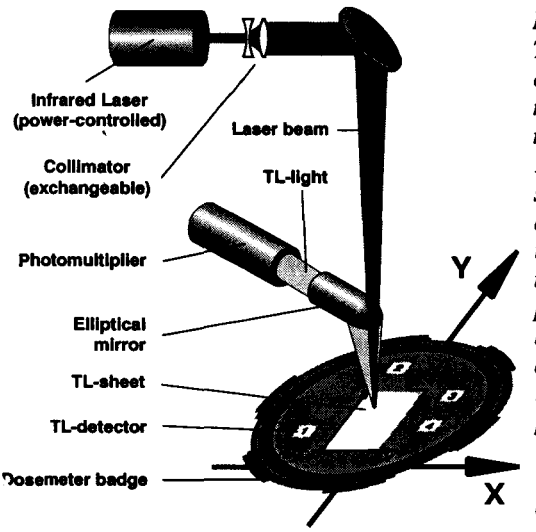

Figure 1. Schematic diagram of the laser TLD system. For evaluation of the TL elements and the sheet, the dosemeter is moved in an x-y plane to place each element in the beam of a power-controlled 10 W CW CO_2 laser (4, 5). A shutter (not shown) is opened for element reading and annealing only. Two types of beam-shaping optics (collimators) are automatically moved into the laser beam. The first type produces a 4 mm × 4 mm uniform heating beam used to read the single elements and anneal both the single elements and the imaging sheet (4, 5). The second type produces a small spot for reading the imaging element with a high spatial resolution (0,3 mm in both the x and the y direction).

Determination of the personal dose equivalent $H_p(10)$

All TL-elements of the dosemeter are calibrated using gamma radiation of ^{137}Cs. The dosemeter is read to determine the personal dose equivalent $H_p(10)$ over an energy range from 17 keV to 1250 keV and over an angular range from 0° to 60° (Figure 2). For dose determinations, information about irradiation conditions is not necessary, because an algorithm based on linear programming is used (1, 2). The algorithm determines the lowest (H_{min}) and the highest (H_{max}) dose values compatible with the signals of the four single elements. The geometric mean of the extreme dose values, H_{min} and H_{max}, is taken as the dose value M_p of the dosemeter. The response matrix (1, 2) used for the calculations consists of the four single element responses to X-ray radiation of the ISO narrow spectrum series (N-30 to N-300) and to gamma rays of ^{137}Cs and ^{60}Co and angles of 0°, 30°, 45° and 60° on an ISO water slab phantom. The maximum difference between the irradiated dose and the dose measured for $H_p(10)$ by this dosemeter determined with linear programming is less than ± 16 % for mixed photon fields in an energy range of 26 keV to 1250 keV and an angular range of 0° to 60° (2).

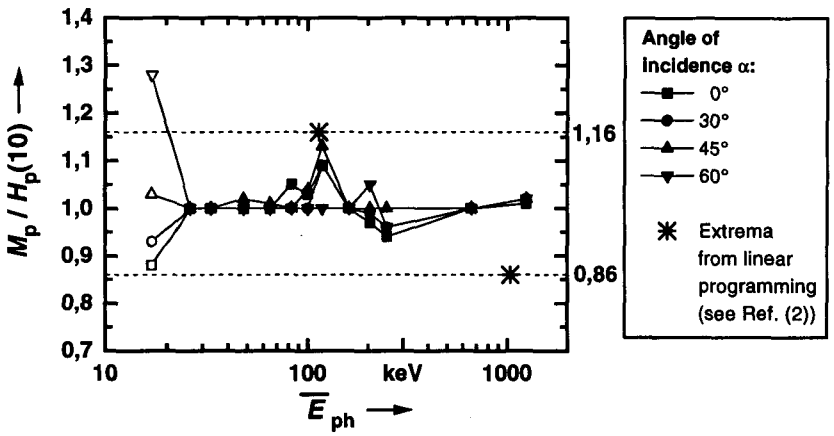

Figure 2. *Dosemeter response to $H_p(10)$ using a linear programming algorithm to calculate the dose based on the responses of the four single elements. The radiation energy range is obtained with X-rays of the ISO narrow spectrum series (N-20 to N-300) and gamma rays of ^{137}Cs and ^{60}Co. The open symbols denote irradiation conditions outside the range defined by the response matrix. The dashed lines indicate a deviation of the response of + 16% / – 14 % from unity. The small angular dependence is a result of specially designed filters. $\overline{E}_{ph}$ is the mean photon energy.*

Direction of incident radiation

The direction of radiation incidence is determined by scanning a $CaSO_4$ imaging element when the measured personal dose equivalent exceeds a specified threshold. The collimator in the laser beam path will scan the sheet with a 0,3 mm spatial resolution (both in x and y direction). The sheet is annealed by scanning with the large (4 mm × 4 mm) heating beam. The imaging sheet has sufficient sensitivity to provide incident radiation direction information for X-ray (30 kV - 300 kV tube potential) doses higher than or equal to 0,2 mSv.

The direction of incident radiation is inferred from the "shadow" projected by the two lead alloy plugs (one arranged above and the other below the sheet) onto the sheet. If the incident radiation is perpendicular to the sheet, a circular shadow is produced on the image. Non-perpendicular irradiation produces an oval shadow (Figure 3). The two plugs are staggered to distinguish radiation incident from the front or back of the dosemeter.

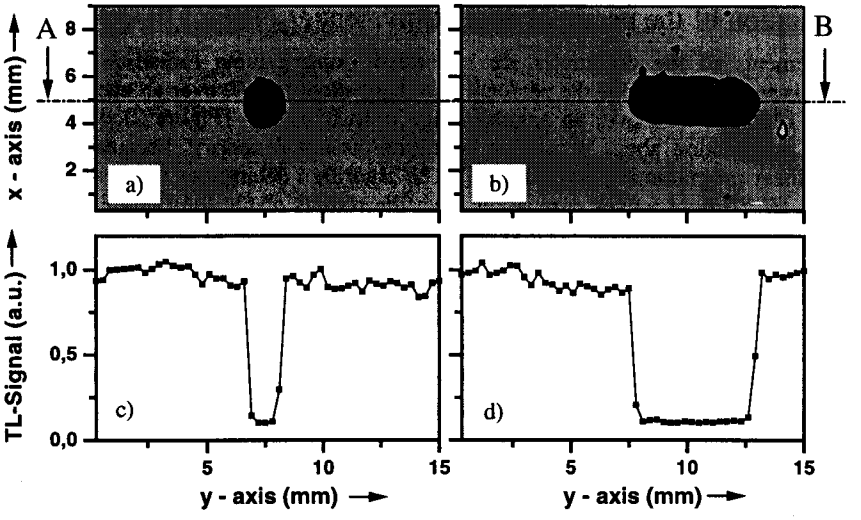

Figure 3. *Contour (a, b) and cross section (c, d) plots of the dose distribution of a $CaSO_4$ imaging sheet (9 mm × 15 mm) after irradiation with 1 mSv 60 kV X-rays. The contour plots show that the shadow of the metal plug is circular (a) and oval (b), when irradiation takes place perpendicular or at 45°, respectively, to the imaging sheet. The cross section plots (c, d) show the dose distribution along the line AB as shown in figures a and b.*

Conclusions

The laser-heated TLD system has a unique 2-dimensional dose image based on TLD, which provides information about the direction of incident irradiation. The system also allows the personal dose equivalent $H_p(10)$ to be determined with sufficient accuracy for a wide range of the photon energy and the angle of incidence. Besides the features of the system shown here, it also allows the personal dose equivalent H_X to be determined and the mean energy of the incident photon field(s) to be estimated.

INTRODUCTION

For safety operation of high energy accelerators, radiation dose measurement for accelerator components is very important since severe damages of electric parts, such as a breakdown of insulation and change of electric properties, take place if they receive high radiation doses. A dosimeter, which can measure integrated radiation doses up to at least 1 M Gy, is needed for this purpose. There are a couple of simple devices applicable to the measurement for a wide range of integrated doses; the dosimeters using conducting polymers are promising candidates for the measurements in high radiation fields.

Conducting polymers, represented by polyacetylene (1, 2) and polyaniline (3), are known to exhibit drastic increases in their electrical conductivities from insulator to conductor by doping. The device consisting of a conducting polymer and a source material of a dopant can be used as a dosimeter (4, 5). A dopant gas is produced through the radiation decomposition of the source material, and the polymer is doped with the released gas. In this dosimeter, radiation doses can be easily measured as an increase in conductivity of the polymers with a simple resistance meter. We applied this method to polyaniline systems, and the basic characteristics of the dosimeter using polyvinylchrolide powder (PVC) as the source material were reported in the previous paper (6).

In this study, the new system of a polyaniline and SF_6 gas was adopted as a dosimeter, and the conductivity change by radiation-induced doping was examined extensively. The relation between the integrated radiation dose and the conductivity change is described.

EXPERIMENTAL

1) Samples The polyaniline used in this work was of the emeraldine base form which was chemically synthesized from a 1 M perchloric acid solution of aniline. The polyaniline film was prepared by gently drying the solution of polyaniline on a glass plate placed horizontally. *N*-methyl-2-pyrrolidone was used as the solvent, and was evaporated completely at 80 °C under vacuum for 1 day.

The polyaniline system consisted of a polyaniline strip (0.5 × 4 cm, *ca.* 40 μm thick) and SF_6 gas (purity: 99.99%), which were sealed in a Pyrex glass tube (volume: *ca.* 2.5 cm^3). The pressure of SF_6 gas was 0.1 or 1 atom.

2) Irradiation The samples were irradiated with ^{60}Co γ-rays at room temperature. This irradiation was carried out at the ^{60}Co irradiation facilities of Japan Atomic Energy Research Institute. During the irradiation, the radiation-induced doping proceeds in the glass tube.

3) Measurement of Electrical Conductivity The resistance of the polyaniline film was measured with an ultra-high resistance meter (Advantest Co., Model R8340A) in a pure nitrogen atmosphere at room temperature. After γ-ray irradiation, the glass ampoule of the sample was open, and the resistance of the irradiated strip was measured.

4) Determination of Fluorine in the Polyaniline In order to examine the relationship between the conductivity change and the fluorine content of the strip, the content was determined by neutron activation analysis. A piece of the strip after the radiation-induced doping was irradiated by neutrons in the PN-3 pneumatic tube of the JRR3 reactor in Japan Atomic Energy Research Institute. The repeated irradiation technique was applied to the samples with low content of fluorine to obtain high precision of determination. The intensity of the 1633-keV γ-ray of ^{20}F (half life: 11 sec) formed by the (n, γ) reaction of ^{19}F was measured with a Ge semiconductor detector system. The fluorine content was determined from its γ-ray intensity, compared with reference samples.

RESULTS AND DISCUSSION

The volume conductivity of the undoped polyaniline film prepared was 1×10^{-13} S/cm and the surface conductivity was 1×10^{-13} S. The film prepared (the emeraldine base form) is very stable to radiation. The conductivity of the film decreased by only one half of its original conductivity even for ^{60}Co γ-ray irradiation up to 3.6 M Gy under vacuum. This change is negligibly small compared to an increase in conductivity by doping mentioned below.

Figure 1 shows the conductivity change of irradiated polyaniline strips with different pressure of SF_6 gas (0.1 atm and 1 atom). The abscissa represents the absorbed dose for the polyaniline film, and the ordinate shows the conductivity ratio of irradiated to non-irradiated polyaniline. The conductivity increasesd almost linearly on a log–log plot along with an increase in the dose over a wide region of about 10^3 to 1 M Gy; the maximun conductivity reached 10^8 times its original value above 1 M Gy. As shown in Fig. 1, the threshold dose can be controlled by changing the pressure of SF_6 gas.

The surface of the polyaniline film was doped more homogeneously in this polyaniline–SF_6 system than in the polyaniline–PVC system (6) where a heavy dopant gas (HCl) is produced by radiolysis in the solid source material. This indicates that gases are much suitable for the source material of the dopant.

Figure 2 shows a relationship between the content of fluorine (μg/cm^2) introduced on the surface of the polyaniline film through the radiation-induced doping and its relative conductivity. The content was obtained by subtracting the fluorine content originally contained in the undoped polyaniline film from the total content in the doped polyaniline obtained by the neutron activation analysis. The original content was determined to be 1.4 μg per 1 cm^2 of the film with the same method as the doped polyaniline films.

The conductivity change through doping is very influenced by species of the dopants and their amounts on the surface of conducting polymers. The concentration of the dopant gas depends on the G-value of the dopant gas liberated from the source material, the amount of the source material and the integrated radiation dose.

The linear increase range in this SF_6 system (Fig. 1) was narrower than that of the polyaniline–PVC system (6); however, the increase in the SF_6 system continued to *ca.* 1 M Gy, while that reached saturation at 0.1 M Gy in the PVC system. This SF_6 system is, therfore, considered to be more suitable for a dosimeter which is used in high radiation fields. A prototype dosimeter

with electrodes will be discussed.

THE FEATURES OF RADIATION DAMAGES IN L-ALANINE CRYSTALS

V.R. Zaitov[1] and V.A. Onischuk[2]

[1]Institute of Radioecology, Tolstoy St. 14, Kiev, Ukraine
[2]Institute for Nuclear Research, Prospect Nauki 47, Kiev, Ukraine

INTRODUCTION

The method of the ESR alanine dosimetry has appeared the most convenient one for measurement of radiation dose in the range $1\text{-}10^6$ Gy (1). Its peculiarities are the wide dose range, the high accuracy, the absence fading at room temperature, the possibility of many times repeated measurements as dosimeter accumulates dose, the simplicity of measurements.

Because of this performance ESR alanine dosimetry technique can be applied to continuous monitoring radiation doses absorbed by materials on nuclear power stations as well as of dose fields and restoration doses after an accident situation. In order to determine accurately the absorbed dose in an accident on background of accumulated dose for previous period, it is necessary to the utmost increase the accuracy of dosimetry system.

For this reason it is necessary to know how the properties of free radicals which formings in irradiated L-alanine are displayed in signal ESR.

PROCEDURE

With the purpose to detect the structure of the free radicals the ESR spectra the L-alanine and L-alanine-d_3 single crystals were studied. The samples were grown by slow evaporation of the saturated aqueous solution. For obtain the L-alanine-d_3 the three-divisible recrystallisation in heavy water had been used. The samples were irradiated with ^{60}Co at room temperature and in liquid nitrogen. The irradiation doses were 10 kGy and dose rate was 8,3 Gy/s. To increase the resolution of the ESR spectra hyperfine structure the second derivative for the absorption curve was registered. The measurements were conducted in X-range at temperatures 77-430 K.

RESULTS AND DISCUSSION

The primary anion-radical is formed when an undamaged molecule carboxylic group trap an electron that expulsion by radiation from other molecule of initial substance

$$CH_3CH(NH_3)^+COO^- + e^- \Rightarrow CH_3CH(NH_3)^+CO^-O^-.$$

At once after it the amino proton of the adjacent molecule passes on the carboxylic group of anion-radical. The free radical $\dot{C}H_3CH(NH_3)^+CO^-OH$ (I) is formed and it's observable experimentally(2).

The charge of damage is localised on adjacent molecule. At T>110K the C-N bond in radical I is broken off, then the intermediate radical CH_3CHCOO^- (II) and molecule $NH_3$are formed(3,4). At last, at T>220 radical II is transformed to stable radical $CH_3CHCOOH$ (III) (5,6). Its ESR signal is used to determine an absorbed dose.

The structures of radicals I-III are good investigated and known. The radical III is different from the radical II by space structure, orientation in crystal lattice and the hindered internal rotation of methyl group. The width of ESR lines, relaxation time and consequently, signal strength, on which the absorbed dose is defined, depend on the internal rotation frequency. The most drastic dependence is observed in area of frequencies $\nu_c \cong \delta\omega$; where $\delta\omega$- is distance between the exchanging lines of spectrum in the frequency units.

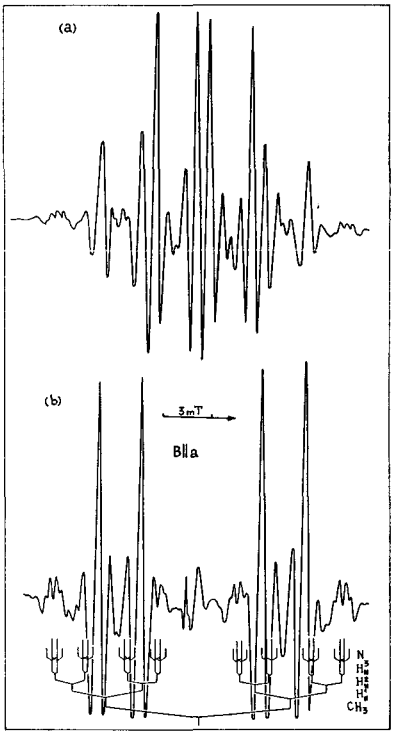

Fig. The spectra ESR γ-irradiated L-alanine single crystals: at T=293K (a); at T=160 K (b)

For internal rotation of methyl group of the radical III the frequency ν_c is reached at T≅160K. At room temperature the rotation frequency $\nu >> \nu_c$, the ESR spectrum this radical is completely averaged and the internal rotation of methyl group not appreciable influence on the ESR signal strength.

However, in 1987 the new type of movements of the radical III was described as conformational transitions[7,8]. Has appeared that the ESR spectrum, which registered in range 250-430K is means between spectra of two conformers.

It is essentially, that the frequency of these movements is reached ν_c at room temperatures. Thus, the measured ESR signals at different temperature in range 18-28 °C will have be the different intensity.

From this it follows that the phenomenon of the conformational transitions of radical III must take into account to increase the accuracy of the ESR alanine dosimetry. It is interesting, that the space structure and orientation in unit cell of the one conformers of the radical III coincides with structure and orientation of the intermediate radical II. Photo stable radical $CH_3CHCOOH$ has the same structure and orientation also. It is formed under action of light with the wave length λ≤365nm on irradiated crystal of L-alanine. The stability of this radical is the same that the radical III. So, the radical CH_3CHCOO^- may have dissimilar stability depending on treatment of the crystal.

To clarify the cause of this fact the simulation of transform the anion radiation damage from primary to stable state was performed. The calculations were carried out by AM1 and INDO. As the model of the radiation damage was used cluster $[CH_3CH(NH_3)^+COO^- + 3*(NH_3)^+CH_2COO^-]$. The central molecule that is rearranged to radical, is connected with three adjustment molecules by hydrogen bonds on carboxylic group. For simplification of computations the methyl groups of these molecules are replaced by the hydrogen atoms.

At transition I ⇒ II the C– N distance is increased from 1.47 to 2.85A. The energy E≈110 kJ/mole is thus allocated. As a result the radical $CH_3CHCOOH$ and NH_3 molecule are separated. The carboxylic proton is discharged from chain O–H...N and then is seized in a nearest trap. The oxygen atom of the radical is connected with the nitrogen atom of the molecule and the radiation damage energy is decreased. It explain the parallel displacement of the radical II in comparison with initial molecule as well as the absence of proton in the carboxylic group of the radical and in the amino group of the appropriate molecule[4].

At T≥220K the proton trapped on nearest environment comes back on the carboxylic group of the radical. It results in breakage of connection O...N. The radical II displaces back in situation which characteristic for radical I and the initial molecule. However for maintaining the equilibrium distance between molecule NH_3 and C_α atom the radical is turned in unit cell. As a result the distance between the ammonia and the methyl group of

the radical is decrease. This is tended to occurrence of barrier for internal rotation of methyl group. Then the reduction of energy radiation damage and stabilisation of radicals III is accounted for by this interaction. The appearance of stable radical CH_3CHCOO^- under action UV on irradiated L-alanine may be explain by moving the proton from chain O–H...N to remote traps and the return transition does not happen at room temperature.

The primary radical for cation radiation branch is σ-radical with delocalized unpaired electron density. The most the probable structure is the neutral radical $[CH_3CH(NH_3)COO]$ (V) [10]. Positive charge is transferred ammonia proton to adjacent molecule[11]. At T≈110 K this radical decay and the second type of the stable radical in L-alanine is formed. Its ESR spectra are observed on background spectra of radical III. In order for identify this radical the angular and temperature dependencies of ESR spectra of irradiated L-alanine and L-alanine-d_3 crystals were investigated. Earlier[12,13], the CH_3CHNH_2 structure had been assumed for it. However an analysis of our experimental data follows that the unpaired p_z electron interacts with three protons of a methyl group and three ammonia protons through superconjugation and with nitrogen through configuration mechanism. Interaction with α-proton was not found. It was concluded[14], that the radical structure is $CH_3C(NH_3)^+COO^-$ (VI). It is essential that characteristic frequency of the methyl group rotation in radical VI is reached at the same temperature that for radical III.

CONCLUSIONS

The $CH_3C(NH_3)^+COO^-$ (VI) radical is stabilised in irradiated L-alanine in addition to $CH_3CHCOOH$ (III) radical. Their concentrations are the same approximately. Both radicals exhibit internal motions and characteristic frequency ν_c of the conformational transition of the radical III as long as the amino proton's exchanges in the radical VI are reached at room temperatures. These phenomena should be considered in order to increase the accuracy of ESR alanine dosimetry.

Extremity Dosimeter by $Li_2B_4O_7(Cu)$ and its Response to β Rays

Noboru Soramasu, Sueki Baba and Yoshitake Yasuno
Matsushita Industrial Equipment Co. Ltd.
3-3-1, Inazu-cho, Toyonaka, Osaka, 561 Japan

An ideal dosimeter to evaluate skin dose should be a $5mg/cm^2$ detector with a $5mg/cm^2$ window. To realize the TL detector using $Li_2B_4O_7(Cu)$ of density $2.2g/cm^3$, the thickness of the phosphor layer must be as low as 23μm. However, a thin TLD such as this would lack the sensitivity necessary to practical use.

In designing an extremity dosimeter composed of a single layer of phosphor grains, we first investigated β ray response of samples prepared using various combinations of grain size and window thickness. The $Li_2B_4O_7(Cu)$ grains of three grades in size, 38 to 45μm, 45 to 53μm and 53 to 75μm, were fixed on plastic films to form single layers. These samples were exposed to ^{90}Sr-Y, ^{204}Tl and ^{252}Pm β rays through polyethylene windows of thickness 1.2 mg/cm^2, 3.6 mg/cm^2 and 6.0 mg/cm^2. Figure 1 shows the β ray energy response of these samples indicating that the window thickness more affects the energy response than grain size. Even the largest grains (53 to 75μm) showed a flat response when the window thickness is 3.6 mg/cm^2. The lowest detectable dose of the sample using this grain size was 0.2 mSv.

Figure 2 shows the structure of the extremity dosimeter using 53 to 75μm grains. A circular phosphor layer of diameter 2.5mm was formed on a black polyimide film of 30mm x 5.5mm x 0.07mm, with the phosphor guarded by a hard frame of 9mm x 5.5mm x 0.6mm. A dosimeter number is given by both barcode and numerical characters. The dosimeter is worn on the fingers with a thin plastic cover with thickness approx. 3.6 mg/cm^2.

Figure 3 shows the conceptual view of the main part of the extremity dosimeter reader. A magazine guides the dosimeters first to barcode scanner then to the dosimeter reading position. The infrared ray beam from the lamp heats the dosimeter, and the photomultiplier detects the TL by a photon counting method.

The requirements to extremity dosimeter is somewhat contradictory. For example, a dosimeter must be small to be worn on finger, whereas it must be big enough to be treatable by human hands. The dosimeter above, which is a combination of small detector guarded by hard frame and a larger flexible tail where visible numbers are printed, could be one solution.

DOSIMETRY OF ELECTRON AND GAMMA RADIATION WITH DL-ALANINE

Zélia Maria da Costa and Letícia Lucente Campos

Instituto de Pesquisas Energéticas e Nucleares- IPEN

Comissão Nacional de Energia Nuclear - CNEN

Caixa Postal, 11049, Pinheiros, CEP 05499-970- São Paulo, SP -Brazil

INTRODUCTION

A dosimetric method based on the quantitative determination of stabilised free radicals in irradiated crystalline DL-alanine by electron spin resonance (ESR) spectroscopy was proposed as early in 1962[1]. Since then, alanine dosimeters owing to their unique properties have been investigated by many authors and used in dosimetry of various types of radiation, namely gamma rays, electron and neutrons.

Alanine is a simple aminoacid, on irradiation at room temperature predominantly free paramagnetic radicals of the type CH_3 - CH - COOH are produced.

This paper reports the application of powder DL-alanine/ESR dosimeter for measurement of absorbed dose of gamma radiation from ^{60}Co sources and reactor nucleus and electron beams from accelerator. The obtained results give useful information about the instrumental care necessary to obtain the needed overall accuracy in determination of absorbed dose.

MATERIALS AND METHODS

Commercially available purified crystalline amino acid DL-alanine (Merck) has been investigated for use in radiation detection. The chemical composition of alanine (CH_3 - $CHNH_2$ - COOH) is close to that of tissue, thus providing good similarity to biological systems in absorption of radiation energy[2].

The microcrystalline powder is transferred to suitable sized quartz tubes for X band ESR spectrometry.

The irradiations were performed using a panoramic ^{60}Co gamma ray source, electrons emitted from an accelerator (Dynamitron II) for industrial purposes with samples sealed in glassy ampoules. The samples irradiated at the IPEN Reactor - IEA-R1 were sealed in poliethylene film and covered with Cd foil. All doses given further are expressed as dose to water, as determined by of Fricke dosimetry for gamma ray irradiations.

The ESR spectra were all recorded at room temperature using a JEOL spectrometer (model: JES-ME 3X) with a microwave cavity (TE_{011} mode) operating a frequency of 9400 MHz (X band) and an constant microwave power of 0.1 mW. The magnetic field setting was 334 mT, the field scan range was 25 mT, the scan time was 0.3 s, and the magnetic field modulation amplitude and frequency were 0.5 mT and 100 kHz, respectively, for all dose - response measurements. The gain was always adjusted so that an optimum ESR signal was obtained. The ESR spectrometer sensitivity was checked by introducing into the cavity a DPPH sample (2,2- diphenyl - 1- picrylhydrazyl) contained in a sealed quartz tube.

The ESR spectra was recorded as the first derivative of the paramagnetic absorption spectra where the response of the alanine was expressed as the maximum peak to peak amplitude of the ESR spectra and measurement taken at different days were normalised using a Mn^{2+} reference sample.

RESULTS AND DISCUSSION

The Figure 1 shows the first derivative (ESR spectrum) of the microwave absorption signal of an alanine dosimeter irradiated with ^{60}Co gamma rays at 1 kGy.

The reproducibility of ESR signal height depends on the short and long term stability of the instrument parameters, as well as on the reproducibility of the position of sample inside the microwave cavity. Short-term stability was investigated by carrying out repeated recordings of an irradiated sample. Each parameter was changed after a recording had been completed and then adjusted again, keeping the sample inside the cavity all time. Variations in the shape of ESR spectra of DL -Alanine irradiated with gamma ray and electrons measured at different microwave power were studied.

Post irradiation stability of the DL-alanine response as a function of absorbed dose was investigated for absorbed doses from 1 to 60 kGy over a storage period of 180 days at room temperature (about 15-28 ^{0}C) and indicates sufficient longevity.

Figure 1. ESR spectrum of alanine irradiated with ^{60}Co gamma rays at 1 kGy[3].

The same signal-dose relationship was obtained for both gamma rays (1.25 MeV) and electron beams (1.14 MeV). No dependence of the response on dose rate has been found in the range from 0.21 to 1.16 kGy/h.

In the dose range of 10^2 to 10^5 Gy, the dose-response signal showed a linear relationship and the precision was less than 2%. At dose levels greater than 10^5 Gy the dose response curve begins to saturate, it is shown in Figure 2.

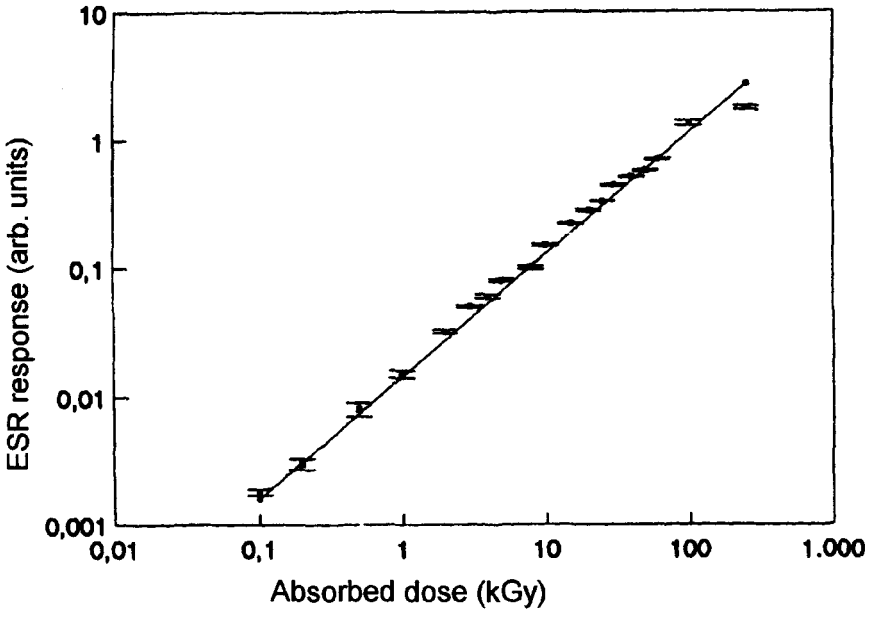

Figure 2 .Dose-response curve of DL-alanine irradiated by ^{60}Co gamma rays[3].

CONCLUSION

The obtained results in this work using a non-destructive readout technique demonstrate that the alanine dosimeter has the long-term stability of radiation induced response, accuracy and reproducibility to be suitable for application in high-level dosimetry. The dosimetric information obtained from the measurement of the gamma absorbed dose in reactor nucleus, are in general accordance with the results determined by thermoluminescence.

NEUTRON DOSIMETRY IN FRENCH NUCLEAR POWER PLANTS. PROBLEMS AND THEIR SOLUTIONS IN 1995

Yves GUIBBAUD[1] - Raymond DOLLO[1] - Alain RANNOU[2]

[1] EDF - EPN. Generation and Transmission. Paris la Défense 92 060 - France.
[2] Institut de Protection et de Sûreté Nucleaire IPSN. Fontenay-aux-Roses 92 265 - France.

Background and development of the problem.

Exposure to neutron radiation in the nuclear industry is normally limited to a small number of workers essentially EDF employees operating in specific areas. Operational collective dose due to neutron exposure is almost negligible compared to the rest of the external doses (less than 2 % in the collective dose equivalent). But this risk represents a significant fraction of the annual dose equivalent of those exposed.

Suggest specifications for individual dosemeters which would idealy meet both technical and practical requirements.

Present situation of Neutron Monitoring in the French Nuclear Power Plants [2]

Exposure of the workers to neutron is mainly related to interventions in the containment building. Fields of radiation in the reactor environment are well known to present energy spectra which can be divided in 2 components :

- The high energy neutrons in the range 50 keV - 2 McV with a maximum of intensity between 200 keV et 600 keV. The dose equivalent rates due to this component lie typically from 0.05 to 500 $mSvh^{-1}$. High energy neutron beams mainly occur locally due to less efficacy of the shieldings and thus are subject to strong variations in space.

- The neutrons from thermal to 10 eV with a maximum of intensity between 0.05 and 0.3 eV. The dose equivalent rates slightly vary around 0.05 $mSv.h^{-1}$. Due to multiple scattering thermal neutrons constitute almost isotropic fields.

Interventions inside the containment building are limited both in frequency (less than one per month in each plant) and duration (about 1 hour). Gamma dose rates in the containment building are in the same order of magnitude than neutron dose rates mentioned above. Collective dose received per intervention is about 0.6 mSv (neutron : 0.26 mSv and gamma 0.34 mSv) distributed between 3 persons on average.

Discharge of irradiated fuel elements from the reactor and receipt of MOX also contribute to exposure of the employees. Neutron energy spectra present a maximum in the region 200 keV - 2 MeV. Dose rates typically measured are in the order of $0.1 mSv.h^{-1}$. Individual doses received during each operation vary between 0.1 and 1 mSv. On average 5 interventions are made each year on a reactor.

Exposure to neutrons at EDF is characterised by doses received during operations of short duration. Workers generally move from place to place where radiation fields can change rapidly in intensity as well as in energy spectrum and angular distribution. This explains why individual dosimetry is particularly critical for this category of workers.

None of the passive techniques existing for individual monitoring was considered to be convenient owing to their limitations, i. e. high energy response dependence, poor lower limit of detection for neutrons or high sensitivity to photons. Thus, till now individual dose assessments are extrapolated from ambiant monitoring. While the reactor is functioning at reduced power, ambient measurements with rem-counters are carried out in the different locations where workers will then operate. In some cases spectrometry systems are used to measure fluence spectra in working areas. Neutron dose rates are extrapolated at the nominal power of the reactor.

At last, individual doses are calculated taking into account main residence duration for each worker in the different locations. Further measurements with rem-counters and electronic gamma devices are made by the personnel during their interventions. This allows to consolidate individual dose assessments based on the ambient monitoring and also to prevent any risk of over exposure.

Results and conclusion

At present, the problem of personal dosimetry for people working in neutron radiation fields is still far from solved to a level comparable with gamma radiation. None of the passive personal detectors developed prior to 1985 are suited to neutron dosimetry in nuclear power plants, either because of poor spectral response or because of inadequate sensitivity.

Before the advent of bubble detectors, the only form of personal dosimetry was based on ambient dosimetry, in accordance with approved procedures applied uniformly in all power plants. The dose equivalent is therefore obtained by multiplying the dose equivalent rate by the time spent in each work area. The dose equivalent rate is monitored using the rem meters carried by the personnel and is checked against the mapping values recorded during the startup period.

This form of dosimetry, the accuracy of which is relatively rudimentary, still compares well with the forecasts based on neutron and gamma dose mapping. It has the advantage of being reliable albeit difficult to implement.

In 1992, this situation led EDF to set up a task group made up of representatives of the various French operators concerned with neutron dosimetry (CEA*, COGEMA*, EDF* and DGA*) and the CEA IPSN, with a dual objective :

- in the short term: to establish procedures for the use of Canadian BTI bubble detectors, which have just undergone successful certification testing [3].

- in the medium term (1996 - ...) : to adopt an advanced, direct reading dosimeter incorporating dose equivalent and equivalent dose rate alarms, in accordance with joint specifications drawn up by the operators.

The main difficulty in developing an electronic neutron dosimeter lies in achieving correct discrimination of the spurious signals generated by gamma photons. This will require a great deal of on-going effort and scientific discipline.

At present, the direct reading electronic dosimeter is still at the basic research stage and is unlikely to come on to the market in the next 5 years. This delay is due to two main reasons: the limited size of the market, some 3000 units in France for the nuclear industry as a whole; and the lack of knowledge of the problems specific to this industry. The existence of joint specifications should enable research organisations to better manage their research efforts. Furthermore, there appears to be renewed interest in personal neutron dosimeters and several laboratories throughout the world are developing potentially successful techniques.

MEASUREMENT OF REACTION RATE DISTRIBUTIONS IN PHANTOM IRRADIATED BY INTERMEDIATE ENERGY NEUTRONS FOR EFFECTIVE DOSE EVALUATION

Y. Nakane, H. Nakashima, Y. Sakamoto and S. Tanaka

Japan Atomic Energy Research Institute
Tokai-mura, Naka-gun, Ibaraki-ken 319-11, Japan

ABSTRACT

Reaction rate distributions in a plastic phantom irradiated by 41- and 64-MeV quasi-monoenergetic neutrons were measured with a ^{238}U fission counter and solid state nuclear track detectors. Measured distributions were compared with those calculated by using the HERMES code system.

INTRODUCTION

From the view point of radiation protection in the radiation shielding design of high energy accelerators, it is important to establish an evaluation method of effective dose due to high and intermediate energy radiations. The HERMES code system (1) has been extended to calculate the effective dose (2). The accuracy of the code system, however, has not been evaluated for intermediate energy neutrons by experiments. Therefore, experiments were carried out for 41- and 64-MeV quasi-monoenergetic neutrons generated by the $^{7}Li(p,n)$ reactions with 43- and 68-MeV protons at an AVF cyclotron facility, TIARA (Takasaki Ion Accelerators for Advanced Radiation Application) facility, of Japan Atomic Energy Research Institute.

EXPERIMENTS

Figure 1 shows a cross sectional view of the experimental arrangement. Quasi-monoenergetic source neutrons ("41 MeV" and "64 MeV") of about 41- and 64-MeV were produced in 3.6 mm and 5.2 mm thick ^{7}Li-targets by 43- and 68-MeV protons, respectively. Source neutron spectra above 6- and 7-MeV were measured with a 5"ϕ x 5" BC501A liquid scintillation detector for the "41 MeV" and the "64 MeV". Absolute fluences of source neutrons in the monoenergetic peak were also measured with the recoil-proton counter telescope. Source neutrons emitted in the forward direction were introduced to an iron collimator of 11 cm diameter, while proton beam penetrating through the ^{7}Li-target was bent down by a clearing magnet to a Faraday cup. The phantom of 30 cm cube made of an acrylic resin was placed at the exit of the collimator. The intensity of source neutrons was monitored with a proton beam Faraday cup and two fission counters placed near the ^{7}Li-target, of which the efficiencies were calibrated by the recoil-proton counter telescope. Reaction rate distributions along the center line in the plastic phantom were measured with a ^{238}U fission counter (Centronic FC4A) and SSNTDs (Nagase Landauer Ltd. MR-3) which had been calibrated with a ^{252}Cf source.

EXPERIMENTAL RESULTS, ANALYSIS AND DISCUSSIONS

Energy spectra of transported neutrons were calculated with the HERMES code system. In the code system, neutron energy spectra above 19.6 MeV were calculated by the HETC-KFA2 code and those below 19.6 MeV

were calculated by the MORSE-CG code with the DLC-119/HILO86 multi-group cross section library (3). Figure 2 shows the calculated energy spectra at the depths of 3 cm and 25 cm in the phantom for the "41 MeV". Error bars of the calculations in Fig. 2 show the fractional standard deviations. The relative energy spectra of source neutrons below 6- and 7-MeV were assumed to be the values at 6- and 7-MeV for the "41 MeV" and the "64 MeV", respectively. Reaction rate distribution of the ^{238}U fission counter was obtained from the neutron spectra and fission cross sections (4, 5). Calculated and measured distributions of the reaction rate of the fission counter are compared in Fig. 3. The calculated distributions are in good agreement with the experimental ones at the depth up to 15 cm in the phantom, while overestimates about 25% at the depth of 25 cm. The neutron energy spectra for whole regions were also calculated by the MORSE-CG code with the HILO86 library. The calculated distributions with these energy spectra are also in good agreement with the experimental ones even at the depth of 25 cm.

Reaction rate distributions of SSNTDs were also obtained from the neutron spectra and an energy response calculated by a newly-developed Monte Carlo code (Y. Nakane et al.) in which the energy range of incident neutrons had been expanded to intermediate energy. Calculated and measured distributions of reaction rates of SSNTDs are shown in Fig. 4. The calculated distributions for the "41 MeV" are in good agreement with the measured ones within 15% at the depth between 10 and 25 cm in the phantom, while those for the "64 MeV" are about 50% higher than the measured ones at the depth after 20 cm. These disagreements probably come from the energy response of SSNTDs for the incident energy of around 64 MeV. At the depth up to 5 cm, the calculated distributions for both the "41 MeV" and the "64 MeV" are lower than the measured ones. The contribution of the incident neutron spectra below 6- and 7- MeV to reaction rate distributions is estimated about 30% for the SSNTDs at the depth up to 5 cm. This discrepancy can be attributed to the assumption of source neutron spectra below 6- and 7-MeV. For the fission counter, that contribution is estimated to be in less than 4%.

SUMMARY

Reaction rate distributions of the fission counter and the SSNTDs in the plastic phantom using 41- and 64-MeV quasi-monoenergetic neutrons were measured and compared with those obtained from fission cross sections, an energy response and energy spectra calculated with the HERMES code system. Calculated distributions of the reaction rate of the fission counter obtained with the energy spectra by the MORSE-CG code and the HILO86 library are in good agreement with the experimental ones for the "41 MeV" and the "64 MeV". Calculated distributions of the reaction rate of the SSNTDs for the "41 MeV" are in good agreement with the measured ones within 15% at the depth between 10 and 25 cm in the phantom, while those for the "64 MeV" are about 50% higher than the measured ones at the depth after 20 cm.

Real Time Neutron Dosimeter Response Calculations

A. Seghour and F.Z. Dehimi

Laboratoire de Dosimétrie des Rayonnements. Centre de Radioprotection et de Sûreté. 02, Bd Frantz Fanon. B.P. 1017. 16000 Alger. Algeria.

Abstract

The response of a real time neutron dosimeter using a thin LiF target sandwiched between two parallel surface barrier semiconductor detectors is studied for different neutron distributions and different angles of incidence. Calculations of the response function defined for a simultaneous detection by the two detectors of the particles emitted when the reaction $^6Li(n,t)\alpha$ occurs in the target are fulfiled by geometrical considerations of the reaction kinematics and the differential cross section variations. Finally, the efficiency of the studied detection system is analysed for dosimetric uses.

Introduction

A good neutron dosimeter will present good sensitivity and a known neutron energy response. These conditions are generaly fulfiled by neutron spectrometers, reason for which many neutron dosimeters derive directly from neutron spectrometer designs. Recently [1], a neutron spectrometer using a thin LiF target and two surface barrier detectors has been studied, designed, and applied to determine neutron energy distributions at different irradiation sites in a nuclear reactor. This design is easily modified to serve as a neutron dosimeter.

Dosimeter description

Two surface barrier detectors which active surfaces face each other are used to detect charged particles from ^{6}Li(n, t)α reactions occuring in a thin LiF layer sandwiched between the two diods. The response of a neutron dosimeter based on the use of such a detection assembly is strongly dependent on the kinematics of the ^{6}Li(n, t)α reaction and the geometrical considerations of the emission and the detection of the charged particles. In this work, the attention is focused on the detection assembly in order to calculate the response function of the neutron dosimeter.

Response function calculations

Neutron fluxes are generally contaminated by γ. In order to realize a neutron dosimeter only suitable for neutrons in a mixed $n - \gamma$ field, a coincidence detection mode is used. In the first approach, it seems that such a detection assembly will have a poor detection efficency

for intermediate and fast neutrons. Nevertheless, it has been shown in another work [1], that the charged particles issued from the reaction $^6Li(n,t)\alpha$ are emitted in an angle greater than 140^0 for neutron energies as important as the fission neutron energies ($17 \sim 20\,\mathrm{MeV}$).

The total number of the particles detected with the coincidence condition is :

$$N(E_n) = N_0\ \Phi(E_n)\ G(E_n) \tag{1}$$

where the geomerical function $G(E_n)$ is defined as :

$$G(E_n) = \int_0^e dx \int_0^R r dr \int_0^{2\pi} d\phi \int_0^{\theta_{max}} \int_{\beta_{min}(\theta,\phi)}^{\beta_{max}(\theta,\phi)} \frac{d\sigma(\cos\theta)}{d\cos(\theta)}\ P\ R(\beta)\, d\beta\, d\cos(\theta) \tag{2}$$

whith :

N_0 : target nuclei number, $\Phi(E_n)$: neutron flux of an energy E_n, e : ^6LiF target thickness, R : detector active surface radius, P : coincidence detection condition : P = 1 if the detection coincidence is fulfiled, P = 0 if the detection coincidence is not fulfiled, and $R(\beta)$: the ratio of the detected particles emitted within a solid angle $d\Omega = d\beta\, d\cos(\theta)$ to the total emitted particles.

Results of calculations of 78 neutron energy groups are reported in Fig.1.a. were the response functions for normal and lateral incidences, i.e. 0^0 and 90^0. It can be seen that geometrical function follows 1/E form for neutrons below 1 keV and the dosimeter angular dependence is only sensitive to fast neutrons.

The neutron energy response of the dosimeter is calculated using several well known neutron distributions. Calculations are fulfiled taking into account the energy detection resolution of diods (fwhm $\simeq$ 15 – 20keV). This conduct to express the total number of the detected particles of a neutron incident energy E_n as :

$$N(E_n) = N_0 \int_{E_n-\Delta E_n}^{E_n-\Delta E_n} \Phi(E)\ R(E_n - E)\ dE \tag{3}$$

with:

$$R(E_n - E) = \frac{1}{\sqrt{2\pi}\,\sigma} G(E)\ \exp(E_n - E)^2/2\sigma^2 \tag{4}$$

Results of the neutron dosimeter responses for : 1/E distribution, fission distribution and reactor distribution (moderated 1/E plus fission) are reported on figures 1.b.c. and d.

Conclusion

For neutron energies below 1 keV, the response of the real time neutron dosimeter has a 1/E form independently of the angle of incidence and the neutron distribution. Whereas, for fast neutrons it is found that the dosimeter is sensitive to angle and energy variations.

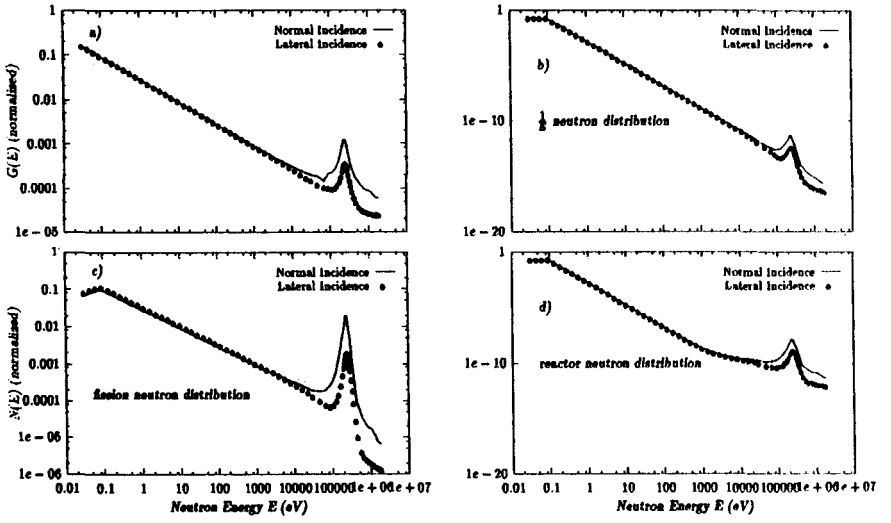

Fig1. a) The geometrical function. Neutron response functions for : b) 1/E distribution. c) fission distribution. d) reactor distribution.

ABSTRACT (See instructions overleaf)

For the 5 last years, the concept of realistic neutron spectra simulating practical conditions encountered at workplaces has been investigated by several laboratories involved in radiation protection dosimetry and collaborating in the frame of a Joint CEC Contract and Eurados Working Committees. At a further step, the ISO/WG2 is also involved in preparing standards which define the characteristics of reference radiations and calibration procedures. As a consequence, the radiation field of a RNSF has to be accurately specified in terms of both angle and energy distributions. This is particularly important for the calibration of individual dosemeters which the angular response has to be taken into account for. Calibration facilities mimic as closely as possible the features of an aligned and expanded field in order to comply with fluence-to-dose equivalent conversion coefficients of ICRU operational quantities. This paper intends to report on techniques which have been developed at the SDOS/Cadarache RNSF to satisfy with those requirements and to implement the appropriate calibration procedures assuring traceability to primary references. This research work relies on a computational part to optimise the modifications of the facility and is complemented by an experimental validation involving irradiations of several types of dosimeters distributed by routine dosimetry services.

NEUTRON SPECTROMETRY FOR RADIATION PROTECTION AT THE JINR

V.E.Aleinikov and G.N.Timoshenko

Joint Institute for Nuclear Research, 141980 Dubna, Russia

The major basic facilities of JINR are the Nuclotron - a superconducting accelerator of relativistic nuclei, the U-400, U-400M and U-200 heavy ion cyclotrons, the Synchrophasotron - a 10 GeV proton and light nuclei accelerator, the Phasotron - a 680 MeV proton accelerator, the IBR-2 fast neutron pulsed reactor and the IBR-30 neutron pulsed booster multiplier. These nuclear facilities generate the different types of radiation fields with wide energy range and complex composition. The main radiation component of the fields behind thick biological shielding is neutron with energy from thermal up to several hundreds of MeV. The energy spectra of these neutrons vary widely, depending on the type and design of the facility and its shielding. Development of broad energy range neutron spectrometry techniques for measurements in mixed scattered radiation fields is the one of the prior topics in radiation protection. There are no experimental techniques to cover an entire neutron energy range, but the problem can be solved by the combining the measurements with a set of different spectrometers. The key information for efficient accelerator shielding design is true determination of the source term. Double differential (on angle and energy) distributions of neutrons produced by primary particles in thick targets which imitate the construction parts of accelerators are the crucial data to define the source term. There is a lack of such experimental information available especially for heavy ions. This presentation is intended to give the flavor of our work on the problems, its objectives, range of interests and methods.

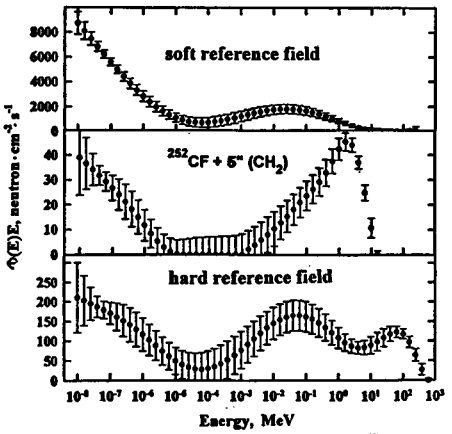

Fig.1. The neutron reference fields of JINR.

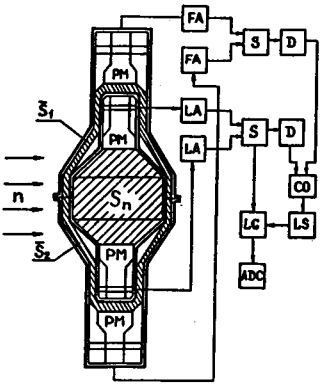
The JINR has significant experience in the implementation of neutron detectors having near 1/v response with different moderators to detect wide-range energy neutrons. The spectra of the JINR neutron reference fields, design for neutron metrology purposes, are shown in Fig.1 for example /1/. The soft reference field is formed by scattered neutrons into the 660 MeV phasotron labyrinth.The next neutron reference fields are produced using a ^{252}Cf source within polyethylene moderators. The hard neutron reference field is formed behind thick concrete shield of the 660 MeV phasotron irradiated by the secondary radiation from the accelerator chamber and the target station. The spectra have been measured by multisphere neutron spectrometer with LiJ(Eu) detector (4 mm diameter, 4 mm height) and unfolded by the statistical regularization method. The 2,3,5,10,12 inches polyethylene moderators, "bare" and "bare" + cadmium data has been included in the system of equations. The response functions were taken from the /2/.

Widely used multisphere spectrometer has a wide energy range, low sensitivity for photons and charged particles and isotropic response, but it yet does not give enough information content at high energies.The estimations of the hadron fluences with energies above 20 MeV by using ^{12}C(n,2n)^{11}C activation method and other suitable a priori information about neutron spectra are often applied to improve the spectra shapes



The construction of the high - energy neutron spectrometer and the block diagram of the electronic system.

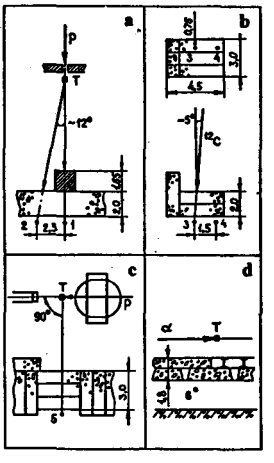
at high energy region. Nevertheless, there seemed to be a need of a new type of dosimeter and spectrometer for high energy neutrons. To meet this need in JINR was developed a new high-sensitive technique /3-5/ for measuring the energy spectra, fluence and dose equivalent The construction of the spectrometer is shown schematicaly in Fig.2. The device consists of the neutron counter with near spherical plastic scintillator as a neutron detector (volume is about 1.6 l) coupled with twq PMT. This neutron counter is surrounded by a composite veto scintillator for charged particles rejection equipped with two PMT. The principle of operation of the device is based on the dependence of the readings of the neutron counter on the differential energy neutron flux at various thresholds of signal registration. The calculation of the plastic scintillator neutron detection efficiency vs. threshold was performed using the Monte Carlo code /6/. The influence of the veto counter on the neutron efficiency was taken into account and led to a considerable decrease in the efficiency at neutron energies above approximately 100 Mev. The problem of energy spectrum unfolding from apparatus spectra in this case is similar to the unfolding of multisphere spectrometer spectrum, but instead of counting efficiencies for moderators, one uses scintillator efficiencies at different thresholds. Neutron spectra behind various shields of phasotron and synchrophasotron have been measured by the prototype of the spectrometer. Fig.3 illustrates some high energy neutron spectra in different geometries. The location of the measurement points and shielding configurations are given in Fig.4 (a,b,c,d). The high sensitivity of the spectrometer permits to measure the cosmic neutron spectrum near the Earth's surface as well.



The location of measurement points (solid circles) and shielding configurations. All sizes are given in meters. In (b) the front surface of the shielding is also shown.

The next problem of neutron spectrometry dealt with measurement of the angular-energy distribution of neutron yields from targets irradiated by the particles. The energy spectra of neutrons with energy more than 10 MeV produced in thick copper target by 3.65 Gev/nucleon carbon ions were obtained by TOF method /6/. For this aim the TOF neutron spectrometer with triggering by ions passing through the counter's telescope before the target was designed. The Fig.5 shows the setting and block diagram of the spectrometer. The signal "Start" was formed by the second telescope counter with selection of ^{12}C ions energy losses in the detector and rejection two or more events (ions) in each bunch. The signal "Stop" was formed by the neutron counter on base of plastic scintillator with known detection efficiency in case of the absence of veto counters signals rejecting the charged particles. The difference method by the shadow bar for subtracting the background was used at each measurement. The spectra of neutrons with energy over than 10 MeV from the target (diameter 10 cm, length 13 cm) under two angles are shown in Fig.6. The calculation method for description of hadron double differential yields in thick targets, bombarded by relativistic ions have also been developed on base a thermodynamic "firestreak" model and the solution of the transport equation. The verification of this program have been done by the experiments and gave a satisfactory result.

The experimental check of the calculated response function for the multisphere neutron spectrometer at energies over than tens MeV and for the high-energy spectrometer (especially at high thresholds) is a very crucial problem of these methods. We are planing now to carry out the experiments on verification of the response function on base of the medical facility of the JINR phasotron. This facility permits to have a wide and narrow neutron beams with variable energies from 100 to 500 MeV produced by protons irradiating the light targets (Li, Be) under 0 degree. The other task is the combination of multisphere and high-energy spectrometers data to unfolding of

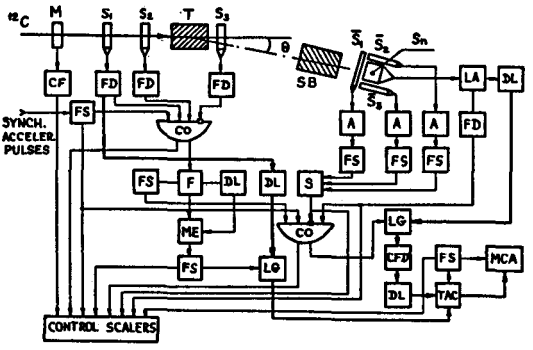


Fig.5 The experimental arrangement and block diagram of the TOF spectrometer. neutron spectra in entire energy range from thermal up to several hundreds of MeV. In the field of determination of the source term we are planing to study a neutron double differential distributions from thick targets irradiated by heavy ions with energies of tens MeV/nucleon on base of the U-400 JINR facility.

INTRODUCTION

Interpretation of neutron detector readings in terms of dose equivalent is an important problem. Since response of a neutron detector has usually an energy dependence which is not adequately simulating the energy dependence of dose equivalent, its using as a dosimeter in real neutron fields of nuclear-physics device after a simple calibration in a neutron field of radionuclide source (such as ^{252}Cf) leads to considerable errors. There are some different approaches to solve this problem. One of them [1], [2] proposing the dosimeter's calibration in workplace fields is available for personnel and area dosimeters. Another method [3] is the calibration at neutron field having the spectrum simulating the real neutron field one. The method of superposition of calibration fields [4] to obtain weighted neutron response is a following step in this direction. All of these approaches one way or another are concerned with application of neutron reference fields for these goals.

THE IHEP NEUTRON REFERENCE FIELDS

Requirements to neutron field to be "reference" are the following. First of all it would have a neutron spectrum which is simulating typical workplace neutron spectra. Its main characteristics such as neutron spectrum, dose equivalent rate, angular distribution, etc. must be well established. It would be reproducible and enough intensive to provide possibility of quick calibration.

At the Institute for High Energy Physics (IHEP), the workplaces concerned with personnel irradiation are concentrated mostly at the experimental hall of IHEP 70-GeV proton synchrotron. The radiation fields behind the biological shielding of the accelerator have rather component composition where neutrons in a wide energy range from thermal energies up to primary proton beam's energy of 70 GeV are dominated. Numerous investigations of real radiation fields behind the accelerator's shielding [2] ,[5] ,[6] ,[7] , show that they can be separated into three main groups: 1) high energy fields behind the upper shielding (320--350 cm of concrete); 2) low energy neutron fields behind the side shielding (600 cm of concrete); 3) radiation fields with large contribution of charged particle nearby the charged particle transport beams. The IHEP neutron reference fields include the high energy reference field and four radionuclide reference neutron fields [10] formed by filtered and direct radiation of ^{252}Cf and ^{239}Pu-Be radionuclide sources: ^{239}Pu-Be in free air (PU), ^{252}Cf in free air (CF), ^{252}Cf at the centre of polyethylene sphere $\otimes$ 30 cm (CH) and ^{252}Cf at the centre of iron sphere $\otimes$30 cm (FE). The radionuclide reference neutron fields are reproduced at the middle of a special calibration room having dimensions of 5.4 m $\times$ 13 m and 4 m height. The distance between a radionuclide source creating the field and a reference point is the same for all the four fields (0.75 m) as well as the distance from a floor (1.65 m). The high energy reference field (HEF) is reproduced at 1 m height outside the upper shielding in the experimental hall of the IHEP 70-GeV proton accelerator. Inside a volume of 0.5 $\times$0.6 $\times$0.3 m^3 with the centre at the reference point the intensity of radiation varies in the range less than 10%.

MEASUREMENT TECHNIQUES

The dosimeters and spectrometers being used in measurements are listed in the Table 1. The detailed description of measurement procedures may be found in the original the main spectral papers. Briefly, the tissue-equivalent proportional counter TEPC allow one to obtain dose equivalent and absorbed dose of radiation of any kind by simultaneous measuring the charge produced in a cavity and the event spectrum. The analog component remmeter ACR includes three high-pressure ionization chambers (IC): argon-filled IC with aluminium wall (γ and charged particles absorbed dose), tissue-equivalent IC (total absorbed dose) and ^{3}He-filled IC in a 10"-diameter polyethylene moderator (neutron dose equivalent). Other instruments are: multysphere spectrometer (MS) with ^{6}LiI(Eu) detector (the method of linear combination of six spheres readings), thermoluminescent proportional counter SLETCP with aluminum wall.

Table 1. The instruments used in dose equivalent measurements in the IHEP reference fields.

Instrument	Refs.	Measuring components.	Scopes, limitations.	Errors	Certification
TEPC	[8]	Photons and charged particles, neutrons.	E_n > 0.3 MeV	9%	VNIIFTRI, State Standard
ACB	[9]	Photons and charged particles, neutrons.	$H_n/H\gamma$ <100, $H_n/H\gamma$ >0.1	18%	VNIIFTRI, State Standard
MS	[10]	neutron	--	15%	VNIIM, State Standard
TLD	[11]	Photons and charged	--	15%	VNIIM, State Standard
SLETCP	---	Photons and charged	--	10 %	----

RESULTS AND DISCUSSION

The results of neutron and photon ambient dose equivalent measurements for the IHEP Radionuclide reference neutron fields are given in Table 2. They are relate to one neutron of a radionuclide source generating a field, for convenience of further applications. The results are the expert estimation of the values usually taken as an average between TEPC, ACR and MS results except the cases when the error obtained after treatment of an instrument readings exceeds the permissible level for the dosimeter here we use the data for IKS and SLETCP.

The neutron spectra of the IHEP reference fields have been measured in[10] by the IHEP multisphere spectrometer [4]. Cadmium-covered polyethylene spheres of 2",3",5",8",10" and 12" diameter with ^{6}LiI(Eu) ⊗ 10× 10mm^3 thermal detector have been used in measurements. For spectrum measurements in high energy neutron fields a 18"-diameter sphere and activation carbon-based scintillation detector $^{12}C(x,xn)^{11}C$ were used. The neutron spectra of radionuclide reference neutron fields are shown at Fig.2 in comparison with accelerator low energy spectra outside the side shield. It could be noticed that the radionuclide fields do not closely simulate the real ones, but nevertheless have more spread neutron spectrum like real ones and rather similar shape of a separate part of a real spectrum which could be interesting from a point of view of a detector response. Then, in Table 3 the components of a neutron spectrum as well as the main spectral characteristics are given for the reference fields in comparison with the same values for the real neutron fields behind the IHEP accelerator shielding, measured in [5] and [7]. The real neutron spectra are divided on several groups according to spectrum hardness. As it is seen from the Table, the range of ambient dose equivalent conversion factors (193--322 pSv. cm^2) and the mean neutron energies in spectrum (0.76--3.32 MeV) as well as the ratio between a separate parts of neutron spectra cover a most part of a real neutron spectra behind the side shielding of the IHEP accelerator . The main advantage of the radionuclide neutron reference fields is a constant spectrum and component composition, good reproducibility and intensity (30--200 nSv/s) which we cannot reach in real fields behind the accelerator shielding.

The neutron spectrum at the high energy reference field is measured by the IHEP multisphere spectrometer with using apriori information. Comparison of neutron spectrum at the IHEP high energy reference field with theoretical spectrum behind shielding calculated by FLUKA [13] and ROZ6H [14] computer codes presence of two peaks - in evaporation region and near 100 MeV is confirmed by all authors. Such behavior of high-energy neutron spectrum appears also in the cosmic neutron spectrum measured in [15].

CONCLUSION

Investigations of dosimetric characteristics of the IHEP reference neutron fields have been fulfilled by different dosimeters specially developing for measurements in mixed radiation fields. The ambient dose equivalent data obtained with an accuracy of 10-20%. It is shown that the main spectral characteristics of this set of reference fields are cover a most part of a real neutron spectra behind the side and the upper shielding of the IHEP accelerator. It allows one to using these reference fields for routine dosimeter calibration purposes, dosimeter intercomparisons and other applications as cosmic spectrum simulations.

ELECTRONIC NEUTRON SENSOR BASED ON COINCIDENCE DETECTION

B. Barelaud, J.L. Decossas, F. Mokhtari, J.C. Vareille

C2M, University of Limoges, 123, Av. Albert Thomas
87060 Limoges Cedex - France

INTRODUCTION

The last Symposium on neutron dosimetry which took place in Paris in November 1995 have shown again that it doesn't exist any individual active neutron dosemeter. The state of art on electronic device (1), the needs of the nuclear power industry in individual neutron monitoring (2, 3) and the new trends of researchs (4) were presented. They confirm the relevance of our studies in progress in the C2M team of the University of Limoges. The aim of this work is to realize an individual electronic neutron dosemeter.

The device in the progress of being development will operate either as a dosemeter or as ratemeter giving $H_p(10)$ and $\dot{H}_p(10)$ either as a spectrometer permitting to caracterize the primary neutron beam.

PRINCIPLE OF THE ACTIVE MONITOR

The reactions used are given : - for Boron 10 there are two mechanism

a - ${}^{10}_{5}B + {}^{1}_{0}n \rightarrow {}^{7}_{3}Li + {}^{4}_{2}\alpha$ with Q-value = 2.79 MeV (6%) (E_{li} = 1.01 MeV, E_α = 1.78 MeV)

b - ${}^{10}_{5}B + {}^{1}_{0}n \rightarrow {}^{7}_{3}Li^{*} + {}^{4}_{2}\alpha$ with Q-value = 2.31 MeV (94%) (E_{li} = 0.84 MeV, E_α = 1.47 MeV)

$\downarrow$

$Li + \gamma + 0.478$ MeV

- for Lithium 6

a - ${}^{6}_{3}Li + {}^{1}_{0}n \rightarrow {}^{3}_{1}H + {}^{4}_{2}\alpha$ with Q-value = 4.78 MeV (100%) (E_H = 2.73 MeV, E_α = 2.05 MeV)

The monitor has two parts : the sensor and the electronic for the signal processing. The sensor (fig.1) is composed of two facing diodes which enclose a reactive layer of ^{10}B or ^{6}Li. These elements have a high cross section to low energy neutron. Several parameters influence the response of the device :

1 - The area of the reactive layer is limited by the area of usual wafers available for microelectronic chips. The increasing of layer thickness leads to an absorption of particles from the nuclear reaction that occurs inside the layer, and in order to use the device as a spectrometer that last-mentioned must be thin as possible. However, it's not compatible with the need for high sensitivity necessary in dosimetry.

2 - The thickness of the dead layer of the detecting diodes must be minimised since it always acts as an energy absorber for the recoils.

3 - The thickness of the depleted layer must be adapted to the range of the most energetic particles crossing the various layers.

4 - The bulk of the wafer should not have any influence on the response of the sensor.

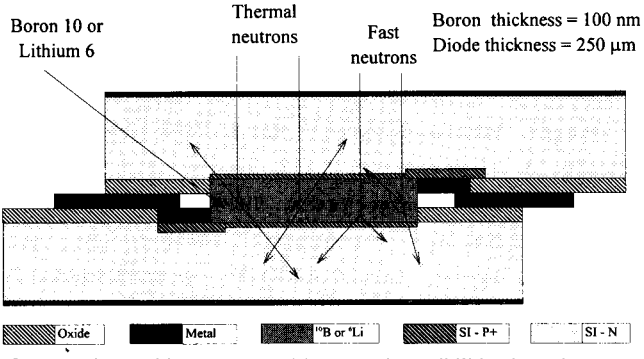

Fig.1 : Schematic view of the detector

Signal processing consists of an usual coïncidence system (5). Several possibilities have been used experimentally to measure the spectra of each detector or, by summing the pulses from both detectors, to get the distribution of the total energy of the nuclear reaction particles.

DESCRIPTION OF THE DETECTION SYSTEM

In order to obtain dose equivalent, we need to know characteristics of neutron beams with different energy ranges because quality factors are function of neutron energy. In these conditions the aim of this work is to realize a rough spectrometer. Next explanations are presented in the case of ^{6}Li reactive layer ; relation between energy is : $E_\alpha + E_{Li} = Q + E_n$ with E_α energy of α particle, E_{Li} energy of ^{6}Li ion, Q value of the energy reaction and E_n energy of the incident neutron.

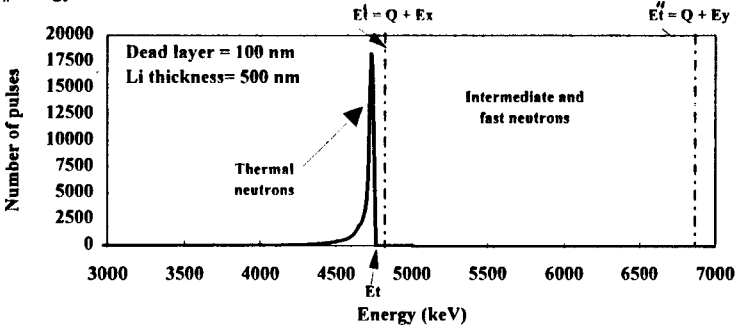

Fig.2 : Spectrum obtained by sommation of the two particles energy and thresholds

Working on spectra obtained by sommation of the two particles energies (fig.2), energy thresholds may be used so that we obtain :

1 - under the energy threshold, $E_T = Q$ (E_T = total energy = $E_\alpha + E_{Li}$) , pulses are due to thermal neutrons,

2 - between two energy thresholds $E_T^{'} = Q + E_x$ and $E_T^{''} = Q + E_y$ ($E_T^{''} > E_T^{'}$) lies spectrum of pulses due to neutrons with energy $E_x < E_n < E_y$. This method is interesting for intermediate neutrons and fast neutrons of low energy.

We have point out that it is necessary to satisfy two conditions :

- $E_x \geq \varepsilon$,where ε is the energy resolution of the device (sensor and electronic system). Electronic are in progress to optimize the resolution.

- $E_y \leq E_M$, where E_M is the maximal energy which allows to consider that in the nuclear reaction ^{6}Li (n, α) ^{3}H the value of angle θ (θ = angle between the two products of the reaction) leads to coïncidence detection.

Modelisation are in progress to define this value.

FIRST EXPERIMENTAL DEVICE AND PERSPECTIVE

In order to show the device feasibility, we used commercially available diodes (Hammamatsu) including a reactive layer (Boron 10) which was realized in the laboratory. The dead layer thickness is larger than 1 µm (which is too high), the depleted zone thickness is 100 µm and the boron 10 layer thickness is 100 nm. The device was tested thanks to an AmBe source with paraffin shielding. The registered spectrum is presented on figure 3. Two peaks appear for α particles and two other peaks for Li ions. This result is in agreement with the response obtained by simulation.

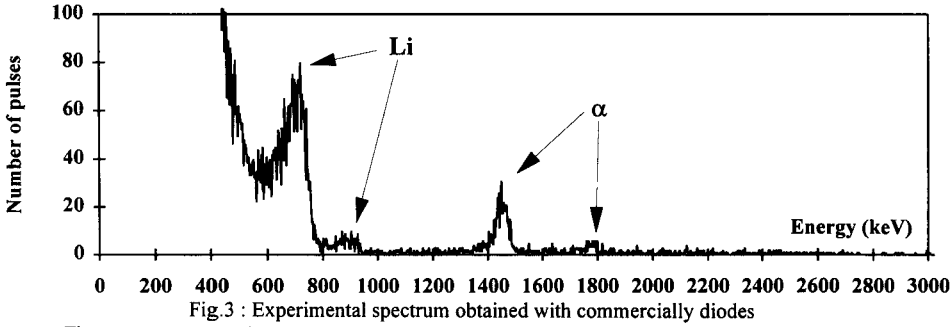

Fig.3 : Experimental spectrum obtained with commercially diodes

The sensor response has been modeled thanks to calculation codes developped in our laboratory and it appears that reaction with ^{6}Li reactive layer is more interesting because it doesn't present an excited state and the

energy of particles is higher than in ^{10}B case. But a technological difficultie exits for Li which is able to diffuse inside silicium bulk of the diode. So, it is impossible to use a ^{6}Li reactive layer.

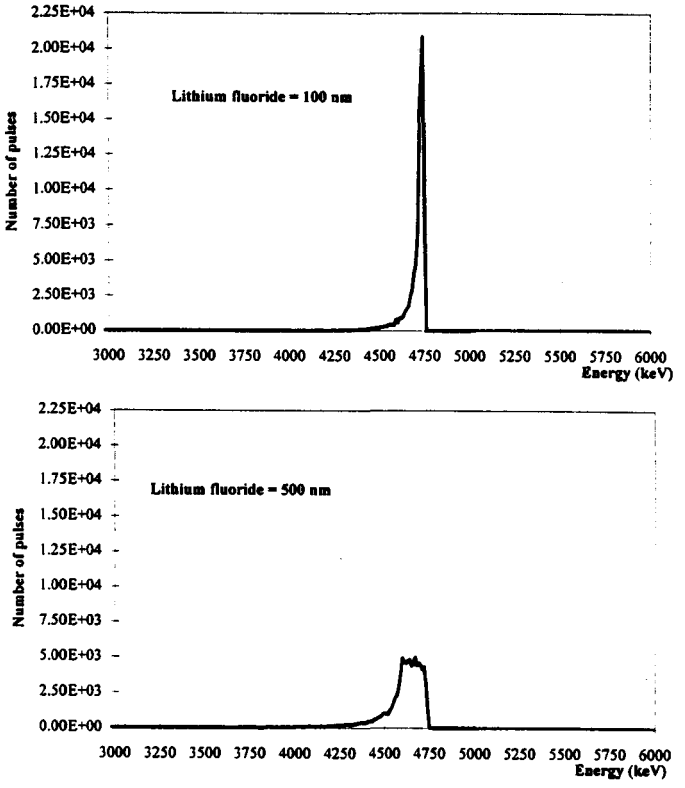

Fig.4 : Distribution of the total energy deposited in the sensor for 100 nm dead layer thickness and a LiF reactive layer

In these conditions, it is necessary to realize a reactive layer with a compound which contains ^{6}Li. We propose LiF. The modelization was made and the first results are given figure 4.

In conclusion, it appears that LiF will be used as reactive layer in the coïncidence device and technological realization of LiF layer is in progress.

ACKNOWLEDGEMENTS

This work was supported by the Commission of European Community (contract FI3PCT9 30072) and EDF - France (Comité de radioprotection). We are very grateful for these helps.

INTRODUCTION

In the vicinity of high temperature plasma experiments for nuclear fusion studies, mixed radiation fields which are composed of X-rays and neutrons are expected to arise as burst-like pulses according to plasma shots. A typical operational condition is such that several-to-ten seconds plasma shots are given repeatedly in every ten minutes or so. It is therefore important from radiation protection point of view to have a monitoring sensor effective for real time and separate measurements of X and n components with a good dynamic range.

For that purpose we have designed and tested a dual type ionization chamber system to be used as area monitors around the coming Large Helical Device (LHD)[(1)] of NIFS. This might also be applicable to other case, for instance, radiation fields surrounding accelerator experiments. This system is composed of a pair of cylindrical vessels of the same size and shape, one containing ^{3}He gas sensitive to both n and X, and the other ^{4}He insensitive to neutrons. The ionization chambers have been examined with various kinds of radiation sources[(2),(3)]. In the present study, we have carried out further irradiation experiments and discussed about the results.

CHAMBER SYSTEM

As the radiation dose sensor we have adopted the ionization chamber scheme to obtain the response in the current form, since it is required to cover a rather wide range of neutron fluence levels, sometimes accompanied by much stronger X-ray components, without suffering from the pile-up counting failure. In order to distinguish neutron contributions from X-rays, a dual-chamber system is proposed.

A dual type ionization chamber system is consisting of two cells of the same geometric shape, volume and wall material. The system turns the difference of reaction between isotopes to account. One of them is filled with pressurised ^{3}He gas, being sensitive to both neutrons and X-rays, and other filled with ^{4}He gas being sensitive only to X-rays. It will be possible to find out the neutron contribution by subtraction of the signal.

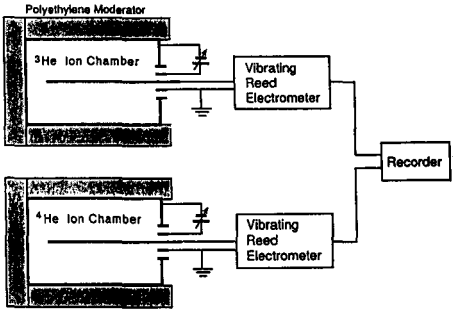

Figure 1. Chamber system.

Each chamber cell is a cylindrical vessel (80mmϕ x 200mm) of stainless steel (3mm thick) to give a gas volume of 1 liter. Measurable current range is 10^{-5}A $\sim 10^{-14}$A with a moderate time constant. Chamber cells with ^{3}He and ^{4}He gases of different pressure (1,2,3 atm) are prepared. Since we are interested in neutron energies up to a few MeV, a detachable polyethylene moderator (5 cm thick) is usually placed surrounding the chamber cells.

IRRADIATION EXPERIMENTS

(1) Responses to gamma rays ; The chamber characteristics irradiation against ^{60}Co gamma rays has been

carried out. The field intensity is varied by means of changing the source distance or source intensity. The response of ^{3}He and ^{4}He are quite similar to each other. Gas pressure dependence of the saturation current levels was given, there seems to hold good proportionality as expected. An apparent linear relation is attained to cover 8 orders of magnitude from 10^{-5} Gy/h to 10^3 Gy/h.

(2) Responses to thermal neutrons ; The neutron response of ^{3}He chamber has been surveyed by means of D_2O themarised neutron irradiation at the KUR fission reactor of Research Reactor Institute, Kyoto University. The chambers were placed about the center of the irradiation room, where is 1.5 m distant from Bi surface. The reactor power has been changed from 0.1 kW to 30 kW. The thermal neutron flux at this position is estimated by a different experiment as $0.96 \sim 1.88 \times 10^4$ n cm^{-2} s^{-1} at 1 kW operation, so that the observed ^{3}He current 0.35 nA should imply the sensitivity of the 1 atm ^{3}He chamber with moderator to be $0.019 \sim 0.036$ pA/(n cm^{-2} s^{-1}). Both output currents from ^{3}He and ^{4}He chamber are closely proportional to the reactor operating powers, or fission neutron yields, though the current ratio ^{3}He /^{4}He is high as $\sim 10^3$.

(3) Testing with mixed n-X fields ; Response to source distance characteristics have been examined by means of ^{252}Cf and ^{241}Am-Be whose neutron emission rate were 1.5, 3.6, 5.1×10^5 n/sec and 4.66×10^6 n/sec, respectively. The ^{3}He response reveal $r^{-1.8}$ or $r^{-1.7}$ decrease with distance r. This trend may be due to the increasing of thermalised neutron component or incidence of scattered neutron to the flank. For the 1 atm ^{3}He chamber with moderator, response currents against ^{252}Cf and ^{241}Am-Be are evaluated as 0.07 and 0.05 pA/(n cm^{-2} s^{-1}).

In addition, in order to estimate the effect of moderator, polyethylene blocks have been put on between ^{252}Cf source and ^{3}He ionization chamber. When 50 mm thick moderator was put on, the sensitivity of the chamber was recorded the highest value.

DISCUSSION

The ^{4}He response to several sources those are ^{60}Co, KUR(D_2O), ^{241}Am-Be are plotted in Fig.2, showing very good fitting to the line. This implies that the small amount of gamma rays coexisting with neutron can easily be separated with the dual-chamber.

Table 1 shows the sensitivity related with ^{3}He gas pressure and moderator. This response ratio means output current ratio to that of the 1 atm ^{3}He chamber with moderator.

Table 1. Sensitivity related with the ^{3}He gas pressure and moderator.

		Response ratio	
Neutron source	moderator	1 atm	3 atm
Thermal neutron	5 cm	1	1.87
	0 cm	6.26	13.1
^{252}Cf	5 cm	1	1.82
	0 cm	-	0.09
^{241}Am-Be	5 cm	1	1.82
	0 cm	0.04	0.11

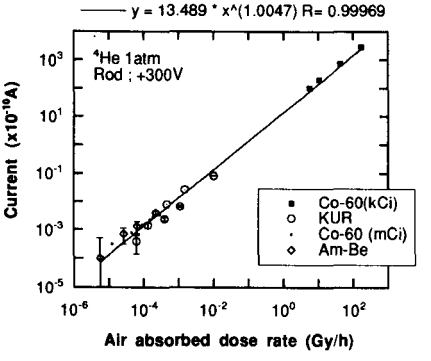

Figure 2. Responses to gamma rays, (1 atm ^{4}He chamber).

In order to compare the experimental result with estimation, ^{3}He reaction rate has been calculated by means of ANISN which is one dimensional discrete ordinates neutron transport code. The conditions of the calculation have been changed about type of neutron source, ^{3}He gas pressure, thickness of polyethylene moderator.

The 3 atm chamber generates 1.8 times current than the 1 atm one, as shown in Table 1. This result can not

be explained by one dimensional calculation. This is related with mean free path of neutron in the chamber. The shape of the chamber is cylinder. From two dimensional view, the chamber is circle. The thickness of that is the same as the diameter at the center, and becomes thinner when recede the center point. When neutrons go into the 1 atm chamber from one direction uniformly, 48 % of neutron collides with ^{3}He, the remainder go through it. On the other hand, 96 % of neutron make reaction with ^{3}He in the case of the 3 atm one. These calculation can explain the results of the experiment.

When gas pressure in the chamber is made higher, the sensitivity for X(gamma)-rays is increased correspondingly, but that for neutron is not risen so much. Even if the gas pressure is 7 atm, the sensitivity is ascended only 1.02 times as large as that of 3 atm. Therefore, the gas pressure in the chamber is rather considered for the sensitivity of X-rays.

The neutron signals from ^{3}He are due to a thermal capture process which is high sensitive for thermal neutron and low for fast neutron. It is important to select a suitable thickness of moderator. A polyethylene moderator gives reducing energy, shielding and reflecting for neutron. As shown in Table 1, moderator performs only as neutron shielding in the thermal region. The same value has been given by the calculation of ANISN. On the other hand, for the fast neutron, moderator slows down neutrons to thermal neutron. The result of calculation indicates that the 5.5 cm thick moderator gives the highest sensitivity for a few MeV neutron. The ^{252}Cf irradiation test shows the same consequence as this.

Fig. 3 shows the response characteristic of ^{3}He chamber against neutron energy. By the effect of the moderator, the sensitivity of ^{3}He chamber becomes quite uniform for neutron energies up to a few MeV.

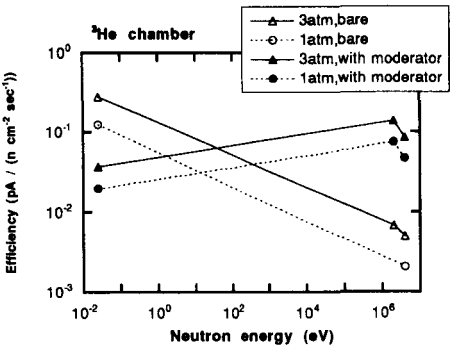

Figure 3. Response characteristic of ^{3}He chamber against neutron energy.

SUMMARY AND REMARKS

A dual type cylindrical ionization chamber system has been developed for dosimetry use of neutrons and X(gamma) rays. Several tests so far carried out in various field conditions seem to show good capability of the system.

Task and issues left for the future : (i) Tests in the burst-like pulse radiation fields (use of existing accelerators or plasma devices) using fast responsive electrometer (ii) n-X separation test in the field where n/X is small.

ACKNOWLEDGEMENT

The authors thank Prof. T. Tsujimoto and T. Yoshimoto (Research Reactor Institute, Kyoto University) for their kind arrangements in making the irradiation tests.

INTRODUCTION

A neutron monitoring system that could measure the contribution of neutrons separately from that of γ-rays in a n-γ mixed field has been developed in order to evaluate such a mixed field as encountered around a thermonuclear fusion reactor, a particle accelerator and a nuclear fission reactor. The characteristics of the detectors have been pre-checked with an Am-Be neutron source and then the experiments have been carried out around a target of the electron linear accelerator installed at the Radiation Laboratory in Osaka University and also in the D_2O facility of the research reactor in Kyoto University. In the former case the radiation field consists of burst X-rays and fast neutrons, which could simulate the field around a proposed fusion reactors such as Helical or Tokamak. On the other hand, in the latter case the field consists of stationary thermal neutrons and γ-rays, and it would be useful for the detector system to be tested in simulating the field of environmental level.

The main purpose of the present experiments is to establish a detecting system of a wide dynamic range that could measure all kinds of n-γ mixed fields, that is, various fluence rates and mixed ratios which could be realized just near the radiation generator and also far from it, namely the environmental level.

EXPERIMENTAL APPARATUS

In order to detect neutrons separately from γ-rays it is essential to explore such materials possessed with different sensitivities for neutrons and γ-rays. Namely, one is sensitive to both neutrons and γ-rays, and the other is only to γ-rays. The difference between the two output signals could correspond to that of neutrons. In case of a gas counter ^3He and ^4He gases are usually adopted. In the present experiments, however, a twin-type ionization chamber filled with $^{10}BF_3$ and $^{11}BF_3$ gases in each chamber has been prepared. The chamber is of a disk shape, diameter and thickness of which are 16 cm and 6 cm, respectively, and a rod-type electrode is inserted to each chamber. The applied voltage has been so adjusted as could be operated within the ionization chamber region. In the $^{10}BF_3$ chamber the thermal neutrons would react with ^{10}B and the emitted α-particle and ^7Li-particles would ionize the $^{10}BF_3$ gases. This chamber, however, also acts as a usual ionization chamber for γ-rays, and hence the output signal is attributed to both

neutrons and γ-rays. On the other hand, as $^{11}BF_3$ chamber is insensitive to neutrons, the output would correspond only to γ-rays, that is, the exposure due to γ-rays could be measured without the influence of neutrons.

With this twin-type chamber the mixed field of high-fluence rate could be measured by the output current, while that of an environmental level by the counting method.

EXPERIMENTAL RESULTS AND DISCUSSIONS

In the beginning the experiments have been carried out with the Am-Be neutron source to obtain the fundamental characteristics of the twin-type chamber. In Fig. 1 are shown the output currents of both $^{10}BF_3$ and $^{11}BF_3$ chambers as a function of the distance from the source, where the dose equivalent rate due to γ-rays evaluated with an air-equivalent ionization chamber is also shown. It is found that both signals of $^{11}BF_3$ and ionization chamber are possessed with the same attenuation gradient, that is, they would satisfy the inverse square law of distance. The gradient of the output signal from $^{10}BF_3$ chamber which correspond to (n + γ) signals is a little larger than the other's. This is probably due to the scattered thermal neutrons coming from all directions around the chamber. As the difference of both signals could clearly be observed, the contribution due only to neutrons would be found out by taking subtraction between both signals.

In Fig. 2 are shown the experimental results with this chamber set around the target of the electron linear accelerator. The energy, the peak current and the repetition rate of the electron beam are 28 MeV, 1 A and 60 pps, respectively, and the material of the target is Ta. The angular dependence of the output current from both chambers set at 3 m from the target is shown in the figure. The signals of both chambers increase towards the beam direction, which corresponds to the fact that the intensity of the Bremsstrahlung X-rays is extremely intense in the forward direction of scattering. However, the subtraction of both signals comes to be flat, that is, the neutrons generated in the Ta-target by the X-n reaction reveal no angular dependence.

In Fig. 3(a) and (b) are shown the experimental results obtained with those chambers set inside the D_2O thermalized neutron irradiation facility of the fission reactor. It is found that both output currents due to thermal neutrons and γ-rays increase linearly with the reactor power and there exists difference of about two orders of magnitude between both signals. The linearity of the exposure due to γ-rays for the reactor power has also been ascertained with an air-equivalent ionization chamber.

CONCLUSION

The twin-type $^{10}BF_3$ -$^{11}BF_3$ ionization chamber has been operated in such various n-γ mixed fields as of Am-Be neutron source, as around a target of the electron linear accelerator and as inside the D_2O thermalized neutron irradiation facility of the research reactor. As a result it has been confirmed that both neutrons and γ-rays could be evaluated independently in the mixed field with satisfactory accuracy by taking subtraction of both output signals.

The present measuring system will be expected to be useful to evaluate the mixed field that would appear around various kinds of particle accelerators and also proposed large-scale devices for the thermonuclear fusion.

INTRODUCTION

In order to estimate doses received by people in a case of nuclear accident it is important to have convenient sensors of mixed radiations and to discriminate heavy particles from ionizing radiation, becouse their biological effects are different. Semiconductor devices are widely used for such purposes. In comparison with traditional sensors (ionization chambers, Geiger-Muller counters,TLD and track detectors), semiconductor dosimeters have certain advantages because of their high sensitivity, small sizes and weights and simple readout. They can work in both passive and active modes, can store information for a long time, and can operate in count integrating mode. They register different kinds of radiation over wide ranges of doses and energies and are useful for accident and for routine dosimetry as well.

Possible use of semiconductor devices for dosimetry were described previously (for instance,MOS transistor for gamma (1,2) and PIN diode for neurton (3,4) - irradiation).New gamma and neutron sensors have been produced in our Institute and their main dosimetric parameters have been published in (5,6).

The purpose of this work was to describe all functional opportunites of PIN and MOSFET dosimeters, designed in our Institute.

PRINCIPLES OF SEMICONDUCTOR DOSIMETERS AND EXPERIMENTS.

The non-ionizing loss induced by neutrons in the bulk of silicon structures generates atomic displacements leading to defects in the crystal. These act as generation-recombination centers. PIN structures have relatively small sensitivity to gamma-rays , which produce few displacements, so they can be used for neutron radiation measurement only. Extensive studies have been performed on the effects of neutrons on the behaviour of PIN structures. The variation of forward voltage under fixed carrent shows a simple dose dependence by the equation:

$$\Delta U_f = U_f - U_0 = kD \qquad (1)$$

where U_0 and U_f are the initial bias and the bias after irradiation, respectively; D is the neutron dose. Sensitivity k has a complicated dose dependence on minority carrier lifetime τ_0 , resistivity ρ and diode geometry and can be expressed as:

$$k = dU/dD = k_\tau \tau_0 f(d/L) \qquad (2)$$

were k_τ is the damage constant, d is the base thickness and L is the diffusion length.

The known PIN diodes for dosimetry (4) were made from p- and n-Si ($\rho \sim 10 \div 100\ \Omega$ cm) and have been studied at a high level of injection, where damage constant depends on lifetime only. The authors found a value of k = 100 mV/Gy and dose dependence was linear up to 12 Gy.

We have studied (both theoretically and experimentally) PIN diodes on the high-resistivity base under intermediate injection level (6). In this case one can vary three parameters (d, L, ρ) to achive the best neutron sensitivity.

Thus for PIN diodes on the base of n-type silicon we have received a higher sensitivity over a wider dose range in comparison with a case of high level of injection (for $\rho \sim 1k\Omega$ cm, d=0,12÷0.3cm, k=0.1÷1.0 V/Gy, dose range from 0.1 Gy to 100 Gy; for $\rho \sim 40k\Omega$ cm, d=0.5cm, k=5V/Gy, dose range (0.005 ÷3.0)Gy).

The discrimination coefficient to gamma irradiation in mixed field is ~1000.

An accuracy of neutron dose determination depends on a temperature instability coefficient (TIC). For PIN diodes on the base of high resistivity silicon TIC is smaller and decreases with neutron dose in contrary with diodes on the low-resistivity base.

PIN sensors described above have been tested in count integrating mode under ^{137} Cs and ^{139} Ce gamma irradiation and had readout cut-off ~40 keV. Lower limit for gamma dose rate was 0,7 msv/h. Radiation defects created by fast neutrons do not effect significally on count characteristics up to neutron dose 10 Gy.

Proposed PIN diodes may be usful to measure the gamma dose rate and the accident fast neutron dose at the same time.

The mechanism of radiation sensitivity of MOS structures have been studied in details by many authors (1,2). A positive charge is stored in the gate oxide and the radiation-induced charge on the $Si-SiO_2$ interface appears under ionizing radiation. This leads to the threshold voltage shift, ΔU_t, for MOSFET or flat-band shift, ΔU_{FB}, for MOS capacitors. The built- in charge in the oxide and, therefore the value ΔU_t, depends on the concentration of hole traps, their space and energy distribution and the gate bias during irradiation. This dose dependence can be expressed:

$$\Delta U_t = (\Delta U_t) \max [\, 1 - \exp (- \beta D_\gamma \,)], \qquad (3)$$

where sensitivity β depends on the oxide structure and is proportional to $N_t d^2_{ox}$, d_{ox} is the oxide thickness, N_t is the trap concentration. In order to get higher sensitivity one must increase d_{ox}.

Our previous measurements have been extended to n-channel MOSFET sensors on the base of p-Si substrate with resistivity 10 Ω·cm and oxide thickness 1 μm.

MOSFETs channel lengths have been varied from 10 to 50 μm.The dosimetric sensitivity to ^{137} Cs gamma irradiation was 150 mv/Gy in a passive mode and did not depend on channel length up to 40 μm; For standard radiotechnical transistor with 0.1μm oxide thickness β is three orders of magnitude less.In an active mode (with the positive gate bias V_g) the sensitivity is higher and varies as $\beta \sim V_g^{2/3}$.

Irradiation temperature (-60°÷60°C) does not effect on the sensitivity both in passive and active modes.

Studies of MOSFETs irradiated at the high dose rate (with pulse gamma rays source) has showed that sensitivity was practically independed on the dose rate up to 10 Gy/s.

Temperature instability coefficient depends on readout current. We have found experementally thermostability current 43 μA, when TIC=0.

A coefficient of discrimination to neutrons in mixed radiation field is ~100 and strongly depends on dosimeter encapsulation (7).

For dose measurement applications it is important to know the fading of devices.

Changes of voltage shifts with time for our MOSFET sensor are ~15% in two months storage, while the main change takes place during the first hour after irradiation (as in the case of PIN diodes).

The MOSFET dosimeters described above have been tested on the 3-d block of Tchernobyl atomic pover station after accident and have shown good agreement with results for standard TLD dosimeters (see table).

Gamma ray dose (rad)		
MOSFET dosimeters	Termoluminiscence dosimeters	Place of exposition
599	450±30	roof
365	370±20	roof
253	247±15	roof(Pb-3mm)
247	320±30	bulding, point 12
300	320±30	bulding, point 12
318	320±30	bulding, point 12
897	900	roof
394	353±13	bulding, point 12

Our next step was to combine PIN diode and MOS transistor in one sensor. For this purpose p-channel MOSFET with thick gate oxide and high resistivity base have been taken. Source-base and/or drain-base give P-N diodes with a linear response, changes in their current-voltage curves under irradiation could be used to measure neutron dose. Influence of gamma ray and neutron irradiation on dosimetric characteristics of such p-MOSFET has been investigated. The sensitivi to ^{137} Cs gamma rays was 100 mV/Gy , to fast neutrons of nuclear reactor ~ 30 mV/Gy. The last value may be increaced by using MOSFET with a thicker base.

CONCLUSION

Silicon dosimeters described above were developed for reliable selective determination of gamma and neutron radiation at accident , routine measurements and medical application:

1. PIN diodes on high resistivity base for fast neutron dose measurement, n-MOSFET transistors for gamma dosimetry.
2. PIN diodes to measure gamma dose rate in routine dosimetry and accident fast neutron dose at the same time.
3. Accident dosimeter for mixed radiation fields, using PIN diode together with MOSFET transistor.

A MODERATOR TYPE NEUTRON DOSEMETER BASED ON SILICON DIODES

T. Moiseev
Institute for Physics and Nuclear Engineering - Laboratory 7
Magurele, P.O.Box Mg-6, Sect. 5, Bucharest, Romania

ABSTRACT : A moderator type neutron dosemeter is described and its response to realistic neutron fields from C.E.N. Cadarache-France is investigated, as well as its sensitivity to the gamma rays generated along with the realistic neutron fields.

Changes in response induced by the use of a moderator are observed throughout the experiments, with respect to the energy distribution of the neutron fluence and the dose equivalent. The Silicon detector sensitivity to the gamma ray component of these fields is also discussed.

Compared to an electronical neutron dosemeter without a moderator, for the same active area of the Silicon detector, the actual design shows a response 10 to 40 times higher to realistic neutron fields and a sensitivity to gamma rays up to 10 times lower.

INTRODUCTION

Previous work in the field[1,2,3,4] showed that the main problems in designing a neutron dosemeter based on Silicon diodes consist in finding the means to provide high gamma ray discrimination and to improve the response in the intermediate neutron energy range. A new approach to these problems is made using 2 Silicon detectors of 19.6 mm^2 active area surrounded by a small-size moderator.

While moderator type neutron equivalent monitors using passive detectors[5] require full moderation of neutrons over the whole neutron energy range (from thermal to 14 MeV), the use of Silicon detectors led to the concept of a "selected" energy range for moderation, which consist in moderating neutrons up to a certain energy and detecting higher energy neutrons directly as fast neutrons, using the same detector.

This is possible by using a polyethylene foil radiator deposed with a ^{10}B layer, positioned on the active surface of the Silicon diode. This radiator allows the detection of thermal neutrons through the $^{10}B(n,\alpha)^{7}Li$ reaction and fast neutrons detection through protons issued by fast neutron elastic scattering on Hydrogen atoms in polyethylene.

This "selected moderation" of neutrons requires moderators smaller in size than those used for "full moderation", allowing their use for personal dosimetry.

The use of a small size moderator has also the advantage of increasing the potential detection area of the dosemeter and allows a higher low amplitude threshold in order to discriminate pulses due to the gamma ray background.

THE MODERATOR TYPE NEUTRON DOSEMETER BASED ON SILICON DIODES

The detection assembly (moderator + diodes) shown in Fig.1 consists of 2 implanted Silicon diodes, having an active area of 19.6 mm^2, one of the diodes being provided with a polyethylene radiator deposed with 2 μm layer of B_2O_3 (96% ^{10}B enriched).

The pulses from the diodes are fed through two acquisition chains and then treated by a differential method.

Each diode is covered with an Aluminium shielding (0.3 mm thick), and both diodes are included in a hemispherical moderator provided with a cylindrical opening (Fig.1) intended to provide a direct detection for fast neutrons at normal and near normal incidence.

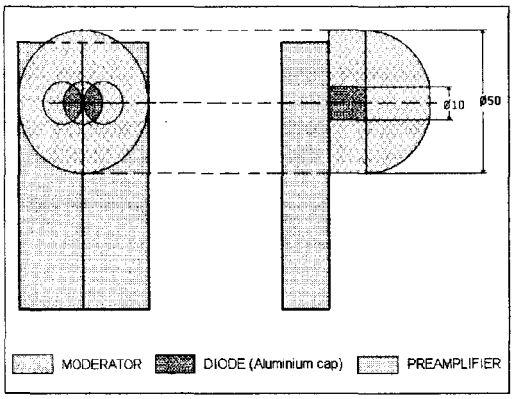

Fig.1. The detection assembly with moderator.

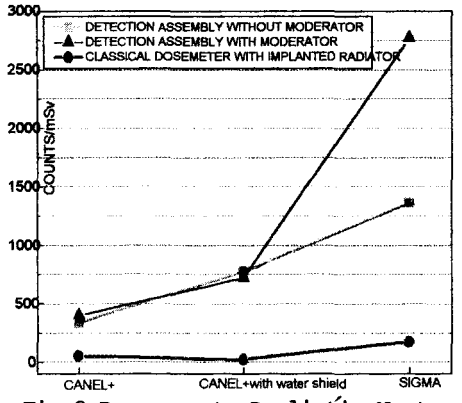

Fig.2 Response to Realistic Neutron Fields (Cadarache)

The low amplitude threshold of the system was at 100 keV and an informatic cutoff was imposed at 290 keV in order to discriminate gamma rays generated pulses up to a sensitivity of 10 counts/mSv for a ^{137}Cs gamma ray source.

THE IRRADIATION TESTS

Irradiation tests have been performed using the "Realistic Neutron Fields" from CEA/CEN Cadarache-France. The main parameters characterizing these fields are indicated in Table No.1, data being provided[6] by CEA/CEN - Cadarache and CEA/ IPSN/ DPHD Fontenay-aux-Roses. The following parameters are indicated: the spectral distribution of the neutron fluence Φ and neutron dose equivalent H for three neutron energy ranges : thermal (0.025 eV - 1 eV), intermediate (1 eV - 10 keV) and fast neutrons (10 keV- 14 MeV); the average neutron energy E(keV); and the effective energy E_H(keV), which is the dose equivalent average neutron energy.

Characteristics Neutron Field	Φ_{th} %	Φ_{int} %	Φ_{fast} %	E keV	H_{th} %	H_{int} %	H_{fast} %	E_{eff} keV
CANEL+	36	20	44	150	6	3	92	610
CANEL+ with water	43	26	31	80	10	7	83	68
SIGMA	97	1	2	72	46	4	50	1323

TABLE No.1.: Characteristic data for the Realistic Neutron Fields from Cadarache (France).

Irradiations of the detection assembly with and without moderator have been performed at normal incidence for each neutron field, with and without a PMMA phantom.

For each measurement, it was provided the value of the ambient dose equivalent H*(10) obtained from neutron fluence monitoring and the values of the corresponding fluence to dose conversion factors, as indicated by ICRP 60.

RESULTS

Dosemeter's response for the irradiation tests described above is shown in Fig. No.2, and is compared to the response of a differential detection system with two PIPS detectors, provided only with a radiator (and no moderator), developed at CEA/IPSN/DPHD/SDOS Fontenay-aux-Roses[2]. To enable comparison, the Silicon diodes active area has been normalized to 19.6 mm^2. In the diagram (Fig.No.2) the three type of fields (CANEL+, CANEL+ with water and SIGMA) were placed in an order reflecting their content of thermal neutrons. A statistics on the number of the pulses counted and an

investigation of their spectral distribution to observe the influence of the moderator to the dosemeter response, is shown in Fig.3 and Fig.4.

A part of this study is focused on the dosemeter response to the gamma rays generated along with the realistic neutron fields.

The response to gamma rays and the eventual direct neutron interactions with Silicon atoms in the diode were observed as the response on the diode without a radiator .

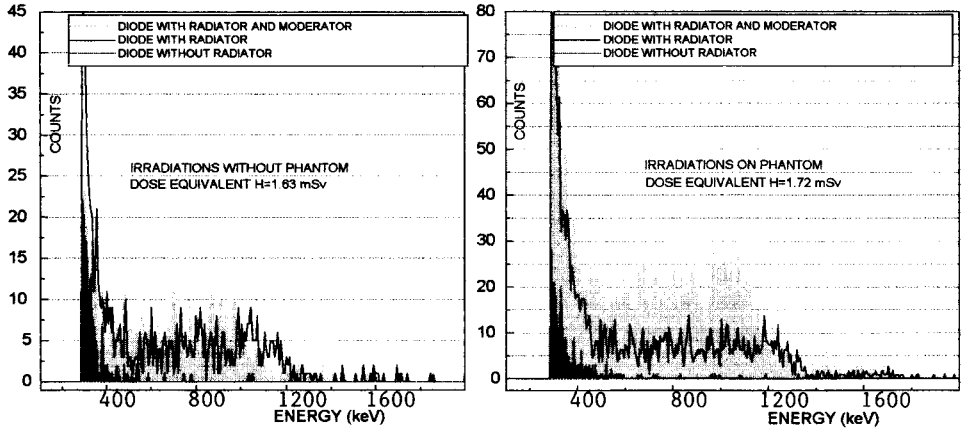

Fig.3 and Fig.4 : Cadarache irradiations on CANEL+with water shield. Pulse height spectra.

DISSCUTION AND CONCLUSIONS

For thermal neutrons and on phantom measurements it was obtained an over response when using the moderator, which is an expected result. A Cadmium shielding of a certain extent on the moderator's surface could overcome this inconvenient.

In the intermediate neutron energy range the sensitivity of the moderator system is higher than that obtained for the "classical system" using only the radiator. This is mainly due to the higher ^{10}B concentration in the radiator, but also to the presence of the moderator.

In conclusion, the moderator type neutron dosemeter investigated shows a high sensitivity for neutrons in the intermediate energy range where other detection systems using Silicon detectors proved to have a gap in response.

The small active area of the Silicon detectors, as well as the differential system used allows a very low gamma ray sensitivity of the detection system (10 counts/mSv), but it has also the disadvantage of providing a low sensitivity to fast neutrons.

THE THERMOLUMINESCENCE CRITICALITY DOSIMETRY AT COGEMA

Michel Espagnan [1], R. Prévot [2], H. Truffert [2], X. Le Chaftois [2]
P.L. Douillard [1], P. Chatenet [1]

1 Cogema Marcoule Nuclear center, France
2 Cogema La Hague Nuclear center, France

1 - Introduction

Through its activities, and in particular in enrichment, fabrication and nuclear fuel reprocessing, COGEMA has to master the dosimetry in case of a criticality accident event.

The COGEBADGE®, equipped with a film and a 4 dosimeter (2LiF600, 2 LiF700) thermoluminescent card provides with satisfaction routine dosimetry for beta, gamma and neutron rays.

Other COGEBADGE® éléments (ebonite, gold (naked and cadmium shielded)) are also available for criticality dosimetry. This personal dosimetry system is completed by an area one, using the SNAC 2, a neutron spectrometer by target activation and counting.

The counting and spectrometry operations of the targets last for a long time in order to obtain the dosimetric quantities, neutron, kerma and photon dose.

So, COGEMA in collaboration with IPSN (National Safety and Protection Institute) and ETCA (Etablissement Central de l'Armement) have carried out a series of critical experiments, using the SILENE reactor (in VALDUC Nuclear center) especially devoted to this task.

In the SILENE cell, different screens in nature and size, have been disposed in order to simulate as closer as possible a criticality accident event. Two configurations have been used, unshielded and lead shielded Silene. The main goal has been to test the thermoluminescence dosimetry capacity in the field of the criticality personal dosimetry.

2 - Procedures and results

The reference values (neutron kerma and photon dose) have been given by the IPSN and ETCA.

A special procedure has been set off for the dosimeter treatment. It uses, in particular, a light signal attenuation filter (1/100) in the reading procedure.

Results

For the different configurations studied, giving rise to a ratio (neutron kerma/photon dose) ranging from 0.21 to 4.17, the results are as follow :

the neutron kerma response Rn (calculated/reference) = 1.03 ± 35 %
the photon dose response Rγ (calculated/reference) = 1 ± 15 %

3 - Conclusion

In regards to the above described experiences and results obtained, the thermoluminescence technics allows a first assessment of the dosimetric quantities in a rapid and simple way.

One hour after the arrival of the dosimeters in the laboratory, the dosimetric quantities, for about 50 persons, at the location of the dosimeter, can be obtained under the following conditions :

kn (Gy) within ± 35 %

Dγ (Gy) within ± 15 %

24 hours later, these above performances are improved by the results coming from the use of the different targets (ebonite and gold) of COGEBADGE® and of the criticality belt.

A STUDY ON NEUTRON AND GAMMA-RAY RESPONSES OF LABORATORY MADE LiF:Mg,Ti SINGLE CRYSTAL TLD

ABSTRACT

The main objective of this study is to determine the neutron and gamma-ray sensitivities of laboratory made LiF:Mg,Ti thermoluminescence dosimeter (TLD) for practical application in neutron-gamma mixed field dosimetry.

INTRODUCTION

In recent years the application of TLD in neutron and gamma-ray mixed field has steadily increased to assess the dose burden of radiation workers. The dosimetry of neutrons in a mixed field is not as simple and precise as that of pure gamma-ray fields due to energy transfer processes and to variation in the reaction cross-sections with energy (1). In the presence of a mixed field (neutron+gamma), the separate evaluation of the neutron and gamma-ray contributions is essential. Thermoluminescence (TL) dosimeters are now extensively used in radiation dosimetry. Numerous investigations for the development of TL materials have been performed for mixed field radiation dosimetry (2-4). The most frequently used TLD in neutron and gamma-ray mixed field dosimetry is LiF:Mg,Ti. The isotopic constituents of the LiF:Mg,Ti family are: ^{6}Li 7.5% and ^{7}Li 92.5% for the TLD-100, ^{6}Li 0.01% and ^{7}Li 99.99% for the TLD-700 and ^{6}Li 95.62% and ^{7}Li 4.38% for the TLD-600. It is well known that TLD-700 is practically insensitive to neutrons and TLD-600 is sensitive to both neutrons (to a greater extent) and gamma-rays. TLD-100 is also sensitive to both neutrons (to some extent) and gamma-rays. The LiF:Mg,Ti (equivalent of commercially available TLD-100) single crystal of natural isotopic composition has been developed in the laboratory in order to use it for radiation dosimetry . The LiF:Mg, Ti dosimeters have been used for gamma-ray dosimetry (4-6). The objective of this study is to determine the neutron and gamma-ray sensitivities of laboratory made LiF:Mg,Ti single crystal for practical application in radiation monitoring in neutron and gamma-ray mixed field.

EXPERIMENTAL METHODS

The single crystal of LiF:Mg,Ti has been produced at the Atominstitut der Osterreichischen Universitaten,Vienna, Austria using the Czocharalaki technique (7). LiF:Mg,Ti single crystal, totally transparent, measures about 6mm x 6mm x 1mm in size. These TL dosimeters were submitted to the standard pre-annealing thermal treatments; heating at 400 ^{o}C for one hour followed by 2 hours heating at 100 ^{o}C. The photon irradiations were performed at the Secondary Standard Dosimetry Laboratory (SSDL), AERE, Savar with the standard radiation sources. Two gamma sources were used: ^{137}Cs and ^{60}Co, with gamma energies of 662 keV and 1250 keV$_{eff}$, respectively. The X-ray generator was used to produce normalized X-ray beams of 33, 48, 65, 83, 100 and 118 keV$_{eff}$. The collimated beams are horizontal, the dosimeters are positioned on the calibration bench at a distance of 1m by means of a laser beam. The

beams were calibrated with two secondary standard chambers NE2571 and NE2575. Thermal neutron irradiation was performed at the thermal column of the 250 kW TRIGA Mark-II research reactor at Vienna. The themal neutron flux was measured by using a gold foil activation technique. Fast neutron irradiation were performed in the ^{252}Cf (2.1 MeV), Am-Be (4.5 MeV) and neutron generator (14 MeV) neutron fields. The neutron doses were measured using a rem counter. After irradiation the TL responses were read by means of a laboratory made TLD DAT-II and a Harshaw TL reader Model 4000, using a linear heating rate of 10 °C/s from room temperature to 300 °C with a constant flow of nitrogen (about 3 l/min). No further treatment procedure was used in the period after irradiation and before evaluation, because all measurements of the irradiated TLDs were made at least 48 hrs after irradiation to allow decay of low temperature peaks. The responses to thermal neutrons were calculated after subtracting the gamma-ray contributions. A computer aided procedure was set up in order to store data and to display the glow curve. The LiF:Mg,Ti single crystal samples are totally transparent so that the emission of thermoluminescence light during readout is much larger compared to other similar lithium fluorides (TLD-100 and TLD-600) which are totally or partially opaque. The sensitivity was calculated by taking into account the integrated light from the most important peak only. The detailed procedures for calibration and messurement are described elsewhere (5).

RESULTS AND DISCUSSIONS

The shape of glow curves for gamma-rays from ^{60}Co source and neutron+gamma-ray mixed radiations from reactor are shown in Figs.1a & 1b. Two main peaks at 200 °C and 250 °C are evident in case of gamma radiation from ^{60}Co source (Fig. 1a). The peak at 200 °C has to be considered as the main peak whereas peak at 120 °C appears as a shoulder of the main peak on

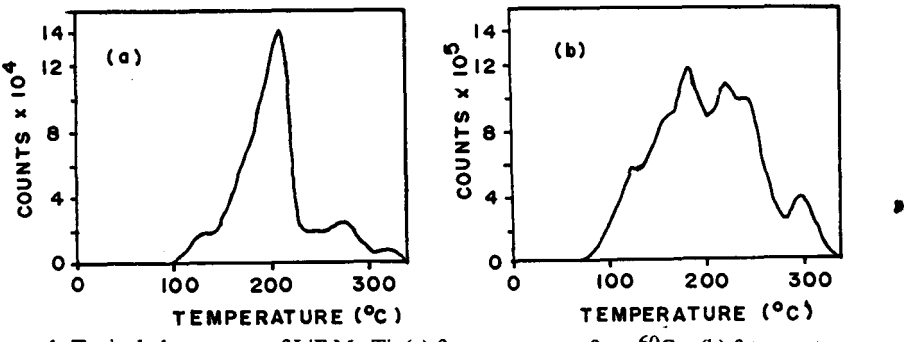

Figure 1. Typical glow curves of LiF:Mg,Ti: (a) for gamma-rays from ^{60}Co; (b) for neutron+ gamma-ray mixed fields from research reactor.

its low temperature side. From the Fig. 1b, it is found that the glow curve of laboratory made LiF:Mg,Ti TLD obtained from neutron+gamma-ray mixed radiations is quite different from those obtained from a gamma source (^{60}Co). In case of thermal neutron irradiation, a peak at 250 °C is produced more efficiently as compared to the 200 °C peak produced by the gamma-rays as well as the neutrons. Hence by following the difference between the two peak heights one can estimate the thermal neutron exposure from laboratory made single LiF:Mg, Ti dosimeter. Table 1 shows all the X and gamma-ray sources, the corresponding energies and the TLD sensitivities for each point of energy. The sensitivities were calculated by dividing their responses by the exact equivalent-dose delivered by each source. The relative gamma-ray sensitivity of LiF:Mg, Ti

compared to TLD-100 was found to be 0.97 which means that the dosimetric properties of laboratory made LiF:Mg,Ti TLD are comparable with those of TLD-100.

Table 2 shows all the neutron sources, the corresponding energies and the TLD sensitivities for each point of neutron energy. From Table 2, it is evident that the neutron sensitivities are highly dependent on neutron energies. The fast neutron sensitivity is less than that of thermal neutron sensitivity. The thermal neutron responses were reported interms of ^{60}Co equivalent roentgen (R) per 10^{10} n.cm^{-2} . The thermal neutron sensitivity varies from 325 to 389 R per 10^{10} n.cm^{-2} with an average value of 368 R per 10^{10} n.cm^{-2}. This value agrees well with the values quoted in the literature for TLD-100 (2). The accuracy in neutron and gamma-ray responses in the present study was within $\pm$10%.

Table 1. TLD sensitivities at various photon energies.

Source	Energy (keV)	Sensitivity (nC/mSv)
X-ray	33	8.45
X-ray	48	6.35
X-ray	65	5.98
X-ray	100	5.12
X-ray	118	4.78
^{137}Cs	662	4.21
^{60}Co	1250	4.56

Table 2.TLD sensitivities at various neutron beams.

Neutron energy (MeV)	Source	Neutron fluence (cm^{-2})	Sensitivity (nC/mSv)
2.5E-08	Reactor	1.45E07	78.56
2.1	Cf-252	1.78E05	2.56
4.5	Am-Be	1.25E05	1.98
14.0	Neutron generator	2.35E05	1.24

CONCLUSIONS

From these results it can be concluded that the laboratory made LiF:Mg,Ti single crystal is suitable for practical application in thermal neutron-gamma mixed field dosimetry around the nuclear facilities. Further, this dosimeter can be used in fasst neutron dosimetry purposes if the dosimeters are embeded with fast neutron moderating materials.

ABSTRACT (See instructions overleaf)

Intensive investigations of new materials for thermoluminescent dosimetry (especially of ^{6}LiF/^{7}LiF-Mg,Cu,P) are now performing. Therefore the comparison of dosimetric characteristics for different TLDs on the basis of LiF has a great interest. The comparison of russian TLDs: TLD-6011/7011 (Moscow State University-"Practica",Moscow), DTG--4-6/7 (Institute of Geochemistry, Irkutsk) with TLD-600/700("Harshaw") is presented. The comparison has been performed on the basis of neutron dose equivalent measurements of these TLDs in IHEP neutron reference fields. The absolute sensitivity and the ratio of neutron and gamma sensitivities were estimated from the experimental data. The neutron dose equivalent has obtained by a passive monitor which consist of the LiF pairs in 25,4 cm diameter spherical polyethylene moderator. The comparison shows that photon sensitivity of new TLD--6011 is higher than one of TLD-600 by factor 50. The neutron sensitivity of TLD-6011 is higher than one for TLD-600 in 9 times and than for DTG-4-6 by a factor of 4. The neutron-to-photon responce ratio for the TLD-600 is about two times higher than that for TLD-6011 and DTG-4-6. The analysis of TLD perspectivity for area, environmental and individual monitoring given taking into account the new ICRP recommendation is presented.

EVALUATION OF THE FAST NEUTRON DOSE EQUIVALENT USING THE THERMAL NEUTRON RESPONSE OF LITHIUM FLUORIDE TLD

Caliopia Turcus, Cornelia Craciun, Ana Stochioiu

Institute for Physics and Nuclear Engineering,
Bucharest, Romania

INTRODUCTION

For estimation of the fast neutron dose equivalent we used the albedo method which consists in the detection of the albedo thermal neutrons. The albedo neutrons are the fast neutrons which leave the body as thermal neutrons after having been scattered in the human body. The albedo neutrons are detected at the surface of the body by means of the detectors for thermal neutrons.

For the measurement of the albedo thermal neutrons we used a Multifunctional Personal Dosimeter which contains 6 detectors of lithium fluoride with natural lithium. This has realized at Institute for Physics and Nuclear Engineering., in Bucharest.

The detectors of lithium fluoride with natural lithium are sensible at the photon radiations, at the beta radiations and at the thermal neutrons. The discrimination is realized with the help of the filters.

This dosimeter was designed so that with a suitable choice of Cd (0,8 mm), Sn (0.8 mm) and Al (1 mm) filters size and thichness he is suitable to measure the thermal neutron dose equivalent, the photon radiation dose equivalent and the beta radiation dose equivalent.

THE CONDITIONS OF IRRADIATION

The irradiation have been effectuated in the centre of a room with the next dimensions: (12 x 20 x 10) m on a support at 3 m height over of the floor.

In this way have been provided the ideal conditions of irradiation.

For to simulate the real conditions of utilization in the personal dosimetry, the dosimeters have been situated on the phantom, with the dimensions: (200 x 300 x 400) mm. The phantom has been filled with the water.

We were started with measurement at the Am-Be source with and without the phantom for to investigate the influence of scattering from the wall and the floor. We have found the thermal incident neutrons representing it a negligible contribution.

RESULTS

The experiments were performed with the neutrons from an Am-Be source and from an ^{252}Cf source.

For each fast neutrons source was determined the calibration factor, with which has been passed from the thermal neutron dose equivalent into the fast neutron dose equivalent.

The distance from the source at the phantom has been 30 cm both for the Am-Be source and for the ^{252}Cf source.

The irradiations of the Am-Be source were performed at the next values for the fast neutron dose equivalent: 0.385 Sv; 0.852 Sv and 1.331 Sv.

The irradiations of the ^{252}Cf source were performed at the next values for the fast neutron dose equivalent: 0.557 Sv and 0.751 Sv.

In the table no. 1 are presented the obtained results from the Am-Be source and in the table no. 2 are presented the obtained results from the ^{252}Cf source.

TABLE No. 1 - Am-Be Source

	$H_{nr, true}$ [Sv]	$H_{nr, ev}$ [Sv]	ε [%]	n
1.	0.385	0.385 ± 0.123	0	7
2.	0.852	0.982 ± 0.396	15.26	8
3.	1.331	1.171 ± 0.391	12,02	11

TABLE No. 2 - ^{252}Cf Source

	$H_{nr, true}$ [Sv]	$H_{nr, ev}$ [Sv}	ε [%]	n
1.	0.557	0.564 ± 0.24	1.25	12
2.	0.751	0.728 ± 0.227	3.06	10

In these tables the significance of the sizes is next:

- $H_{nr,\ true}$ is the true fast neutron dose equivalent at which has been the irradiation;
- $H_{nr,\ ev}$ is the mean value of the evaluated fast neutron dose equivalent;
- ε - the measuring error;
- n - number of the dosimeters which have been irradiated in the identical conditions and for which has been obtained the mean value.

The confidence level has been of 95 %.

The effectuated experiments have been affected in principal of the next sources of the errors:

- the little distance between source and phantom;
- the distribution of the dosimeters on the phantom;
- the long time for irradiation (the largest time has been > 1 month);
- the detectors of lithium fluoride have not been specially selected for this experiment.

From the experimental data presented results that the dose equivalent of fast neutrons can be estimated on the basis of the albedo method using our personal dosimeter with satisfactory results, only with an adequate calibration for each case.

We hope that the results can be improved.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 3.2 (see page 7)

For dose measurements in unknown mixed (n,γ)-fields the neutron energy dependence of the TL-response was measured using TLDs embeded in spheres of 25 cm diameter (ICRU sphere). For this purpose the pair-method using ^{6}Li (TLD-600) and ^{7}Li (TLD-700) was approached. For optimizing the neutron shielding of TLD-700 and TLD-200 a special arrangement of the TLDs inside the spheres was considered.

The irradiation was performed with several neutron sources (thermal, Pu-Be, Am-Be and 14 MeV neutrons) with known equivalent doserates. Using the peak 5 maximum of TLD-600 glowcurves a neutron energy dependent calibration factor was calculated. It is further shown that the analysis of the peak height ratio of the neutron glow-curves of TLD-600 gives information about neutron energy dependent effects in material with different LET. The results were applied for measurements in aircrafts.

For determination of the equivalent dose the neutron spectrum is of great importance. To estimate the neutron spectrum a neutron spectrometer consisting of Bonner spheres with different diameters is used. This spectrometer was tested with known spectra of several neutron sources. The theoretical response of the spheres were calculated using the neutron spectrum and the energy dependent response and were compared with the measured values. The method was applied for determination of the equivalent dose in aircrafts.

MEASUREMENT OF TLD ALBEDO RESPONSE ON VARIOUS CALIBRATION PHANTOMS

T. Momose,[1] N.Tsujimura,[1] K. Shinohara,[1]
H. Ishiguro,[1] and T. Nakamura[2]

[1]Power Reactor and Nuclear Fuel Development Corporation, Tokai, Ibaraki, Japan
[2]Cyclotron and Radioisotope Center, Tohoku University, Sendai, Japan

INTRODUCTION

The International Commission on Radiation Units and Measurements (ICRU) has recommended that individual dosemeter should be calibrated on a suitable phantom and has pointed out that the calibration factor of a neutron dosemeter is strongly influenced by the the exact size and shape of the body and the phantom to which the dosemeter is attached. As the principle of an albedo type thermoluminescent personal dosemeter (albedo TLD) is essentially based on a detection of scattered and moderated neutron from a human body, the sensitivity of albedo TLD is strongly influenced by the incident neutron energy and the calibration phantom.(1) Therefore for albedo type thermoluminescent personal dosemeter (albedo TLD), the information of neutron albedo response on the calibration phantom is important for appropriate dose estimation. In order to investigate the effect of phantom type on the reading of the albedo TLD, measurement of the TLD energy response and angular response on some typical calibration phantoms was performed using Dynamitron accelerator and ^{252}Cf neutron source.

DOSEMETER

Table 1 shows the constitution of PNC/Panasonic TLD badge used in this experiment. This TLD badge was designed to detect thermal neutron and fast neutron by using 4 TLD elements and cadmium and tin filters.(2) Element 1 has the sensitivity only to photon and used for photon compensation. Element 2 has major sensitivity to thermal neutron from working field. Element 3 has sensitivity only to epithermal neutron. Element 4 has major sensitivity to albedo neutron which was refracted from human body. The calculation of fast neutron dose equivalent is performed by following equation.(3-4)

$$H = Kn(T4-T1-C(T2-T3))$$

where H is the dose equivalent of fast neutron, Kn is the conversion factor, C is the correction factor for thermal neutron compensation, T1,T2,T3 and T4 are measured values of each TLD element.

Since, the value of Kn is based on T4 sensitivity, it is influenced by phantom characteristics such as material and shape.

EXPERIMENTAL METHODS

The fast neutron experiment was performed by using the Dynamitron accelerator at Tohoku university which produces monoenergetic neutrons of around 210 keV and 560 keV by the Li(p,n) reaction, around 1.1 MeV by the T(p,n) reaction, 5.0 MeV by the D(d,n) reaction, and 14.9 MeV by the T(d,n) reaction. The neutron energy was determined by using time of fright technique. The TLD on the phantom was placed in the forward direction to the axis of the projectile beam. The direct neutron flux incident on the TLD was measured with the ^{235}U fission chamber placed on in front of the TLD. Since the ^{235}U fission chamber is sensitive to low energy neutrons scattered from the surrounding objects, a hydrogen proportional counter which was sensitive only to fast neutrons was also placed at 45 degree to the beam axis as subsidiary monitor of the neutron flux. The experiment on angular response was performed by using the ^{252}Cf source at the PNC calibration facility.

The calibration phantoms used in this experiment were as follows. (a) paraffin phantom, (b) polymethyl methacrylate(PMMA) slab phantom (specified by Japanese Industrial Standard for calibration phantom of gamma ray personal dosemeter; JIS phantom), (c) cylindrical water phantoms. (we used two types, one was full water phantom and the other was cavity water phantom). These were chosen by the point of view of typicality and availability. (d) special anthropomorphic phantom which was made of neutron tissue equivalent material(5-6) and of which the physique was same as normal Japanese man of age from 30 to 35.(7) We considered that the anthropomorphic phantom was equivalent

to living human body for neutron scatter. Table 2 shows phantom specification which were used in this experiment.

RESULTS AND DISCUSSION

Figure 1 (a) and (b) show the TLD energy response on various calibration phantoms. The element 4(T4) had higher sensitivity to fast neutron than a element 2 (T2) and a element 3 (T3) because of the absorption of albedo neutron by Cd filters beside T2 and T3. Sensitivitys of T2 and T3 are same to fast neutron. On the paraffin phantom, the sensitivity of element 4 which has high sensitivity to albedo neutron is same as the anthropomorphic phantom below about 1MeV, but in the energy range over 1MeV, the sensitivity on the paraffin phantom becomes about 1.5 times higher than anthropomorphic phantom. On JIS phantom, TLD response was higher than anthropomorphic phantom at the all irradiated energy region.

Figure 1 (b) shows comparison of anthropomorphic phantom and water phantoms. The response on the water phantom is in good agreement with the response on the anthropomorphic phantom, but cavity water phantom become lower than anthropomorphic phantom by a factor of 0.8. These experimental results suggest that water phantom is suitable for calibration phantom because of a good agreement with the anthropomorphic phantom which is considered as equivalent to human body.

The reason of the difference of energy response between the paraffin phantom and the anthropomorphic phantom seems to be the effect of the lung in the anthropomorphic phantom. The anthropomorphic phantom which have imitated lung with low density material has different scattering and moderating effects from the paraffin phantom which has uniform density.

The reason of the difference between the acrylate phantom and the anthropomorphic phantom seems to be the difference of the mean density. The density of 1.19 g/cm^3 of acrylate phantom seems to be too high as tissue equivalent.

The observed difference of energy response on cavity water phantom and anthropomorphic phantom seems to be because of the difference of lung volume. The cavity water phantom have large cavity of about 8 liters volume for lung which is two times as large as that of anthropomorphic phantom. Therefore incident fast neutron cannot be scattered and moderated well because of large volume of cavity in former phantom.

Figure 2 shows the angular response on various phantoms by using ^{252}Cf source. The distance between source and phantom surface was set at 75 cm and incident angle were changed from 0 degree to 180 degree. As the result of angular response of TLD element 4, the cavity water phantom is in good agreement with the anthropomorphic phantom. The water phantom has the good agreement at the front side incidence (from 0 to 90 degree) with the anthropomorphic phantom, but at the back side incidence(from 120 to 180 degree) it had a different response and the maximum difference ratio was about +400% at the 180 degree.

The acrylate phantom has also different response from the anthropomorphic phantom at almost all conditions and the maximum difference ratio was about -60%.

CONCLUSION

The energy response of the TLD on the 46x30x20cm elliptical cylinder phantom filled with water was in good agreement with the response on the anthropomorphic phantom. The TLD response on the 40x40x15cm PMMA slab phantom became higher than the anthropomorphic phantom at the all irradiated energy region. The TLD response on the 46x30x20cm elliptical cylinder paraffin phantom was in good agreement with the anthropomorphic phantom below about 1MeV, but in the range over 1MeV, the TLD response on the paraffin phantom became about 1.5 times higher than the anthropomorphic phantom. The angular response of TLD on the cavity water phantom considered as lung geometry was in good agreement with the anthropomorphic phantom. The phantom filled with water had different response from the anthropomorphic phantom with the maximum difference ratio of +400% at the back side incidence. The PMMA phantom had also different response from the anthropomorphic phantom at all incident angles and the maximum difference ratio was about -60%.

These experimental results suggest that water phantom (filled/cavity) is suitable for calibration of albedo TLD because of the good agreement with the energy/angular response of anthropomorphic phantom considered as equivalent to human body.

ABSTRACT

This work studies the most important factors which affect the response of albedo neutron dosimeters containing LiF TLDs with the aim to improve their sensitivity. It includes tests of thickness and shape of the polyamide moderator body prototypes, albedo window diameter and TLD position inside the moderator. Analyzing the results, an albedo neutron dosimeter prototype, B_4C covered, was developed. The prototype has a response three times higher than the albedo dosimeter now in use in Brazil.

INTRODUCTION

Albedo dosimeters have been extensively used in neutron personnel monitoring with good results (1). Since 1983, Instituto de Radioproteção e Dosimetria (IRD) operates the only Neutron Personnel Monitoring Service in Brazil. This service monitors about two hundred workers in nuclear and non-nuclear facilities. An albedo dosimeter developed in 1975 is used (2). For ^{241}Am-Be sources, the IRD albedo neutron dosimeter is about 50 times less sensitive than for neutron fields around reactors (3).

The restrictions on individual dose limits recommended in ICRP60 (4), together with the lack of a neutron dosimeter with a low detection limit, mainly for fast neutron fields, have stimulated the research to obtain a more sensitive personal neutron dosimeter. Also, the IRD needs a cheaper and easier to manufacture neutron dosimeter than the actual. The objective of this work is to identify the most important factors which affect the response of albedo dosimeters containing TLDs and improve their sensitivity, taking into account cost-benefit considerations.

MATERIAL AND METHODS

All prototypes were made with a moderator body of polyamide. And, for the detection system ^{6}LiF and ^{7}LiF TLD chips (3.2x3.2x0.89 mm^3 TLD600 and TLD700 from Harshaw Chemical Company, respectively) were used. Three prototype sets with a cavity in the geometric axis for the TLD pairs were manufactured:

a) semispherical shape with same height (24.2 mm) and albedo window diameters from 32 to 52 mm;
b) cylindrical shape with same albedo window (32 mm) and heights from 18 to 36 mm;
c) cylindrical shape with same albedo window (50 mm) and heights from 5 to 20 mm.

To understand the influence of some geometrical factors in the albedo dosimeter response, some tests were carried out, changing the moderator body of the prototypes:

a) the influence of shape: cylindrical or semispherical;
b) the influence of the LiF TLD pair position;
c) the influence of the moderator dosimeter thickness, for a same shape;
d) the influence of albedo window diameter.

The assays took place in a low scattering room with the prototypes on a cubic water phantom of polymetylmethcrylate. In the experimental set-up, the total phantom area for

irradiation of prototypes was 0.4x0.4 m^2. Irradiations were made with a ^{241}Am-Be bare source, at 1 m distance, with doses around 8 mSv. The response of TLD-600 and TLD-700 were evaluated in a Harshaw model 3500 TLD reader, using a nitrogen flow of 0.13 $m^3.h^{-1}$. Annealing procedures for TLD are those recommended by Harshaw: 1 h at 400°C plus 2 h at 100°C. After irradiation, the TLDs are heated during 15 minutes at 100°C before their evaluation. The reading cycle consists of no pre-heat and a linear heating of 10°C.s^{-1} from 70°C up to 350°C. The total heating time was 30 s. For neutron dose evaluations the difference between TLD600 and TLD700 integration value of peak 5 was used.

RESULTS

Concerning the results, it can be summarized that:

- The response increases in proportion with albedo window area, however it tends to saturate.
- Independently of the geometric shape, but for a same albedo window, the response has a linear decrease when the TLD position is changed from surface (phantom) to inside the moderator body. Figure 1 shows this effect for different shapes and thickness of the moderator. These results are in agreement with the ones obtained by Hankins (5) using polyethylene moderator and cadmium absorber.
- For a same geometric shape (cylinder), the response increases for higher height (however it tends to saturate), as it is shown in figure 2.
- The angular dependence difference is statistically non significant for semispherical or cylindrical shape.

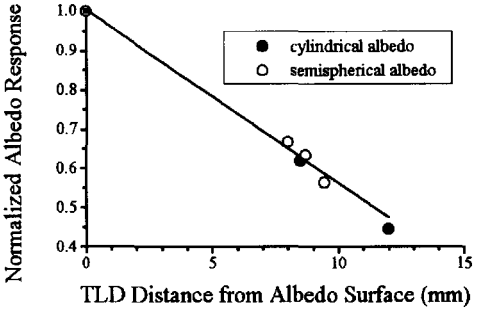

Figure 1. Variation of albedo response as a function of TLD distance from surface.

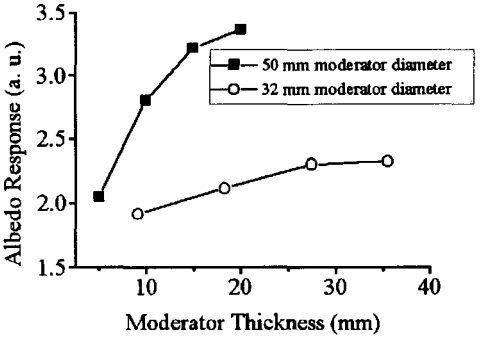

Figure 2. Albedo response as a function of polyamide moderator thickness.

CONCLUSION

Analyzing the results, a cylindrical albedo neutron prototype with a polyamide moderator body (46 mm diameter and 15 mm height), covered with 2 mm of boron-resin, was developed using two LiF TLD pairs: one for albedo and another for incident neutrons (figure 3). This prototype has a response about three times higher than the albedo dosimeter now in use in Brazil. For ^{241}Am-Be bare source, the new low detection limit is around 0.15 mSv, lower than the Register Level (0.2 mSv) adopted in Brazil. This prototype is now in test on other neutron fields.

INTRODUCTION

Thermoluminescent dosimeters (TLD), widely experimented and utilised in personal dosimetry, have some advantageous characteristics which induce one to employ them also in radiotherapy. The new radiotherapy techniques are aimed at selectively depositing a high dose in cancerous tissues. This goal is reached by utilising both conventional and other more recently proposed radiation, such as thermal neutrons and heavy charged particles. In these inhomogeneous radiation fields a reliable mapping of the spatial distribution of absorbed dose is desirable, and the utilised dosimeters have to give such a possibility without notably perturbing the radiation field with the materials of the dosimeters themselves. TLDs, for their small dimension and their tissue equivalence for most radiation, give good support in the mapping of radiation fields.

After exposure to the high fluxes of therapeutic beams, some commercial TL dosimeters have shown a loss of reliability. An investigation has therefore be performed, both on commercial and on laboratory made phosphors, in order to investigate their behaviour in such radiation fields. In particular the thermal neutron and gamma ray mixed field of the thermal column of a nuclear reactor, of interest for Boron Neutron Capture Therapy (B.N.C.T.) and a proton beam, of interest for Proton Therapy, were considered. Here some results obtained with new TL phosphors exposed in such radiation fields are presented, after a short description of some radiation damage effect on commercial LiF TLDs exposed in the (n_{th},γ) field of the thermal column of a reactor.

COMMERCIAL LiF DOSIMETERS IN HIGH FIUXES OF THERMAL NEUTRONS

LiF dosimeters are typically utilised for absorbed dose determination in thermal neutron fields. In fact, as well known, the high cross section (945 barns) for the capture reaction $^6Li(n,\alpha)^3H$ and the small cross section (0.04 barns) for the reaction $^7Li(n,\gamma)^8Li$ gave rise to the standardisation of the employment of a couple of ^6LiF-^7LiF dosimeters for dose determinations from thermal neutrons and γ-rays in personal dosimetry, where the low thermal neutron component makes the response of ^6LiF TLDs reliable and makes the response of ^7LiF TLDs attributable, with very good approximation, to the γ-component alone. In contrast, some difficulties occur when LiF dosimeters, not ^6Li depleted, are exposed to high fluxes of thermal neutrons.

The dosimeters investigated are:

i) LiF:Mg,Ti (chips 3.1× 3.1× 0.9 mm^3) from the Harshaw Chemical Corporation: TLD-600 (with 96.5% ^6Li), TLD-700 (with 99.99%. ^7Li F) and TLD-100 (with 7.5% ^6LiF).

ii) LiF:Mg,Cu,P (circular chips 4.5 mm diameter, 0.8 mm thick) from the Beijing Radiation Detector Work, People's Republic of China: GR-206A (^6LiF:Mg,Cu,P) and GR-207A (^7LiF:Mg,Cu,P).

For all dosimeters the recommended annealing procedures were utilized, i.e.:

LiF:Mg,Ti	400°C for 1 h, 100°C for 2 h
LiF:Mg,Cu,P	240°C for 10 min, followed by rapid cooling down to RT.

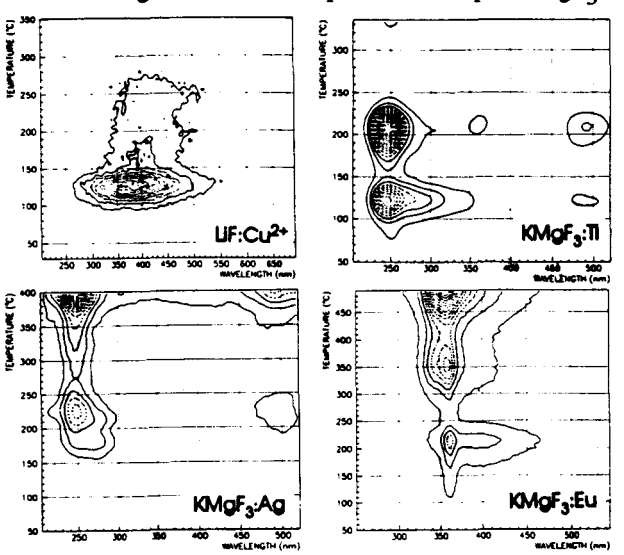
Dosimeters were exposed in the swimming-pool-type facility or in the thermal column of a TRIGA MARK II nuclear reactor at various fluences, up to about 10^{12} n cm^{-2}. The response of TLDs that were never exposed to thermal neutrons before shows a small lack of linearity in the case

of TLD-600 and a dramatic lack of linearity in the case of GR-206A. Moreover, both dosimeters, after high fluences of thermal neutrons, show radiation damage that is not removed by annealing. After exposure to thermal neutrons, read-out and annealing, in fact, their response to γ-rays is lower, the more higher the previous thermal neutron fluence has been. Therefore, ^{6}LiF dosimeters exposed to high thermal neutron fluences do not give a reliable response and, moreover, they can no longer be utilised after such exposure. In contrast, ^{7}LiF dosimeters do not show any sensible radiation damage in the fluences considered, and may therefore be utilised in such radiation fields. In the (n_{th},γ) mixed field of a reactor thermal column, however, the response of ^{7}LiF dosimeters is due to both components of the field, and a method for separating the two contributions has to be properly set up.

TL SINGLE CRYSTALS

With the purpose of identifying phosphors whose emission characteristics allow reliable dose determinations in therapeutic radiation fields, and for which radiation damage do not hinder successive utilization, we have started analyses concerning single crystals, because they have the peculiarity of allowing high annealing temperatures. Single crystals of LiF, doped with Mg,Cu,P or only with Cu, and fluoroperovskite crystals $KMgF_3$, doped with Tl or with Eu or with Ag, were grown using the Czochralski technique. For all crystals the chosen annealing procedure was heating at 500°C for 30 min, followed by rapid cooling down to room temperature. The samples were variously irradiated in n_{th}, proton and γ-ray fields. Thermal neutron exposures were made at the TRIGA MARK II reactor, 13.6 MeV proton irradiations at a CYPRIS cyclotron. ^{137}Cs γ-rays (at a rate of 0.14 Gy/s) for calibrations and ^{60}Co γ-rays (at a rate of 0.23 Gy/s) for high dose studies were utilised. The glow curves were obtained from a Harshaw 3500 TLD Reader, at a constant heating rate of 4°C/s, up to 400°C.

In order to better characterise the materials, some dosimeters from each group were also analysed by means of a laboratory-made spectrometer for wavelength resolved TL measurements. LiF:Mg,Cu,P crystals display an emission at 410 nm. LiF:Cu crystals have undergone, during preparation, an OH^- contamination from aqueous vapour, and consequently they show a relevant emission, centred at 400°C, which masks the characteristic emission of Cu^{++}, at 425°C. A contour plot of the crystal is shown in Fig.1. Fluoroperovskite crystals ($KMgF_3$) show different emission characteristics. Tl and Ag doped crystals have their main emission in the spectral range 240-260 nm, that is outside the wavelength range (350-700 nm) of the commonly used commercial readers. $KMgF_3$:Eu samples show a high peak centred at 360 nm, and so a large part of the emission is detected by commercial readers. In Fig. 1 the isometric plots of all doped $KMgF_3$: crystals after γ-irradiation are shown.



In LiF:Mg,Cu,P the glow curve after γ-irradiation displays two pronounced peaks at 230°C and 350°C and two shoulders on both sides of the 230°C peak and above 350°C. Thermal neutron irradiation mostly increases the peaks at 260°C and 280°C and seems to quench the 350°C peak in favour of two peaks at 330°C and 370°C. This anomalous behaviour is observed to be persistent after a subsequent γ irradiation. The response to γ and neutrons becomes lower with use. The absolute value of the TL signal is much lower (by at least three orders of magnitude) than that obtained from commercial chips.

The glow curve of LiF:Cu^{2+} displays a dominant peak at 150°C and much weaker secondary peaks at 220°C, 270°C and 330°C, whose relative height is doping dependent. The area of the main peak is strongly dependent on the irradiation dose. These samples display a good linearity for γ irradiation in the range 1-5 Gy. The glow curve after thermal neutron exposure displays a strong population of the 270°C and 330°C peaks, proportional to the fluence. Limited damage (about 10%) after strong neutron irradiation was observed. Some samples were irradiated with γ-rays at a dose of 10^3 Gy. No relevant difference in the TL emission was discovered, and only a light sensitisation after this high dose was observed.

Fluoroperovskite crystals $KMgF_3$ have been investigated because these phosphors, recently proposed as dosimetric materials, have shown some interesting features (for example, Tl doped crystals have revealed a linear response even up to doses of 10^3 Gy). The responses after a dose of 1 Gy in tissue from γ-rays or from n_{th} are of the same order. With reference to the possibility of discriminating between contributions in such mixed fields, no different emission characteristics after n_{th} or γ-irradiation were discovered.

The glow curve of $KMgF_3$ samples exposed in the proton beam, shows a peak population different from that after γ-irradiation, not only for a different population of the peaks that are characteristic of γ-irradiation, but also for the evidence of new trap creation. These traps are removed by annealing; this fact suggests that protons induce, by knock-on, a lattice configuration unstable at high temperature.

In the Table the results obtained are shown schematically.

phosphor	λ_{emiss} (nm)	TL peaks (°C)	R_γ / R_γ(TLD-700) * 10^{-2}	R_n / R_n(TLD-700) * 10^{-2}	R_n / R_n(TLD-600) * 10^{-3}
LiF:Mg,Ti (TLD700)	400	210	100.	100.	2.28
LiF:Mg,Cu,P	410	230,350 140,260	0.18	163	3.71
LiF:Cu (OH-contaminated)	425	150 220,270,330	1.83	240	5.49
$KMgF_3$:Ag	245	190,220,280	5.75	3.26	0.074
$KMgF_3$:Eu	360	250,340 150	319.	627.	14.3
$KMgF_3$:Tl	245-370	140,230 190,320	4.38	5.29	0.121

The above data may give only a summary indication of the behaviour of the dosimeters. The reported values are obtained as averages of the measured ones, but the dispersion of experimental values is very high. In fact the trap configuration in a crystal, and consequently the glow curve shape, are strongly dependent upon doping concentration, and this concentration is not uniform in the laboratory-grown crystals out of which our samples were cut. From these results however a qualitative understanding of the behaviour of phosphor is possible, and a direction for subsequent experiments is deduced.

ACKNOWLEDGEMENTS

The authors are grateful to Mr.-G. Di Corato (GAMMATOM - Guanzate, Co, Italy) for his useful cooperation in irradiating samples with the ^{60}Co source.

COMPARATIVE STUDY OF DIFFERENT LiF TLDs FOR NEUTRON DOSIMETRY

A.G.Alexeev [1], N.A.Karpov [2]

[1] The University of Tokyo , the Research Center for Nuclear Science and Technology, Yayoi 2-11-16, Bunkyo-ku, Tokyo 113, Japan.

Permanent address: Institute for High Energy Physics, Radiation Research Department, Protvino, Moscow region, Russia ,142284.

[2] Moscow State University ,Moscow ,Russia.

The passive neutron dosimetry based on the thermoluminescent detectors (TLD) is a promising trend in the area, environmental and personnel radiation monitoring of accelerators. However, a successful TLDs application for the neutron dosimetry is limited by their low neutron response. The necessity of increased TLD response is associated with the new national standard in radiation protection, based on the recommendations of the International Commission on Radiological Protection (ICRP, Recommendation ICRP-60). In recent years some new TL materials (such as LiF:Mg,Cu,P) having higher sensitivity as compared to the well-known LiF:Mg,Ti have been developed. The characteristics of the LiF:Mg,Cu,P and LiF:Mg,Ti TL detectors from the point of view of neutron dosimetry was compared[1]. The absolute sensitivity and the ratio of neutron and gamma sensitivities have been estimated from the experimental data for different TL-detectors. The following TL-detectors are compared:

DTG-4-6 (^{6}LiF:Mg,Ti),

DTG-4-7 (^{7}LiF:Mg,Ti), (Institute of Geochemistry, Irkutsk, Russia);

TLD-6011 (^{6}LiF:Mg,Cu,P),

TLD-7011 (^{7}LiF:Mg,Cu,P), (Moscow State University -"Practica",Moscow);

TLD-600 (^{6}LiF:Mg,Ti),

TLD-700(^{7}LiF:Mg,Ti), ("HARSHAW", USA);

The annealing procedure for all detectors was carried out in accordance with the recommendations of the TLD manufactures. The HARSHAW 2080 Reader was used for the readout. The dose measurements are performed according to the

glow-curve integration. The integration has been performed above 100 ^{0} C distiminator level for the glow curve.

The comparison of TLD characteristics has been performed on the basis of neutron dose equivalent measurements with the IHEP passive radiation monitors (PMS). The PMS used for area and environmental radiation monitoring at the IHEP accelerator and consists of the LiF pairs located in the 25.4 cm in diameter spherical polyethylene moderator.

The PMS with TLD was irradiated in the following fields: The standard calibration field with ^{137}Cs proton source in a lead collimator. The reference field based on the ^{239}Pu-Be neutron source.This field is used for PMS calibration in units of the neutron dose equivalent. The reference field based on the ^{252}Cf neutron source. The reference field based on the ^{252}Cf source in the 30 cm-diameter spherical iron moderator (^{252}Cf+Fe). The reference field based on the ^{252}Cf source in the 30 cm diameter spherical polyethylene moderator (^{252}Cf+CH_2).

Table 1. presents the measurement results of the ratio of detector response .The data for DTG-4-7 and TLD-7011 to the TLD-700 values and ones for DTG-4-6 and TLD-6011 are normalized to the TLD-600 values. The of neutron-to-photon response rations are given in Table also.

Table 1.

Detectors	Ratio of photon response detectors , rel. unit .	Ratio of neutron response detectors, rel.units	Neutron-to-photon response ration, rel. units.
DTG-4 -6(7)	4.2±0.3	1.8 ±0.2	0.4±0.05
TLD-7011(6011)	18±1	4.3±0.2	0.6±0.06
TLD-700(600)	1.0	1.0	1.0

The neutron-to-photon response ratio for DTG-4-6 (DTG-4-7) and TLD-6011 (TLD-7011) are the same, but this ratio for TLD-600 (TLD-700) is higher by a factor of two as compared to other detectors. LiF:Mg,Cu,P have lower efficiency to high LET radiation. And low neutron-to-photon response ratio for LiF:Mg,Cu,P is an ionization density effect [2] . The decrease of neutron-to-photon response ratio leads to the increase of the measurement errors of the neutron dose equivalent in fields under large photon contribution into a total dose .

Usually the contribution of photons, muons and charged particles into

the total dose equivalent is less than 10% behind the shield of high energy accelerators. The exception is the so-called "muons torch" at the IHEP experimental hall, when the neutron dose equivalent contribution is less than 5%. Therefore a decrease in ratio of neutron-to-neutron does not restrict applications for the neutron dosimetry at accelerators.

The minimum measurable dose depending on the TLD type is the most

important characteristic for dosimetric methods. The minimum measurable dose for photons was obtained as a "zero dose" of the TLD readings immediately after annealing. The minimum measurable neutron dose equivalent for different detector types and dosimetric method (HARSHAW 2080 reader) without nitrogen atmosphere are presented in Table 2.

Table 2.

Detector type	Minimum measurable neutron dose equivalent of PMS, mSv.	Minimum measurable neutron dose of albedo individual dosimeter, mSv.
DTG-4-7(6)	0.02	0.1
TLD-7011(6011)	0.008	0.04
TLD-700(600)	0.03	0.15

The lower limit of detection according to ICRP-35 Recommendations should be 0.1 of an annual limit. It should be borne in mind that comentionally administrative limits are less than annual limit. The annual level is equal to 2 mSv according to ICRP-60. Therefore in the individual monitoring a monthly measured dose at the lower limit of detection should be 0.17 mSv. It is TLD-6011, 7011 for the albedo dosimeter that provides the neutron equivalent dose measuring at the lower limit of detection. The PMS with TLD-6011, 7011 allows one to carry out the area monitoring with the minimum measurable dose 0.1 of the recommended dose limits for population (1 mSv a year). At the same time the new TL-detectors are intended to be used in area and individual monitoring even under the new ICRP recommendation in radiation protection.

ABSTRACT (See instructions overleaf)

Different etching solutions, which are suitable to evaluate the particle tracks in CR-39 detectors at room temperature were systematically tested for electrochemical etching. The CR-39 detectors were irradiated with α particles and neutrons of different energy. The response of electrochemically etched detectors was measured. The background of detectors were determined.

A METHOD FOR CALCULATION OF THE NEUTRON RESPONSE FUNCTION OF AN ELECTROCHEMICALLY ETCHED CR-39 SSNTD UP TO 65 MEV

A. Fenyvesi
Institute of Nuclear Research of the Hungarian Academy of Sciences
P. O. Box 51, H-4001 Debrecen, Hungary

N. A. Greenhouse
Lawrence Berkeley Laboratory, University of California Berkeley
MS 90-0026, Berkeley, CA 94720, USA

Development of a personal dosimeter capable of detecting neutrons of energies above 20 MeV is an important problem of radiation protection at high energy accelerators. The electrochemicaly etched CR-39 SSNTD seems to be applicable for this purpose but the determination of the neutron response function of this detector has many difficulties.

Above 14 MeV, practically it is not possible to produce beam of really monoenergetic neutrons. Neutron spectra of the sources used for calibration have significant low energy tailors. Their contribution to the measured track densities are not negligible because of the low detection treshold of the electrochemicaly etched CR-39.

The evaluation of the neutron response function from measured track densities needs the employment of an unfolding method. Unfolding codes need not only the neutron spectra used for the calibration but a "good" input response function to avoid divergencies in the iteration.

We have developed a method for calculating an "input" response function for the unfolding. We have calculated the number of the latent tracks crossing an internal surface at depth "h" in CR-39 using the neutron spectrum and double differential cross sections of neutron induced nuclear reactions on hydrogen, carbon and oxygen nuclei. Track etch kinetics and the Smythe-model were applied for the calculation of the density of tracks contributing to the electrochemical etching response.

ANALYSIS OF HIGH DOSE NEUTRON IRRADIATED CR-39 USING COHERENT LIGHT SCATTERING

J.E. Groetz[1], A. Lacourt[2] and A. Chambaudet[1]

[1]Laboratoire de Microanalyses Nucléaires, Université de Franche-Comté, U.F.R. Sciences et Techniques, 16 route de Gray, 25030 Besançon cedex, France

[2]Laboratoire d'Optique P.M. Duffieux, URA 214, Université de Franche-Comté, U.F.R. Sciences et Techniques, 16 route de Gray, 25030 Besançon cedex, France

ABSTRACT

In case of high neutron flux and high doses of irradiation, the Solid State Nuclear Track Detector (SSNTD) CR-39, used in neutron dosimetry, is unsuited for optical microscopy analysis after chemical etching. This is because track overlapping makes counting and exploitation impossible. We therefore developed a new method that allows the reading of irradiated samples based on the measurement of the angular distribution of coherent light (He-Ne laser) transmitted through the SSNTDs after chemical etching. The scattering of coherent light gives us a statistical and comprehensive view of track morphology (size and orientation of track openings).

INTRODUCTION

Although they are themselves not ionizing, neutrons are registered in CR-39 through recoil protons, produced either in the radiator or in the detector. These protons cause latent tracks in the detector. It will be recalled that only a fraction of these tracks is developed after chemical etching (NaOH 7N during 180 min.). Their characteristics are the track density (or even track volume density), track size, shape and orientation. This study aims to examine, with the use of the BTDF (Bi-directional Transmissive Distribute Function), the relationships between the neutron field parameters and those that characterize the microscopic aspect of the CR-39 surface after chemical etching. First we will present a study of SSNTDs irradiated under mono-energetic and mono-directional proton flux. Next, we will move on to neutron irradiations by neutron-proton radiators.

EXPERIMENTAL SET-UP

The light source is formed by a He-Ne laser beam (λ = 632.8 nm). A reference detector is used to enable the computer to ratio out laser power fluctuations. The sample mount is perpendicular to the laser beam. The receiver-rotation stage is motorized and computerized, enabling a full rotation of the input aperture on any point of the sample. Optical microscopy measurements are taken with an Olympus microscope connected to a computerized CCD camera.

PROTON IRRADIATIONS

The list below shows the characteristics of the samples studied. The choice of samples was guided by etching conditions and incident protons energy. Choosing too little energy would have led to over-etching tracks and thus to circular track openings regardless of the incidence angle of the protons. Moreover, the conditions of particle incidence were limited by the etching critical angle, which was itself dependent on the energy of incident particles **[1] [2]**.

Sample	Proton energy	incidence (°)	track density	average area (μm^2)	min. ferret (μm)	aspect ratio
P7	847 KeV	0	9.98×10^5	14 ± 4.44	4.05 ± 0.50	0.8472
P12	850 KeV	20	1.16×10^6	11.9 ± 4.2	3.57 ± 0.65	0.7819

SSNTDs are irradiated under proton flux (Van de Graaf accelerator) with to incidences of 0° and 20°. The minimum diameters of track openings decrease with the angle of irradiation and the aspect ratios (min. diameter/max. diameter) do likewise. Figures 1 and 2 are histograms showing the orientation of the track openings. The orientation of the plane of the track opening is defined as the angle between horizontal reference axis and the largest diameter of the opening track.

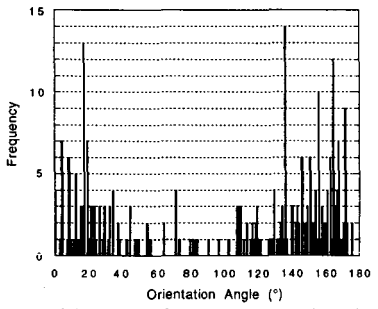

Fig. 1. Histogram of track opening orientations of ssntd P7.

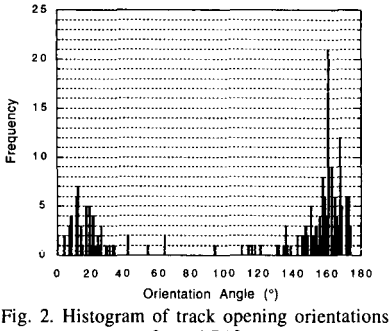

Fig. 2. Histogram of track opening orientations of ssntd P12.

In the case of SSNTD P7, the histogram seems to show two preferential directions in the neighborhood of 20° and 150° (Fig. 1). A close study shows that a quasi-circular track opening does not present a specific direction in the plane of analysis. The direction can thus vary from one track to another. In fact, a 90°-rotation of CCD receiver in its plane gives the same histogram. This stressed the optical defaults of the camera which can subsequently be rectified.
In the case of SSNTD P12 with a proton incidence of 20° (Fig. 2), the orientation histogram is much narrower than the former. This clearly shows a real orientation of the track openings (with a camera rotation of 90°, the shift of histogram is unmistakable).

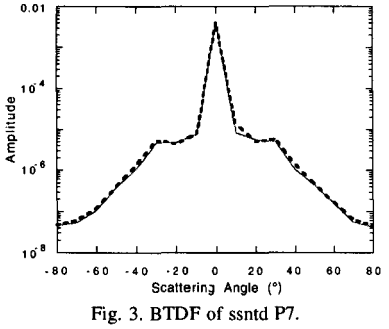

Fig. 3. BTDF of ssntd P7.

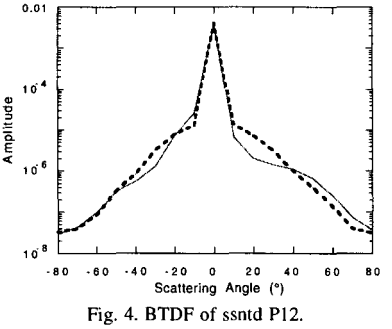

Fig. 4. BTDF of ssntd P12.

The scattering indicators, or BTDF, in the case of P7 sample were measured in the two perpendicular planes through the laser beam axis (Fig. 3) [3]. The two BTDF are symmetrical with the direct transmitted beam (the Optical Transmission, i.e. the scattering angle value 0°). They also have the same profile width. The BTDF characteristics clearly show the symmetry of track revolution with the perpendicular axis of the sample.

In the case of P12, the two BTDFs are not superposed. Their profile widths are different and their symmetry with the 0° scattering angle no longer applies (Fig. 4). These relationships can be corroborated by analyses made by optical microscopy (Fig. 2), which confirm that there is a specific track orientation that can be highlighted by laser scattering.
There is thus a reciprocal relationship between track openings and the shape of the BTDF.

NEUTRON IRRADIATION

1. BTDF as a function of the angle of irradiation.

The irradiated SSNTDs are surrounded by polyethylene (n-p conversion), with varying incidence angles of the incoming neutron flux (0, 30, 45, 60, 90°). Irradiations are carried out on the CEA's (Valduc) Silene reactor with doses ranging from 0.11 Gy to 62 Gy.

The BTDF profile widths of the samples are symmetrical. It is thus quite clear that there is no specific track-orientation, even in the case of multi-angle irradiations. Whatever the angle of irradiation, the tracks are isotropically distributed.

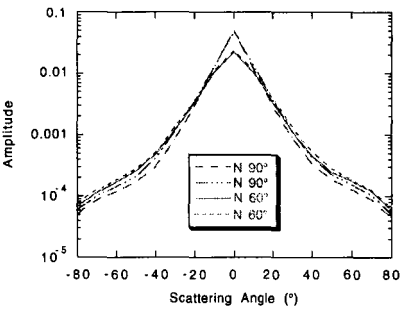

Fig. 5 : BTDF of ssntd's irradiated under neutron flux with incidence of 60° and 90°. We can note the same profile width for these BTDF. The samples have been irradiated with a dose equal to 8.12 Gy.

2- Study of the scattering.

Let us consider a specific intensity $I(\vec{r}, \mathbf{u})$ which is incident (from a distance $\vec{r}$ from the center of the radiation sphere and with a direction $\mathbf{u}$) on a elementary cylindrical volume with a unit cross section and length ds. The volume contains r.ds scattering tracks.
In transport theory **[4]**, the part of the flux which decreases as a result of scattering and absorption is referred to as the reduced incident intensity I_{ri}. Total intensity $I(\vec{r}, \mathbf{u})$ is expressed as follows :
$I(\vec{r}, \mathbf{u}) = I_{ri}(\vec{r}, \mathbf{u}) + I_d(\vec{r}, \mathbf{u})$ where $I_d(\vec{r}, \mathbf{u})$ is called the scattered specific intensity.

$$\frac{dI_{ri}(\vec{r}, \mathbf{u})}{ds} = -\rho . \sigma_t . I_{ri}(\vec{r}, \mathbf{u})$$

Thus, we show that $I_{ri} = I_0 \exp(-\rho.\sigma_t.s)$, where s is the sample thickness pierced by the laser beam.

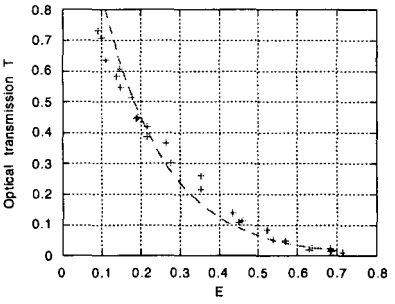

Fig. 6. Representation of T vs E.

The term σ_t refers to the optical cross-section for each particle and includes two contributions, one for light absorption and one for light scattering. We can say that the product $\sigma_t.\rho$ is similar to the exposure E defined by Ilic **[5]** - $E = S_t.\rho$, where S_t is the average track area and ρ the track density. The change of optical transmission vs E is a decreasing exponential function (Fig. 6).
The study of the scattered intensity $I_d(\vec{r}, \mathbf{u})$ must enable us to distinguish (when E is invariable) the variations of the average area of track openings as well as that of track density. The simulation of laser scattering on a set of randomly distributed tracks should enable us to eliminate all ambiguity concerning E.

CONCLUSION

This results obtained show that the study of SSNTDs that are irradiated under strong flux and then chemically developed is possible if the measurement of coherent light scattering is adopted since the data collected is of a statistical nature. The study and simulation of laser scattering by a set of tracks, randomly distributed in size and in orientation will enable us to distinguish the different morphological parameters. This will lead to a better evaluation of the dose.

ACKNOWLEDGEMENTS

We wish to thank J. Dhermain and F. Vettese (ETCA-Arcueil) for hepful discussions and for the financial and irradiation supports.

Abstract

Electro-chemical and chemical track-etch dosemeters were obtained from commercial suppliers (American Acrylics and NE Technology) and exposed to neutrons produced at the LAMPF WNR white neutron source at 15° with no shielding and filtered by polyethylene blocks of 2.5, 5.1, 10.2, 20.3 and 40.6 cm thickness. The neutron spectrum was determined using calculations. Mean energies from 28 to 300 MeV were produced. Dose was calculated from the NCRP-38 flux-to-dose conversion. The results are compared with NTA film which was exposed in the same configuration. The response of track etch dosimeters was found to reach a miniumum and then rise as the the average neutron energy increased. The response of the NTA film increased as the neutron energy increased.

Introduction

NTA film produced by Eastman Kodak is the common method for measurement of dose from high energy neutrons. An alternative is the use of proton sensitive etched track detectors. Two systems were chosen for testing: an electro-chemical etch system described by Hankins (1) and a chemical etch system used by Harvey (2). The exposures were made at the 15 degree, 90 meter flight path of the LAMPF Weapons Nuclear Research (WNR) white neutron source. Development was according to standard methods.

Experimental Method

Materials

NTA film was obtained from Eastman Kodak. The films were placed in plastic holder with a 0.066 cm cadmium pocket. The plastic holder is sealed and holds desiccant. The plastic holder is sealed in a dry nitrogen atmosphere and holds a desiccant. Dosimetry grade American Acrylics and Plastics CR-39 which was 0.063 cm thick covered on both sides with polyethylene of thickness 0.01 cm was laser cut into 3.5 cm. by 1.6 cm foils. The foils were mounted on a cardboard backing for exposure. PN3 foils (NE Technology) were precut into 2.0 cm by 2.5 cm by 0.15 cm foils. The PN3 foils were placed in a five element pyramidal holder. The holder has two dosemeters at the base of a triangular pyramid with the sides inclined at 40° to the base. Three dosemeters are placed on the faces of the pyramid. The configuration is held by a holder consisting of a base and a domed cap. The overall diameter is 5.8 cm and the height is 2 cm.

Neutron Irradiation

The neutrons were produced by an 800 MeV proton beam striking a tungsten target. Exposures were made to the unfiltered beam and with polyethylene filters of 2.5, 5.1, 10.2 , 20.3 and 40.6 cm thickness. Electronic dosimeters (ALOKA CO., LTD., PDM-303) were used to scan the field uniformity. The beam was flat to within 5% over a square field of 10 cm width.. The dosemeters were exposed on an ISO water phantom. The dose for each irradiation was determined using a neutron beam monitor, a small plastic scintillator, normalized by the proton current on the target. The dose per proton was calculated using the LAHET code, the calculation provided the neutron spectra per proton/cm^2 /MeV at the tungsten spallation target. The neutron spectra were then corrected for attenuation by the polyethylene filter and for air in the 90 meter flight path. The NCRP-38 fluence-to-dose conversion was then used to convert the neutron spectrum to a dose equivalent. A 5 kG magnet at the front of the detector shed was used to remove charged particles from the beam. The spectra are shown in Figure 1.

Development

The NTA film are developed in 68 °F baths. The first bath is a Kodak Rapid X-Ray Developer for five minutes with constant agitation. Development is stopped by a two minute running water bath. The film is transferred to a Kodak fixer bath for thirty minutes and then to a final wash bath with running water for thirty minutes. The electrochemical method used CR-39 (American Acrylics) with a three cycle etch. The dosemeters are placed in a 60°C oven overnight before the read cycle begins. The first cycle is a pre-etch for 1.75 hours in 6.5 N KOH solution which is added at the beginning of the cycle. Next a three hour cycle with 3000 volts at 60 Hz is used followed by 3000 volts at 2 KHZ for fifteen minutes. The temperature for all three cycles is 60°C. The dosemeters were taken from one sheet. Each batch of twenty-four foils contained four background foils and four control foils which were used for normalization between runs. The chemical etch procedure used PN3 plastic from NE Technology taken from one sheet. The dosemeters are given a pre-etch in a mixture of 60% by volume methanol and 6.25 N NaOH for one hour at 70°C. This is followed by six hours in a 6.25N NaOH solution at 70°C and ending with a through washing.

Track Counting

The NTA films were read using a microscope with a field size of one mm^2. The CR-39 foils were read using a standard microscope with a video camera. The image of the camera is input to a Biotran III Digimatic Indicator. Three fields totaling 0.6 cm^2 are read to determine the track count. The PN3 foils were read using the NE Technology AUTOSCAN 60. The reader used light incident on the edge of the PN3 plastic which undergoes total internal reflection from the faces where a defect or pit exists. The foil is viewed through a vidcon tube and camera lens and processed using an image grabber by a personal computer. The area read is 1.6 cm^2.

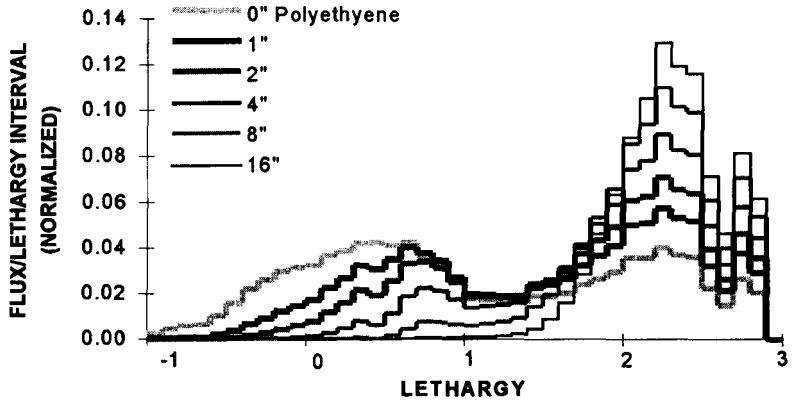

Figure 1. Fluence per Unit Log Energy (Lethargy) Normalized to Total Flux

Results

The results are presented below in Table 1. An interesting observation is the common effect in both plastic dosemeters of a minimum of response ration followed by a rise in response. This would be consistent with the rise in kerma as the energy increases above 70 MeV to 1000 MeV.. A corresponding increase is also observed in the NTA film. The results for the spectra corresponding to lower average energies are consistent with previous work (3). Further studies which could be useful would be around 35 MeV and 66 MeV to fill in the middle energy portion. These studies when combined with the known energy response function from 0.2 MeV to 20 Mev and both a Monte Carlo estimate and comparison with kerma should allow a reasonable estimate of the energy response.

Table 1 Dose Equivalent Response of NTA Film, CR-39 and PN3 to High Energy Neutron Spectra

Material	Bare Cf Response ± SD ($cm^{-2}mSv^{-1}$)	Background ± SD	Filter Thickness (cm)	Response Relative to Bare Cf N	Ratio ± SEM

ABSTRACT (See instructions overleaf)

Superheated liquid neutron sensor containing superheated liquid drops of CCl_2F_2 (M-12 India) in Gel medium has already been reported (Radiation Measurements, Vol. 23 No. 4 pp. 753-755, 1994). Recently authors have developed a superheated liquid neutron sensor (SLNS-2) based on polymer medium. This sensor has better long term stability compared to sensor having gel medium. The temperature range of stability is 10 to 35°C. The experimental results of this sensor pertaining to stability, neutron dose response has already been reported. (Radiation Measurements, 1995 in press).

A reusable device containing SLNS-2 as sensor has been developed recently. The device is portable and can be used in active as well as passive mode also. The device is made of polycarbonate tube of 20 mm Diameter and is 124 mm in length. It is attached with a repressurizing system. The diameter of droplets is in the range 15-20 microns. The density of droplets can be controlled as per sensitivity requirement. The highest sensitivity achieved so far is 60 bubbles/ 10fSv. The device is insensitive to neutrons when the sensor is pressurized by the built in pressurizing system. When the pressure is released, the sensor is ready for use. The bubbles formed due to neutron exposure can be recompressed by pressurizing the device. The performance of the device pertaining to it's response to various neutron sources, shelf life, reusability, temperature dependence, storage and transport conditions will be discussed.

BUBBLE DETECTORS IN INDIVIDUAL NEUTRON DOSIMETRY

F. Spurný, I. Votočková

Nuclear Physics Institute, Czech Academy of Sciences, CZ-180 86, Prague, Czech Republic

INTRODUCTION

Bubble detectors would be able to fulfill requirements following from the ICRP 60 recommendations as far as individual neutron dosimeter is concerned. Particularly, the lowest limit of detection seems to be decreased down to about 10 μSv or even lower. At the moment, there are two types of such detectors commercially available: bubble damage neutron detectors (1) (BDNDs - Bubble Technology Industries, Chalk River), and superheated drop detectors (2) (SDDs - Apfel Enterpr., New Haven). Both these types have been tested in our studies from the point of view of personal dosimetry. Particular attention is devoted to their energetical dependences and their responses in the fields in which they should be used to determine occupational exposures.

EXPERIMENTAL CONDITIONS

BUBBLE DETECTORS TESTED

BDNDs' tested had issued from two deliveries. The first one was constituted from the type BD 100R (threshold neutron energy 100 keV) of two different sensitivities to AmBe neutrons (0.8 and 2.2 bubbles per 1 μSv of H*(10)). The second delivery constituted again of BD 100R (1.0 bubble per 1 μSv), not compensated for the temperature, and temperature compensated PND of the same nominal sensitivity and similar energy dependence.

SDDs' tested had issued from the single delivery. It consisted of AMS reader and sets of detectors with three different energy thresholds: 100 keV (SDD 100), 1 MeV (SDD 1000) and 6 MeV (SDD 6000). The sensitivity of all of them ought to be about 3.3 bubbles (counts) per 1 μSv of H*(10) from neutrons with energies above the threshold.

NEUTRON FIELDS USED FOR TESTING

The response of bubble detectors has been studied in neutron beams and fields characterized in Table 1.

Table 1. Neutron fields used for testing.

Neutron field	$\bar{E}_N$ [MeV]	H*(10) [1] [Sv.cm^2]	Neutron field	$\bar{E}_N$ [MeV]	H*(10) [Sv.cm^2]
SIGMA (3)	0.070	2.29 -11	PuBe	4.2	3.80 -10
CANEL+ (H_2O) (4)	0.096	3.47 -11	AmBe	4.4	3.80 -10
CANEL+ (4)	0.185	7.26 -11	JINR - soft (5)	0.25	2.90 -11
^{252}Cf/D_2O/Cd	0.54	9.10 -11	CERN - iron (6)	1.9	1.60 -10

[1] ICRP 21 conversion factors

RESULTS OBTAINED

Multiple irradiation of several pieces of BDNDs' (type PND) has been realized with neutrons of an AmBe source. The standard deviation of a single reading was found to be close to $\sqrt{N}/N$, where N is the number of bubbles. The precision about ± 30% is hence achieved when total number of bubbles is above 10.

The relative responses of BDNDs' studied in different neutron fields are presented in Table 2.

Table 2. Relative responses of BNDDs' (BD 100R and PND - 2nd delivery) to neutrons.

Neutron source	Relative response	
	BD 100R	PND
SIGMA	0.52 ± 0.04	0.54 ± 0.04
CANEL+ (H_2O)	1.13 ± 0.09	1.06 ± 0.08
CANEL+	1.22 ± 0.09	1.06 ± 0.08
AmF	1.10 ± 0.08	1.16 ± 0.08
^{252}Cf	1.34 ± 0.14	1.38 ± 0.15
AmBe	1.00[1)]	0.94 ± 0.07
PuBe	1.05 ± 0.07	1.03 ± 0.07
JINR - soft	-	1.13 ± 0.13
CERN - iron	1.28 ± 0.13	1.17 ± 0.10
JINR - hard	-	0.70 ± 0.07
CERN - concrete	0.63 ± 0.04	0.62 ± 0.04

[1)] Taken as a reference

One can see there that, with the exception of thermal neutron source SIGMA (50% of H*(10) from thermal neutrons) and high energy reference fields the relative response of both BDNDs' is not too far from 1.0. However, it should be mentioned that the results obtained with BD 100R of the 1st delivery have been slightly different, generally about (19±5)% lower for sources CANEL+ (H_2O), CANEL+, AmF, ^{252}Cf and CERN-iron, i.e. closer to 1.00 as compared with results presented in Table 2. It could be connected with slightly different energy dependence, the BD 100R from the 2nd delivery being relatively more sensitive to neutrons with energies from 0.1 to 1-2 MeV.

The relative responses of SDDs' studied in different neutron fields are presented in Table 3.

Table 3. Relative responses of SDDs to neutrons.

Neutron source	Relative response of SDD with the threshold, [MeV]		
	0.1	1.0	6.0
SIGMA	0.60 ± 0.05	0.12 ± 0.01	0.010 ± 0.003
CANEL+ (H_2O)	0.23 ± 0.03	0.025 ± 0.005	0.0054 ± 0.0010
CANEL+	0.48 ± 0.05	0.006 ± 0.002	0.0028 ± 0.0005
AmF	0.66 ± 0.05	0.081 ± 0.010	0.028 ± 0.005
^{252}Cf	1.03 ± 0.06	0.17 ± 0.02	0.090 ± 0.010
PuBe	0.90 ± 0.08	0.35 ± 0.03	0.16 ± 0.02
AmBe	1.00[1)]	0.38 ± 0.02	0.16 ± 0.02
CERN - iron	0.70 ± 0.10	0.17 ± 0.02	0.09 ± 0.02
CERN - concrete	0.50 ± 0.05	-	-

[1)] Taken as a reference value

One can see there that:

- the drop down in the relative responses for neutrons with energies going down below 1 MeV to 100 keV is faster for SDD 100 as compared with BD 100R or PND;
- the comparison of responses of SDD 100 with SDD 1000 (or 6000) permits clearly to distinguish fission from more energetic neutrons;

the relative response of SDD to high energy neutrons (CERN - concrete) is also, as for BDNDs, lower.

There are two types of occupational exposures for which the use of bubble detectors could be particularly fruitfull:

- degraded spectra of fission neutrons behind the shielding of power and/or research reactors;
- neutron fields behind the thick shielding of primary high energy particles (high energy accelerators, cosmic radiation in the Earths atmosphere.

In both cases, bubble detectors can be used as an individual dosimeter. At reactors, BDNDs with threshold 100 keV can be used even without important corrections on the actual neutron spectrum. As far as SDDs and both types using in high energy neutron fields are concerned, it seems to be appropriate to multiply their readings by a factor of about two to compensate for their energetical dependence.

INTRODUCTION

Several different types of detector are presently used for health physics oriented neutron detection and measurements. These detectors are based on a wide variety of different principles, ranging from activation reactions induced by neutron radiation in materials, nuclear reactions in gas counters, as well as on the use of photographic emulsions or solid state track detectors.

Several years ago Apfel (1-2) and Ing (3) developed a new type of detector, bubble detectors, which have ever since raised considerable interest among radiation protection specialists. These neutron detectors are insensitive to X and γ radiations and are extremely useful for mixed photon + neutron field measurements.

The present article describes studies performed in Orphée, a nuclear reactor, located in the Saclay Nuclear Research Center, providing different wavelength ($\lambda < 20$ Å) cold neutron beams. We have thus determined the response of « thermal neutron » bubble detectors from 3 to 15 Å (i.e. corresponding to energies in the 9 meV to 0.36 meV range) and compared the results obtained with those determined using Li-6F.

Images obtained with a scanner reveal that the heterogeneity in the distribution of bubbles in the detection medium is a function of λ.

1) REMINDER OF PRINCIPLES

Bubble detectors are based on a principle similar to the one used for the bubble chambers employed in high energy physics. Bubble detectors consist of a gel or transparent polymer in which micro droplets of freon have been dispersed. In the absence of radiation these droplets are thermodynamically stable and capable of remaining in a metastable state over a period of several months. When exposed to a neutron field, charged secondary particles induce these droplets to undergo a liquid-to-gaseous phase change. Bubbles can be seen with the naked eye. The dosemeter composition is such as to assure proportionality between the number of bubbles and the dose equivalent (ref. NCRP 38). Dosemeters commercialized by Bubble Technology Industries cover a range of sensitivities (0.03 to 3 bubbles/μSv) together with different energy ranges (thermal energies, energies in the 200 keV to 15 MeV range etc.).

2) MATERIALS AND METHODS

Measurements were performed with BDT (thermal) type bubble detectors from Bubble Technology Industries with sensitivities in the 1.5 to 3 bubbles.μSv^{-1} range for thermal neutrons (sensitivity given by the manufacturer for a temperature of 20 °C).

The experimental equipment used is shown in Figure 1. In order to ensure measurement reproducibility, the detector is housed in a support located at a distance of one centimeter from the beam window (3 cm in diameter). The position of the detector with respect to the beam was checked with a Polaroid photograph. In this way, a corrective factor was determined to take into account the fact that the detector is not completely exposed to the beam. Exposure times, varying between 30 and 90 seconds were measured with a chronometer.

Prior to the positioning of the bubble detector in the beam, flux measurements were performed with an RTC make 4.74 mm diameter CFUF.32.S type fission chamber. Chamber measurements were corrected to take the variations in response as a function of neutron wavelength into consideration.

Measurements were also performed using simultaneously exposed Li-6F (sensitive to both neutrons and photons) and Li-7F (only sensitive to photons) detectors. The dose equivalent due solely to neutrons is obtained by subtraction.

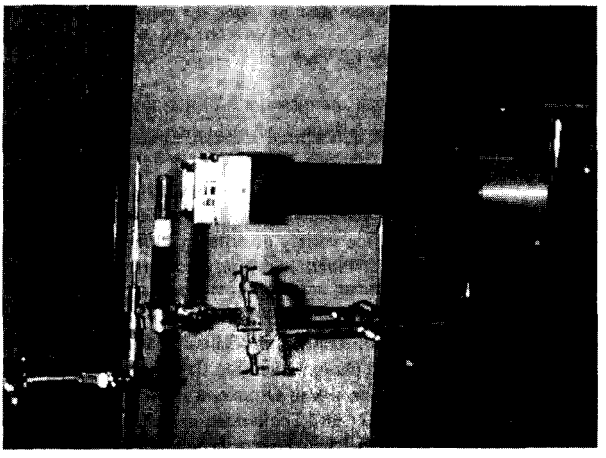

Fig. 1 : Bubble detector and fission chamber in the cold neutron beam

It should be noted that « equivalent thermal neutrons » units are employed for both LiF and bubble detector measurements. It is assumed that bubble-dose equivalent conversion factors or digital - dose equivalent factors remain constant for $\lambda > 1.8$ Å values.

3) RESULTS AND DISCUSSIONS

Figure 2 indicates that bubble detector and thermoluminescent detector responses slightly increase with λ. Extrapolation of the experimental curve to the theoretical « thermal wavelength » (1.8 Å) is in good agreement with the « thermal » point calculated for reference NCRP 38 (4) and shown in Figure 2.

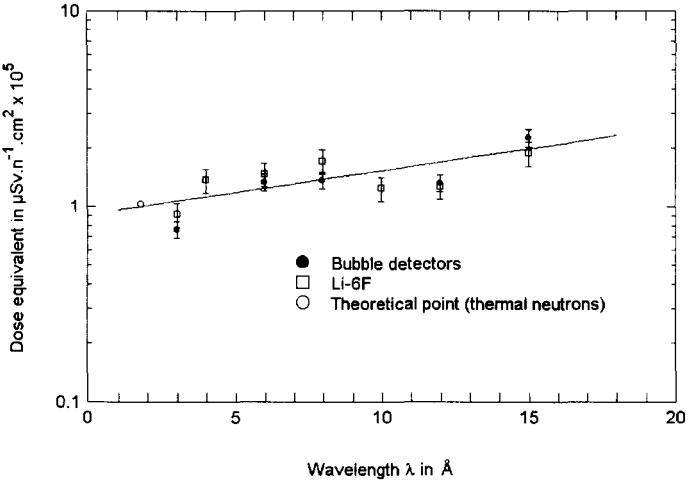

Fig. 2 : Response of Bubble detectors and Li-6F for cold neutrons

Attention is drawn to the fact that dose equivalent (in thermal equivalent units) is practically independent of λ (to within ± 30%), thus enabling bubble detectors to be used as fluence meters. Besides being easy to use in comparison with fission chambers, these detectors also present the advantage of providing a direct readout in terms of bubbles-n.cm^{-2} and do not necessitate the use of any λ dependent correction factor.

Finally, images obtained with a scanner for 3, 5, 10 and 15 Å radiations reveal an increasing bubble distribution heterogeneity with λ (see Figure 3).

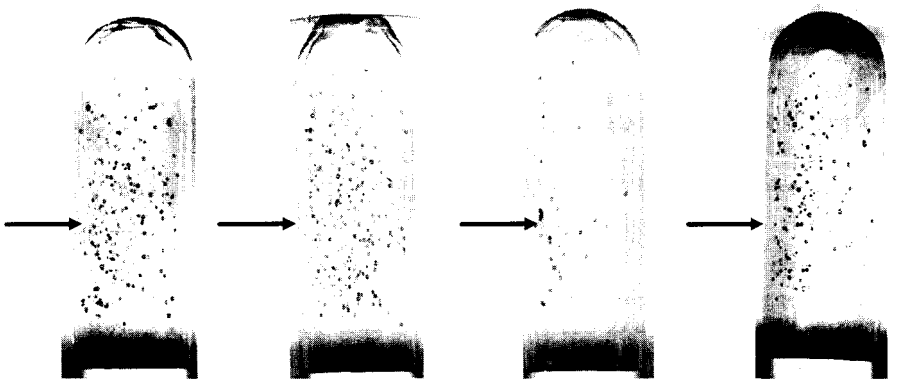

Fig. 3 : Bubble detectors irradied by different wavelength neutrons (3, 5, 10 and 15 Å) (⟶ beam direction)

4) CONCLUSIONS

Radiation protection requirements can be satisfied with the sensitivities and operational energy ranges covered by bubble dosemeters. The responses of bubble detectors have been validated by different laboratories (5,6,7). This preliminary study shows that the « thermal neutron dose equivalent or fluence » responses of these dosemeters to cold neutrons with energies in the 9 meV to 0.4 meV range are practically energy independent (to within ± 30%); furthermore the responses of Li-6F and bubble dosemeters have been shown to be very similar. Radiation protection specialists thus have at their disposal a new easy-to-use tool with a satisfactory response for fluence or dose equivalent estimations in or in the vicinity of cold neutron beams.

INTRODUCTION

Magnetic resonance imaging of a tissue-equivalent phantom is a promising technique for three-dimensional determination of absorbed dose from ionising radiation. A reliable method of determining the spatial distribution of absorbed dose is indispensable for the planning of treatment in the presently developed radiotherapy techniques aimed at obtaining high energy selectively delivered to cancerous tissues, with low dose delivered to the surrounding healthy tissue.

Aqueous gels infused with the Fricke dosimeter (i.e. with a ferrous sulphate solution), as proposed in 1984 by Gore et al. (1-2), have shown interesting characteristics and, in spite of some drawbacks that cause a few limitations to their ulilisation, they have shown the feasibility of three-dimensional dose determinations by nuclear magnetic resonance (NMR) imaging.

Fricke-infused Agarose gels with various compositions have been analysed, considering the requirements of the new radiotherapy techniques, in particular Boron Neutron Capture Therapy (B.N.C.T.) and proton therapy. Special attention was paid to obtain good tissue equivalence for every radiation type of interest. In particular, the tissue equivalence for thermal neutrons, which is a not simple problem, has also been satisfactorily attained.

The responses of gel-dosimeters having the various chosen compositions have been analysed, by mean of NMR instrumentation. Spectrophotometric measurements have also been performed, to verify the consistence of the results.

METHOD

The proposed system is composed of a ferrous sulphate solution (which is the main constituent of the standard Fricke solution) incorporated into a polysaccharide (Agarose SeaPlaque, from the Fluka Chemical Corporation). Agarose is a gelling agent whose role is that of maintaining the spatial localisation of the absorbed dose.

In ferrous sulphate solutions ionizing radiation produces a conversion of ferrous ions (Fe^{2+}) to ferric ions (Fe^{3+}). A modification in some parameters of the system is therefore produced and may possibly be detected. The standard Fricke dosimetry takes advantage of the modification of the optical absorption in the visible spectrum, measurable by means of spectrophotometric instrumentation. In addition, both the spin-spin relaxation rate (R_2) and spin-lattice relaxation rate (R_1) have been shown to be linearly correlated to the absorbed dose, and the linearity is good up to a dose that is dependent on the dosimeter composition, because it requires that the Fe^{2+} ions are not significantly depleted.

We have optimized (3) the protocol for the gel-dosimeter preparation, and therefore we have analysed the response of dosimeters having various compositions. The best sensitivity was achieved with the following composition of the dosimeter:

ferrous sulphate solution	*1 mM $Fe(NH_4)$ $6H_2O$, 50 mM H_2SO_4* in the amount of 50% of the final weight
Agarose SeaPlaque [$C_{12}H_{14}O_5(OH)_4$]	in the amount of 1% of the final weight
highly purified water H_2O	in the amount of 49% of the final weight.

Samples of this gel, contained in cylindrical polyethylene vials 2.5 cm in diameter and 7 cm in height, were exposed to the γ-ray field of a ^{137}Cs biological irradiator, acting at a rate of 0.14 Gy s^{-1}, and than analysed in a Somatom Siemens NMR imaging system operating at 1.5 T and 63 MHz. The transverse relaxation rate $1/T_2$ was measured, because it is more sensitive to ferric ion variations than the longitudinal relaxation rate $1/T_1$, in such low frequency instruments. The dose-response curve is found to be linear up to ≈ 40 Gy, with a slope equal to 0.2 s^{-1} Gy^{-1}. The G value (Fe^{2+} oxidized per 100 eV absorbed energy) of this dosimeter is equal to 183 (Fe^{3+} ions per 100 eV). Good result reproducibility is achieved if the dosimeter response R is defined as the difference between the relaxation rate measured in the irradiated sample and that measured, at the same time, in a non-irradiated sample from the same gel preparation:

$$R = (1/T)_{irr} - (1/T)_{blank}.$$

Samples with different gel compositions prepared, as described below, to satisfy certain specific requirements, such as tissue equivalence for thermal neutrons, have been shown to be less sensitive. In any case, the sensitivity is considerably higher than that of the standard Fricke dosimeter.

The tissue equivalence of all gel dosimeters to γ-rays is very good.

SPATIAL DETERMINATION OF ABSORBED DOSE IN B.N.C.T.

In tissue exposed to thermal neutrons the absorbed dose is due to the energy released by the reaction products. Consequently, a good tissue equivalence is obtained only if the isotopic composition of the substitute is identical to that of the tissue to be simulated, at least as regards the isotopes that give the main contributions to the absorbed dose, namely (in all tissues but bone) ^{14}N and ^{1}H, which give the reactions:

$$^{14}N(n,p)^{14}C \qquad ^{1}H(n,\gamma)^{2}H$$

The nitrogen contribution to the absorbed dose is dominant in small volumes (< 1 cm^3). Therefore we have augmented the gel previously described with the organic compound carbonyldiamide (urea [CH_4N_2O] from the Fluka Chem.Corp.) in the amount of 4% of the final weight. The dosimeter so obtained is a good substitute for brain tissue. In fact, the elemental composition of the gel is found to be very near that of brain (from ICRU-44, 1989), as is shown in the Table. Moreover, Z_{eff}(brain) = 7.4 and Z_{eff}(gel) = 7.8.

Some dosemeters have also been prepared by augmenting the gel with 40 μg/g of ^{10}B, which is the quantity typically accumulated in tumours. Both the dosemeters (i.e. with and without ^{10}B) have been shown to have the same sensitivity to gamma-radiation.

We have analysed (4) dosemeters made with both boronated and non-boronated gel, contained in small cylindrical Teflon vials. When the dosemeters with boron are exposed in the thermal column of a TRIGA MARK II reactor, 86% of the total response is found to be related to the absorbed dose due to ^{10}B. The remaining part, that is 14% of the total, includes contributions from thermal neutrons in tissue, fast neutrons, reactor background and activation of the materials of the containers and holders. The sensitivity of the boronated dosemeter to the secondary particles produced by thermal neutrons reacting with ^{10}B is found to be equal to 0.028 D_B, where D_B is the absorbed dose (in Gy) due to ^{10}B. In Fig.1 the image of a boronated gel phantom after exposure in the thermal column of the reactor is shown. The results confirm the promising features of this NMR dosimeter, and have encouraged us to pursue investigations by analysing broader samples.

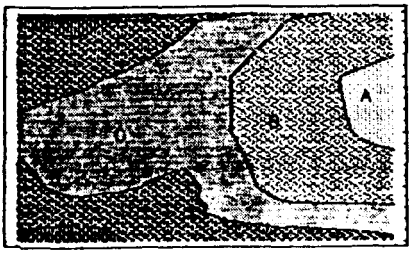

FIG.1

DEPTH-DOSE PROFILING IN PROTON THERAPY

The feasibility of utilising a Fricke-infused Agarose gel for depth-dose profile determination in tissue exposed to a proton beam has been investigated. Considering the fact that ion diffusion requires a prompt NMR analysis after irradiation, if a good spatial resolution is needed, and since at present we do not have the possibility of performing such rapid analyses, we have carried out the experiment by employing the following alternative technique: thin glass capillaries (1.1 mm internal diameter), filled with the ferrous-sulphate-infused gel, were pierced in a plexiglass phantom; the phantom was exposed to a 13.5 MeV proton beam from a CYPRIS cyclotron and, the next day or later on, they were measured in a research NMR analyser (BRUKER AC-300) operating at 7.05 T and 300 MHz. Owing to the high operation field, the longitudinal relaxation rates $1/T_1$ were determined.

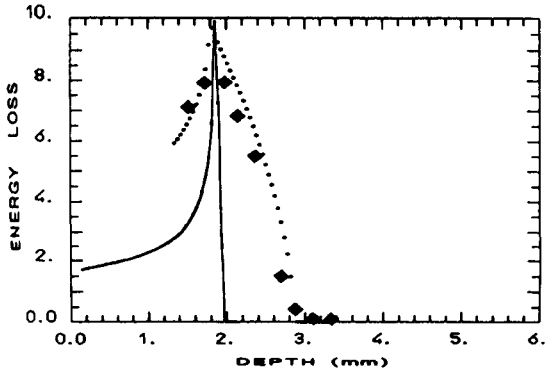

Fig.2

The results are shown in Fig. 2, where each experimental point is obtained as a mean of two values. In the figure the computed curves are also shown: *a) (solid line)* specific energy released in Plexiglas by 13.5 MeV protons as a function of depth, and *b) (dotted line)* energy released in a gel dosimeter enclosed in glass containers with square section, 1mm internal side, 0.2 mm thickness, located at increasing depths in plexiglass. The Bragg peak position is obtained within a tenth of a millimeter uncertainty, and the widening in the ramps is within 1 mm.

Moreover, we have also tested our dosimeter gel by means of spectrophotometric analysis in order to verify the consistence and correctness of the results obtained from the NMR analysis. To this end, we have utilised a UV/VIS Diode-Array Spectrophotometer. An enhancement of the spectrophotometric measurement sensitivity is obtained by adding to the gel components a proper metal ion indicator, which yields absorption in the visible spectrum. We have chosen Xylenol Orange ($C_{31}H_{28}N_2Na_4O_{13}S$), which shows a peak at 580 nm, in the amount of $1.25 \cdot 10^{-4}$ M. We have analysed samples exposed both to gamma and to proton radiation: the good agreement of these results with those obtained by NMR analysis are a further verification of the validity of the method.

Application of Low Pressure Tissue Equivalent Proportional counter for IHEP Radiation Protection

A.G.Alexeev

The University of Tokyo, the Research Center for Nuclear Science and Technology, Yayoi 2-11-16, Bunkyo-ku, Tokyo 113, Japan.

Permanent address: Institute for High Energy Physics, Radiation Research Department, Protvino, Moscow region, Russia, 142284.

Radiation behind shields of high energy charge particles accelerators (for example, the IHEP 70 GeV proton synchrotron (U-70)) is of a mixed composition. The major component of radiation is high energy neutrons with energy above 20 MeV. The dose equivalent measurement of high energy neutrons is a difficult problem for the radiation protection dosimetry, because there are no standard devices for this energy region. Now only a measurement method on the base of low-pressure tissue equivalent proportional counter (TEPC) is used as universal in mixed radiation fields. This dosimetric method has more than 20 year history of application at the IHEP accelerator. The method has been improved in measurements, the counter design and application. The linear energy transfer (LET) spectrometer (SLET-03) on the base of TEPC[1] is used for metrological measurements in IHEP radiation protection.

The spherical tissue equivalent proportional counter has been developed in collaboration with the Institute of Biophysics (Moscow) [2] .The TEPC energy response for neutrons and photons is dependent on the counter design (the thickness and the composition of the counter body, the thickness of the aluminum cover). The dependence of TEPC neutron energy response on the counter design has been shown in [2], [4]. The photon energy response of TEPC in the energy range from 29 to 114 keV has been investigated by the National Secondary Standard Field of absorbed dose (VNIIFTRI) [3].

The energy responses has been calculated for neutrons from 0.01 to 800 MeV [4] , [2]. The TEPC energy response agrees closely with H*(10) in the neutron energy range for 0.3 MeV to 800 MeV. The TEPC response is less than H*(10) function for neutron below 0.3 MeV. Table reflects the TEPC measurements results over the ones obtained with other dosimeters. There is the normalization with the TEPC data and the normalization with the expert data for the IHEP reference fields.

Irradiation fields	Dosimeters	Neutron Dose equivalent, rel.units	Photon and charged particles dose equivalent, rel. units
Radiation field behind the top of the IHEP proton accelerator. The average neutron energy is equal to 71 MeV.	TEPC	1.0	1.0
	ACR	0.60	1.12
The radiation fields behind the iron calorimeter . The average neutron energy is 51 MeV.	TEPC	1.0	1.0
	ACR	0.36	0.98
Pu-Be source (IHEP reference field)	TEPC	1.0	1.01
	ACB	1.0	0.83
	BS	0.99	-
The IHEP reference fields based on the ^{252}Cf neutron source.	TEPC	0.95	0.90
	ACB	0.99	0.80
	BS	1.06	----
The reference field based on the ^{252} Cf neutron source in the 30 cm diameter spherical iron moderator.	TEPC	1.00	0.80
	ACR	0.75	0.0
	BS	0.99	---
The reference field based on the ^{252}Cf neutron source in the 30 cm diameter spherical polyethene moderator.	TEPC	0.95	1.07
	ACR	1.63	0.99
	BS	1.04	---

The comparison was carried out with the following dosimetric systems :

The analog component remmeter (ACR) [1], that includes an argon-filled ionization chamber, tissue-equivalent chamber, ^{3} He-filled ionization chamber into the 25.4 cm diameter spherical polyethylene moderator. To minimize the neutron dose equivalent measurement systematic error, the correction method based on additional information about a behavior of the ionization chamber neutron response in different neutron spectra is applied. The Bonner multisphere neutron spectrometer (the dose equivalent measurement method by 6-spheres has been certified by VNIIM)[5].

The photon dose equivalent data carried out by TEPC are not significant as compared with those measured with other dosimeters. The comparative results show that the TEPC data are systematically lower than those of the Bonner spectrometer within 20 % .The systematic error of neutron dose equivalent measurement may be reduced with a correction factor ,when the average spectra neutron energy is less than 0.5 MeV. The correction factor may be obtained by a procedure based on neutron energy dependence of the ratio of neutron response of TEPC to neutron response of another detector [6].

The application of TEPC for IHEP radiation protection dosimetry showed that one may be successful in a variety of radiation fields of a high energy accelerator.

PERFORMANCE OF RADIOACTIVE MEASUREMENTS BY GAMMA SPECTROMETRY WITH SEMICONDUCTOR DETECTORS USING BIPHASIC SAMPLES

J.M. Lumbreras[1], G.M. Fernández[1], A.J. Aller[2], G. Fernández[1]

[1]Department of Physics and Chemistry, and [2]Department of Biochemistry and Molecular Biology, University of León, E-24071 León, Spain

ABSTRACT

An adaptation of the solid-liquid extraction technique has been developed to determine Hg-203 by gamma spectrometry with a semiconductor detector using biphasic samples, as a part of a study on the retention of mercury on the external membrane of bacterial cells. Three procedures have been tested to extract the radioactive isotope. One of them, consisting of a one-stage extraction using an optimized liquid volume, was seen to be preferable in this case. The three procedures might be useful to monitor the uptake of a contaminant (radioactive or not) by a solid phase, especially in small samples.

INTRODUCTION

A variety of techniques have been applied to the separation of toxic elements. Sorption of metals by microorganisms has proved useful in different types of samples (1). Living and dead cells are able to retain certain elements, like mercury, in a selective way (2). The monitoring of mercury in environmental and biological samples is of great concern because of the high toxicity of this metal. The use of a very sensitive technique like gamma spectrometry may be appropriate to determine mercury in very low concentrations.

Some series of experiments on the retention of mercury on the external membrane of bacterial cells were to be carried out using Hg-203 as a radiotracer (3). The size and shape of the samples are important factors to consider in gamma spectrometry with semiconductor detectors. The use of monophasic samples is usually considered an indispensable condition in this technique. However, it was difficult to obtain homogeneous samples with a specified shape from the small amount of bacteria used in the experiments. On the other hand, repeated separation of phases by solid-liquid extraction may lead to a decrease in accuracy. In these cases the performance of radioactive measurements in biphasic samples could be an option.

MATERIALS AND METHODS

A Canberra GR 2520 high purity Ge shielded detector was used for counting the 279.2 keV gamma rays of Hg-203 , in combination with a Canberra System 30 Plus multichannel analyzer. Detector efficiencies were calculated and radioactive measurements were optimized before gamma counting.

The Hg-203 radiotracer solution was in the form of mercury (II) chloride. The specific activity of the labeled solutions was 522.5 Bq/μg Hg. Nitric acid and other chemicals used in

this study were of the highest quality.

The bacterial cells used were Escherichia coli and Pseudomona putida. They were first cultivated in a solid medium TSA at suitable conditions. The bacteria were pelleted and lyophilized.

A 25 mL aqueous solution containing the radioactive mercury was equilibrated with 25 mg of the lyophilized bacteria for 30 minutes at room temperature at the working pH. The bacteria were separated from the supernatant by centrifugation at 12400 g, and then treated with a fixed volume of a 3.6 M nitric acid leaching solution. The amount of mercury was determined by gamma spectrometry in the biphasic sample obtained and in also in the supernatant. At least three measurements were made for each point.

Living cells, cultivated in a TSB medium, were also used. The density of the bacterial suspension was controlled by measuring the absorbance at 600 nm. Then the suspension was treated as in the lyophilized cell experiments.

RESULTS AND DISCUSSION

A problem was initially present because counting was made in a Hg-biomass pellet treated with a nitric acid solution and a part of the Hg could still be retained by the pellet. The optimization of radioactive measurements by the extraction process was performed in three ways.

One-stage extraction and use of an empirical factor

The following equation was used,

$$\Sigma C_t = \Sigma C_1 (E_p/E_1) + \Sigma C_p f \qquad [1]$$

where C_t are the total counts, C_1 and C_p are the counts from the supernatant and pellet, and E_p and E_1 are the detector efficiencies for the radiation from the pellet and supernatant, respectively. The efficiency varies because the volume of the biphasic sample was 4 mL, while that of the supernatant was 25 mL. The summatory means that counting was made in a number of different samples. An empirical statistical factor is introduced taking into account that the mercury content in the biomass pellet is not homogeneously distributed into the 4 mL volume. The values found for this factor, f, were 0.591 for E. coli and 0.517 for P. putida.

Two-stage extraction

The following set of equations was derived,

$$C_p = C_{12}(E_p/E_1) + xE_0 \qquad [2] \qquad x = (1-s)y \qquad [3]$$

$$y = C_{12}/E_1 s \qquad [4] \qquad C_{p2} = C_p(1-s) \qquad [5]$$

$$z = C_1/E_1 \qquad [6] \qquad P(\%) = [y/(z+y)]\,100 \qquad [7]$$

where C_{p2} are the counts in the second pellet sample (the second biphasic sample obtained after the separation of the 4 mL nitric acid solution and treating again the pellet with a 4 mL nitric acid solution, C_{12} is the counting in the supernatant from the first 4 mL volume after dilution to 25 mL, x is the

number of gamma rays emited in the time unit by the Hg present in the solid phase of the first biphasic sample, y and z have the same meaning as x in relation to the Hg content in the whole first biphasic sample and in the first supernatant, respectively, E_0 is the detector efficiency for samples situated at the bottom of the sample container, s is a separation factor meaning the fraction of Hg present in the biomass and extracted by the leaching acid solution going to the solution named "12", and P(%) is the percentage of the Hg initially retained by the pellet. The separation factor values were 0.92 for E. coli and 0.60 for P. putida.

One-stage extraction using an optimized volume

The usual one-stage extraction was employed combining it with volumes of solution varying from 4 to 100 mL in order to obtain the optimum volume. The equation used was

$$C_t = C_1(E_4/E_{25}) + C_p(E_4/E_v) \qquad [8]$$

where E_4, E_{25} and E_v are the detector efficiencies for samples with a volume of 4, 25 and v mL, respectively. We have found that the counts from the biphasic samples (corrected for the different efficiencies) decrease with the incresing volume of leaching acid. For volumes greater than 25 mL there is no variation, so the optimum volume is assumed to be 25 mL.

The standard errors of the mean values obtained using identical samples by the three extraction procedures, in the same order as described, were respectively 3.1%, 1.7% and 1.4% for E. coli, and 9.2%, 4.0% and 3.3% for P. putida. Using 4 mL of extractant liquid the results are only approximate. However, using 25 mL of leaching acid the Hg is completely released. In the case of P. putida the acid leaching is less effective, and hence the errors are greater.

CONCLUSIONS

Three procedures to measure gamma radiation from biphasic samples have been tested. One-stage extraction and use of an empirical statistical factor is a simple procedure needing less measurements, but it is less accurate. The two-stage extraction procedure improves the accuracy, but the operational complexity is greater. One-stage extraction with an optimized volume of liquid had the best accuracy and was preferable in this case, though more measurements are needed. The three procedures might be useful, according to the circumstances, especially in small biological or other types of samples, and particularly in cases in which the distribution of a contaminant (radioactive or not) between two different media should be monitored.

RADIATION DAMAGE AND PROTECTION OF PLASTIC SCINTILLATORS WITH A BASE OF POLYSTYRENE AND EPOXYPOLYMERS. N.Barashkov[1], F.Markley[2], A.Pla-Dalmau[2], G.Foster[2], M.Rivard[3] 1) University of Texas at Dallas, Richardson, TX 75083-0688,USA; 2) Fermi National Accelerator Laboratory, Batavia, IL 60510, USA; 3) University of Michigan, Ann Arbor, MI 48109-1200, USA

Plastic scintillators are often used in dosimetry of ionising radiation at high and low levels. Some experiments in high energy physics such as modern colliding beam experiments subject scintillators to higher doses of radiation than ever before. Plasticizers (diffusion enhancers) have been used to provide the radiation protection of scintillators. We have shown that the introduction of plasticizers in common polymer matrix has at least two disadvantages. These consist of making the scintillators too soft and increasing the probability of diffusion of the scintillation dyes out of the matrix. Two new approaches for the preparation of scintillators with improved radiation stability have been investigated. The first approach consists of preparing crosslinked copolymers of styrene or epoxypolymers which can be used as the matrix with a large concentration of plasticizers. The second approach eliminates any luminophore migration by covalent bonding of the scintillation dyes into the polystyrene and epoxypolymers. We investigated the dependence of the radioluminescence intensity of these new scintillators on the concentration of the macroradicals formed in the process of gamma-irradiation.

FIBER-OPTIC-COUPLED DOSIMETER FOR REMOTE OPTICAL SENSING OF RADIATION

Brian L. Justus and Alan L. Huston

Optical Sciences Division
Naval Research Laboratory
Washington, D. C. 20375-5338

Remote sensing technologies for the detection and measurement of ionizing radiation exposure are of current interest for applications such as patient dose verification during radiotherapy and the monitoring of environmental contaminants. Fiberoptic-based sensing is attractive due to the advantages of small size, low cost, long life and freedom from electromagnetic interference. Several fiberoptic-based radiation sensing systems have been described that utilize radiation induced changes in the optical characteristics of the fiber such as reduced transmission as a result of darkening of the glass [1], optical phase shifts due to heating [2], or changes in the birefringence of a polarization-maintaining fiber [3]. The measurement of radiation induced darkening is limited in both sensitivity and dynamic range and requires long fiber lengths. Phase shift measurements require the use of single-mode lasers, phase sensitive interferometric detection, long fiber lengths and complex signal processing techniques. Alternatively, thermoluminescent (TL) phosphor powders have been coated onto fiberoptic cables and remote dosimetry measurements performed using traditional laser heating techniques [4]. The sensitivity is limited by the requirement for a very thin layer of phosphor material, due to problems associated with light scattering and efficient heating by thermal diffusion.

In this paper we report the development of an all-optical, fiber-optic-coupled, thermoluminescence dosimeter for remote radiation sensing that offers significant advantages compared to previous technologies. We recently reported the development of an optically transparent, TL glass material having exceptionally good characteristics for traditional dosimetry applications [5]. We also reported a modified TL glass incorporating a rare earth ion dopant in order to absorb light from a semiconductor laser and utilize the absorbed light energy to internally heat the glass and release the trapped electrons [6]. This TL glass contains nanocrystalline ZnS particles and Cu^{1+} ions in a Vycor glass matrix, to which approximately 0.6%, by weight, of Nd^{3+} ion is added. The Nd^{3+} ion is well suited for this application for several reasons: 1) it absorbs strongly at 807 nm (GaAlAs laser wavelength); 2) it transforms a significant amount of the absorbed light energy to heat that is deposited in the glass matrix to stimulate TL; and 3) the absorption of the Nd^{3+} ions does not significantly overlap the thermoluminescence emission wavelengths and therefore does not substantially attenuate the signal. For this fiber-optic-coupled dosimeter work, Nd^{3+}-doped TL glass rods were hand-drawn to ~200 micron diameter. These TL fiber dosimeters (1 cm long) were fusion spliced to commercial, multimode optical fibers (2 m long, 200 μm core diameter).

A schematic of the fiberoptic-coupled, laser-heated thermoluminescence dosimeter is shown in Fig. 1. The 807 nm output of a 1 watt diode laser array was collimated using a microscope objective. The polarized 807 nm light was transmitted through a Glan prism and imaged with a second microscope objective onto the input face of the multimode fiber. The laser light stimulated thermoluminescence from the TL glass fiber dosimeter previously exposed to ionizing radiation from a ^{60}Co source. A fraction of the 500 nm, laser stimulated

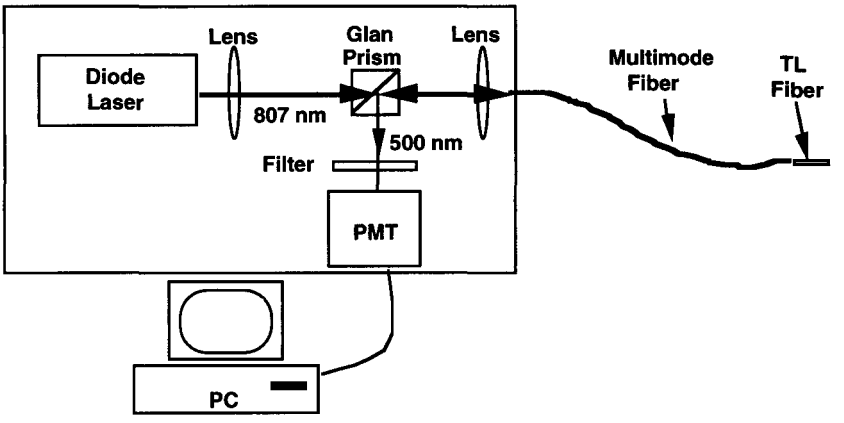

Figure 1: Schematic of the laser-heated, fiber-optic-coupled, remote sensing, thermoluminescence dosimeter.

TL light emission was trapped by total internal reflection and was directed back through the multimode fiber, collimated by the microscope objective and reflected by the Glan prism into a photomultiplier tube. A color glass filter augmented the Glan polarizer in selectively blocking diode laser light while passing the TL signal. The PMT was cooled and the signal was detected using photon counting. The signal collection efficiency could be increased by a factor of two if a dichroic beamsplitter were used in place of the Glan prism.

A laser heated TL signal obtained from a fiber dosimeter exposed to a ^{60}Co γ-ray dose of 2 krad is presented in Fig. 2. The peak of the signal occurs soon after turning the laser on (at t~3 s in this trace), followed by a decay of several seconds. This behavior is in marked contrast to previous studies of laser heated dosimetry [4] in which a TL glow curve, similar to that observed using traditional contact heating methods, is observed. All prior laser heating methods rapidly increase the bulk temperature of the dosimeter to high levels. The laser heating observed in the present work is also quite rapid, however, the mechanism of the laser heating is radically different from that of previous methods and the bulk temperature is not significantly increased. The explanation of this unique behavior lies in the microscopic nature of the localized laser heating and has been described in detail [6]. The key feature of this dosimeter is the use of the optically transparent TL glass that permits efficient local heating but minimal bulk heating of the fiber sensor.

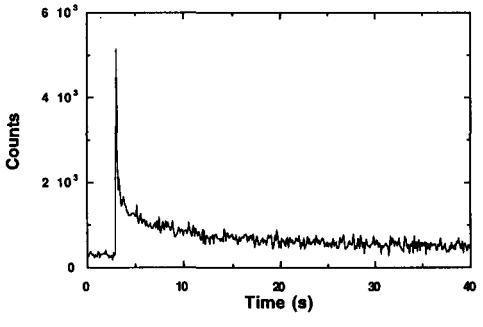

Figure 2: Laser-heated thermoluminescence signal obtained from fiber-optic-coupled TL dosimeter dosed to 2 krad and read using 1 W cw power at 807 nm.

The ^{60}Co γ-ray dose dependence of the fiber dosimeter is shown in Fig. 3. The plot displays the integrated signal area as a function of the dose. Both the integrated areas and the peak values of the TL signals yield identical dose

response curves. The dose dependence is linear up to a value of approximately 500 rad. The dose range of interest for medical diagnostic and therapy applications, 10 to 1000 rad, can be accurately measured with the prototype dosimeter. The optical transparency of the glass permits increasing the sensitivity of the dosimeter simply by increasing the diameter of the fiber sensor. Laser induced TL originating from any point within the fiber can be efficiently collected and utilized, a feature not possible using traditional, highly scattering TL materials. The sensitivity can also be increased by optimizing the concentration of the Nd^{3+} dopant ions and improving the optics and detection apparatus. We estimate that the ultimate sensitivity of our remote dosimeter will be less than 1 mrad.

In summary, we have developed an all-optical, fiberoptic-coupled radiation dosimeter that has excellent performance characteristics for remote radiation sensing applications. The enabling feature of the dosimeter is an optically transparent, Nd^{3+}-doped TL glass that exhibits efficient localized laser heating. The dosimeter utilizes relatively low cost components such as a solid state diode laser, commercial multimode optical fiber, simple optical elements and direct photodetection. Dose information is correlated with either the signal amplitude or the total integrated count, and minimal signal processing is required. Remote sensing applications for this fiberoptic-coupled dosimeter include medical applications, such as near-real-time, in vivo, dose monitoring in patients undergoing radiation therapy, and environmental applications, such as monitoring for leakage of nuclear wastes around contaminated sites.

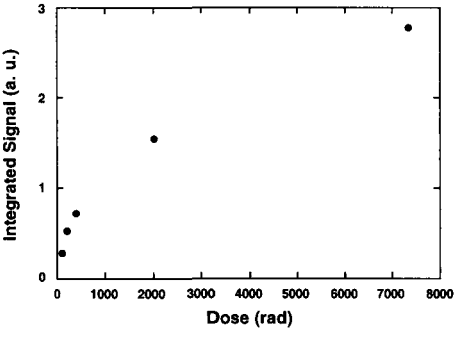

Figure 3: Dose response of the laser-heated, fiber-optic-coupled dosimeter.

MAJOR SCIENTIFIC TOPIC NUMBER .3.2 (see page 7)

ABSTRACT (See instructions overleaf)

The dose response of LiF:Mg,Cu,P TLDs has been investigated for gamma radiation in the dose area between 0.001 to 100.0 Gy. It has been determined that the dose response for this dose range is non-linear. This effect can be explained by the following reasons:

A) The dependence between the resolving time of the photomultiplier tube of the TLD reader and the photon fluence rate from the TLD during the heating, acquisition cycle.

B) The relative dose response of the LiF:Mg,Cu,P TLD is a function of the number of free electron centers with in the detector. Our data demonstrates a very close approximation with our theoretical model.

COMPARATIVE STUDY OF COMPUTERISED GLOW CURVE ANALYSIS IN ROUTINE DOSIMETRY

D. Mebhah and F.Z. Dehimi

Laboratoire de dosimétrie externe, Centre de Radioprotection et de Sûreté
2, Bd Frantz Fanon, B.P. 1017, 16 000 Alger, Algeria.

A computer program for the glow curve deconvolution analysis in radiation dosimetry, mainly personal and environmental dosimetry carried out with LiF: Mg,Ti and CaF_2:Dy has been studied. The program is based on knowledge of the physical parameters of the glow peaks determined using two different peak shapes. The first peak shape is calculated by the first order kinetic and the second one by a gaussian technique.

Three ways of determining these parameters have been investigated. They consist of marking the initial parameters on the curve, initiating the deconvolution process from choosen parameters and calculating the parameters automatically in the global program. The intercomparaison of the capacity to reproduce the real curve involving the three options, and their performances in field applications for two processing options (research or production mode), will be presented. The advantages of these methods of glow curve analysis in routine dosimetry on precision and low detection limits compared to the conventional methods will be discussed.

MOLECULAR OXYGEN AS THE RADIATION PROTECTER OF THE PLASTIC SCINTILLATORS

V.K.Milinchuk[1], V.B.Taraban[2], I.P.Shelukhov[2],G.S.Zhdanov[2], N.I.Voronkina[2], E.R.Klinshpont[2]

[1]Obninsk Institute of Nuclear Power Engineering,249020 Obninsk, Kaluga Region, Russia
[2]Branch of Karpov Institute of Physical Chemistry,249020 Obninsk, Kaluga Region, Russia

INTRODUCTION

The yield of the luminescence plastic scintillators decreases on the action of an ionizing radiation. The absorbed dose at which the luminescence yield decreases by 20 % is equal to 15 - 20 kGy for such the most suitable polymeric matrices as polystyrene (PS), polyvinyl xylene (PVX), polyvinyl toluene (PVT) and polymethylmetha crylate (PMMA). The luminescence yield decreasing is caused by the different reasons, for example, the deactivation of the excited states of polymeric matrices by the intermediates that are formed under the scintillator radiolysis, the lowering of the scintillator transparency as a result of new absorbing or scattering events (1). The paper summarizes the results of the study of the formation and reactions the macroradicals in vacuum and presence of oxygen and deterioration of the plastic scintillators under gamma-irradiation.

RESULTS AND DISCUSSION

The dependencies of the stabilized macroradical concentration and light yields vs absorbed dose in vacuum are antiabatic (at 300 K). The same changes of macroradical concentration and light yields vs heating time at 360 K are observed. Thus, the light yeild recover as a result of macroradical decay. The decreasing of the macroradical concentration take place on the postradiation oxydation process. On the contrary the light yeild increases in the presence of an atmospheric oxygen. The macroradical concentration and the light yeild dependencies on the absorbed dose in PS and PVX in presence of dissolved oxygen are an induction period on the curves. The induction period is absent when the dissolved oxygen is removed from the sample (2). These results show that an atmospheric oxygen and dissolved oxygen induces the decay of the macroradicals and promotes the light yield preservation. The molecular oxygen is the "victim" type. The reversible character of the radiation damage makes it evident that the macroradicals are the exited state quenchers. The overlapping of the energetic donor and acceptor levels are necessary for quenching. In the case of PMMA, PS and its substituted, this condition is fulfilled for both dopant containing matrix and macroradicals. The energy transfer from the matrix and primary dopant to the macroradical is allowed. Probably the macroradical quenching of the electron-exited states has an unlike mechanism caused by the spescific structure of macroradicals near the dopants. The dopant locations are the defects in which all radiation processes (such as the localization of the absorbed energy, the formation and reaction macroradicals and so on) proceed. The mechanism of the radiation-chemical processes in the plastic scintillators shows the following ways of the scintillator radiation resistance increasing: it is necessary to promote the oxygen diffusion into bulk of the scintillators by incorporation of low molecular additives or by decreasing the scintillator sizes; the decreasing of the macroradical radiation-chemical yield in polymeric matrices; the increasing of the macroradical dycay rate by the intensifying of the matrix molecular mobility (plasticizing, rise of the temperature and so on).

MAJOR SCIENTIFIC TOPIC NUMBER ..... (see page 7)

ABSTRACT (See instructions overleaf)

In radiotherapy solid state dosimetry is the common method for in-vivo dosimetry. The "one shot" character of the lyoluminescence method suggests the search for alternatives, which provide most of the advantages of this technique like tissue equivalence and reliability.

The ESR (electron spin resonance) spectroscopy allows non destructive premeasurement of lyoluminescence probes and hence confirmation of the results of that method.

In this study some organic materials (glucose, dextrose, mannose) were used for both techniques to test their comparability. The dosimetric materials were irradiated with photons (1.2, 6, 10, 15, 25 MeV), electrons (6, 10, 15, 18 MeV) and protons in the dose range of 1 to 20 Gy. ESR measurements were made with a commercially available low cost ESR device developed for identification of irrdiated foodstuffs.

STUDY OF X-RAY PHOSPHORS USED FOR THE VISUALIZATION OF IONIZING RADIATION

M.Ignatovich, A.Eremenko, V.Ogenko, A.Chuiko
Institute for Surface Chemistry National Academy of Sciences. 252022, Prospect Nauky, 31, Kyiv, Ukraine.

There is considerable interest in Ukraine after Chernobyl accident in dosimetric X-ray luminescent materials which can convert the energy of ionising radiation into the visible emission.

A special request is for X-ray luminophors for high-dose and high-temperature conditions.

The main requirements which X-ray phosphors have to satisfy for the visualization purposes are:

i) high converting efficiency (high intensity of visible emission);

ii) radiation stability (preserving the luminescent properties under the high-dose and high-energy radiation)

The aim of the study is - to test the feasibility of application of X ray phosphors currently used under irradiation of soft X-ray (in X-ray screens in medicine) for high-energy, high-dose and high-temperature conditions.

Materials - solid powders of europium-doped X-ray phosphors.

Techniques - 1) steady-state X-ray luminescence. For luminescence excitation X-ray, γ- and β- radiation in the range of energy from 40 keV to 5 MeV were used.

2) time-resolved laser-induced photoluminescence (λ-excitation 337 nm). On the basis of the luminescence decay measurments the life-times were calculated

The main results obtained in the study (summarized in the table) are the following:

№	Composition of samples	Visible emission, λ nm	life-time, τ	luminescent center
1	BaFCl·Eu	390	6.3 μs	Eu^{2+}
2	$Sr_3(PO_4)_2$·Eu	410	32 ns	Eu^{2+}
3	Y_2O_2S·Eu	585	67.2 ns	Eu^{3+} cluster
4	Y_2O_3·Eu	400	10.2 μs	Eu^{3+}
		630	~4000 μs	

i) all tested phosphors under high-energy excitation revealed the bright visible emission in blue-green and yellow-red region

ii) luminescent properties are preserved after high-dose (300 Gy) irradiation and high-temperature annealing (300 C^0) of samples.

The next important feature of tested phosphors is that in most cases the spectral shape of radioluminescence is practically the same as for laser-induced luminescence.

For the BaFCl·Eu and for $Sr_3(PO_4)_2$·Eu the luminescence consists of mono-band emission and can be attributed for Eu^{2+}.

Spectrum of Y_3O_3·Eu contains two luminescent species - mono-band emitting near 400 nm and the second one with fine-structure centered near 630 nm. The last spectrum consists of f-f transitions characteristic for Eu^{3+}. It must be noticed that these two luminescent species have also considerably different life-times.

The influence of the host solid-matrices on the life-time of the luminescent species will be discussed.

CODE: 10318 CITY: Berlin COUNTRY: Germany

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER: 5.1 (see page 7)

ABSTRACT (See instructions overleaf)

A review is given on the surveillance of workplaces exposed to short-lived radon progeny in the Eastern part of Germany. According to the present different legal regulations in Germany only in the Eastern part of Germany workplaces with exposures to short-lived radon progeny are regularly monitored not only in uranium mining and uranium milling and in the closeout of the uranium industry (since 1991), but also in non-uranium mining and other workplaces, such as caves, radon spas and water treatment facilities.

20 years experience in this field shows that a special system for quality assurance is the prerequisite to reliable results for the individual exposure of workers. This system includes the selection of suitable measuring methods and devices, the first and the repetition calibration of the devices and the careful interpretation of the results.

The equipment available in the Federal Office for quality assurance, the measuring methods and devices used at workplaces and the results of surveillance are described. Recommendations for further development are given.

OCCUPATIONAL RADIATION EXPOSURE IN SOME EGYPTIAN PHOSPHATE MINES

A.Z. Hussein [1], Mohamed I. Hussein [1] and M.L.Abd-El-Hady[2]

1 National Center for Nuclear Safety and Radiation Control, Atomic Energy Authority, Nasr City, P.O. Box: 7551, Cairo, Egypt.

2 Physics Department, Faculty of Science, El-Minia University, Egypt.

ABSTRACT:

Radiation levels in some working phosphate mines in the Egyptian Eastern Desert have been investigated to estimate the occupational exposure to the workers in those sites. Such results may help in the preparation of the corrective actions as well as the improvement of the safety measures if needed in those working mines. Beta and gamma levels as well as radon gas concentration and its decay products have been measured. Active techniques are employed to fulfill the objectives of measuring radon gas and its daughters.

Some working conditions and environmental parameters such as the working time, type of available ventilation, temperature and humidity have been studied during the period of measurements. The maximum reported values for radon daughter concentration in units of working level are 1.28, in Safaga area south mine, 1.22 in Hamraween area B mine and 0.67 in El-Quser area Youns C mine. The maximum annual dose for the worker in all locations under investigation is about 100 mSv/y which is clearly much higher than the recommended international value. According to the above estimated values the question of ventilation economics in such mines is created. The classification of the miners in conventional mines as radiation workers should also be put into consideration.

INTRODUCTION

The main phosphate mines in Egypt are sited in the Eastern Desert. There are three regions Safaga, Hamraween and El-Quser which are considered as the producing mines. The three regions are separted by about 60 and 20 km from each other. The depth of the mines ranges from 10-50 meters.

It is well known that phosphate rocks contain the trace elements of uranium, thorium and their decay products in equilibrium. All technical processing leads to a high release of long and short half-life radionuclides from uranium mining and milling. (5).

In this study a radiation monitoring programme was carried out in the mining areas, γ and β levels are measured as well as radon gas concentration and its decay products in units of working level.

EXPERIMENTAL

1. Monitoring External Beta and Gamma

An Eberline survey meter model L.B. 1200, was used.

2. Radon Gas Measurement

Alpha scintillation cells was used. Scintillations from Lucas cell were counted using a photomultiplier tube in a light-tight enclosure and a counting system made by EDA of Canada.

3. Air Sampling

Air samples were taken using air sampler having a flow rate of 1-10 1/min.

4. Rodon Daughters Measurement

Air was passed through high-efficiency filter paper (milipore) to trap radon daughters. Filter papers were counted using the same counting system by placing the filter paper on a scintillation tray coated with the same material as the Lucas cell.

5. Calculation of Radon Daughter Concentration

Rolle method was used to calculate radon daughter concentration in units of working level, (2,3).

RESULTS AND DISCUSSION

The results of radon and radon daughters concentrations, effective dose equivalent and annual dose for the workers are shown in table (1) for Safaga, Hamraween and El-Quser areas.

It is clear from table (1) that γ and β levels in the three mines are within the range (0.03-0.25 mR/h) which is higher than the natural background level.

The maximum radon daughters levels in units of WL were found 1.2 in south mine at Safaga, 1.2 in mine B at El-Hamraween and 0.6 in Youns C mine at El-Quser. These levels are higher than the ICRP recommended value for the workers (0.3), also the maximum values of radon gas concentration are found 90 pCi/1 in south mine, pCi/1 in mine B and 108 pCi/1 in Youns C mine. (3)

The maximum values for the annual dose for the workers are found 121 mSv/y in south mine, 116 mSv / y in mine B and 65 mSv/y in Youns C mine. We notice that these levels are higher than the recommended value (20 mSv/y) (4).

It is clear from the results obtained for radon, radon daughters concentrations and gamma exposure rates that most values are higher than the recommended limits and require corrective actions. These higher levels are due to bad ventilation.

The following corrective actions are recommended :

1. An efficient mechanical ventilation system should be establised to decrease the annual dose equivalent to the accepted limit of 20 mSv/y.

2. Job rotation could be used as a helping action to decrease the exposure.

Table (1) : A Summary of Exposure Rates, Effective Dose and Annual Dose in Phosphate Mines.

ABSTRACT (See instructions overleaf)

WMC (Olympic Dam Corporation) is a major Australian producer of copper and uranium and consists of an underground mine and multifunction metallurgical plant. The facilitites have been in production for 8 years and the company is currently examining a major expansion. Occupational and environmental radiation protection is considered to be a critical management function and is formalised through a radiation safety management system. The performance of the system is audited by a group of radiation protection professionals via an established radiation monitoring programme. The programme successfully quantifies the occupational and environmental radiation exposure levels and demonstrates the effectiveness of the management system. The results of the programmes indicate that occupational and environmental exposures are low and well controlled with occupational levels averaging at 20 percent of the 20 mSv limit and the most exposed public group being less than 10 percent of the member of public limit of 1 mSv.

The monitoring programme is only one part of the overall radiation safety management system and this paper will outline the monitoring programme and exposure and dose assessment methodologies from a practical perspective.

ABSTRACT (See instructions overleaf)

The assessment of radon daughter exposure and dose to underground miners at WMC (Olympic Dam Corporation) copper and uranium mine is required to ensure that doses remain low and well controlled. The current methodology for exposure and dose assessment involves collecting information from employee time cards and combining this with the results of the routine workplace monitoring programme. This method, while very comprehensive, is labour intensive. Consequently, the approach to radon daughter dose assessment underwent a formal review to determine the most appropriate method. The review primarily examined various types of personal radon daughter dosimetry as options to the manual method and found that of the dosimetry examined, none was appropriate to conditions at WMC (Olympic Dam Corporation).

This paper will outline the review process and the results of the review.

RADIATION PROTECTION IMPLICATIONS FOR THE NORTH RANGER MINE

R F Auty[1], V A Leach[2] and G W Mitchell[3]

[2]COMPRAD Pty Ltd, PO Box 3003, Clontarf, Qld 4019, Australia
[3]G W Mitchell & Associates Pty Ltd, 67 Hinkler Crescent, Lane Cove, NSW 2066, Australia

INTRODUCTION

The North Ranger ore deposit is located approximately 20 kilometres north of the existing Ranger mine and mill and 250 kilometres east of Darwin in the Northern Territory of Australia.

The proposed mining operation will use "open stoping" as its preferred method for recovering the ore; subsequently the ore will be transported to the existing Ranger mill for processing.

The Radiological assessment of an underground uranium mine is complex; it needs to assess the radiation exposure from three different pathways, namely gamma ray, radon progeny and radioactive dust exposure. Of the three pathways the assessment of radon progeny exposure is by far the most complex.

At the North Ranger mine radon progeny exposure has been minimised by good ventilation practice and is the least significant of the three exposure pathways.

Gamma radiation is the most significant exposure pathway and this is due to the grade of ore being mined and the mining method.

There are two major phases to the mine development (Case 1 and Case 2 - 600 000 and 900 000 tonnes per annum respectively) and therefore two distinct radiological assessments have been made in line with the mine ventilation and production schedule.

RADON PROGENY MODEL

In ventilating a uranium mine the knowledge of the distribution of radon progeny throughout the ventilation system is essential. The major source of radon gas into the air is from the walls, floor and roof as the air travels down the drives. In the ventilation model the width of the ore intersection for each airway is entered as well as the estimated uranium ore grade. This was achieved by overlaying the ventilation design plans and sections with the geological block model and where any development intersected ore greater than 0.05 % U_3O_8, ore grades and widths were calculated. An emanation rate of 49 Bq $m^{-2}s^{-1}$ per % U_3O_8 was used (2).

The model calculates the average radon emanation rate, the air transit time, and the average radon progeny concentration for each branch, finally the average radon progeny concentration was calculated for each worker category. Full details of the radon progeny model can be found in (3).

GAMMA RAY DOSE RATE MODEL

The theoretical calculation of gamma exposure rates for a rectangular tunnel was used. The various elements such as attenuation of gamma ray by shields and build-up of gamma rays due to a broad beam source (ore) and thick shields (waste rock on the floor and shotcrete on walls and roof) were considered.

The theory shows that geometry is critical to the exposure rates calculated. However, the theory can not take into account the non-uniform nature of the ore in a tunnel and the shielding provided by machinery (4). It appears that theoretical gamma dose rate models may overestimate the actual dose rate by a factor of about two.

This study assesses the theoretical model "Gamma Model A" and a practical model "Gamma Model B" that uses a dose rate of 50 μSv h^{-1} / % U_3O_8 (4).

Gamma Model A uses theoretical calculations (5), it derives the exposure rate per unit solid angle in an orebody and gives equations for calculating the solid angle subtended by various surface slopes. The resulting theoretical gamma dose rate was 109 μSv h^{-1} / % U_3O_8.

DUST MODEL

The literature survey by Leach (6) showed that for 0.1 per cent uranium ore grade, the typical long-lived alpha activity is, at worst, 0.05 Bq m^{-3}. Similar results have emerged at Olympic Dam, a modern copper/gold/uranium underground mine.

To calculate the effective dose due to the inhalation of uranium ore dust, an average long-lived alpha dust concentration of 0.1 Bq m^{-3} was assumed. This figure was extrapolated from data from Olympic Dam. It is recognised that the actual dust concentrations will vary greatly depending on locality and activity.

WORKPLACE OCCUPANCY

For the purpose of calculating radiation doses to workers it has been found useful to group various workers into categories. This process assists in the administration of radiation protection practices and dose assessments. Five major categories have been determined with these categories being further broken down into various work functions. The locations which the various worker categories occupied during a shift are divided into three specific work place areas, namely high, medium and low grade areas (0.45 %, 0.13 % and 0.02 % U_3O_8 respectively).

DOSE ASSESSMENT

The dose assessment model was developed to estimate likely doses that may be received by the various worker categories.

For each worker category the percentage of the effective hours worked that was subject to shielding were estimated together with a shielding factor. Three forms of shielding were included in the model: equipment shielding, work place shielding due to waste rock on the floor and shotcrete on the walls and roof of ore drives, and, thirdly, the attenuation of dust provided by the air-conditioning on the various types of mobile equipment.

The dose assessment model uses the following shielding factors:

Equipment shielding for gamma	-	50 %
Equipment shielding for dust	-	50 %
Workplace shielding for gamma	-	57 %

The model gives individual work function dose estimates as well as average dose estimates for the five other category groupings.

Table 1 gives the estimated doses for the various work categories using the Gamma Models A and B for Case 1 and Case 2 and the various shielding combinations.

RESULTS AND CONCLUSIONS

Table 1 shows that workers involved in development and supervision receive the highest doses. It is likely that the practice of shielding afforded to the development crews will be less than that for production workers because of the work they perform. In the same way, supervisors will receive higher doses as they experience less equipment shielding. However, when shielding is applied to the high grade cross-cuts to attenuate gamma rays it is possible to reduce the predicted radiation doses to all work categories.

For development and production drillers in particular, advances in equipment technology permitting remote or automatic drill operation may be feasible in the future and would further reduce radiation levels.

If the ventilation design principles are adhered to then the exposure to radon progeny will be low.

A breakdown of the three components of the dose received by development and production categories can be seen in Table 2.

By designing the ventilation system to provide fresh air to each work place as quickly as possible and then exhaust the air, radon progeny exposure is minor.

The gamma radiation is by far the most significant exposure pathway and this is primarily due to the grade of the ore and the mining method. It is therefore necessary to attenuate the gamma rays by use of shotcrete on the walls and roof and waste rock on the floor in the high grade cross-cuts.

Proper management and minimisation of time spent in high grade cross-cuts is critical for the overall control of radiation doses.

With a properly designed ventilation system, shielding, and management control of operator exposure, it is feasible to mine North Ranger in a regime of 20 mSv per annum radiation limit.

MAJOR SCIENTIFIC TOPIC NUMBER: 5.1 (8.8)

In Romania, untill 1989, state economical and political reasons requiered to give up using individually dosemeters, in the uranium mines.

It atteined that object by an intensive disinformation campaign based on the extreme poverty of workers and their desir to obtein "unpropers" benefits - special rights for the exposed people (almost vital, for anyone). The slogan was that radiations danger for the human health is only "fairy tales". Ideas were:

1. If EDE admitted is reached, it significates that miners must nomore work in exposed places so, **they will nomore have the special benefits.**

2. If EDE admitted is not reached, it significates **there are no reasons to give them these special benefits.**
So, the individually dosemeters were completely discredited and nobody regretted them!

The Special Service (S.A.D.) created to monitorise the occupational exposure in any working place had insufficient earmarked money and its members were forced to don't register unpleasant data.

In present, in other forms but partly from the same reasons, the situation goes on (individually dosemeters are still not used).

A sustainable solution is to aware the workers. Public NGOs could assume an important role but they are not agreed (it attached to them the image of "public ennemy no. 1" and their members working in nuclear lostes their working places). In Romania, almost everything about radiations is still "top secret" so, NGOs interrested must activate in other domains, for the moment, and approaching to radioactivity with maximum of prudence.

RADIATION DOSE CONTROL IN THE MINING OF HIGH GRADE URANIUM ORES

Stephen T. Webster[1] and L. Denis Brown[2]

[1]Saskatchewan Labour, 122 3rd Avenue North, Saskatoon SK, Canada, S7K 2H6
[2]BB Health Physics Services, 55 Leopold Crescent, Regina SK, Canada, S4T 6N5

Introduction

The control of radiation doses received by uranium miners is an unusually complex procedure, as three separate components of their total effective dose may be significant and may have to be evaluated separately. Apart from external and internal doses evaluated in the usual way, it is also necessary to evaluate the inhalation dose from radon progeny separately. Although this essentially forms part of the internal dose received, it is not evaluated in the conventional way since the associated dose equivalent must be derived from conversion factors based on epidemiological studies, instead of by the usual approach of calculating the dose to tissue from the inhaled activity and multiplying this by a recognised conversion factor to derive a whole body effective dose. Historically the traditional unit used for monitoring the concentration of radon progeny in a workplace is the Working Level (WL), this is now defined as a concentration such that the potential alpha emission from all the short lived progeny present in the sample will total 1.3×10^8 MeV per m^3. The corresponding unit of exposure is the Working Level Month (WLM) and is the exposure that would be received by a reference man working in such an atmosphere for a standard working month lasting 170 hours. Unfortunately the relationship between exposures, measured in WLM, and the conventional radiation dose to the target tissues is complex and calculated values depend greatly upon the assumptions made in the lung model that must be used. Risks are therefore still controlled by limiting exposures in WLM on the basis of epidemiological studies of lung cancer incidence among miners employed at a time when the magnitude of the risk was not fully appreciated, and cancer incidence was high enough to permit reasonably accurate risk estimates to be derived directly from exposures in WLM.

The Mining of High Grade Ores

Where the grade of the ores being mined is relatively low, the risk to underground workers is dominated by the inhalation of radon progeny; and frequently in the past the contributions to the worker's total radiation dose from gamma radiation, or the inhalation of ore dust containing uranium and its long lived decay products, was neglected in comparison. This is no longer acceptable, both because the majority of ores currently being mined are of far higher grade than was usual in the past, and because radiation dose limits for occupationally exposed workers have been reduced significantly. In other industries the introduction of lower dose limits has generally not led to serious difficulties, revised working procedures, coupled with better shielding, have ensured that the new standards can still be achieved. This can be much more difficult in the case of the mining of high grade uranium ores. Conventional mining techniques can result in the worker being surrounded by ore, this leads to an omnidirectional gamma flux from which it may be very difficult or impossible to shield the worker effectively. Radon concentrations are traditionally reduced to levels that are acceptable by ventilating the workings with fresh air brought in from outside. If the radon emission rate is too high this may require such massive ventilation systems that all operations have to be carried out in near gale force winds. Such high ventilation rates lead to very exhausting working conditions and will, in turn, also increase the resuspension of dust in the workings. When the grade of the ore is very high, this can also lead to a large potential dose to the miners from long lived radioactive dust inhalation. Ultimately, in the case of very rich ore deposits these problems become so severe that conventional mining methods cannot be attempted . Consequently in Saskatchewan, where several such very high grade deposits are currently under development, the approach has been for the development of new technologies in which the miners are excluded from the workface and operate from higher or lower stopes lying outside the main ore body, with all ore being extracted by means of remote boring operations.

Such automated mining methods need to be planned in detail right from the moment when the development of a new mine is first considered, they cannot usually be economically introduced into an existing mine. In such mines, meeting the more stringent standards required to comply with ICRP 60 recommendations may have to be accomplished without the introduction of fully automated mining methods. The provincial Occupational Health and Safety Branch has therefore been investigating the magnitude of the problems likely to be encountered, and the changes in working procedures which may be possible and may help in alleviating these problems. Since each mine is fundamentally different there is not a large body of existing data that can be accessed, and it was found to be necessary to conduct a series of studies in some of the existing mines which were designed to determine the relative importance of the three different components of the miner's dose for groups of workers in different categories.

Contributions to the Miner's Effective Dose

The whole body dose limits for occupationally exposed workers recommended in ICRP 60 are 50 mSv effective dose in any one year with an average of not more than 20 mSv per year over any five year period. In the case of uranium miners, compliance with these recommendations requires that for both the one and the five year period the external gamma ray dose received by the worker, expressed as a fraction of the one or five year limit, added to the inhalation dose from long lived radioactive dust, expressed as a fraction of the ALI (or five times the ALI as appropriate), and to the separate inhalation doses from radon and thoron progeny expressed as fractions of the corresponding one or five year limits, does not exceed unity. Clearly maintaining records designed to provide both one and five year summation doses on an ongoing basis for every miner places complex requirements on the mine operator. Monitoring, recording and reporting all these components of the miners total dose also involves a number of very complex considerations, including the relative importance to be attached to personal and workplace monitoring. The recommended procedures for meeting these requirements are still being extensively studied and no final decisions have yet been made as to the procedures the mine operator will be expected to adopt, although it is recognised that the relative importance of the various contributions to the total radiation dose experienced will differ considerably between one mine and another. This will prevent agreed universal dosimetric protocols being developed and means that the procedures adopted by each mine will have to be agreed between the appropriate regulatory agency and the mine operator at an early stage. To enable realistic requirements to be formulated it will be necessary for all parties be very clear as to the relative importance of each contribution to the workers dose in each individual mine.

The only type of personal dosemeter which is currently available and which has the capability of being used to determine all these contributions to the workers total dose is the CEA track etch monitor which has been further developed in Canada and is supplied here through the Canadian Institute for Radiation Safety. Essentially this monitor employs an active filtration technique, it is worn on the workers belt and samples the ambient air in which he works. Alpha particles from the radon progeny collected on the filter paper pass through a mechanical spectrometer and impact on a conventional plastic foil where their tracks are displayed following etching. The alpha tracks in each energy group enable the radon and thoron progeny present to be individually identified. Subsequently the residual activity on the filter paper can be used to evaluate the long lived alpha emitting dust that was collected. If the external gamma dose is not being monitored by other methods, this can also be determined by incorporating a TLD chip into the dosemeter system. Personal dosemeters of this type have been in routine use in some Saskatchewan uranium mines for the evaluation of radon progeny dose for more than a decade, but until recently no attempt has been made to use them to determine the internal dose received from the inhalation of long lived radioactive dust. In 1991 the Saskatchewan Occupational Health and Safety Branch, in conjunction with the Canadian Institute for Radiation Safety, initiated a research project designed to determine what proportion of the dose received by workers in different categories was associated with each of the contributing factors that have been discussed above, and also what problems might be expected in attempting to meet the more stringent dose limits of ICRP 60 in some of the operating mines in Saskatchewan. Some of the results of this study can be seen on the two figures below which show the distribution of effective doses among different categories in the workforce both as they are under the present dose limits and as they would be under the new dose limits recommended in ICRP 60.

Conclusions from this study

It is important to recognise that evaluating the risk from the inhalation of uranium dust involves consideration of chemical toxicity as well as radiological dose, and that both of these quantities will be strongly influenced by the solubility of the uranium in the dust. In this respect the dust inhalation risk for millworkers, which arises primarily from processed yellowcake, will be quite different to that for underground miners. Neither can be directly calculated in terms of the listed ALI without consideration of the solubility of the dust compared with the solubility of the compounds for which the ALI was determined. These considerations may warrant a re-examination of the absolute value of the dust component of the workers dose used in preparing the following figures, but nevertheless the data presented here is not generally available from other sources and provides a great deal of useful information about what are likely to be the principle problem areas when ICRP 60 limits are first implemented in existing Saskatchewan uranium mines. The most important conclusions to be drawn from this study are that mill workers already receive doses well below the intended new dose limits, and that this also applies to several other categories of the total workforce. It is only in the case of underground miners extracting high grade ore by largely traditional methods that there appears to be any significant likelihood of individual annual effective doses exceeding 20 mSv. With high grade ores, sufficient mill stock for an extended period of milling can be extracted in a relatively short time and these underground mines are therefore generally operated on a seasonal basis. This has led to a situation where the existing practice in Saskatchewan is for such mining to be carried out under contract and not by permanent members of the mine workforce. With careful monitoring, it would then be easy for the contractor responsible for the mining operation to divert members of the workforce who were approaching their acceptable dose limit into a non-uranium mine where no significant radiation dose was encountered. This makes it unlikely that there would be any intrinsic difficulty in implementing ICRP 60 in such mines. Whether it would be regarded by the regulatory agencies as acceptable to continue mining in working conditions where the permissible annual dose limit might well be approached after significantly less than a full years work, is a different issue. Ultimately ALARA and optimisation are best satisfied by operating mines under conditions where there is a maximum of product per unit of collective dose received by the workforce. With high grade ores, large volumes of yellowcake can be produced by a relatively small workforce; and, even though individual doses may be higher, this requirement is therefore much more likely to be satisfied than when mining lower grade ores.

SEARCHING FOR A LOST RADIOACTIVE SOURCE IN A MINING-MILLING FACILITY

José Olympio N. M. de Castro, Murillo Senne Jr

Comissão Nacional de Energia Nuclear

Centro de Desenvolvimento da Tecnologia Nuclear

Belo Horizonte - MG, Brazil

THE INCIDENT

The mining-milling facility in question has a radioactive level gauge installed at the beginning of its conveyor-belt system, used to turn it on when the run-of-mine ore reaches the chemical plant. The gauge was not in use when the incident occurred (radioactive source installed, detector and associated electronics not installed), the conveyor-belt being controlled manually.

During a routine inspection, a maintenance worker found the inner part of the gauge's lead shielding on the floor. Since he knew that that equipment was "dangerous", he called a technician supposed to know how to deal with it. The technician monitored the fallen piece, found no activity and concluded, erroneously, that the radioactive source was inside the shielding (actually, his detector was not working). The fallen part was put in its place. All this happened in a Saturday, October 1st, 1994, beginning of a long weekend, so the occurrence was only reported to the responsible for the radiation protection in the following Tuesday.

THE SOURCE

The lost source was a 185 MBq (5 mCi) Cs-137 source, of unknown making. A bibliographic search led us to believe that the radioactive material was prepared as a vitrified pellet.

AN ANALYSIS OF THE CAUSES OF THE OCCURRENCE

The gauge is installed on an equipment subjected to a high level of vibration. Since no preventive maintenance was routinely made, the vibration destroyed a safety pin which impeded the inner part of the shield to be removed. This was the cause of the mechanical failure.

Notwithstanding, it should be concluded that the incident, the loss of control over a radioactive source, was caused primarily by the mismanagement of the radiation protection matters in the facility without trying to be exhaustive, we can point: lack of preventive maintenance, source installed without motive since the detector was not installed; incompletely trained technician; lack of a routine to check the functioning of the sole radiation monitor of the facility; responsible for radiation protection with other more pressing activities.

THE SEARCH FOR THE SOURCE

On October, 18th, 1994 the engineer in charge of radiation protection of the facility, feeling unsecured with the situation, contacted our Center, asking for help, 17 days after the probable loss of the source.

Our emergency group, using scintillation detectors, searched for the source all over the facility, as well as the houses of all employees with even a remote possibility of inadvertently having take the source home. We found nothing.

During this unfruitful search for the source we noticed that the ore that have fallen under the conveyor-belt

was frequently swept and introduced again in the process. Reckoning that there was a good probability of the source being also processed we started looking for activity in ore samples collected for process control.

The samples were counted in a HPGE detector, in a low background shielding, for periods of 24 hours each. We found clear peaks of Cs-137 in the samples collected at points 1, 2 and 3 (Figure 1).

The first activity was detected at point 1, on October, 14th, that is, 14 days after the date on which we believed the source was lost. This delay should be attributed to the big ore storage bin that exists between the conveyor-belt and the input to the flotation cell bank. At the same day the activity was detected at the output of the flotation cells (overflow, point 2), which is understandable if we consider the low inventory of material in the flotation cell bank.

On the other hand, it took at least 2 more days for the activity to appear at point 3, the output of the concentrate stock tanks, were it appeared extremely diluted. This time leg and dilution can be easily explained by the volumes of the mill, thichener and concentrate stock tanks.

THE FATE OF THE CONTAMINED ORE

With the sparse data we get, the best conclusion to which we could arrive is that a good part of the activity went to backfill the underground mine and to the tailings pond. Part of it, however, entered the process and, probably, reached the end product. In this product, we were not able to find any activity, at least in the limits of sensitivity of portable scintillation detectors.

It should be noted, too, that the dilution of the radioactive material was very high, leading to contamination levels below regulatory limits (1,2).

ANALYSIS OF DIFFERENT MEASURING METHODS APPLIED IN EVALUATION OF INDIVIDUAL EXPOSURE OF MINERS TO RADON DAUGHTERS.

J. Olszewski

The Nofer Institute of Oecupational Medicine
8 Sw. Teresy Str. Pl-90950 Lodz POLAND

INTRODUCTION

Various measuring techniques are used for the evaluation of individual exposure of miners to radon daughters in Polish mines. Among the most widespread techniques are: passive dosimeters, mining radiometers and ALFA-31 detection unit to passive Barbara 3A dustmeters. The individual, active dosimeter is also prepared to be used.

MEASURING METHODS INCLUDED IN THE COMPARISON

The Mining Radiometer

The mining radiometer (RGR) is a portable device destined to the measurement of momentary concentrations of alpha potential energy of radon daughter products in the air. The radiometer can work in the automatic cycle, acc. to Markov's method [1], or the manual cycle, acc. to an optional method. The measurement is based on the filtration of a particular portion of air, containing radioactive aerosols, through the filter. A number of alpha particles emitted from the filter is counted by means of the semiconducting detector. The usual time of filtration is 5 min. The flow of air is 2 l/min.

The ALFA - 31 detection unit to Barbara 3A dustmeters

The ALFA - 31 detection unit to Barbara 3A dustmeters is used to the periodic measurement of concentration of radioactive aerosols in the mine air. The measurement is based on pumping over of air portions through the filter. The concentration of radioactive aerosols is calculated by means of thermoluminescent detectors $CaSO_4$: Dy. The time of air filtration is about 8 h [2].

The Passive Dosimeter

The passive dosimeter is used to the measurement of exposure to radon daughters or the periodic concentration of these daughters in the air. The track detector of alpha radiation, type Kodak LR 115 foil, is used in the dosimeter [3]. Chemical etching of tracks detectors enables the analysis of tracks' density on their surface, on which basis it is possible to establish the exposure or the periodic concentration of radon daughters.

The Active Dosimeter

The active dosimeter is applied to measure the exposure to radon daughters or the periodic concentration of these daughters in the air. It comprises a measuring head joined to a micropump by means of a flexible tubing. The air is sucked in by the micropump and radioactive aerosols deposit on the filter. Alpha particles emitted from the filter are registered by the track detector (type Kodak LR-115) placed in the head.

THE COMMENSURABILITY ANALYSIS OF MEASURING METHODS

Research of commensurability of measuring methods was carried out in radon chamber [4]. The measurement of radiational conditions in the chamber was made by means of a special measuring system calibrated with radon generators (Pylon Company from Canada). The measurements were carried out by means of the method of two filters.

Concentrations of radon daughters were measured simultaneously by means of the above mentioned methods. The results of measurements for the ALFA-31 detection unit and the RGR mining radiometer are shown on the figure 1.

POLISH ACTIVE DOSIMETER FOR MEASUREMENT OF INDIVIDUAL EXPOSURE OF MINERS TO RADIOACTIVE RADON DAUGHTER PRODUCTS.

J. Olszewski, W. Chruścielewski, H. Skalski

The Nofer Institute of Occupational Medicine
8 Sw. Teresy Str. Pl-90950 Lodz POLAND

INTRODUCTION

The widespread occurence of radon ^{222}Rn and its daughters, which together with dust make radioactive aerosols, in Polish mines requires several alternative methods of measurement, considering the wide range of existing concentrations. One of these methods is the individual, active dosimeter worked out in The Institute of Occupational Medicine in Łódź used to measure exposures to radon daughters which a miner gets while working under ground.

CONSTRUCTION OF THE ACTIVE DOSIMETER

The active dosimeter for the measurement of individual exposures to radon daughters consists of a measuring head connected with a micropump by means of a flexible tubing. This solution enables to place the measuring head in miner's breathing zone.

Construction of the active dosimeter was based on the micropump AP-02 made in Poland. The chosen technical data of the micropump: air flow - 30 ml/min; working time from accumulators' batteries NiCd - 24 h; micropump's mass - 0,4 kg; casing dimension - 140x75x56 mm.

The micropump is supplied with the liquid-crystalic projector of cycles' number of the pump's work [1].

The measuring head used in the active dosimeter was designed in the Institute of Occupational Medicine. The scheme of the head is presented on the figure 1. The head is supplied with a microcyclon which has to separate particles of dust of the diameter bigger than 5 μm. The air sucked in by the micropump passes through the microcyclon, and then through the head's chamber, filter and pump's chamber. Radioactive aerosols deposit on the filter. Alpha particles emitted from the filter are registered by the track detector; type Kodak LR-115 [2,3] placed at the bottom of the measuring head, opposite the filter. That flow of air causes that the succeeding layers of dust are not a barrier for the alpha particles coming from the products of radon disintegration. After the exposure, the track detector undergoes chemical etching and microscopic analysis, so as to read the density of tracks on its surface [4].

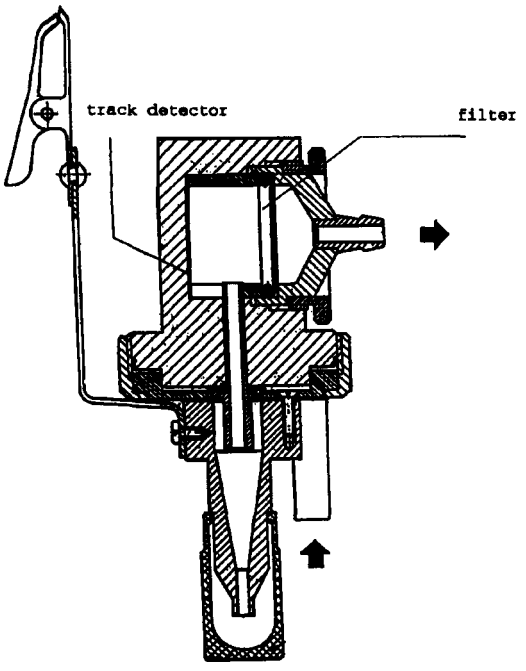

Figure 1. Scheme of the measuring head of the active dosimeter.

PREPARATION OF THE ACTIVE DOSIMETER FOR WORK

Preparation of the active dosimeter for work is mainly based on carrying out the calibration of the dosimetric head. The aim of the calibration is to set the factor K_{WL} defined as:

$$K_{WL} = \frac{g}{E_{RnDp}}$$

where:

g - [trs/mm^2] - surface density of tracks read out from the detector;

E_{RnDp} - [mJh/m^3] - exposure to radon daughters.

Calibration of active dosimeters was carried out in the radon chamber [5]. Each active dosimeter has its own, set calibration factor, considering the fact that there are individual differences of speed of air flow between micropumps. Calibration research showed the independence of the calibration factor from the coeficient F for dynamic radioactive equilibrium between radon and its decay products. The average value of the K_{WL} factor was 10,5 ± 0,5 [(trs/mm^2)/(mJhm^3)]. Research of the stability of the flow of air through the micropump, made by means of the measurer of Digital Flow Calibrators (made by SKC company) showed high stability of the air flow. Measurements of flow were made before and after the exposure in the radon chamber, putting the clean filter to the head. Standard deviation of the measurements was 1%.

MEASUREMENT OF INDIVIDUAL EXPOSURES OF MINERS TO RADON DAUGHTERS

The active dosimeter will be individually given to a miner. The micropump of the active dosimeter will be turned on in the moment of miner's going under ground, and it will be working all the time till he will finish his work. After the end of the work there will be the change of pump's accumulators lasting until the moment of the next miner's going under ground with the dosimeter. The filter of the measuring head is changed twice a working week so as to enable the continuous air flow. After the measuring cycle (1 month), the track detector is changed. On the basis of the read out density of tracks from the detector's surface, there will be established the exposure to which a miner was exposed. There is the special manual for miners who make measurements of individual exposures to radon daughters by means of the individual active dosimeter.

SUMMARY

The active dosimeter worked out in the Institute of Occupational Medicine was tested in the mine of zinc and lead. Fifty monthly measuring cycles were made. The test confirmed the usefulness of the active dosimeter in measuring individual exposures of miners to radon daughters.

However, taking into account high costs of the measurer and great labouriousness of measurements, the use of this dosimeter will be limited to cases where there is considerable radiational danger in a mine.

ABSTRACT

Uranium mining grew fast in saxonia after second world war. No radiation protection was performed in the first "wild" years (1946-1954). Winning with air hammer and drilling had been done without dust reduction and led to an enormous airborne dust concentration. These bad working conditions were unique world-wide. Measurements of dustborne activity concentrations had not been taken. To reconstruct the exposure conditions of miners in these years, four series of experiments under original working conditions were carried out. Stress must be laid on the fact that these measurements should result in the received doses according to uranium and it's long living daughters. Personal and stationary air samplers were used to collect the dust. Activity concentration measurements were done by Gamma spectrometry.

INTRODUCTION

To verify the order of magnitude of the exposure to long living radon-daughters the miners had been exposed to in the first years of the WISMUT, the exposure conditions should be reconstructed as original as possible. To do so, the old pickhammers, the original drilling equipment and other original tools had to be used. Also the poor ventilation conditions had to be reconstructed. In the first years of mining, no technical ventilation was used.(Ventilation speed under 0.1 m/sec). These ventilation conditions could be reached through additional ventilation doors, installed near the experimental area.
Substantial for the large dust concentrations during the investigationes was the fact, that drilling and ore winning had to be done dry as it was done from 1946 until 1954. Four experimental series were carried out in the ore fields of Schlema-Alberoda, Ronneburg, Johanngeorgenstadt and Schneeberg.([1],[2],[3])

MATERIALS AND METHODS

Substantiell contributions to the dust emission did only result from dry drilling and dry winning with pick hammer. The other working activities could be omitted as the measurements had shown.
The dust-sampling was done with stationary and personal sampling-eqipments. Fine- and total dust was sampled separately.. To get an idea of the particles diameter cascade impactors were used.
Each experiment series resulted inmore than about 100 samples which had to be analysed later on in laboratory. The dust concentration had been evaluated by determine dust mass and division through sampling volume.
After verifying the radiological equilibrium with alpha spectrometry, the determination of activity was done by Gamma spectrometry. After decay of the short living Rn-daughters, the activities of the two nuclides Pb-214 and Bi-214 could be measured as representatives for the uranium decay series. Uranium concentration was although measured by chemical analyses

when signal for this purpose was high enough. The results of both methods show sufficient agreement.
Taking into account the exhausting work of drilling and picking a breath rate of 1.5 m^3/h was used for further calculations. The different work done during the shift was analysed and a matrix was evaluated containing values for breath rate, working activity and yearly working time. Multiplication to the measured activity concentration resulted in a yearly intake. With regards to the radiological equilibrium the amount of the yearly inhaled activity is the same for each nuclide in the uranium decay series. Based on the new lung model selected tissuedoses were calculated.

RESULTS
The following tables show the result of measured nuclide-concentration, the estimated yearly intake and some tissuedoses.

Schlema-Alberoda

occupation	time-h/year	breath-rate m^3/h	activity-concentration from	Bq/m^3	up to	input Z^{238} from	Bq/year	up to
picking	525.0	1.5	14.9		71.3	11,734		56,149
drilling	472.5	1.5	1.2		5.3	851		3,756
rest	1,522.5	1.2	0.08		0.15	146		274
sum						**12,731**		**60,179**

(mSv) per yearly intake of all nuclides of the uranium decay series in the determined range of about 13 kBq up to 60 kBq:

lung	bone surface	kidneys	bone marrow	liver	spleen
800 - 3600	900 - 4000	80 - 400	70 - 300	130 - 600	40 - 190

Schmirchau
From the 480 minutes of one shift only 120 minutes drilling time were taking into account, because in Schmirchau we have sediment ore and therefore no worth mentioning picking was done.

time-h/year	breath-rate m^3/h	activity-concentration from	Bq/m^3	up to	input Z^{238} from	Bq/Year	up to
628	1.5	1.333		4.540	**1,256**		**4,277**

Estimated dose equivalent commitments (mSv) per yearly intake of all nuclides of the uranium decay series in the determined range of about 1.3 kBq up to 4.3 kBq:

lung	bone surface	kidneys	bone marrow	liver	spleen
80 - 258	90 - 287	8 - 29	7 - 22	13 - 43	4 - 14

Johanngeorgenstadt

occupation	time-h/year	breath-rate m^3/h	activity-concentration Bq/m^3 from	up to	input ^{238}U Bq/Year from	up to
picking	472.5	1.5	2.33	2.82	1,654	1,997
drilling	630.0	1.5	0.17	0.45	162	421
rest	1,417.5	1.2	0.08	0.15	146	274
sum					**1,962**	**2,692**

Estimated dose equivalent commitments (mSv) per yearly intake of all nuclides of the uranium decay series in the determined range of about 2 kBq up to 2.7 kBq:

lung	bone surface	kidneys	bone marrow	liver	spleen
119 - 160	132 - 178	12 - 16	10 - 14	20 - 27	6 - 8

DISCUSSION

Until now radiation exposure of miners was presumed resulting substantially only from short living Radon daughters. The presented investigations show, that the exposure to the long living decay products beeing taken up by the dust, could contribute fairly high to radiation exposure. Of course this is valid especially for the first years of the WISMUT, while dry drilling and dry ore winning had been performed.

The results are of course first restricted to the experimental situationes. Next step will be to evaluate models to expand the results to other situationes. It is no doubt, that only few of the large number of influencing parameters can been taken into account. Nevertheless will this lead to best known approach to the dosimetric situation of the miners.

The experiments already resulted in a reavaluation of the probility of causation for extrapulmonary cancers of the miners. As known, in former times only lung cancers had been acknowledged as occupational diseases of uranium miners induced by radiation. Taking into account the new results, these cases are now under revision.

RECONSTRUCTION OF THE COMPLEX JOB-EXPOSURE-MATRIX FOR IONISING RADIATION IN DIFFERENT SITES OF THE URANIUM MINERS IN THE FORMER DDR

F. Lehmann[1]; J. Renner[1]; G. Seitz[2]; T. Ludwig[2]

[1] Bergbauberufsgenossenschaft; Gera
[2] Berufsgenossenschaft der Feinmechanik und Elektrotechnik; Köln

As now well known, in the uranium mines of the former DDR higher collective dose had been accumulated as workforce had ever before been exposed to.
More than 400,000 workers had been employed between 1946 and 1990. More than 5000 cancer diseases have been acknowledged as occupational induced by ionising radiation.

The German workmen compensation institutes, who are responsible for the rehabilitation and compensation of occupational accidents and diseases, started a great investigation and research program to secure and evaluate millions of data files and medical reports, stored in the magazines of Wismut, which can contribute to our knowledge of the biological consequences of ionising radiation. Also included in this program is a project for evaluating a job-exposure-matrix [JEM] of those workers.
Of course the project is divided in several sub-projects and a lot of institutions are contributing.

The Bergbau BG (Industrial Injury Insurance Institut [IIII] for the mining Industry) together with the Institute of Radiation Protection of the IIII is working on the JEM.

The idea is, to evaluate -either by data files or by experiments- mean annual exposition from all sources of ionising radiation (that means: Rn; Rn-daughters, Uranium in dust, external gamma exposition) for certain reference-jobs and reference sites and estimate the job-related exposition by scaling for other jobs and sites.

To do so, it must be taken into account, that the expression „WISMUT" does not describe a single site ore factory but a trust which had run more than 30 different mines with more than 400 shafts and tunnels. Surface mining as well as processing plant were operated.

The situation becomes even more complicated when knowing, that a larger number of those facilities had only short operating time and had been shut down 20 or 30 years ago.

The largest problem is given by the missing radiation measurements of the first 10 to 15 years. The first, single measurements of Radon Gas and Photons have been performed 1955. Systematically performed measurements of Radon and short living Radon daughters have not been started before 1967.
That also indicates, that the exposure situation in the first ten years of operation, can not be evaluated by existing measurements. (Experiments to fill this gap of information are described elsewhere in this proceedings.)

Some information is expected to be delivered by a study which is performed by colleges in the former CSSR which has to be implemented in the project.
Other information had already been taken from files who had been kept in Russian records in Moscow. More than 20,000 pages of (written) text and 8,000 mine-drawings have been bought back from there and have already been evaluated.

The project will be finished during 1996 with the reports of the 6 main sub-projects:

1. Radiation protection in the Wismut Mines

2. Radiation exposure in the surface mines of the Wismut

3. Radiation exposure in the processing plants of the Wismut (finished 1995)

4. Radiation exposure in the Thuringia underground mines of the Wismut

5. Radiation exposure in the Saxonia underground mines of the Wismut

6. Radiation exposure by Radon daughters in public mines of the former DDR.

It is of course expected, that the derived JEM, which is first evaluated for compensating purposes is of great value for the just started epidemiological research on the subject.

MONITORING URANIUM DUST CONCENTRATION IN A MINING CONCENTRATE CONVERSION PLANT INTO UF4 AND UF6

COMURHEX is a plant for converting mining concentrates into UF4 and UF6. The operations are carried out in various facilities. The atmosphere of these shops is monitored daily using APA's (Aerosol Sampling Apparatus) placed in selected locations depending upon the work stations used by the operators.

The samples are measured daily; a first count is made immediately after sampling and a second one three days later. The first and second counts are plugged into a computer program developed within Comurhex-Malvesi. This program enables the data in $Bq\alpha/m^3$ and $Bq\beta/m^3$ from the APAs to be displayed for each shop on individual diagrams and for the whole of the APAs of the plant on a single diagram.

Guide values are reference values corresponding to the usual values for the shop. They are indicated on the diagram for immediate comparison with the present values.

It is possible to display each APA over a set period. The period that is displayed by default is the last 30 days. Incidents and gradual drifts may thus be identified immediately.

Each incident may be commented and the commentary introduced into the program. A very quick access to them makes querying given events easy.

This program allows, from a medical standpoint, to target urinary uranium analyses on workers: any increase of the APA values over a given threshold and/or a certain period of time results in another urinary uranium analysis. These analyses are done on top of the systematic analyses performed periodically.

This program comes also in support of the operators for the maintenance of their shop. It allows the facilities where repetitive incidents occur to be pinpointed much more easily and, better still, to locate those where a gradual drift occurs.

For Comurhex, this program is a tool which makes the medical surveillance of workers easier and helps the operators in the maintenance and management of their shop.

3. EDF DER Research and development department

1 - EDF General Policy in terms of and remote systems for the nuclear generation capacity

Safety and competitiveness are the sine qua non conditions to the durability of the nuclear industry in France, as in the other countries involved in electronuclear programs.
Improving safety, increasing availability and mastering the costs are inseparable and interactive aims, and the cooperating actions are to be managed simultaneously.

Another aim is the undivided attention given to radiation protection. The average annual collective dose per unit has slightly decreased since 1993 despite an increase in the circuit activity and the volume of the works. This result is not thoroughly satisfactory if compared to the performances carried out abroad on similar reactors.

EDF has therefore decided to revise the establishments of contracts with the contractor companies on the following bases :
- a lasting partnership bases on common aims, mutual obligations, and shared benefits
- complete and better integrated services, giving the companies a greater responsibility on the means to be implemented to achieve those aims
- pluriannual contracts, enabling the companies an improved insight of the future load, and thus giving them the opportunity to invest (in personnel training, in tools or in innovation processes, etc.),
- permanent research in the field of the best technologies available in France and abroad, through supplier diversification and international experience feedback.

2 - Maintenance: main intervention field of robotized or remote systems

Robotics is an improvement factor for **maintenance** together with the optimization of programs and organizations and the improvement of performances of the repair **processes** implemented.

Robots are used to implement, in a generally hostile environment, maintenance processes for which the maintenance contractors and EDF have at their disposal specialized skill, mainly :

- welding and related techniques (machining, cutting, ...),
- non-destructive examinations (visual, ultrasonic, eddy currents, dye penetrant testing .),
- handling measurement instrumentation (metrology, vibration, temperature, exposure/contamination ...),
- setting up specialized tools (component assembly or disassembly ...),
- constraint works (setting up shields, air-locks, decontamination ...)

In the field of maintenance, robots and remote systems concern :
- the reduction of personnel exposure to irradiation and the anticipation of more severe regulations in this field,
- productivity increase aiming at an improved availability and a decrease in contractor costs,
- a higher tool changeability to reduce the direct development costs, the costs induced by the storage and the maintenance of contaminated components, as well as an improved integration of work sites requiring several successive processes during outage,
- a higher process reproducibility,
- an improved interventions data memorization capacity,
- adaptable solutions for exceptional or accidental situations in which man cannot act.

This list illustrates the many sides to developing robotized systems. Considering the nuclear plant specificities (geometry, admittance, environment), the development costs and the numerous targets aimed at, the purely technical approach is no longer adequate: the goal is to establish a system in which the maintenance processes, the economy in the broad sense of the term, and the participants are carefully assessed and measured out according to the aims. Apart from this "system" approach, developing robotized systems entails very severe technical and economical risks.

Robots and remote systems are globally considered as possible intervention means competitively to other means, in the following situations :

- Planned maintenance

The nuclear generation capacity maintenance is essentially preventive. The preventive maintenance operations concern components in a non-failure state and cover various techniques: inspections, examinations (eddy currents, ultrasonic, X rays,...), repairs (excavation cavity, welding,...). They are defined and planned according to preventive maintenance programs. Most are carried out during refueling outage occurring every twelve or eighteen months.

- Exceptional maintenance

Exceptional maintenance corresponds to repairing, refurbishing or replacing parts subject to unexpected damages. As an example, the crack in the vessel head adapters required the implementation of a three-fold problem determination strategy: adapter control to detect possible cracks, repair and refurbishment of the vessel heads. to this example. robots played an important part in the control.

- Post accidental interventions

The post accidental situations taken into consideration go as far as partial core meltdown with or without radioactive release outside the plant.

A distinction must be made between the needs in identification and preparation of the environment on the one hand, and the actual maintenance or operation interventions on the other hand.

Due to the high number of unknowns which are the main concrete characteristics in this type of scenarios, it has not been estimated realistic to enter into robots or remote systems to achieve maintenance (components repair or replacement ...) or operations (device operations...) strictly speaking.

The development focuses as a matter of priority on robotized or remote control systems for environmental survey (radioactivity, temperature, obstacles, identification of the state of equipment ...) prior to the operation itself. Robots or remote systems may nevertheless have a useful application as a means of assistance to the operator (tool carrier, protection shields ...) or even to carry out first level light interventions (sealing off leaks, picking up objects ...).

These applications are entrusted to GIE INTRA, in charge to developing and maintaining a set of mobile equipment into operation on behalf of three French nuclear operators : EDF, CEA (the French Atomic Energy Commission) and COGEMA.

- Robotized or remote systems maintenance of the future standardized plants

Experience feedback has shown the difficulties in relying on robots or remote systems when the interventions have not been considered in the original design of the plants. Being the industrial architect of its own plants, EDF takes part in designing the future plants so as, subsequently, to facilitate the implementation of robotized or remote systems. The arrangements contemplated mainly concern the high capacity communication networks, easy ways to achieve absolute locating in space, a less constrained spatial environment.

3 - Short historical review

During the design of nuclear power plants, a certain number of arrangements were made to facilitate maintenance operations, in so far as they could be planned. A certain number of accesses, of utilities, of pressure equipment access ports have thus been planned according to the corresponding timely criteria: maintenance type and volume, technology of the maintenance means, degree of equipment contamination, health physics regulations. In addition to the design rule book, there were compulsory in-service inspections criteria for the important to the safety equipment. To this effect, a certain number of tools were designed and supplied from startup: In-service inspection machine, automatic controller of the steam generator tube bundles

("Spiders"). As for a certain number of maintenance operations directly linked to plant operation, tools have been designed almost as early as the beginning to reduce personnel integrated doses or to improve the quality of operations (consideration for the parameters, traceability, productivity): simultaneous stud tensioning machines, fuel handling station.

These two concomitant factors modified the initial data and justified deep changes:

- the progressive discovery of youth defects requiring, on the one hand, interventions on equipment not initially planned in the maintenance programs, and, on the other hand, the intensification of control or maintenance programs on a certain number of equipment,

- the evolution of technologies in the field of maintenance tooling (power actuators, instrumentation and control equipment, sensors ...) which progressively enabled the development of remote machines such as spiders towards robots allowing a greater site integration and an increased supervision of operations.

Competition was therefore stimulating and the technical evolution enabled the realization OT the t projects. The robots thus replaced automatic machines. The [movements of the automatic machines (Spiders, SMOR...) are tdesign indexed according to the steam generator tube plate. They are controlled by on-off sequencers. The multi jointed robots (ARAMIS for FRAMATOME, ROSA for WESTINHOUSE, RITMIC for INTERCONTROLE, FLEXIVERA fort ABB-CE) can reach the entire work area, change tools or process without carrier replacement (See figures 1,2,3).

Technologically, this evolution was only possible because of the contributions from the industrial sectors independent from the nuclear industry: this is probably one of the main lessons for the future. To be more precise, this evolution was due to the contribution of hardware and software progress to instrumentation and control. All the instrumentation control "layers" have undergone profound evolution, from the lower level of servo-control up to the supervisor responsible for quality and data memorization capacity.

4 - Research and Development in Robots and Remote control at EDF

3.1 - Main objectives

EDF intend keeping a Research & Development activity in Robotics and remote control operations for several reasons :

- on the one hand, to have some knowledge and an ability of assessing the technologies available in France and abroad, a standing action of technological survey being carried out on the subject,
- on the other hand, to carry out research and development actions in a certain number of fields considered significant so as to have a technical expert assessment available, and to participate in the removal of certain technical locks; these: actions are either achieved on technological components (or technological bricks), or in selected subject themes.
- and lastly, to stress the interest of the process with laboratory experiments, and the possible improvements.

Part of this process is achieved within a pluriannual Research and Development Project: the START (Projet de Système de Téléintervention Avancé Robotisé Transposable, or "Advanced Remote Robotics system for Intervention project"). Part of this R&D also concerns the use of remote systems and robots for non nuclear EDF applications interventions on energized electric lines, robotized repair of hydraulic turbines bladings, etc.

4.1- Handling systems

The current approach consists in identifying the handling systems available on the market and to assess their capacities. Some adaptations and improvements may then be suggested and carried out. One of the handling systems withheld is the hydraulic industrial robotics arm (SCHILLING TITAN) with a high load capacity of around a hundred kilos as comparable to its own weight. It has been characterized and has been implemented for various demonstration operations in remote control or robot mode.

It proved necessary to have a second and lighter handling system, with a smaller load capacity and yet higher repeatability characteristics to carry out more precise operations (in particular welding). Following a study of the world market supply, the choice fell on a ten-kilo-capacity industrial electric handling system weighing thirty five kilos, with 7 degrees of freedom. This is an interesting characteristic feature from the point of view

A GENETIC ALGORITHM APPROACH TO OPTIMIZATION FOR THE RADIOLOGICAL WORKER ALLOCATION PROBLEM

– DISCUSSIONS ON DIFFERENT HARD CONSTRAINTS –

Yan Chen,[1] **Masakuni Narita,**[1] **Masashi Tsuji,**[1] **Sangduk Sa** [1,2]

[1] Department of Nuclear Engineering, Hokkaido University, Sapporo, Japan,
[2] Present Address : Ministry of Science and Technology, Republic of Korea

INTRODUCTION

The worker allocation optimization problem in radiological facilities inevitably involves various types of requirements and constraints relevant to radiological protection and labor management. Some of these goals and constraints are not amenable to a rigorous mathematical formulation. Conventional methods for this problem rely heavily on sophisticated algebraic or numerical algorithms, which cause difficulties in the search for optimal solutions in the search space of worker allocation optimization problems.

Genetic algorithms (GAs) are stochastic search algorithms introduced by J. Holland in the 1970s based on ideas and techniques from genetic and evolutionary theories. The most striking characteristic of GAs is the large flexibility allowed in the formulation of the optimal problem and the process of the search for the optimal solution. In the formulation, it is not necessary to define the optimal problem in rigorous mathematical terms, as required in the conventional methods. Furthermore, by designing a model of evolution for the optimal search problem, the optimal solution can be sought efficiently with computational simple manipulations without highly complex mathematical algorithms.

We reported a GA approach to the worker allocation problem in radiological facilities in the previous study (2). In this study, two types of hard constraints were employed to reduce the huge search space, where the optimal solution is sought in such a way as to satisfy as many of soft constraints as possible. It was demonstrated that the proposed evolutionary method could provide the optimal solution efficiently compared with conventional methods. However, although the employed hard constraints could localize the search space into a very small region, it brought some complexities in the designed genetic operators and demanded additional computational burdens. In this paper, we propose a simplified evolutionary model with less restrictive hard constraints and make comparisons between the two models.

MODEL CONSTRUCTION

A simple test problem is specified as follows : a job is assumed to be accomplished when the required working time on the job is fulfilled. The predicted dose that a worker is exposed to is estimated by multiplying the Area Dose Rate (ADR) with the Working Time (WT):

$$\text{Predicted Dose} = \text{ADR (mSv min}^{-1}) \times \text{WT (min)}.$$

- Input Conditions:
  - (*A*) 12 workers to be assigned to 5 jobs (each with one workplace) to accomplish the project.
  - (*B*) The Cumulative Dose for a worker before the assignment is CD[1-12] = 0.4, 2.2, 1.5, 0.7, 1.2, 0.0, 0.9, 0.0, 0.0, 0.2, 1.8, 0.0 mSv.
  - (*C*) The Area Dose Rate for a job is ADR[1-5] = 0.1, 0.02, 0.05, 0.04, 0.04 mSv min^{-1}.
- Dose Limitations:
  - (*D*) Worker exposure should not exceed the Dose Limit, DL mSv. Here, DL is set to 5 mSv.
  - (*E*) Working assignments to a workplace should satisfy the Dose Constraint of that workplace, DC[1-5] = 5.0, 3.0, 4.0, 3.0, 4.0 mSv.
- Labor and Safety Constraints:
  - (*F*) The Working Time required to carry out a Job is JWT[1-5] = 120, 200, 360, 300, 100 minutes.

(*G*) The working time for a worker should be longer than 30 minutes, but should not exceed 120 minutes.

(*H*) For special skill requirements, worker[1] is required to work at workplace[1] for more than 50 minutes, and worker[2] to work at workplace[3] for more than 80 minutes.

(*I*) In this test model, workers [1-6] are set as skillful workers, and their total working time in workplace[3] should be more than twice as long as that of workers [7-12].

(*J*) All the working times assigned to workers are integers.

GA APPROACH

Genetic algorithms(GAs) are search and/or optimization algorithms based on the mechanisms of natural evolution. GAs maintain a population of a finite number of individuals during the evolutionary process. The evolutionary process is an iteration process which seeks better and better solutions from generation to generation. In each iteration, a new population is formed by applying genetic operators to the old population. Based on the fitness ranking, individuals can hand down their genes to the next generation by one of the following three genetic operators : reproduction, crossover, or mutation. After the evolutionary process approaches an equilibrium state, the best individual is considered as the optimal solution.

For a highly constrained problem like the worker allocation problem in radiological facilities, various types of constraints including even mutually conflicting ones should be taken into account in the process of optimization. In the previous study, we presented an evolutionary model where the concepts of hard constraints and multiple fitness were introduced to search efficiently for the optimal solution. The constraints (D) for dose limits and the constraints (F) for labor power requirements were employed as hard constraints. The optimal solution was sought among feasible candidates defined as individuals that satisfy both of the hard constraints. However, the proposed genetic operations required complicated algorithms and even repair mechanisms to keep the feasibility of each individual in the evolutionary process. In this paper, we propose an evolutionary model that can seek the optimal assignment more efficiently with simpler genetic operations. The proposed model is outlined as follows :

Chromosome : The chromosomes of the individuals are specified by two dimension matrices whose entries, for example WT_{ij}, express the working time of the worker[j] at workplace[i].

Hard Constraints : For simplifying the genetic operations, only the constraints (F) are employed as hard constraints. Other constraints are treated as soft constraints. Weighting coefficients are assigned to the soft constraints in accordance with their priorities in the radiological protection and labor allocation. The first priority is given to the constraints (D) for dose limits to compensate for being removed from the hard constraints.

Evaluation Functions : Three types of fitness functions with different priorities are introduced in this model. 1) The total number of satisfied soft constraints is used as the principal fitness function; 2) The total sum of the weighted degree of violation of the unsatisfied soft constraints is defined as the secondary fitness function. 3) The total number of times required for workers to change workplaces during the project is employed as the third fitness function. A certain portion of individuals having low fitness are discarded from the population at every generation in the evolutionary process.

Mutation : The mutation defined here is much simpler than that in (2). The individual to be mutated is selected randomly. The mutation is performed by reassigning some workers' working times at some workplaces. For example, ith row is selected to be mutated, 2 entries in ith row are selected randomly, at least one of them is not zero. The working time is reassigned randomly in one of the following two ways: 1) assign a worker the maximum working time within the dose limit, and allocate the rest of the working time to the other; 2) redistribute the total working time of the two workers randomly between them.

Crossover : The parents are selected from the individuals and the row positions of the matrix chromosome for the crossover operation are determined randomly. A simple arithmetical crossover is applied to the selected rows of the parent chromosomes. In the crossover process, two offspring are born to maintain the number of the population during the evolutionary process. Since the genetic operators employed here always ensure the feasibility of the offspring, therefore the repair algorithms as defined in

(2) are not necessary.

RESULTS AND DISCUSSIONS

With the evolutionary model described above, the first feasible solution was found within 600 generations, and an equilibrium state was gradually reached after 15,300 generations. The results show that the labor allocation satisfies all other soft constraints except the special skill requirements. In addition, by virtue of the special skill requirements, the skilled workers, [1] and [2], are assigned to the specified workplaces with the maximum times allowed under dose limits. The number of times required for workers to shift workplaces can be reduced to 7 times. An optimal labor allocation is given in Table 1.

	Individual												
Workplace	1	2	3	4	5	6	7	8	9	10	11	12	Total [min]
1	46	0	0	0	0	0	16	0	0	48	0	10	120
2	0	0	0	58	40	0	102	0	0	0	0	0	200
3	0	56	66	62	0	80	0	47	49	0	0	0	360
4	0	0	0	0	75	23	0	64	63	0	75	0	300
5	0	0	0	0	0	0	0	0	0	0	0	100	100

Table 1: Results of the present model.

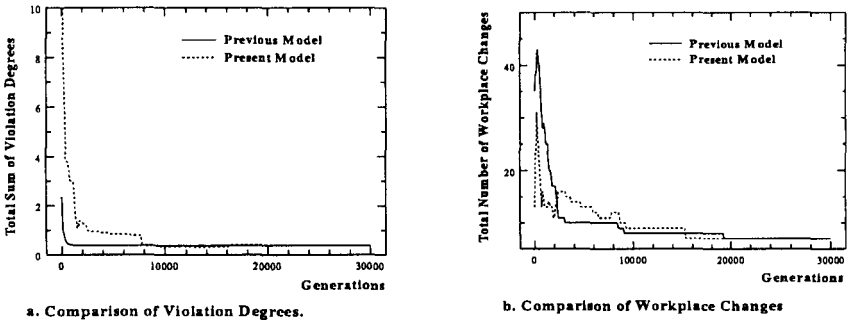

Figure 1: Comparisons between the two models.

For the purpose of comparison, the model proposed in (2) is also applied to the same problem. The results are almost the same as those of the model provided in this paper. The first feasible solution was found within 100 generations, and the best solution was found after 19,300 generations. The comparisons between the two models are shown in Fig.1.

From the comparisons, we found that the previously proposed model gave the first feasible solution very quickly, while the present model established the best solution faster than the previous one. As previous model employed more hard constraints than the present one, the search space became smaller. As a result, it was easier to find the first feasible solution. On the other hand, because of the much more strict restrictions of the previous model, it brought some complexities such as repair algorithms in designed genetic operators, which influenced the convergence efficiency.

ABSTRACT

This paper describes the control and limitation of dose uptake to operators during the early stages of decommissioning of the Windscale Piles. This was achieved by careful planning, the use of inactive trials, thoughtful use of remote handling techniques and review and feedback of information. Built between 1947 and 1950, the Windscale Piles were shut down following the Windscale Incident in 1957. UKAEA Government Division are now undertaking the early stages of decommissioning of these facilities, removing material from the air and water ducts and preparing for subsequent core removal. As part of the overall strategy of UKAEA GD, this work is being carried out using contract staff including the use of a Managing Agency, W S Atkins (Northern).

Decommissioning utilises the same means of dose reduction and control as any other nuclear operation although sometimes in novel ways. In the Windscale Piles, fully remote operations have been used to remove fuel and debris from the environs of the core which was damaged during the 1957 incident. Much use has also been made of training in mock-up facilities allowing manual techniques to be used for some jobs. The implications of using various different contractors rather than an in-house team is also discussed. It is concluded that decommissioning of major facilities can be carried out within acceptable dose uptake criteria by utilising both novel and adaptations of traditional, active handling techniques.

INTRODUCTION

The Windscale Piles were constructed between 1946 and 1950 primarily to produce material for the nuclear weapons programme but also to produce radioisotopes for industrial and medical uses. The first pile went critical in October 1950. The Piles consisted of a graphite moderator block containing 3444 fuel channels running horizontally through the core and cooled by forced draught filtered air which after passing through the core was exhausted via the 125m chimney at the top of which were filters. Fuel cartridges were introduced via a hoist at the charge face and discharged into water ducts at the back of the pile from where they were taken for reprocessing. The reactors operated at a power of 180 MW until 1957.

On 10 October 1957 an accident occurred in Pile 1 during a routine Wigner energy release, involving severe overheating of parts of the core. The emergency, which was to be the most serious for several decades was finally brought under control on 12 October 1957 by shutting down the ventilation blowers and by the application of copious amounts of water to the Pile. Following the fire, both piles were shut down and fuel and isotope cartridges discharged, except for some 10% of the Pile 1 core which could not be moved. Sealing of the pile concrete shells and inlet air ducts was carried out and the associated buildings cleared and put to other uses. The piles were kept under care and until planning for decommissioning was begun.

Recently surveys were carried out and work has begun on the removal of loose fuel and debris from the air ducts and water ducts. This work has involved handling highly radioactive materials in difficult and poorly documented areas. In line with UKAEA policy the work has been carried out by various companies under contract and has been assisted in the project management by a Managing Agency (W S Atkins). This work has shown how standard radiological protection methods can be adapted even in these severe situations and the value of harnessing the experience of the wider contracting community has been shown. Some examples of this are given in this short paper.

AIR INLET DUCTS

The inlet air ducts were the route from the blower buildings either side of each pile for cooling air to enter the reactor cores. Visual and radiological surveys showed that the ducts contained dust and debris and in Pile 1, a quantity of fuel in various conditions. Using the results of these surveys, methods of clearing the ducts were developed. Radiological containment tents with local ventilation were used at points where access was gained to the ducts by cutting through the duct walls. These allowed the deployment of remotely operated vehicles (ROVs). Dose budgets were prepared for each task and dose uptake was monitored using daily issue electronic personal alarming dosimeters.

The Pile 2 air inlet ducts were cleaned and seismically qualified barriers were installed near to the Pile. The barriers consisted of steel formwork and precast, interlocking concrete blocks. They were installed manually using portable lead screens to shield the workers from radiation from the core. Bulkhead doors are now in place and work is complete. The total dose uptake for the installation of the Pile 2 barriers was 9.4 man.mSv with a maximum individual dose of 3.1 mSv.

Because of the fuel in the Pile 1 inlet air ducts, the dose rates were higher than for Pile 2 (700μSv/h cf 120μSv/h). Cost benefit analysis for the clearance work would have resulted in a manual method but a policy decision was taken to use remote techniques. A mock-up facility was used for the testing of the ROV and the training of the operators. The ROV was then used to collect all the fuel and debris in the ducts and put it into specially designed canisters which were then removed by flask. The ducts were then vacuumed remotely. A more remote method had been considered, but on completion of the clearance work the dose rates were sufficiently low (320μSv/h) to allow the same manual construction of the barrier as had been used in Pile 2. Temporary shielding was used and minor modifications to the installation method allowed reduced occupancy times (eg delivery of grout though a hole in the duct roof). The total dose for the installation of the Pile 1 barriers was 15.6 man.mSv with a maximum individual dose of 3.1mSv.

AIR EXHAUST DUCTS

As with the Air inlet ducts, considerable amounts of fuel and debris lay in the air exhaust ducts. It was necessary to collect this material and transfer it to Disposal/storage locations. The obvious access route was via the base of the Pile chimney on the adjacent BNFL Nuclear Licensed site. Installation of equipment through this route would have been dose-intensive and there would have been potential radiation exposure from the packages as they were removed. There were also administrative complications since nuclear materials would be transferred to another site and back again.

An alternative scheme for the exhaust air duct clearance was adopted. This scheme took advantage of the existing shielding of the Pile bioshield. Air dams installed in the duct during an earlier part of the decommissioning could be modified to provide an ROV deployment route which did not require personal significant radiation exposure.

A jib crane was designed for deployment through the existing pile inspection holes. This crane was used to suspend fuel containers in a position where they could be loaded by ROVs. The crane then allowed the containers to be lowered onto the floor of the water duct so that they could be removed along with fuel from the water duct itself (see below).

WATER DUCT

The clearance of the pile water ducts was broken down into a number of tasks: Barrier Installation; Sludge pumping; Fuel/Debris removal; Decontamination; Drainage.

The installation of a seismically qualified barrier was done early in the process to secure containment of the pile should an earthquake or large dropped load breach the duct. Work on two tasks could then take place at the same time, one in the section of duct behind the pile and the other in the external section of the duct. Most work in the ducts was done by ROV.

The flocculent sludge found in the duct had to be cleared from the duct to prevent debris being hidden and allow it to be retrieved by ROV. The method used for this was almost entirely remote using a sludge pipeline from the duct

The flocculent sludge found in the duct had to be cleared from the duct to prevent debris being hidden and allow it to be retrieved by ROV. The method used for this was almost entirely remote using a sludge pipeline from the duct to the Pond. The ROV was then connected to the pipeline and deployed. Dose uptake on the sludge pumping was almost entirely due to the operations to install the pipeline and the deployment/retrieval of the ROV. The ROV was purpose designed for the job and could not practicably be proved to very high levels of reliability before work started. Several retrievals and redeployments of the vehicle were needed before the task could be finished and this had the effect of increasing the dose uptake.

Another purpose designed ROV was used for fuel and debris removal. This vehicle was equipped with a remote manipulator arm, a γ dose rate probe and stowage for fuel and debris containers. The γ probe was used to identify any items such as ^{60}Co pellets which would have a high dose rate when retrieved at the access shaft. Fuel and isotope cartridges were retrieved into shielded containers for transfer to a flask loading facility. Careful assessment of the dose rates from fuel, based on the calculated inventory of the material and dose rate measurements in the air ducts, made it possible to relax the shielding requirements for the fuel transport flask loading facility. It was possible for workers on a platform at the flask top to transfer fuel from the recovery containers underwater within the flask itself using long handled tools.

All work on the water ducts needed careful planning to ensure that an ALARP solution was found. Outline designs were prepared and subjected to a HAZOP study. From this any need to compare options to achieve the optimum dose uptake was identified. The firm design was prepared by the contractor selected for the work and ALARP meetings held to discuss the detailed design where the HAZOP had identified the potential for high dose uptake. Regular progress meeting with the implementation contractor allowed the opportunity to review the dose uptake implications of the work and discuss controls to minimise dose. Contractors were selected with proven experience of nuclear work and, where appropriate, experience of remotely operated technology. Contractors were selected from companies from UK and France.

The total dose uptake predicted for water duct clearance operations to date was 61.1mSv. The total actually accrued is 44.8mSv. No individual received more than 4μSv, well within the dose restraint objective of 8mSv/year. A more detailed breakdown of the dose uptake figures is given in the table below:

Task	Predicted (mSv)	Actual (mSv)
Water Duct Barrier Installation	20.7	11.8
Water Duct Sludge Pumping	15.6	15.3
Water Duct Fuel/Debris Removal	36	15.3 (work continuing)
Exhaust Air Duct Clearance	6.8	2.4

CONCLUSION

At UKAEA Windscale experience is being gained in the decommissioning of facilities which present a much greater challenge than power reactors will. This experience has indicated that in terms of radiological protection the operations involved, even in the extreme example of the Windscale Piles, are little different from those encountered in everyday operations of a nuclear establishment. By careful planning, inactive trials and training use of remote handling equipment and by using techniques common in other industries, dose uptakes can be kept ALARP.

ACKNOWLEDGEMENT

The Windscale Piles project is funded by the UK Department of Trade and Industry and the Ministry of Defence.

The International System on Occupational Exposure, ISOE Status and Results for 1995

Edward Lazo, OECD Nuclear Energy Agency, 92130 Issy-les-Moulineaux, France

Introduction

Throughout the world, occupational exposures at nuclear power plants have been steadily decreasing over the past decade. Regulatory pressures, particularly after the issuance of ICRP 60 in 1990, technological advances, improved plant designs, and improved water chemistry and plant operational procedures, as well as other factors, have contributed to this decreasing trend. However, with the ageing of the worlds nuclear power plants the task of maintaining occupational exposures ALARA has become increasingly difficult. In addition, economic pressures have lead plant operation managers to streamline refuelling and maintenance operations as much as possible, thus adding scheduling and budgetary pressure to the task of reducing operational exposures.

In response to these pressures, radiation protection personnel have found that by properly planning, preparing, implementing, and reviewing jobs, occupational exposures can be kept as low as reasonably achievable. To facilitate this global approach to work, sometimes referred to as Work Management, through the exchange of techniques and experiences in occupational exposure reduction, the Nuclear Energy Agency (NEA) of the Organisation for Economic Co-operation and Development (OECD) launched the Information System on Occupational Exposure (ISOE) on 1 January 1992 after a two year pilot program. This four level data base joins utilities and regulatory agencies throughout the world, providing occupational exposure data for trending, cost-benefit analyses, technique comparison, and other ALARA analyses.

The ISOE Structure

The ISOE system consists of four data bases of occupational exposure information. Data is collected via user-friendly computerised questionnaires, and accessed via a Windows-based, relational data base system. The first data base, NEA 1, concerns operating reactors, and those in cold shutdown (stored separately). For each participating reactor various radiation protection performance indicators: total annual collective dose, non-outage annual collective dose, outage annual collective dose divided into 20 job categories and 75 sub-categories, annual collective man-hours and number of workers associated with each job category and sub-category, and annual individual dose distribution are included. Although not all reactors provide data for all categories, all the data provided are updated annually.

The second data base, NEA 2, contains for each participating reactor information concerning methods and techniques used for dose and dose rate control. Primary water chemistry, cobalt replacement/reduction programs, primary water filtering, surface preconditioning, decontamination, work practices, ALARA organisation and management, tools and procedures, and motivation and training practices are listed. The dosimetric effect of each practice is quantified as best possible. This type of information normally evolves rather than changes, thus this data base is updated by the participating utilities on an as needed basis. Information for this data base is still in the process of being collected.

The third data base, NEA 3, contains details on the dosimetric results of specific operations. Items as large as the removal of the reactor temperature detector bypass system, or as specific as reactor vessel head control rod drive penetration inspections have been the subjects of NEA 3 reports. Important radiological aspects of the operation, and the name, address, and phone number of a contact person for further information are listed. The participating utilities are encouraged to complete NEA 3 reports as often as they perform operations with interesting radiation protection aspects.

The fourth data base, NEA D, is not yet operational. This data base will contain information similar to that contained in NEA 1, however exclusively for plants which are definitively shut down or are in some phase of decommissioning. It is hoped that this data base will be operational in early 1996.

Current Status of Participation

As ISOE nears the end of its fourth full year of successful operation, its list of participants continues to grow, and currently includes 59 utilities from 19 countries, and 14 national regulatory authorities. Additional data from some non-participating reactors is collected from published reports, such that the data base now represents

approximately 350 reactors (over 80% of the operating reactors world-wide), including PWRs, BWRs, CANDU reactors, and GCRs. The data base also includes 34 definitively shut-down reactors.

In terms of ties between ISOE and other organisations, the International Atomic Energy Agency (IAEA) cosponsors ISOE for non-NEA Member countries, the European Commission (EC) and the NEA have signed a co-operative agreement such that the ISOE data base now also serves the European Community's data needs, and the Paris Centre of the World Association of Nuclear Operators (WANO-PC) and the NEA have signed a Memorandum of Understanding to assure co-ordination of the activities of the two organisations in the field of occupational exposure. Finally, to administer the collection and distribution of data, a system of Regional Technical Centres has been established. This includes the IAEA for non-NEA Member Countries, the Nuclear Power Engineering Corporation (NUPEC) for the Asian Region, the Centre d'Etude sur l'Evaluation de la Protection dans le Domaine Nucléaire (CEPN) for the European Region, and the University of Illinois for the North American Region.

Thus ISOE has a wide following and is the most complete occupational exposure data base in the world. The value of such a widely used system is its ability to efficiently facilitate the exchange of occupational exposure reduction experiences and practices among participants.

The Use of the ISOE System and Network

There are several diverse ways in which ISOE can be used by its participants. The ISOE System, consisting of the four data bases and their associated software, can be used for statistical and comparative studies, and as a source of good practices and experiences. As a brief example of the type of data available through ISOE, below are listed the average annual collective doses, per reactor, for various countries and reactor types participating in ISOE, as well as a figure showing the progression of various doses and durations associated with steam generator replacements around the world.

The ISOE Network, which consists of all Participating Utilities and Authorities, Regional Co-ordinators for certain countries, and the ISOE Technical Centres, serves as an open line of communication for the real time exchange of data, experiences, policies, practices, etc. Participants interested in the experience of others in specific areas not already covered in the data bases may request that the Technical Centres solicit the needed information. Participating utilities, authorities, and national ISOE co-ordinators are then contacted by the Technical Centres and the resulting information is passed on to the requester, and made available to all other participants.

In addition, ISOE Expert Groups are established from time to time to perform specific studies based on participant's needs. For example, many companies have adopted a very global approach to their work, stressing the importance of approaching jobs from the multi-disciplinary team perspective, and of following jobs completely through the stages of conception, design, planning, preparation, implementation, and follow-up. By focusing such attention on jobs, their successful completion - on schedule, within budget, with a sufficient level of quality, with minimum cost, and with a maximum chance of fulfilling the originally desired goal - can be assured. This multi-disciplinary, start-to-finish approach to jobs can be broadly termed ***Work Management***. To facilitate the application of Work Management principles in the nuclear industry, an NEA ISOE Expert Group is currently preparing a "Handbook of Good Practices". In each of seven areas, this Handbook describe what is currently seen as good practice, and will cite specific case studies to illustrate the techniques used to quantify the impacts of work management actions in that particular area. The areas addressed by the Handbook are; 1. Work Management Policy, 2. Regulatory Issues, 3. Worker Involvement, 4. Work Selection and Planning, 5. Work Preparation and Scheduling, 6. Work Implementation, and 7. Assessment and Feedback.

The Annual ISOE Steering Group meeting includes a Topical Session during which current issues of interest to the participants are presented and discussed. Recent topics have included steam generator replacements, fuel failure, chemical decontamination, and electronic dosimetry.

Conclusion

After four years of operation and expanding participation, the ISOE system has entered a period of "usefulness and stability". Continued growth, and efforts by all participants to deliver timely and useful information, will help to assure that ISOE remains an up-to-date conduit for the exchange of occupational exposure experience throughout the world.

Average annual collective dose per operating reactor by type for a number of countries in 1994 (in man Sv)

	Country	PWR	BWR	CANDU	GCR
OECD	Belgium	0.98

The International ISOE Programme
ISOE Asian Regional Technical Center Activities

Hiroshi Kawaguchi, Yoshihiko Shibata, Nana Aiyoshi

Safety Information Research Center
Nuclear Power Engineering Corporation
Tokyo, Japan

INTRODUCTION

The ISOE Asian Regional Technical Center was established on April 1992 in the Safety Information Research Center of the Nuclear Power Engineering Corporation (SIRC/NUPEC)*1 according to the commission of the Japanese authorities, after the ISOE establishment in January 1992. The participating authorities in Japan are the Science and Technology Agency and the Ministry of International Trade and Industry, and the participating utilities are all (ten) Japanese electric power companies operating the nuclear reactors and the PNC (Power Reactor and Nuclear Fuel Development Corporation). These participants, the Authorities and the Utilities, are actively exchanging with each other dose related operating information. The number of participating reactors is fifty-one; 49 Light Water Reactors, one Gas Cooled Reactor and one Advanced Thermal Reactor (Heavy Water Moderated Light Water Cooled Reactor).

*1 SIRC: The Safety Information Research Center was established on October 1984 as the neutral and public organization, that collects, manages, analyses and evaluates the safety related information using the sophisticated information processing technology, based on the report of the Committee on Information Sophistication of Nuclear Power Generation that was set up in the Agency of Natural Resources and Energy of the Ministry of International Trade and Industry.

ACTIVITIES to NOW

(a) Data Collection

All NEA1, NEA2 and NEA3 data from FY 1990 to FY 1994 were collected from 10 electric power companies and PNC, and transferred to the European Regional Technical Center at the CEPN in France.

(b) Distribution of Information

- Asian Regional Technical Center issued Information Sheets No. 1 and No. 2 in October 1995 that contained the graphs of Japanese occupational exposure trends, by reactor type, and also the periodical inspection dose trends by reactor type.
- Third Annual Report and Information Sheets were translated to Japanese, and distributed to the participating Japanese authorities and utilities.

(c) Software developments for data collection and retrieval

- The Data Collection Software

  The Asian Technical Center developed NEA1 data input module for Japanese data collection with the commercial software (MAGIC) in FY 1992 and modified every year according to the change of the DIF file format.

- The Data Retrieval Software

  The AsianTechnical Center developed the data retrieval system for selected NEA1 data with commercial software of PARADOX for Windows in order to enhance the typical retrieval function and distributed the database system using a Run-Time version to the Japanese utilities for better understanding of ISOE data base.

PROGRAMME of WORK for FUTURE

(a) Participation

The Republic of Korea shows the interest in participating in ISOE and is expected to join in the near future through the Asian Regional Technical Center.

(b) Data Collection and Exchange with the other Technical Center

The Asian Technical Center will collect for every year all of ISOE data from Asian region and transfer the collected data to CEPN with DIF files

(c) Distribution of Information

The Asian Technical Center will issue the Information Sheets to introduce the dose control status, the dose reduction activities and so on inside Asian region. Also, the annual report and Information Sheets from other Technical Centers will be distributed to members and translated to Japanese for the Japanese participating Authorities and Utilities.

(d) Software Development

- The Data Collection Software

  The data input module will be modified every year according to the change of data collection format, the addition of new term or so.

- The Data Retrieval Software

  The data retrieval system for selected NEA1 data will be modified using the commercial software of PARADOX for Windows in order to distribute the more sophisticated analysis tool for utilities.

ABSTRACT (See instructions overleaf)

Officially opened in 1993, the ISOE North American Technical Centre has become the focal point for ISOE data collection and distribution for Participants in the United States, Canada, and Mexico. Established at the Nuclear Engineering Department of the University of Illinois, sponsored by the American Health Physics Society's Power Reactor Board, the Technical Centre is overseen by an appointed Board of professional utility radiation protection managers from the United States, Canada and Mexico. This Technical Centre is actively soliciting the participation of all American Utilities (all Canadian and Mexican Nuclear Utilities already fully participate). The Technical Centre is developing new and innovative ISOE products to promote timely information exchange among participants, especially studies on reduction of station dose due to shorter refuelling outages, and analysing the impact of shorter refuelling analyses on station person sieverts. Refinements in work selection and planning derived from European plant experience exchanges have resulted in significant dose and cost reductions in 1994 and 95 in some US plants. For example, in addition to standard ISOE data management, the North American Technical Centre is developing quarterly updates of year-to-date collective exposure, both projected and actual. Other services, such as informal information exchange visits among participating radiation protection managers, have also been accomplished with positive results. This presentation will focus on the current activities of the ISOE North American Technical Centre, and on its plans for future activities.

ABSTRACT

The CEPN has been involved from the beginning in the NEA Information System on Occupational Exposure (ISOE). As ISOE European Technical Centre, the CEPN is responsible for the collection and distribution of European data to the various ISOE partners, the collection of data from the other Regional Technical Centres, and the custodianship of the full ISOE data base. This full data base is updated annually and distributed to all the European participating utilities and to other Regional Technical Centres. The European data are also sent to the European Commission (EC) as a contribution to their own occupational exposure data base.

In addition to these activities, the CEPN has developed two computer programmes under Windows to facilitate the management of ISOE data bases. The first software, called ASPIC, allows participating utilities to electronically complete NEA1 and NEA3 questionnaires, as well as to consult the NEA3 data base using key words search routine. This software is available in six different languages. The second programme is a relational data base for the performance of statistical analyses using data from NEA1.

The CEPN also contributes significantly to the efficient flow of information through the ISOE Network. This includes participation in the preparation and distribution of the ISOE Annual Report (which presents and analyses NEA1 data), ISOE Information Sheets (providing short synthesis using NEA1 and NEA3 data), and Technical Reports. Participating Authorities and Utilities have each made information requests to the CEPN concerning dosimetric data, radiation protection experiences, policies and practices. Some examples of these requests, and of the types of data provided, will be presented.

INTRODUCTION

The CEPN has been involved since its inception, with the NEA Information System on Occupational Exposure (ISOE), supporting the OECD Nuclear Energy Agency in promoting the ISOE system and developing computerised tools to accelerate the dissemination of operational experience, and to facilitate the exchange of first-hand information between utilities on specific dosimetric problems and new maintenance operations. Since the launching of ISOE in 1992, the CEPN has acted as the ISOE Regional Technical Centre for the European countries, and has been charged with the operational management of the ISOE data base. In addition, the CEPN contributes significantly to the efficient flow of information through the ISOE Network.

PROVIDING ISOE PARTICIPANTS WITH SOFTWARE

The CEPN has provided ISOE participating utilities with two computer programmes, under Windows, for ISOE data collection, data storage and ISOE data search and analysis. These programmes are also available to participating authorities, but without data base.

The first programme, called ASPIC[1], allows participating utilities to input NEA1 and NEA3 Questionnaires data corresponding to the agreed data collection formats. ASPIC also allows the consultation of the NEA3 data base, by the use of key words, to identify the NEA3 specific reports which are of interest to the participants. This programme is available in six different languages of the European Community (English, French, German, Spanish, Italian, Dutch). The annual collection of NEA1 and NEA3 data, performed using ASPIC, allows the direct transfer of data from the participant to the data base, eliminating the need for manual transfer and the associated time consuming verification step. The ASPIC Software is now used by all the participating utilities in Europe, in Canada, in Mexico and in the ISOE participating Non-OECD Countries. Moreover, the authorities in Sweden, Germany and Spain collect their respective national data using the ISOE NEA1 Questionnaire.

Furthermore, an additional tool is being developed to provide participants with the ability to perform statistical analysis using data from NEA1 Questionnaires. This new software will use a data base management system (DBMS), such as the Microsoft Access DBMS, which allows the exchange of generic features between Users and Regional Technical Centres such as standard data requests or reports, formats, as well as the exchange of data with other commercial products (such as Excel, Paradox, dBase, etc...). It also gives users the possibility of using the programme in a Network Environment, and the benefit of evolutions to come.

MANAGING THE OPERATION OF THE ISOE DATA BASE

The CEPN, as ISOE European Technical Centre, is responsible for the collection of information, quality control of data, storage and protection of information, and retrieval service in Europe. In addition to these activities, which characterise each of the ISOE Regional Technical Centres, the CEPN is also responsible for receiving occupational exposure data from other Regional Technical Centres, and the custodianship of the full ISOE data base. This means that the CEPN has to set-up and maintain an up-to-date whole data base on the various levels of information. This full data base is updated annually and distributed to all the European participating utilities and to other Regional Technical Centres. Moreover, an agreement has been concluded between the European Commission (EC) and the NEA which states that the CEPN is responsible for the collection of NEA1 data from European utilities and for supplying all these data from Europe to the EC as a contribution to their own occupational exposure data base.

The dissemination of information is one of the most important task of the European Technical Centre. For that purpose, the CEPN works in close collaboration with other ISOE Regional Technical Centres in order to guarantee to the participants the access to continuously updated information and to put the updated computer programmes at users' disposal.

FACILITATING INFORMATION EXCHANGES THROUGH THE ISOE NETWORK

The CEPN is deeply involved in the ISOE Network, which facilitates the rapid exchange of operational dose reduction experiences and good practices, and contributes to efficient transfer of information by participating

1 : ASPIC is a Windows based Software System for input and retrieval of data. ASPIC is available, on request, from the Regional Technical Centres or directly from the NEA ISOE Secretary.

actively to the preparation and the distribution of documents such as the annual ISOE Report (which presents and analyses NEA1 data) [1 to 4] or Technical Reports [5]. The CEPN also provides the participants with ISOE Information Sheets. For example, the CEPN provides each year in May an ISOE Information Sheet presenting the first European dosimetric results including data from the previous year for general distribution to all European participants and other ISOE Technical Centres. The CEPN also provides an ISOE Information Sheet, having a restricted distribution to utilities, presenting the NEA3 Questionnaires received during the year. ISOE Information Sheets may also provide summaries of data from both the NEA1 and NEA3 data bases, as the ISOE Information Sheet on steam generator replacements.

European participants interested in the experience of others in specific areas not yet covered by NEA3 Questionnaires, have made requests to the CEPN to solicit the needed information. Both participating authorities and utilities have made information requests concerning data, experiences, policies, practices,... Recent examples of the use of this network system have included a utility's request for information concerning the decontamination of the residual heat removal (RHR) system for the replacement of an RHR heat exchanger channel head; an authority's request for information concerning the dosimetric impact of vessel head inspections in France, Switzerland, Sweden and Belgium; a utility's request for experience in reactor vessel decontamination; a utility's request for information regarding experience in refuelling-pool decontamination and, a utility's request for experience in the repair of fuel storage rack anti-seismic snubbers. In all these cases, the European Technical Centre questioned the ISOE Network and the resulting information collected from participating utilities was passed on to the requester within a very short period , and was then available to all other participants.

CONCLUSION

Since the beginning of the CEPN participation in ISOE, the number of the CEPN members involved in the data base management and communication network is regularly increasing, having reached in 1995 seven different members on part time basis. So far, the European Technical Centre mainly focused its efforts on preparation of the annual ISOE Report, data management (expansion of the ISOE data base to GCR and definitively shutdown reactors) and software development. The NEA3 data base is a way to facilitate efficiently the exchange of experiences and practices concerning occupational exposure reduction among participants. The ISOE network serves as an open line of communication for the real-time exchange of data, experience, policies, practices, etc. Therefore, for the next years, major efforts will be focused on soliciting actively from ISOE Participants an increasing number of NEA3 Questionnaires. For that purpose, the CEPN will select, in collaboration with the ISOE Steering Group and ISOE participants, topics of general interest for the international community, and will make information requests using the ISOE Network. A syntheses of such information will then be made available to participants as ISOE Information Sheets.

THE INTERNATIONAL ISOE PROGRAMME
ISOE IAEA Technical Centre Activities

Monica Gustafsson

Radiation Safety Section, Division of Nuclear safety, IAEA

INTRODUCTION

The objective of the sub-programme on Occupational Radiation Protection in the International Atomic Energy Agency, IAEA, is to promote a harmonized approach to optimizing occupational radiation protection by developing guidelines for controlling radiation doses in the workplace and on current occupational radiation protection techniques. A significant part of this programme is the provision of assistance to developing Member States to bring their radiation safety infrastructure to an appropriate level for the usage of radiation in the State.

In consistence with these objectives the IAEA has been involved with the ISOE Programme from its inception and has contributed actively to its growth. In 1993 an arrangement was agreed between the IAEA and the Nuclear Energy Agency, NEA, by which the IAEA co-sponsors ISOE inviting those IAEA Member States which are not members of the NEA to participate cost-free in the programme.

ISOE MEMBERSHIP THROUGH IAEA

The first countries to join ISOE through the IAEA Technical Centre were China, Czech Republic, Hungary and Mexico. While Mexico is now a member of NEA, the utilities in Brazil, China, Czech Republic, Hungary, Slovenia and South Africa, representing seven power plants with a total of 15 nuclear power reactors are now participating through this co-sponsorship. In addition the regulatory authorities in China, Czech Republic and Slovenia take part. Since the value and usefulness of the system is very much dependent on its coverage of the world's nuclear power plants, those from several other Member States are being solicited to join, some of these have indicated their most probable acceptance of the ISOE terms and conditions.

The IAEA Technical Centre acts as representative of its ISOE Participants on the ISOE Steering Group and according to the recently revised arrangement between the NEA and IAEA the participants in ISOE through IAEA will also send an observer (rotating observers) to the Steering Group meetings. The IAEA ISOE Centre is also disseminating information on related topics and meetings among its members and an ISOE Information Sheet has been issued.

MEETING ON TRAINING AND INFORMATION EXCHANGE

In order to provide its members with information on the ISOE project and to enable guided practical exercises with the database software, the IAEA organized a one-week ISOE Meeting in France in December 1994. The practical arrangements were made by the ISOE European Technical Centre at CEPN, with the active participation from the NEA office. The objective of the meeting, which was attended by eight persons representing China, Czech Republic, Hungary and Mexico, was also to give the participants possibilities to exchange ideas and to gain experience on optimization and the implementation of the ALARA principle in French facilities.

The programme of the first three days included, for example: ALARA: Principle and programme implementation; Work management; ALARA and outage organization; ASPIC Presentation - NEA 1 and NEA 3 exercises; Software presentations.

The participants were also invited to the CETIC training centre and the CRUAS Nuclear Power Plant, where they had the opportunity to share feedback experience with their French colleagues.

The initiative to hold this meeting was very much appreciated by the participants and the general consensus was that it was most successful.

FUTURE PROGRAMME FOR THE IAEA ISOE CENTRE

The IAEA Member States participating in ISOE represent four continents, thus geographically more spread out and, culturally, significantly more diverse than participants affiliated to the other Technical

Centres. Special attention therefore has to be paid to the co-ordination of the activities and the communication between the members. The meeting in France in 1994 was one means of improving the contacts between the members.

In order to advise on the programme for the IAEA ISOE Technical Centre a consultants meeting was convened in October 1995. The consultants took into consideration how to improve the implementation of the optimization principle in the ISOE member plants and authorities, the need for quality assurance of the data input into the data base and the different possibilities the Agency has to support their ISOE members through workshops, training, co-ordinated research programmes and publications, also making use of available software programmes and other tools. The group based their recommendations on their knowledge on the present participants in ISOE through the Agency as well as presumptive future members, such as the Russian Federation and Ukraine.

It was concluded that, as far as ALARA culture and implementation are concerned, the situation is very different from one country to another. Some common needs exist, however, and the IAEA ISOE Centre was recommended to take these into account and adapt them to the individual national contexts.

To facilitate the exchange of feed back experience

A very efficient method of sharing past experience is to arrange seminars for those involved in similar activities. In the radiation protection field, in addition to the ISOE topical meetings and workshops, a number of such seminars are regularly organized, e.g by CEC, Westinghouse, Candu Owners Groups as well as BWR and PWR Owners Groups. Other useful meetings are organized on a less frequent basis by, for example, Brookhaven National Laboratory (BNL), Electric Power Research Institute (EPRI) in the US, and National Radiation Protection Societies.

Before the break down of the former Soviet Union similar seminars were arranged regularly for radiation protection staff of the WWER reactors, but these meetings do not exist any more and the Agency was recommended to promote the exchange of experience between its member plants by initiating the formation of radiation protection groups for WWER and, later, RBMK reactors.

The Agency should also facilitate regular participation of radiation protection staff in such types of groups, and encourage participation in international meetings focused on other types of reactors.

The Consultants Group also recommended that specific working groups composed from users of the same type of reactor should be created to discuss the analysis of data and the usefulness of the ISOE network for that type of reactor as well as basic problems in the field of occupational exposure, evaluation methods, calibration procedures, recording systems, etc.

To ensure the dissemination of an ALARA culture in non-NEA Member States

The distribution of information on ALARA theory and practice is a key element in the worldwide dissemination of the ALARA culture. The lack of application of the ALARA principle in the legislation and practice in some countries, as well as language barriers and geographic isolation are the factors preventing general application of proved international practices. Existing literature and other sources of information are frequently not known for radiation protection staff working in nuclear power plants.

The Agency was advised to provide information on relevant publications and promote the dissemination of ALARA culture, for example by inviting managers to an "ALARA awareness day", organizing scientific visits for qualified experts with special emphasis on practical ALARA methods and tools and organizing ALARA courses at regional or national levels. To facilitate training in different native languages and provide participants with radiation protection optimization training tools, the Agency should also organize training courses for ALARA trainers in English.

To ensure the practical implementation of the optimization principle through the use of ALARA tools.

It was recommended that the Agency collects information about existing ALARA tools and organizes a working group in order to evaluate them. Those tools considered as cost effective by the working group should be provided by the Agency to their ISOE participants.

CONCLUSION

By its co-sponsorship of ISOE the Agency enables non- NEA Member States to obtain access to the database on occupational exposure and to exchange feed back experience with radiation protection staff from nuclear power plants all over the world. The distance, both geographically and culturally, between the IAEA Member States participating in ISOE calls for special efforts in the co-ordination of the activities and the communication between the members. There is no doubt, however, that the Agency can, by disseminating information on internationally accepted radiation protection principles, contribute to a significant improvement in the implementation of the ALARA principle in these nuclear power plants.

OCCUPATIONAL EXPOSURE EVOLUTION IN SPANISH NPP'S

P. O'Donnell, T. Labarta, and I. Amor.

Consejo de Seguridad Nuclear, Madrid, Spain

INTRODUCTION

After extremes fluctuations in the early 1980's, the evolution in occupational collective dose in the operating nuclear power plants in Spain seems to be stabilising and lightly decreasing in the last years, within the same range of the average level of the OECD countries.

It is clear that only a well structured, systematic and practical approach to optimization of protection, as a strict selection process and as a "state of thinking", ensures that no important aspects are overlooked and the appropriate decisions are taken to perform the different tasks in conditions to achieve the optimum level of exposure. During the last decade we can affirm that a progressive development of ALARA culture is having a positive influence in Spanish PWR and BWR.

In this presentation the main indicators of the occupational dose trends to assess the present development level of this criterion, the collective dose per reactor, the task related collective dose, individual doses, etc. are reviewed and the key elements that have shown a clear effectiveness to improve the practical application of it, organizational modifications, increasing commitment, global strategies to reduce the source term, increasing presence of robots, etc. are discussed.

COLLECTIVE DOSE

Occupational collective dose per reactor evolution in the operating LWR's in Spain the scope showing in figure 1.

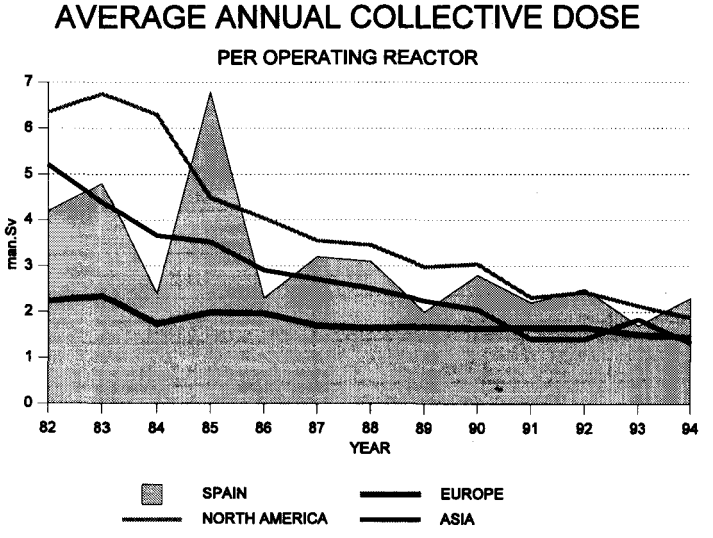

Figure 1.- Annual collective dose per reactor unit for LWRs plants at Spain and different regions.

After extremes fluctuations in the early 1980's, because major modifications to enhance the safety in CN JOSE CABRERA and the recirculation piping system replacement in CN ST^{a} M^{a} GAROÑA took place, the trend in occupational exposure seems to be stabilising last few years within the same range of the average level in the OECD member countries.

Surely, this tendency of the collective occupational dose for Spanish LWR's is however far to reach an ALARA plateau that it is not cost effective to reduce exposure with the current nuclear reactor design and technology.

Comparing the situation for PWR's within the international context, size and age tacking in account, we can see according with the data of the table 1 that while collective occupational exposure at last generation of Spanish PWR's is in a balanced level, otherwise is the behaviour at first generation.

Table 1. Average collective doses in 1993 as a function of reactor size and age for PWR's (man.mSv).

COUNTRY	OLD & SMALL PLANTS	INTERMEDIATE & MEDIUM	MODERN & MEDIUM
SPAIN	3* (01)	1.7 (04)	1 (02)
NORTH AMERICA	1.4 (7)	1.7 (9)	0.9 (7)
ASIA	1.6 (5)	0.7 (1)	0.5 (1)
EUROPE	1.7 (10)	2.3 (18)	-

* Three years average, because the 1993 data is not representative.

NOTE: The values in the parenthesis are the numbers of reactors. The regional data are taken from Ref. 4

Similar terms of comparison can be established for BWR's. Here, the relative situation on occupational exposure is nearly the same for the new plant than for the old one, as can be seen in Table 2.

Table 2. Average annual collective doses in 1993 as a function of reactor size and age for BWR's (man.mSv).

COUNTRY	OLD & SMALL PLANTS	INTERMEDIATE & MEDIUM
SPAIN	4* (1)	4.7 (1)
NORTH AMERICA	3.1 (7)	3.4 (2)
ASIA	2.5 (3)	1 (2)
EUROPE	2.7 (8)	4.7 (1)

* Date of 1994, because the 1993 date is not representative.

NOTE: The values in the parenthesis are the numbers of reactors. The regional data are taken from Ref. 4

TASK RELATED COLLECTIVE DOSE

Operational monitoring systems besides the regulatory individual dosimetry are established in all Spanish LWR's, most of them, except one, are digital and computerising system. This type of dosimetry allows a link to be made between the daily doses received by workers and a set of generic operations taking place during the operation and maintenance of the plants.

Following the recollected data up to date, some jobs involving higher average collective doses in PWR's are represented in figure 2.

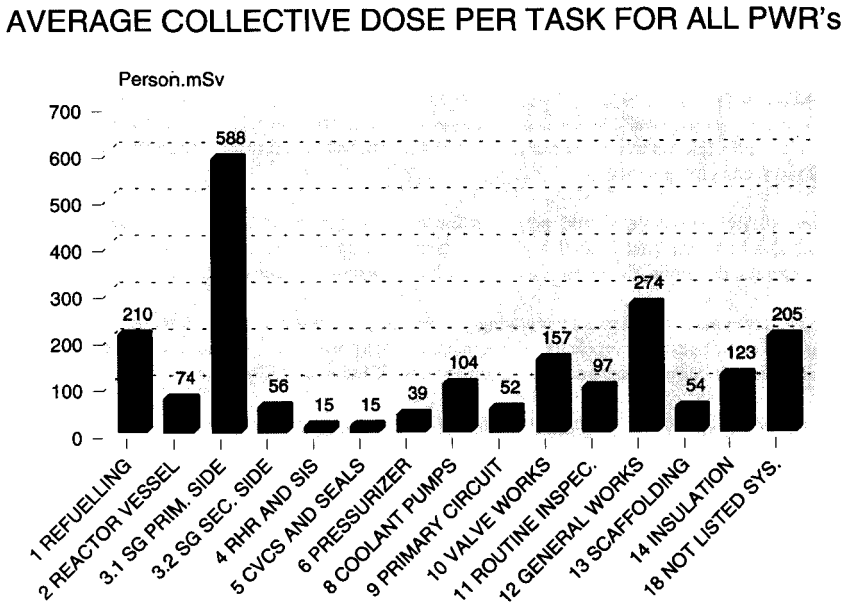

Fig. 2. Average collective dose per task for Spanish PWR's in the period 1988-92.

INDIVIDUAL DOSES

The average individual dose is also a global indicator that is often used to assess the performance of nuclear power plant operation in relation with radiological protection. Only slight variation between the reactor types exists, the international average being about 3 mSv per year. In Spain, this parameter is stabilising on the same order last five years, in 1994 the value was 2.27 mSv. Anyway one should be aware of when using this indicator, which different criteria are used in different countries to record and report doses and it is not a solid basis for firm conclusions concerning the general radiological situation.

In order to approach the previous situation in Spain to face in the early future the new dose limits recommended by the ICRP, more explicit results the evolution of the individual dose distribution, specially to define the size of the critical groups of workers, typically mechanical maintenance workers.

According with the 1994 data, 85% of workers have received less than 5 mSv, only 3% are over 15 mSv and 1.5 % workers exceeding 20 mSv/year, i.e.140 workers over 9,053.

ALARA application IN SPANISH NPP'S. NEW APPROACH.

P. O'Donnell, T. Labarta, and I. Amor.

Consejo de Seguridad Nuclear, Madrid, Spain

INTRODUCTION

One main objective of all nuclear installations is to underlie the Principle of Optimisation. The focus in the application of this principle varies considerably, from Cost-benefit techniques in the design phases to Commitment, attitude and motivation in operation.

The ALARA principle should permeate the entire organisation of the company during operation. Management should be the first link of a chain originating with explicit corporate commitment, leading to increasingly specific decisions, finally to reach those who are responsible for actual performance of each task.

The safety culture is an element integrating the mentality that is to prevail throughout the organisation. The organisation shall contribute to incorporating the principle of optimisation in all plant operations and all phases of activity. Management's commitment and motivation are transferred to all the workers and organisations involved.

The ALARA commitment naturally extends to all outside organisations.

The ultimate objective is to reduce collective doses through the promotion and enforcing of an ALARA culture and compliance with the operating collective dose objectives.

PREVIOUS PRACTICAL APPLICATION

The optimization criterion was carried out in the 80's in Spanish NPP's trough the "Dose Reduction" programmes, characterized by:

- Responsibility delegated to the Head of the RP Department.
- Specific structures for ALARA reviews of refuelling tasks.
- Occasionally the Plant Nuclear Safety Committee involved in ALARA proposals.
- No systematic approach relating to the source term, design modifications or the role of external companies.

THE STRATEGY

In order to improve the effectiveness of the practical application of the optimisation principle, the CSN established in 1991 a new strategy, in cooperation with the utilities, to change the way of carrying out this criterion from the formerly through the global Approach.

Explicit responsibilities and commitment at certain management level and at key personnel of other sections, the awareness of personnel by ALARA training beyond general radiological protection indoctrination, a specific management structure, the direct implication of contractors companies, the definition of general plans to reduce the source term, these are some main features of the ALARA programs to strengthen their operating efficiency and in which ALARA is regarded primarily as a "state of thinking" that pervade the various levels of management and workforce.

RESULTS

During 1994 most of the plants have changed radically their organization and, what is more relevant, their mentalities to adapt to this approach. The results in collective doses in that period suggest that these organizational changes are not only-formal but effective.

The terms under which these programs are going to be reviewed are commitment, promotion of ALARA culture, administrative system, scope and structure.

COMMITMENT

- Specific ALARA responsibilities.
- ALARA policy and collective dose objectives.
- The principle that responsibility is shared by all.
- The ALARA policy affects contractor companies.

PROMOTION OF THE ALARA CULTURE

- Talks and presentations at plant management levels.
- The ALARA philosophy in the basic training on RP.
- ALARA courses to the design, engineering, mechanical maintenance, RP, etc. personnel.
- Open and general information.
- Dose budgeting for different plant departments and at certain plants also for the different contractors.

ADMINISTRATIVE SYSTEM

- The ALARA organisation and responsibilities included in the Operating Regulations.
- The procedures developing the ALARA program are general administrative procedures.
- The ALARA procedures are included in the QA Manual as auditable documents.
- The drawing up of minutes for meetings held by:

  Owner's NS Committee

  Plant ALARA Committee

  ALARA task forces

SCOPE

The scope of the ALARA programmes includes:

- Normal operating activities and scheduled and non-scheduled shutdown.
- Initiatives aimed at reducing the source term.
- Revision of design modifications having a potential positive or negative impact on the collective dose objectives.

STRUCTURE

- Interdisciplinary company management Committee.
- Plant management.
- Interdisciplinary plant management Committee.

- Head of RP and/or ALARA Engineer or Coordinator.
- Interdisciplinary task performance group.
- ALARA Coordinators.

CONCLUSIONS

In view of the results presented above, it may be stated that we are achieving the objective of undertaking practical application of the ALARA criterion with wider scope, ALARA as one element of safety culture and total quality, based on personnel motivation and involvement, supported by an organisational structure, set up adequate forums for a systematic approach to optimised operation of nuclear power plants.

THE PRACTICAL ACHIEVEMENT OF RADIOLOGICAL DESIGN CRITERIA THROUGH COST EFFECTIVE DESIGN

M J Hobson, S P Erhardt, D D Winstanley

BNFL Engineering Group, Warrington, UK

INTRODUCTION

BNFL has for many years been designing, building and operating nuclear facilities at its various sites. The Consultancy Services division is responsible for ensuring that the design of these facilities achieves all appropriate radiological safety criteria. It is essential for the Company's commercial interests that this high level of safety is obtained at minimum lifetime cost. The Company has recently reviewed and revised its internal design criteria for occupational radiation exposures, making them more restrictive following an international trend of reduced dose limits. At the same time, the assessment methodology by which compliance with these criteria is demonstrated at the design stage, has been revised to improve its relevance to the actual operational situation. Thereby, it should be possible to achieve a greater standard of safety whilst keeping costs down.

This paper discusses the achievement, at minimum cost, of design criteria for radiation exposure, by reference to examples of several different nuclear facilities.

DESIGN DOSE CRITERIA

BNFL operates a voluntary annual individual dose restriction for its workforce of 20 mSv per year, with a maximum of 75 mSv over 5 years, for all existing facilities. More recent facilities were designed to lower dose targets, which essentially limit the maximum individual whole body exposure to 15 mSv per year and the average exposure to the workforce on a facility to 5 mSv per year. Following the publication of ICRP60 and other developments, such as the introduction by the UK Nuclear Installations Inspectorate (NII) of the Safety Assessment Principles (SAPs), BNFL have reviewed the design criteria for new facilities. As a result of this review, future facilities are being designed to dose targets that restrict the maximum individual exposure to 10 mSv per year. The design target for average exposure to the workforce is not changed at 5 mSv per year.

In addition, there is always an over-riding requirement to demonstrate that all assessed doses are As Low As Reasonably Practicable (ALARP).

METHODS OF DESIGN DOSE ASSESSMENT

There are many techniques available to analysts in Consultancy Services to ensure that the design criteria for radiation exposure are achieved at minimum cost. These are based around analytical techniques, computational methods and a broad base of experience of the design, construction and operation of nuclear facilities. The experience of individual analysts, coupled with the job control procedures ensure that appropriate tools are used for each task. Invariably, the design assessment includes an estimate of dose, which has two primary functions:

1. to provide, with a very high level of confidence, evidence to Company Safety Committees and external Regulators that demonstrates that the proposed facility can be reasonably operated to achieve relevant dose targets and ALARP requirements;
2. to give a realistic indication of how and where doses will be received within the facility, with the intention of aiding optimisation of the engineered radiological protection and operational dose controls and restrictions.

The first of these purposes is served by producing a demonstrably robust estimate which will, in practice, over-predict the actual doses that will be received in the facility. The conservatisms in this estimate need only be reduced as far as is needed to confirm that the doses will be below the dose target. However, this conservatism

will often obscure the likely actual doses within the facility. If the designer is not careful, large amounts of money may then be spent unnecessarily on engineered solutions to purely theoretical dose problems (for example, shielding may be built to a standard dictated by a theoretical dose that may never occur in practice). More importantly, the designer could be deflected from targeting limited resources on the areas where the greatest real dose, and hence potential benefit, is concentrated. Therefore, the derivation of a more accurate dose estimate may also be appropriate.

DOSE ASSESSMENT FOR A MIXED OXIDE FUEL FABRICATION FACILITY

A new facility for the production of Mixed Oxide (MOX) fuel is currently under construction at BNFL's Sellafield site. Early calculational assessment, along with operational experience from a similar, smaller-scale facility already in operation, indicated that dose uptake would need to be carefully considered during the design process in order that dose criteria would be met, mainly due to the significant neutron component. Consultancy Services therefore initiated dose and ALARP reviews to identify areas where dose could be reduced most effectively. These reviews were performed against the initial design and have been ongoing throughout the project. They utilised the experience of designers, plant operators and Health Physicists as well as Consultancy Services staff, and concentrated on areas of high predicted dose. The outcome led to many significant modifications, including changes in the design, operating and maintenance philosophies such that significant reductions to the dose estimate have been made and the dose criteria will be met.

Specific items covered during the review process were :

- Whether the cost of automating particular high dose operations could be justified;
- Plant and room layouts to reduce the occupancy in areas of high ambient dose rate or to optimise the shielding requirements for such rooms;
- The use of transparent shielding on some gloveboxes to aid in-box visibility and hence reduce the time taken to perform dose intensive operations; removable shielding panels were added where this would lead to reductions in ambient dose rates but still enable access for maintenance operations;
- Reduction in dose for maintenance operations by ensuring bulk sources could be removed prior to maintenance where practicable, locating maintainable items in low dose rate fields (e.g. external to gloveboxes) and designing these to be quicker to maintain or change. This has had the added benefit of reducing the time necessary for maintenance and hence increased the plant's operational capability.

As the MOX facility project is progressing to very tight timescales it has been important in terms of both time and cost to minimise the number of modifications necessary to the facility following completion of the initial design. Hence, by reviewing and optimising the methods of dose control from the preliminary stages of design, before detailed design work was undertaken, Consultancy Services have enabled substantial, but necessary, dose savings to be made in the most cost-effective manner, with the added benefits of improving the actual operability and maintainability of the facility.

DOSE ASSESSMENT FOR A WASTE VITRIFICATION FACILITY

Many new facilities being built today are similar at least in some respects to existing facilities. Where appropriate, therefore, Consultancy Services have been able to take advantage of existing plant experience to enable fit for purpose designs to be developed for our customers. An extreme example of the use of operational plant experience is the design recently of an additional Waste Vitrification facility at Sellafield. As the design of the new facility is based on an existing Vitrification facility, a detailed review of the exposures on the existing facility has enabled optimisation of the radiation protection design for the new facility. The design dose assessment was performed by considering the features of the new facility that would cause dose uptake to be different from that measured on the existing one. Such features include differences in the source data, changes to the design of high maintenance items, optimisation of shielding thicknesses etc. These factors were used to scale the measured doses to produce design dose estimates for the new facility.

DOSE ASSESSMENT FOR A DECOMMISSIONING PROJECT

In addition to new facility design, Consultancy Services are also involved in projects involving the decommissioning of existing facilities. An example of this is the emptying of corroded fuel cladding from a silo storage facility at Sellafield. Structural considerations have placed weight restrictions on the facility which leads to limits on the amount of shielding that can be used. Additionally, the operating areas on top of the silos are in high background dose rate fields due to significant amounts of contamination.

Optioneering studies involving Consultancy Services, Health Physics, plant operators and design office staff have taken place in order to determine the best options for emptying the silo contents. Dose and ALARP have been major considerations in these studies, whilst operational requirements and structural restrictions have also been taken into account. Some of the areas addressed by the studies are considered below. Dose assessments have been performed throughout the design of the plant. Measured dose rate data from the silo facility, and other plant at Sellafield handling similar material, have been utilised in addition to theoretical dose rate assessments to ensure that dose estimates are as realistic as practicable.

- Detailed studies were undertaken to examine options for constructing the silo emptying machine either in-situ or outside the building. The resultant solution ended up with minimum dose uptake and also lowest overall cost by bringing the machine into the building in modular form and constructing on the silo top.
- Complex computer modelling has been used to optimise the effectiveness of shielding on the machine in terms of positioning, thicknesses and use of different materials.
- Dose surveys have been performed in the existing building to identify contamination sources leading to high dose rates. Subsequently, methods of dose reduction have been considered, including removal of redundant or contaminated equipment, the use of localised shielding and decontamination of the building floor.

ASSESSMENT METHODOLOGY DEVELOPMENT

To improve the way in which we produce design dose assessments, BNFL is investing in research and development covering a variety of issues from the collation and use in design of operational data to analysis of the lifetime costs associated with radiation protection. The primary aim of this research is to provide the design analyst with information and analysis tools that will enable him to practically derive a realistic indication of dose. He must be able to produce this estimate speedily and at optimum cost, in order to meet the requirements of the typical design programme, which in turn means that he must have the relevant information readily available to him. Consequently, much of the development is concerned with collating and databasing such information.

The main areas are as follows:

- Analysis of design engineering and operating costs of radiation protection.
- Collation of empirical dose, dose rate and operational data from operating facilities.
- Collation of theoretical dose and dose rate data from historic design analyses.
- Development of methodologies for the use of the collated information.
- Review and development of methods for predicting internal doses from inhaled radio-isotopes.
- Review and development of dose rate calculational methods.

CONCLUSION

The estimation of dose to the workforce is a necessary part of the process of design for facilities handling radioactive materials. At BNFL a range of design dose assessment techniques are used, from theoretical evaluation of calculated dose rates and predicted occupancy durations, to comparison with existing, operating facilities and measured doses.

The production of a realistic dose estimate allows it to be used to optimise the radiation protection design of the facility, and thereby keep design costs to a minimum. Research and development is currently being undertaken to provide tools that will enable the design analyst to produce more realistic estimates within the constraints of the design process.

ABSTRACT (See instructions overleaf)

The paper will address how elements of a safety culture were identified and reviewed on the BNFL Sellafield Site in the United Kingdom. Sellafield Site is BNFL's largest site with Magnox reprocessing plants, the new Thermal Oxide reprocessing (THORP), waste treatment and storage facilities, and four of the company's Magnox reactors. With reference to the large workforce comprising of such diverse range of activities, the paper will address the dynamic nature of safety culture, both in the formation of new cultures for new plants, and the shaping/development of safety culture within existing teams and their interactions. The paper will describe how the shape of the existing safety culture with its emphasis on radiological safety was established, describing the methodologies employed and the practical considerations of carrying out and interpreting the findings of such studies. The paper will also describe the ways in which that knowledge was disseminated for use by management to reshape our safety culture with the objectives of maintaining a high standard of safety performance (both radiological and conventional), and achieving continuous improvement through and by the workforce.

ABSTRACT (See instructions overleaf)

Implementing the optimisation principle at the design stage of nuclear installations involves to maintain the collective exposures as low as reasonably achievable keeping at the same time a fair distribution of individual doses among exposed groups (equity principle). This general objective can only be achieved by anticipating from the very start of the design phase, not only the doses that can be received by workers but also how the levels of exposure will be distributed among them.

The assessment of workers exposures heavily rely on the feedback experience which provide necessary data as well as on specific tools to estimate dose rates and to combine all relevant exposure parameters. The detailed radiological analysis of technical options must be done through source-terms identification and assessment, the description of future operating modes, the prediction of incidents, the knowledge of workers locations and physical characteristics of the conceivable biological shielding. Then, all these data must be integrated with appropriate tools to *a priori* determine the most exposed areas, important sources, efficient protections and constraining tasks.

These tools devoted to the evaluation and selection of technical options at the design stage must be compatible with complex sensitivity analyses to properly quantify the efficiency of possible corrective actions of protection (e.g. reinforcement of biological shielding, withdrawal and specific shielding of sources, moving workers away from " hot spots " using robotics tools or remote controls...).

Methods and adapted tools developed during recent years at CEPN to help nuclear designers will be presented in the poster and in the corresponding paper.

Requirements and recommendations for cold shutdowns of nuclear power plants

A. CARAMEL - A. ROCHER
Electricité de France / Department of Safety, Radiation Protection and the Environment
EDF/DEPT, SAINT-DENIS (FRANCE)

Within the framework of the optimisation of the shutdown of units, a procedure for moving to cold shutdown aimed at reconciling the length of shutdowns with dosimetry and the control and limitation of the production of waste is being extended to all 54 PWR reactors being operated by EDF. This procedure, which has been in place since 1984, has developed in the light of the feedback of experience gained.

1 - Aims of the shutdown procedure

The modification of the physical and chemical characteristics of the primary coolant during cold shutdown for refuelling (drop in temperature and pH, going from a reducing to an oxidising environment) leads to a considerable increase in the activity concentration of the primary coolant in terms of corrosion products (see Table 1).

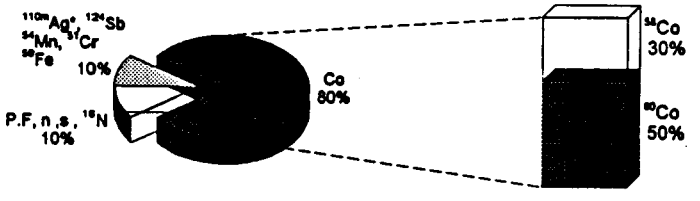
^{58}Co	^{60}Co	^{124}Sb	^{110m}Ag
150	4	10	2

Table 1: Activity values (GBq/t) at the oxygenation peak

In addition, the de-pressurisation of the primary cooling system may result in fission products (xenon, iodine, etc...) passing into the primary coolant and this may pose problems for the protection of workers when the primary cooling system is opened up.

The main objectives of the cold shutdown procedure are as follows:

- to reduce the activity of the primary coolant as quickly as possible and to avoid the contamination of out of flux areas through the deposition of active corrosion products on items of equipment. This is a very important point, since the active corrosion products (^{60}Co and ^{58}Co) are responsible for approximately 90% of integrated doses during maintenance operations (see Figure 1).
- to limit the risk of contamination of the atmosphere in the reactor building during the opening of the primary cooling system (volatile fission products),
- to limit the production of waste and to comply with stack release criteria,
- to facilitate fuel handling operations by ensuring the transparency of the water and by reducing the dose rate at the surface of the reactor cavity.



* impact of ^{110m}Ag varies greatly from unit to unit
n = neutrons, s = active structures

Figure 1: Contribution of corrosion products to collective shutdown dosimetry

2 - Oxygenation of the primary coolant

Since the oxygenation of the primary coolant during cold shutdown for refuelling is inevitable, it was decided to control this operation by provoking it deliberately. The activity is released quickly which enable the primary coolant to be purified efficiently.

This operation has evolved as follows:

- from the start up of unit up until 1994: aeration through scavenging the air of the CVCS tank from a temperature of 120°C
- since 1994: aeration through the injection of hydrogen peroxide at a temperature of 80°C.

In both cases, the temperature is reduced to the oxygenation temperature as quickly as possible (in accordance with technical operating specifications) and continues during the oxygenation phase.

A qualification program has been carried out before the use of hydrogen peroxide in PWR plants, in order to ensure that this reagent did not affect the materials used (Stellites in particular) and that the primary cooling system was not contaminated.

The use of hydrogen peroxide has the following main advantages:

- saving in time: the oxygenation phase last 0.5 hours instead from between 5 hours (lack of fuel cladding defects) and 10 hours (presence of fuel cladding defects).
  Where oxygenation is carried out in the air, the scavenging rate (and therefore the speed of oxygenation) is limited by compliance with stack activity limits (in order to remain below the pre-alarm threshold of $4.10^5 Bq/m^3$)
- improved control over oxygenation, particularly in the presence of fuel cladding defects and therefore improved control over the risk of contamination of out-of-flux equipment by active corrosion products.

3 - Radiochemical specifications adopted and justification

In order to achieve the objectives set out above, thresholds were established for the various steps of the cold shutdown of the reactor.
These limits are set out in Table 2 and the justification for their application is as follows:

- **Hydrogen**
  The objective is to remove hydrogen from the primary cooling circuit in order to prevent dangerous hydrogen-oxygen mixtures.

- **Xenon and Iodine**
  The limits concern ^{133}Xe and ^{131}I and are intended to limit:
  - gas releases,
  - the risk of contamination of the reactor building when the primary cooling circuit is opened.

- **^{58}Co and γ_{total} activity**
  The objective is to ensure adequate purification of the primary coolant and to limit the risk of contamination of out-of-flux equipment by active corrosion products.
  These limits concern ^{58}Co, which is the most abundant radionuclide and γ_{total} activity which enables the presence of other radionuclides, such as antimony and silver, to be taken into account.

SHUTDOWN				
TRANSIENT STAGE	With RCS aeration			Without RCS aeration
	With reactor cavity filling	With RCS opening and without reactor cavity filling	Without RCS opening	
Load reduction	H2 : 5 ml/kg TPN Xe133 < 8 GBq/t I131 < 2 GBq/t

COMPUTERISED DOSIMETRY MANAGEMENT SYSTEMS WITHIN EDF

Guy DAUBERT
Department of Safety, Radiation Protection and the Environment
EDF/DEPT, SAINT-DENIS (FRANCE)

EDF, using the ALARA approach, has embarked an ambitious project of optimising the doses received in its power plants. In directing its choice of actions and the effectiveness of such actions, the French operator is using a computerised personal and collective dosimetry management system. This system provides for on-going monitoring of dosimetry at personal, site and unit level or indeed for the entire population of EDF nuclear power plants.

OBJECTIVES

EDF is seeking to improve the personal dosimetry in its power plants, that is to optimise the dose received by all workers, whether EDF employees or those of external contractors, with the greatest benefit going to those works who are most exposed. One of the means to achieving this objective is to reduce the collective dosimetry on sites, which implies the implementation of an experience feedback system: forecasting, monitoring results and analysis of discrepancies.

RESOURCES

To direct its activities and evaluate the effectiveness of such activities, EDF uses systems which continuously update the dosimetry situation of each individual and the collective dosimetry of each site. The doses managed by these systems are the operational doses, of both EDF employees and external contractor personnel, recorded on leaving controlled areas (areas of exposure to ionising radiation).

Given the millions of doses and the tens of thousands of people concerned (6000 to 7000 additional persons per year), the system is fully automated but it is designed so that man remains in control of important decisions and is able to make corrections as necessary. The complete system has two main components; the local system on each site and the national "DOSINAT" system, which consolidates the data from the various local system (See Figure 1). These systems have devices which ensure that only authorised persons have access to the data. They are endorsed by the CNIL[1].

LOCAL SYSTEMS

At each entry to or exit from a controlled area, the gates transmit batches of data, known as "movements" to the local system. For a given worker, the "entry movement"-"exit movement" pair represents a dose movement, which takes into account the length of time the work is in the controlled area and which indicates in particular: the identity of the worker, the site on which he is working, the dose he has received, the time of the operation, etc...).

The local system which receives these data is capable of supplementing them with data gathered when the worker arrived at the site concerned, such as: personal details (name, first name, date and place of birth, sex), his employer, his speciality, his training, his qualifications, etc. In addition, the local system receives the personal dosimetry data for the worker over several months from the national system and which is compiled from the data from the EDF sites at which he has worked (in 1994, some 7000 people worked on more than one site).

Using all these data, which are updated continuously, we can monitor the situation of each individual and each site.

NATIONAL STATISTICS
•collective dosimetry for all the installation
•analysis per population concerned

For the individuals on the site concerned, we can identify those which have been exposed for the longest period, either during a specific operation or over a longer period. We can therefore develop areas for improving personal dosimetry received during specific operations. We are also able to identify those workers with the highest cumulative doses to direct them towards less exposed activities.

For each site, we are able to monitor the overall dose received more closely, which enables us identify any discrepancy immediately, to analyse the reasons for it and to optimise the end of the operation. Later, we are able to analyse in detail the discrepancies between the forecasts and the actual results. Positive differences may represent good practices and negative differences may direct us to areas in which progress can be made and actions taken. The reference values may also be updated according to events of site.

The site dosimetry calculated by the local systems is used for international (ISOE data base) and national statistics in order to compare units and always to identify good practices and areas in which progress is being made.

EDF's NATIONAL DOSINAT SYSTEM

Each elementary dose in the local system is recopied to the national system, which enables us to have an up-to-date, detailed image of the situation of each individual and all EDF nuclear installations. In order to ensure that an individual is allocated his doses and nothing but his doses, highly sophisticated programmes have been developed to prevent two files being created for a same person or a dose being allocated to the wrong person. This includes phonetic recognition of names, for example.

In so far as individuals are concerned, the national system has the same features as the local system to which it transmits data for several months. In addition, a unit can consult the DOSINAT file of a person coming to work on that unit or inform other units of the provisions it had to take, after consultation, for a worker, where the other units did not carry out the same checks when the person concerned arrived.

All doses received in EDF installations will be transmitted by DOSINAT to the French system, which is being set up, to supplement the doses received in other environments.

Finally, statistics can be established for all those populations which can be derived from data concerning workers, employers or the type of work carried out. We can also obtain an overview of the number of individuals for each annual dose level and decide on improvements to be made from one year to another.

For EDF nuclear installations, we can monitor the evolution of overall dosimetry in relation to the targets which have been established, thus enabling the Nuclear Power Plant Management to take the actions required to correct the situation.

DOSIMETRIC OPTIMISATION OF WORKSITE INVOLVING THE INSTALLATION OF VATS CONTAINING HIGHLY ACTIVE EFFLUENT

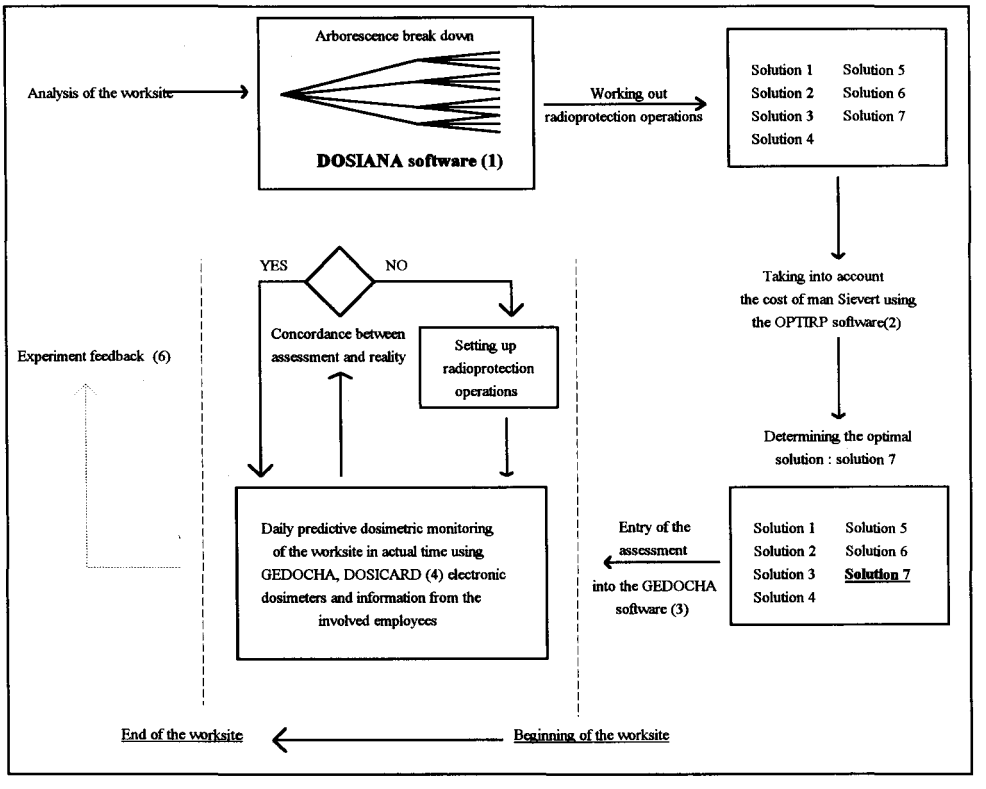
F. Legée,[1] J. Busani,[1] Y. Madigand,[1] J. Pailloux,[1]

[1] Commissariat à l'Énergie Atomique , Fontenay-aux-Roses, France

Introduction

Within the framework of safety improvements at the CEA, CEA-FAR, concerned to formalize the ALARA initiative, has carrried out for information and training purpose and to create awareness a dosimetric asssessment of the worksite where new storage vats for highly active effluents are to be installed.

This study has led to the following organizational chart:



The numbers in brackets relate to the following informations

(1) DOSIANA software

This software developed by the Centre d'Etude sur l'Evaluation de la Protection dans le domaine Nucléaire (CEPN) (Center for the study of Safety assessment in the Nuclear Field), allows to create with the help for data collected on site, an arborescence specific to the worksite by capturing the values which constitute each elementary task, that is :

- lenght of time
- received dose
- number of employees involved in this task
- working outfit
- category of worker

The second stage was to study the radioprotection operations likely to reduce the doses received by the various employees.

After ruling out a number of financially unfeasable solutions such as robotization, seven propositions was retained.

(2) Cost of man.Sievert

Seven propositions, each modifying the initial arborescence, were made to compete with each other.

The optimization was carried out by considering the cost of man.Sievert according to the following criteria :

The optimization was carried out by considering the cost of man.Sievert according to the following criteria:

- 100 $ per man.Sievert for the employees having received doses between 1 and 5 mSv
- 1400 $ per man.Sievert for the employees having received doses between 5 and 30 mSv

The OPTIRP software of the CEPN brought out the unquestionable superiority of the seventh solution. This arrangement involves the highest investment expenditure but reduces dramatically the operation cost due to faster and more effective work resulting in a 16,1 % saving in collective dose as well as financial saving.

(3) GEDOCHA software

The Service for the Protection against Radiation has developed the GEDOCHA software under Windows environment (GEstion DOsimetrique des Chantiers de Haute Activité : Dosimetric Management of Highly Active Worksites) allowing to establish from the capture of the received doses, of the hours'work and the identity of the employee a series of statistics and indicators in connection with the assessment.

The software indicates (in phasis, sub-phasis and elementary task) the received dose at time t with respect to the estimated overall dose, as well as the amount of hours's work with respect to the estimated overall length of time. A simple indicator is given :

$$\left(\frac{Number\ of\ hours'work}{Estimated\ amount\ of\ hours} - \frac{Received\ dose}{Estimated\ dose}\right) \times 100$$

This indicator is predictive. Indeed, it doesn't reflect an established fact, but an inadequation between assessment and reality in the event the worksite went on operating under the same conditions.

Positive, this indicator shows that the assesssment over estimated the dose (or underestimated the amount of hours); negative, it shows the the assessment underestimated the dose (or overestimated the amount of hours).

Therefore, these indicators allow to make radioprotection measurements while work is in progress in order to fulfil dosimetric objectives.

(4) DOSICARD electronic dosimeter

Each emloyee was given an electronic dosimeter (DOSICARD from NOMATEK) able to memorize the daily doses over a three month period and equipped with an alarm indicating trespassing of the limit. These wear-resistant devices, the size of a credit card, measure reliable doses at the microsievert level.

(5) Information of employees

Any radioprotection measurement involves providing information to all employees, with different skills and coming from various companies.

In order to do this a function for issuing daily "Computerized monitoring cards" was included in the GEDOCHA software. These cards tell the employee working in the frame of an elementary task the maximal dose to be received in order to fulfil the dosimetric objectives. Associated to the dosimetric measurement badge with digital reading and to trespass limit in the badge, reset each day for this objective, the computerized monitoring card increases each employee's awareness of the importance of radioprotection on such worksites.

(6) Experiment feedback

The experimental feedback highlighted various important points :

- the deep involvment of the Radiation Protection Department of CEA/FAR combined to computerized monitoring and a reliable measurement system allows detailled knowledge in actual time of the work in progress as well as an extremly accurate historical analysis.

- the most difficult parameter to assess remains the estimated amount of hour's work. Therefore improvement of the program consisted in adding a menu allowing easily such modification.

Conclusion

The approach used for this worksite is global. Technics used were all complementary, ensuring constant elaboration, expemriment follow-up and feedback of a worksite at a relatively low dosimetric cost (an estimated 36 men.mSv brought down to 30 men.mSv through implementation of the ALARA principle)

This type of global conception of radioprotection involving all the employees (head of project, project managers, companies, radioprotection employees...) which today proves its worth on a modest worksite must now be extended to worksites of a broader scope (several hundreds of men.mSv) where fulfilment of the dosimetric objectives is a major stake.

ALARA PROJECT

J. POTOCZEK
Department of Safety, Radiation Protection and the Environment
EDF/DEPT
SAINT-DENIS (FRANCE)

THE INITIAL CONTEXT

EDF's nuclear power stations were built with provisions being made, as from the design stage, to limit radiation sources and the results observed over the first ten years (annual collective dose and dose per unit of less than 2 m.Sv) were considered to be very good. However, these results began to deteriorate from 1988 onwards. At the same time, considerable progress was being made by other generators of electricity, who were achieving results which were better than those achieved by our later units. Furthermore, radiological protection standards are being revised and personal dose limits will soon be lowered.

A DETERMINED POLICY

A policy aimed at reducing doses has therefore been implemented for the benefit of all EDF personnel and external contractors with the objective of reducing personal dose dispersion - the even-handed aim of ICRP recommendation 60 - and collective doses in order to achieve the following:

- providing all workers with the same level of dosimetric protection, whatever their employer,
- achieving collective dose results similar to those of the best operators throughout the world in the operation of nuclear reactors.

This has led to the establishment of dose targets and decision making criteria (value of the collective dose unit to be avoided). It is not a question of reducing doses at any price, but rather in carrying out a cost/benefit analysis of the possible solutions.

ENCOURAGING RESULTS

The decision to adopt this ALARA approach at national level has been extended to all nuclear installations over the last few years.

Working groups for specific areas and led by various local and national committees, have been able to reverse the trend noted after 1988 and the results for the years 1992 to 1995 prove this.

TODAY

In order to return the Nuclear Operating Division of Electricité de France to the ranks of the world's best operators in terms of collective and personal dosimetry, a national "ALARA" project was set up to co-ordinate a certain number of actions, which are aimed at achieving the following objectives:

1. To define a common language, methods and tools for all nuclear installations in order to achieve a level of standardisation in this field.
2. To make the main levels of management aware of their responsibilities for what is at stake in terms of dosimetry and to encourage them to establish objectives in order to move from a resource driven approach to a result driven approach.

3. To bring external contractors into this overall process.

4. To improve the most costly maintenance sites in terms of doses.

5. To reduce specific sources of exposure.

6. To reinforce the organisation and exploitation of experience feedback in this field and to modify the existing information processing system accordingly.

1) Defining a common language, methods and tools

The implementation of a policy of optimisation, in accordance with the ALARA concept, requires a priori management of exposure levels. In other words, we have to be capable of anticipating and forecasting where, when and how given tasks will be subject to exposure.

Therefore, the first objective of the ALARA Project is to define the common language, methods and tools which are required to operate the ALARA optimisation loop at nuclear installation level and involving all Operational Units.

The main areas of activity concern the following:

- defining the structure for the gathering and detailed analysis of dose data in order to be able to combine them with specific operations and levels of responsibility,

- standardising the establishment of gamma environment mapping in order to transpose the reference doses and to render the results objective, thus facilitating comparison and analysis,

- to establish a dosimetric reference for the main maintenance or retrofit sites, according to type of unit shutdown and according to type.

- to adopt common or compatible methods and tools.

2) Responsibilities

The establishment of objectives is an effective management tool. This is one of the key aspects of the ALARA concept. The initial actions set out above, will greatly facilitate the following, be it at national or local level:

- the commitment of various levels of management (client and prime contractor) to their responsibility for making dosimetry forecasts. Complying with, such commitments necessarily result from the desired actions: consideration, analysis, preparation.

- the examination of results, the analysis of discrepancies and finally the implementation of the necessary corrective actions,

- the gradual introduction of performance evaluation techniques in this field.

3) Bringing external contractors into the overall approach

Approximately 80% of doses received in nuclear installations directly concern the personnel of external contractors and a strategy must be developed to bring such contractors into the EDF collective and personal dose reduction and control project.

For this, various improvements to partnership relationships are being considered and are subject to actions at both national and local level. They are intended to define: the requirements set out in agreements, the possible use of contracts in this field, the dosimetry targets specified in orders, training activities, the involvement of contractors in the experience feedback process and evaluation criteria.

In addition, European regulations are being revised to include ICRP recommendation 60 which, in addition to the annual dose limit of 50 mSv, sets of 5-year dose limit of 100 mSv (or an average of 20 mSv per year).

Without waiting for this, and without endangering the jobs of those concerned, the contractors most concerned will consulted from between now and 2000, in order to achieve the objective of nobody receiving more than 20 mSv in any 12 months.

4) Optimisation of the most costly sites in terms of doses

At the same time as the structural actions taken and as a sine qua non, some twelve maintenance sites or fields of activity will receive special attention. They alone represent 70% of the dose received in all nuclear installations and the optimisation of these sites should achieve a reduction of such dose of 15 to 20% in the medium term.

In this case, it is a question of implementation or continuation of such optimisation, to establish an initial dosimetry reference (reference doses, mapping, operating conditions, good practices) and to pass on the benefits to all nuclear installations.

Included among these operations, we should mention maintenance works on steam generators, operations concerned with the opening and sealing of reactor vessels, maintenance on valves and fittings, non-destructive testing, decontamination and cleaning operations as well as operations concerned with auxiliary systems.

5) Reducing specific sources

Certain components in contact with the primary coolant tend to encourage the appearance of oxides or particles which, when they are active, are deposited evenly on the walls of pipeworks and vessels where "hot spots" may be created.

These components include stellites, materials which are used in valves and fittings for example, and they are responsible for a significant share of the doses. A specific aspect of the Project is concerned with the replacement of the worst components (3 mSv/year for all installations) and to forbid their use in future installations.

In addition, some ten nuclear units are affected, to greater or lesser extent by "hot spots". Their impact on dosimetry justifies the taking of curative actions to clean these units, not forgetting monitoring and preventive operations in unaffected units.

6) Improving the organisation and exploitation of experience feedback data...

The feedback of experience gained on work sites is essential. There can be no significant progress made without ordered communication and the exchange of information concerning good and bad practices.

Accordingly, the existing information and experience feedback system will be improved through the Project by establishing compendiums and data bases and by setting up networks of opposite numbers and colleagues.

In addition, the activities of the Equipment Division during the design stages of future nuclear power stations (and the modification of power stations in service) should lead to an improvement in the choice of materials and of the environment and therefore working conditions during maintenance operations.

This requires EDF to make adequate operating feedback information available. The setting up of an efficient and durable organisation is a long term investment which should be made.

... and developing the information processing system

Finally, the requirements which emerge from the various aspects discussed above must be taken into account in order to develop the "site dosimetry" information processing system into more advanced system.

ABSTRACT (See instructions overleaf)

Simulation of dose rates with appropriate softwares is an important issue when implementing the ALARA process because one of the steps of the ALARA approach is predictive.

Moreover, in the prevision of a task-related dose, the dose rate parameter is more important than other parameters because it does have an influence on working conditions and even on the feasibility of the task.

The PANTHERE V1 software that will be in demonstration is caracterized by its ability to deal with complex situations (geometry, materials, sources). Many existing softwares offer the same ability with the drawback of a laborious data entry task and management of results. PANTHERE V1 benefits from the help of built-in CAD as an interactive means to manage both entry and results. 3 D visualization is avaibable.

The specifications for the development have been elaborated on the basis of the results of a working group gathering different kinds of users.

The final aim of PANTHERE V1 is to contribue to the standardization of the ALARA Approach within Electricité de France.

ABSTRACT (See instructions overleaf)

The implementation of optimisation of radiation protection during operation and maintenance of nuclear facilities implies to adopt a management system of exposures based on an 'a priori' knowledge of interventions, in order to be able to anticipate the level of collective and individual exposures. It is therefore necessary to set up an organisation allowing an efficient collection, analysis and circulation of information. The elaboration of such an organisation can be facilitated by the use of a 'system approach' which allows to structure the action fields by a description of the various components interacting in the management of the facility. When this approach is applied to the management of exposure, four 'systems' can be addressed :

- the 'Aims System' describes the objectives set by the facility in the aim of optimising radiation protection,
- the 'Piloting System' describes the persons in charge of the objectives, their responsibilities, the decision scheme and the program elaborated in order to reach the objectives,
- the 'Information System' describes the relevant data for optimisation and their treatment (methods and tools used for the collection, the storage, the control, the analysis and the diffusion of data),
- the 'Human Factors System' analyses the relationship between individuals, their coordination, their motivation as well as their education.

Based on French and international experience, the paper proposes, for each system, the organisation, the methods and the tools which seems relevant for the optimisation of radiation protection implementation, and points out the interactions between the various systems.

ELECTRICITE DE FRANCE

St-LAURENT des Eaux Nuclear Power Plant

OPTIMIZING RADIOLOGICAL PROTECTION IN STEAM GENERATOR REPLACEMENTS

Abstract n° 90858

A large number of nuclear power operators worldwide have met difficulties with their steam generators through corrosion of the internal pipes. Electricité de France has not escaped this problem. In four nuclear power stations, we have replaced twelve steam generators by cutting the primary pipes, involving significant exposure for the nuclear workers.

In order to reduce the individual and collective doses, EDF developed a general action policy, applying the ALARA concept during the entire phases of the first operation in 1991, on the DAMPIERRE NPP.

The other Steam Generator Replacements (SGRs) managed in FRANCE and abroad, showed the continual decline of the total exposure received during these operations.

PLANT	YEAR	FORECAST	RESULT	RESULT BY SYSTEM (3 SG / nuclear unit)
DAMPIERRE	1991	4.5 man.Sievert	2.13 m.Sv	0.71 m.Sv
BUGEY	1992	2.6	1.55	0.52
GRAVELINES	1994	1.8	1.45	0.48
ST LAURENT	1995	1.43	0.91	0.30

For the St LAURENT SGR, we have made a breakthrough, reaching one of the best results in the world. In particular, we have reduced by one third of our forecast dose.

The main reasons for the importance of the reduction in our forecast dose are the followings:

* the very detailed preparation of each elementary task, one year before, by working groups consisting of multidisciplinary members. This fine preparation allowed us to reduce the work duration in the exposed areas by 10 % in comparison with the previous SGRs.

* the optimized organisation of radiological protection with one person on shift, on each loop, with the unique responsability for radiological protection and industrial safety; and that during the entire SGR operation in the Reactor Building.

* a very intensive training and information was given to the subcontractors in order to motivate every one of them to reduce the collective and individual doses.

* the quantity (about 100 tons) of lead shielding brought into operation contributed to reduce the collective dose.

* a fine forecast of received dose in each task gives good conditions of real time follow up, and allows to compare the results with the dose forecast, in order to immediately carry out the corrective actions if necessary.

* the firm will of the source reduction was carried out through a long purification in spite of the impact of the outage duration.

* after the prototype development period, by our main contractor FRAMATOME, we took benefit of the normal industrial process applied on the french standardized nuclear network, by using the same tools and equipment on the industrial scale; the St LAURENT Steam Generator Replacement was the fourth in France.

The long-term production of nuclear-powered electricity requires the conditions of a good relationship of confidence with the external environment. The demonstration we can manage a large operation while continuously reducing the worker expositions plays a part in the fulfillment of these conditions.

ANALYSIS OF ACTION TO TURN THE TREND OF INCREASING COLLECTIVE DOSES IN SWEDISH LWR'S

Lars A Malmqvist, Thommy Godås
Swedish Radiation Protection Institute

Poster No.: ***P52-21***

ABSTRACT

Since the first nuclear power reactor in Sweden, Oskarshamn 1 was started in 197 l and further on with a total reactor program of 12 reactors (4 NPP sites) the occupational collective dose have been less than the ambition level of 2 manSv per GW installed capacity up to the year 1991. This rather favourable picture was changed for the BWR's in 1992. The trend and some of the forecast discussion shows an dose increase for the BWR's, while the PWR's after 1989 have shown a decreasing dose trend. Increasing safety requirements resulting in extending inspection programs, ageing reactors are factors also contributing to this. The changed situation has called for the establishment of more extended ALARA programs for the LWR's. In April 1993 SSI started a development program in dose reduction. The purpose was to identify the various reasons for the increasing dose levels, study the expected dose- and dose rate- trends for coming years and to advice on concrete actions to reduce occupational doses in the long time perspective. In an other action the SSI has alert the plant management on the situation by direct ALARA inspections where the different components in the radiation protection programme at the various plants has been focused at. In the paper, results from these analysis are presented and expected actions to be taken are discussed.

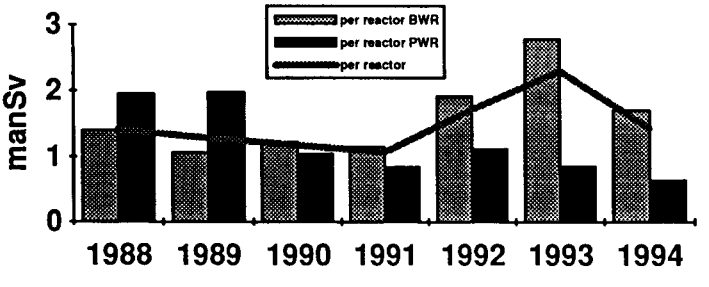
INTRODUCTION

Occupational dose reduction is important not only for the health and safety of the workforce but also because the associated requirement for a good management system enhances safety, quality and reliability of the installation and thus the economy of the plant. Indeed, during the eighties and beginning of the nineties progress has been made and occupational doses have decreased in most countries but unfortunately this is not the situation in Sweden. We have learned that there is no time for complacency because as plants become older there is a general tendency of increased maintenance and repair requirements. Moreover, the ICRP Publication 60, which recommends more stringent dose limits, further draws the attention to the exposure of workers and consequently to ways of reducing such exposure.

TRENDS IN OCCUPATIONAL DOSES

Traditionally occupational radiation doses in the Swedish nuclear industry have been low seen in the international perspective. The decrease in doses we saw in the end of the eightees and in the beginning of the ninetees (figure 1), didn't give any motivation for implementing new ideas with regard to lower the doses.

Figure 1



Unfortunately the situation changed radically 1992. From the positive trend up to 1991, we found the collective dose for 1992 to be "all time high", 20,5 manSv and it become even worse in 1993. In 1993 the total collective dose reached the level of about 28 manSv, i.e. 2.8 manSv per installed GWe, which in fact exceeds the planning level of 2 manSv per GWe which SSI has required as an average for 5 consecutive years.

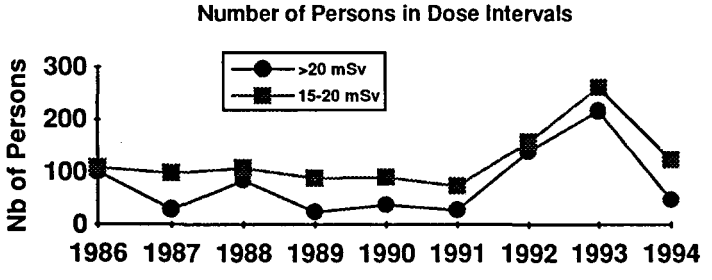
In July 1992, a safety valve in the automatic depressurization system at Barsebäck 2 opened inadvertently at 30 bar and blew steam to upper drywell causing a simultaneous clogging of both trains of the emergency core cooling system. Five of the Swedish reactors, those with external recirculation pumps and small strainer areas, were later that year taken out of operation due to this incident.

At four of the five reactors a decision was taken to replace most of the fibre insulation with metallic insulation. At the fifth reactor fibre-glass insulation was chosen. All of them increased their strainer areas.

From a radiation protection point of view, we have had some unsatisfactory experience from the use of metallic insulation, it requires some time-consuming and troublesome handling.
We have also seen a considerable increase in the individual doses to insulator personnel. Therefore, we had some doubts in the whole operation.
However, the replacement took place and it was not a success neither from a radiation protection nor a technical point of view.
Lack of planning, wrong drawing support combined with an extremely tight time schedule gave a collective dose of approximately 7 manSv in total for the four reactors installing metallic insulation.

Also, the annual individual doses have increased during the same years but are still well below the dose limits (50 mSv for any single year and 100 mSv as a total for five consecutive years). Moreover, the annual average dose for all the work force are below the ambition level of the SSI of 5 mSv per year. However, for some groups the average individual doses have exceeded that level. The number of persons with annual doses of more than 20 mSv was in 1993 about 200 but the number decreased to less than 50 for 1994 (see Figure 2).

Figure 2



REASONS FOR INCREASING DOSES

Collective doses at nuclear power plants are caused by the works that are needed to be carried out i areas where the dose rates are elevated. The dose rates are in general higher the closer to the reactor and its primary systems you are. The five oldest BWR-reactors are here of particular interest in that their recirculation loops require significant inspection and test activities causing important doses to the personnel. In PWR similar problems exist as regard their steam generators.

Works

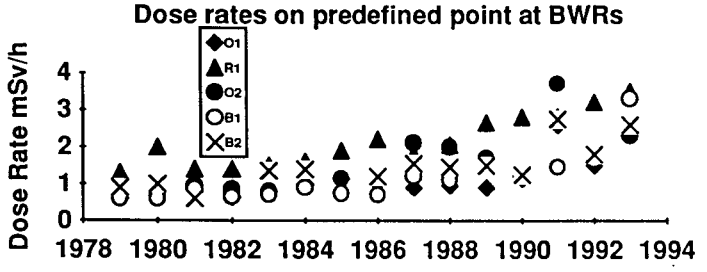
Due to significant amounts of work, the doses have increased considerably during 1992 and 1993. The increasing doses can partly be explained by the fact that some of the reactors are ageing thus requiring significant maintenance and repair works. Increasing safety requirements resulting in extending inspection programs are also contributing to this. In particular, a significant safety related event happened in 1992, when some insulation material was fed into the inlets of the safety injection systems causing risk of clogging . This event led to repair and modification works at all the BWRs of similar design leading to collective doses of about 7 manSv for the five reactors concerned.

Dose rates

Erosion and corrosion of base material in the reactor systems mean that large amounts of corrosion products are fed into the reactor. An important part of them are deposited onto the fuel, activated and thereafter spread in the reactor systems.

Activated corrosion products and in particular Cobalt-60 are the main source of the radiation fields in the nuclear power plants and thus to the resulting radiation doses. Cobalt is one element in stainless steel. The most important contribution comes from stellite which amounts up to 60 percent cobalt in the hard facing alloy, common in valves. Also, fuel failures are causing an increased spread of cobalt-60 from the fuel to the reactor systems. This phenomenon is presently studied in more detail, but it is already now evident that increased attention to fuel failures are needed also from the occupational exposure point of view.
To get a measure of the evolution of the dose rates in the reactor systems, the nuclear industry is measuring regularly the dose rates at a number of places in the reactors. One such series of measurements is shown in figure 3, from which it is evident that the radiation levels at some places in the primary reactor systems are increasing with time. The curve shows the dose rates at all the reactors with external recirculation loops.

Figure 3



At the Radiation Protection Institute (SSI), we cannot accept a prolonged negative dose trend, and therefore, we have worked hard to find countermeasures to turn the trend.

Using our research funds, we started a significant development program in the field of dose reduction. The Swedish "reactor maker" ABB-Atom was on one behalf studying the reasons for the increasing dose levels, estimating the expected dose situation during the years to come as well as giving advice on concrete actions to reduce occupational doses (project DORIS, DOse Reduction In Swedish BWRs).

In the new regulations (SSI FS 1994:2) on occupational exposure, new requirements were included. First of all we decided to introduce a new individual dose limit, 100 mSv in 5 consecutive year in addition to the annual individual dose limit which is 50 mSv.

We have also required an extended education and training program in radiation protection, addressed especially to foreman and team-leaders, working for the utilities as well as for contractors. We believe that this program will increase the understanding and motivation of the personnel to more heavily engagement in dose reduction.

Additionally, we believe in an ALARA, or work management approach, i e where the utilities systematically review their strategy towards radiation protection and develop goals in the area of occupational doses.

In the regulation mentioned above, we also require that each utility have to prepare an ALARA program. These programs shall contain objectives and dose targets for the short and longer terms, discussions on the basic considerations behind the choice of such objectives and targets, dose reduction plans (source and exposure time reductions to be considered) and ways to monitor, follow up and analysing experience. Finally, the plans shall contain programs for education and training of the workforce as well as the organisational aspects related to all the above.

SWEDISH NUCLEAR POWER - DOSES, DISCHARGES, POLICIES

J. Valentin, P. Hofvander, C. Hägg, C.-M. Larsson, L. Malmqvist, B. Å. Persson

Swedish Radiation Protection Institute (SSI), S-171 16 Stockholm, Sweden

ABSTRACT

Occupational doses were low but increased 1992-1993. After corrective action, doses are now low again. In spite of relatively large discharges, doses to the public are only a few μSv, except at Ringhals with doses around 0.05 mSv after fuel damage. Emergency preparation includes a revised strategy for early measurements and upgrading of IT equipment.

INTRODUCTION

The Swedish nuclear power programme comprises 12 light water reactors (9 ABB Atom BWRs, 3 Westinghouse PWRs) at 4 sites, started between 1971 and 1985. The oldest reactor, Oskarshamn 1, has been shut down for repairs 1993-95, but is expected to be restarted early in 1996. These NPPs produce about half of the electricity in Sweden with an energy availability factor of ~75-90 %. Some years, utilisation has been about 10 % lower than availability, due to well-filled water reservoirs for hydroelectric power and low power demand in mild winters.

After the TMI (Harrisburg) accident in 1979, it was decided politically that nuclear power would be phased out by 2010. However, few tangible actions have been taken, and a parliamentary inquiry in 1995 suggests that Sweden should begin shutting down NPPs within a few years, but that it would be prohibitively expensive to complete the phaseout already by 2010.

Dose limits conform with ICRP 60 (1). There is also a supplementary lifetime dose limit for workers of 700 mSv. A supplementary limit of 180 mSv at age 30 was removed in 1994 when the ICRP 60 limit, 100 mSv/5 years, was enacted. Public doses around NPPs must not exceed 0.1 mSv annually. Collective doses to NPP workers should not exceed 2 man Sv/GW, and public collective doses should not exceed 5 man Sv/GW. In 1994, this ambition level for occupational doses was made more stringent as a planning limit per site and 5-year period.

OCCUPATIONAL EXPOSURES

Data on the current nuclear power programme in Sweden, and average effective doses due to external exposures, are given in Table 1. Broadly speaking, individual and collective doses

Table 1. Occupational exposure to external radiation at Swedish NPPs, 1985 - 1994

	Reactors in operation [1]	Energy generated [2]	Installed capacity	Workers w/ doses >0.1 mSv	Annual individual mean dose for:		Annual normalised collective mean dose per:		
					utility	contractors	reactor	GW a	GW [3]
(Year)	(Number)	(GW a)	(GW)	(Number)	(mSv)	(mSv)	(man Sv)	(man Sv)	(man Sv)

1993	11	6.7	9.6	6 574	2.4	4.9	2.5	4.1	*2.9*
1994	11	8.0	9.6	5 886	1.8	3.4	1.6	2.2	1.8

Notes: 1) Oskarshamn 1 temporarily closed for major refurbishment 1993-1995
2) To convert from gigawatt years to terawatt hours, multiply by 8.766
3) Ambition level ≤ 2 man Sv/GW; from 1995, this is a planning limit per site and 5-year period

are low to intermediate in international comparison (2). However, in 1992 and 1993 doses to Swedish NPP staff increased sharply. Safety-related rebuilding of the oldest five BWRs after the so-called strainer clogging incident at Barsebäck in 1992, and major refurbishment of the oldest plant, Oskarshamn 1, were important but by no means sole contributors to this development.

The resulting individual and collective doses still were not, in themselves, very high, and no dose since 1981 exceeds 50 mSv in a year. The normalised collective dose exceeded the regulatory level of ambition somewhat in 1992 and 1993, but no formal rule infractions occurred. Nonetheless, the Swedish Radiation Protection Institute (SSI) found the new trends highly disturbing and reacted strongly. A detailed analysis of the trends and their causes, and a description of the actions taken to offset the trends and their results, are given in the accompanying paper by Malmqvist and Godås (3).

All doses causing concern were due to external exposures. Consistently, very few employees are subject to any intake of radioactive material. Table 2 demonstrates the very limited exposures from intakes.

Table 2. Occupational exposure due to intake of radionuclides at Swedish NPPs, 1988 - 1994

(Year)	Workers with intakes >0.005 ALI (Number)	Range of individual ALI values (min - max ALI)	Maximal committed effective dose (mSv)
1988	5	0.005 - 0.009	0.5
1989	1	0.005	0.3
1990	0	-	-
1991	6	0.005 - 0.095 a)	4.8 a)
1992	0	-	-
1993	5	0.005 - 0.048	2.4
1994	7	0.006 - 0.014	0.7

Note: a) Probably an overestimate due to insufficient surface decontamination before measurement, since a second measurement 6 days later indicated only 0.002 ALI

EXPOSURES OF THE PUBLIC: DISCHARGES FROM NORMAL OPERATION

Calculated annual doses to critical groups and normalised global collective doses from discharges of activity into the environment are shown in Table 3. The collective doses are

Notes: 1) Relevant dose limit = 0.1 mSv
2) Regulatory ambition level for doses due to the sum of all discharges = 5 man Sv/GW
3) Calculated on basis of installed capacity except 1992-93 (with unusually long outages) when based on generated electricity

computed using a truncated 500-year time integral. They are dominated by ^{14}C, the discharges of which are calculated only (not measured).

In general, calculated individual doses remain relatively low, although fuel damage at Oskarshamn 2 in 1988 and a more serious case at Ringhals 1 (BWR) in 1993 are very evident in the Table. Furthermore, the PWRs at Ringhals cause higher calculated doses due to ^{14}C because of lower smoke stacks. The regulatory level of ambition for the collective dose, ≤5 man Sv/GW, is often exceeded somewhat by the calculated ^{14}C discharges.

Whilst computed doses are low to moderate, the underlying activity discharges are in some cases fairly high compared to similar reactors in other countries (4), to some extent reflecting large recipient capacities. This could raise questions about the application of Best Available Technology (BAT) under an ALARA regime.

Admittedly, environmental monitoring indicates relatively minor contamination outside the NPPs. Samples of various plants taken from the marine environment in the immediate vicinity of the plants show elevated radionuclide concentrations which are usually well correlated with reported discharges. For ^{60}Co, these may reach some kBq/kg dry weight for the most exposed organisms (algae scraped from plates 200 m from the discharge pipes). In terrestrial samples, concentrations are very low except for contamination due to the Chernobyl accident (9). Nonetheless, the fact that relatively big discharges cause small doses to humans under the prevailing conditions also pinpoints the question of protection of the environment: does protection of man always automatically provide fully adequate protection for other species, as postulated by ICRP?

EMERGENCY PREPAREDNESS

An extensive programme from 1981, in response to TMI, was further augmented in 1990 as a result of Chernobyl. One of the early components of the measurements foreseen in case of an accident in Sweden comprises indication measurements, performed by specially trained firefighters at predetermined locations around NPPs. Several rounds of exercises have shown that it is unwise to complicate such early actions by trying to deploy available staff at selected locations and times expected to be particularly exposed. Instead, SSI now has the strategy that all locations should be manned and measurements start as soon as possible in an emergency.

Within SSI and in the counties concerned, computer equipment and software are being upgraded. This is not primarily to do with dose calculations, for which fairly simple existing tools are perfectly adequate in the early emergency phase when a paucity of measurement data will in any case limit the precision of prognoses. Instead, the tools which really need to be state-of-the-art deal with communication, record-keeping, and data storage, handling and retrieval. In this context, harmonisation of software tools in different countries and at the various NPPs is important.

ASSESSMENT OF THE INTERNAL CONTAMINATION OF NUCLEAR POWER PLANT WORKERS IN FINLAND

T.Rahola, M.Suomela, E.Illukka and S.Pusa
Finnish Centre for Radiation and Nuclear Safety,
P.O. Box 14, FIN-00881 Helsinki, Finland.

INTRODUCTION

Two nuclear power plant (NPP) sites with two reactors each are located in Finland. At Loviisa the reactors are of the PWR (VVER) type and at Olkiluoto of the BWR (ABB Atom) type. Finnish NPP surveillance regulations require that doserate, air and surface contamination be monitored and that partial-body monitors (also thyroid monitors) be available at the plant site for direct measurements of internal contamination. The risk of NPP workers becoming internally contaminated is highest during the annual refuelling and maintenance outage. During the outage period, a group representing workers with the highest risk of internal contamination must be measured with a system giving nuclide specific results. For this purpose, whole-body counter measurements are performed by the Finnish Centre for Radiation and Nuclear Safety (1).

MATERIAL AND METHODS

The body monitors detection limits of some thousands of becquerels at the NPP:s are used especially for internal contamination control of outage workers. For whole-body counter measurements a mobile unit with chair geometry and one HPGe detector or a stationary scanning type counter equipped with NaI(Tl) and HPGe detectors in Helsinki are used (detection limits ~ 50 Bq for ^{137}Cs)(2). With the mobile whole-body counter at STUK a small group of workers varying from 30 - 130 persons, representing different types of job involving risks of internal contamination is routinely measured once during the annual outage and once during normal operation each year and always if internal contamination is suspected. Each worker showers and changes into clean clothes before the measurement. The measured body content of radionuclides is considered to be internal although part of it might be skin contamination. In the mobile system the measurement time is usually 1000 s and in the stationary system about 1800 s.

After incidents involving risks of internal contamination workers are monitored and further investigations are performed if decontamination procedures are not effective enough. In such cases the stationary scanning counter in Helsinki is used for whole-body counting.

RESULTS

Varying but small amounts of activation and corrosion products have been detected (e.g. ^{51}Cr, ^{54}Mn, ^{58}Co, ^{59}Fe, ^{60}Co, ^{95}Zr, ^{95}Nb, ^{110m}Ag, ^{124}Sb and small amounts of ^{131}I), mainly during outage periods. Figure 1 illustrates two contamination cases at the NPP:s in Loviisa and Olkiluoto. In the present paper all detectable body burdens ($\geq$ 100 Bq) are classified as contamination (Fig.2). The mean body burdens have usually been < 1 kBq (3).

The body burdens of persons working together have been found to vary much thus showing the importance of radiation protection instructions and of good individual working habits. Some profile scan measurements have been done in order to gain more information on the distribution of radionuclides in the body and the retention pattern.

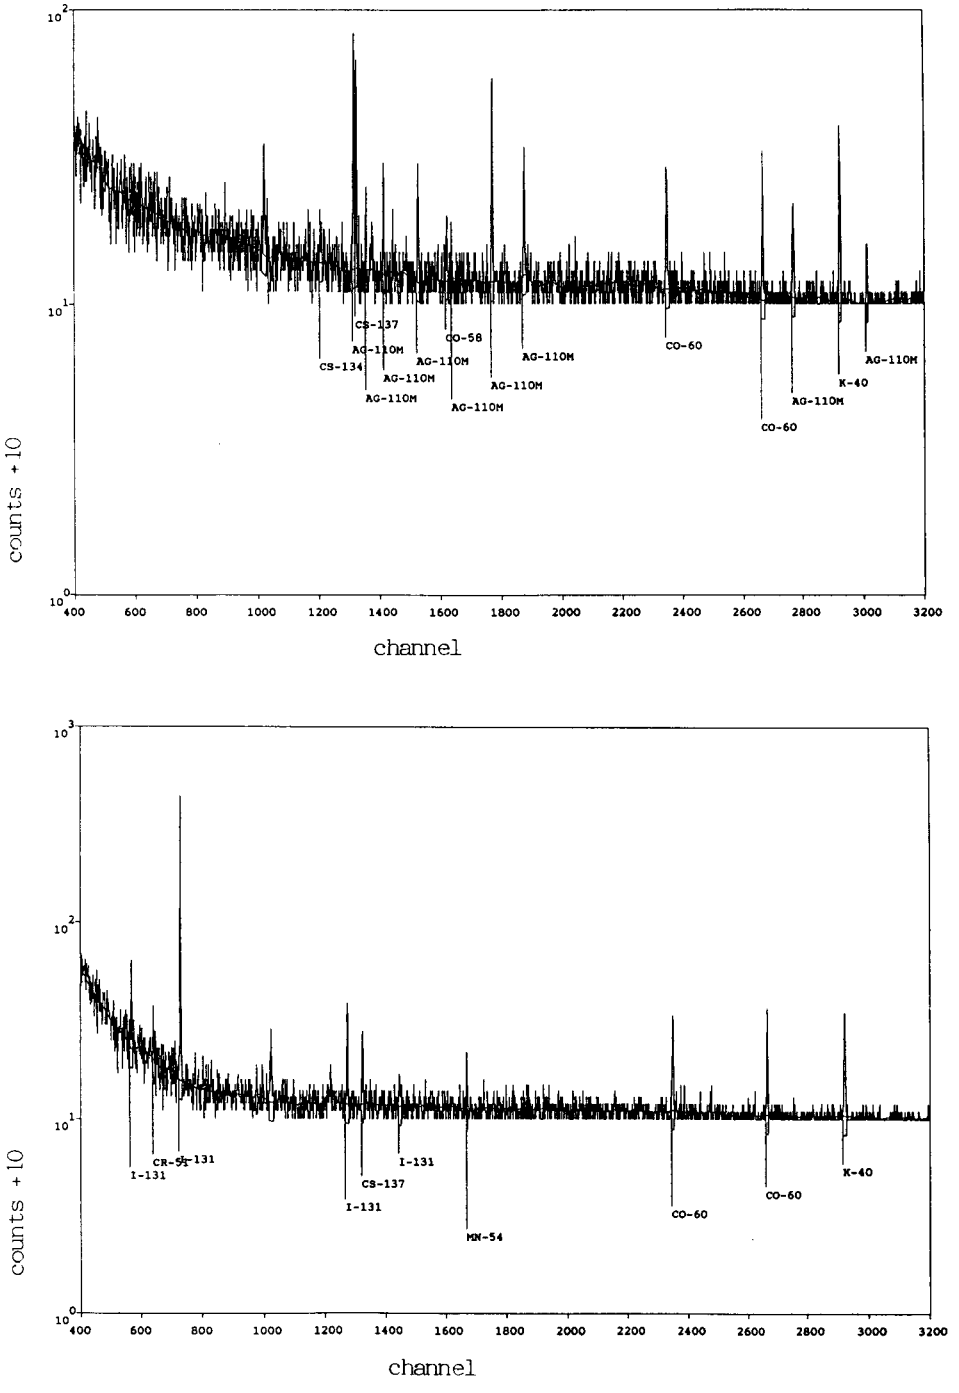

Figure 1. The upper spectrum was measured at the PWR NPP (100 Bq ^{58}Co, 400 Bq ^{60}Co, 1000 Bq ^{110m}Ag) and the lower spectrum at the BWR NPP (1200 Bq ^{51}Cr, 100 Bq ^{54}Mn, 500 Bq ^{60}Co, 2400 Bq ^{131}I) during the annual outages in 1994. The radiocesium originates in the Chernobyl accident.

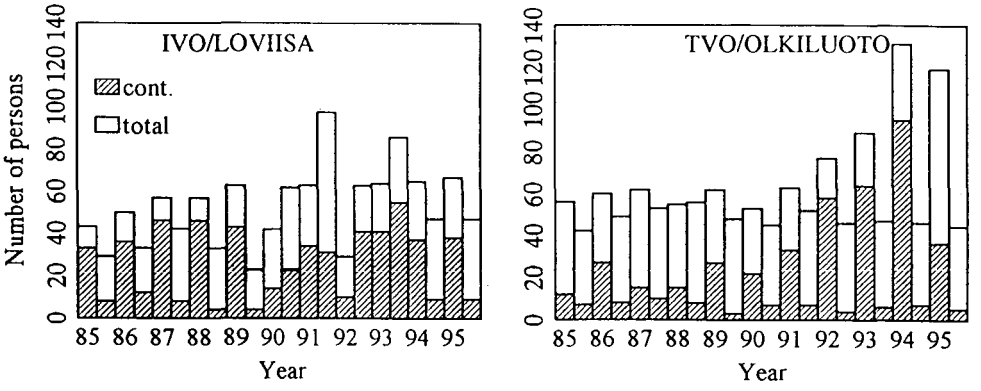

Figure 2. The number of persons measured at both NPP:s from 1985 forwards. The bar to the left represents the outage period each year. All detectable body burdens are classified as contamination (≥ 100 Bq).

DISCUSSION

A typical occurrence for VVER reactors is the appearance of ^{110m}Ag in workers, as also reported by Ormai et al. from Hungary (4). No ^{110m}Ag was detected in workers from the BWR NPP in Finland, although it was detected in the primary coolant. In terms of radiation protection ^{60}Co is the most important radionuclide.

Contamination levels depend greatly on the type of repair and maintenance work done during the outages. Experience has shown that, if the internal effective dose approaches 1 mSv, an incident has occurred. In an outage, usually no more than 20 % of the whole-body counted workers receive a dose of > 0.1 mSv, which is the minimum recording level in Finland. If the body burden of a worker is considerably higher than the mean body burdens during an outage, this person will be remeasured and the radiation history established so that the radiation dose can be estimated more accurately. If possible, such persons are measured repeatedly during a longer period of time to enable even more accurate estimation of the half-lives of the radionuclides in question.

In addition to dose control, whole-body counting aims to monitor radiation hygienic conditions in work areas and especially to motivate workers to pay close attention to their own working habits. The whole-body counter measurements help to keep the doses as low as possible. They are also important for reassuring workers that working conditions are satisfactory.

MAJOR SCIENTIFIC TOPIC NUMBER 5.2 (see page 7)

ABSTRACT (See instructions overleaf)

In Finland, there are four nuclear power plants at two sites, commissioned between 1977 and 1981. A central registry for occupational doses of all radiation workers has been maintained from the year 1965. The computerized registry allows easy follow-up of personal doses, including lifetime and 5-year doses.

In this paper the results of a study of lifetime doses of workers are presented. The results include a table of distribution of lifetime doses and data on the age and work classification of the persons with highest doses. Also distribution of 5-year average in the periods of 1985 - 1989 and 1990 - 1994 are presented.

RADIATION PROTECTION IN TVO AFTER YEAR 2000

Reijo Sundell

Teollisuuden Voima Oy (TVO), 27160 OLKILUOTO, Finland

INTRODUCTION

What is the optimum level of radiation protection in nuclear power plants? Is it still adequate if radiation protection is realized according to ALARA? In most cases I would say no if we are seriously thinking about the acceptability and the future of nuclear power.

Although TVO´s annual radiation doses are very low worldwide, on average 0,74 Sv per unit, they are still too high and must be decreased. There are two ways to do it, either by minimizing the radiation sources or by making people work in such a way that they get less doses. In TVO we are doing both. There is a DOSE-project, the aim of which is to decrease the cobolt-60 content in the reactor water by all available means. This paper only discusses how we must take the human factor into consideration in minimizing personal doses in the future.

INDIVIDUAL RESPONSIBILITY

Given the chance, a worker will look for the most dose-efficient method of doing his work. I am convinced that personnel safety will certainly not be at risk if we allocate responsibility more to the individual.

Who is more interested in the person´s own radiation doses than the person himself? Nobody! A radiation protection organisation is more interested in seeing that personal dose limits are not exceeded or that collective doses are on acceptable level, but an organisation does not have the capacity, and maybe not even an interest, to concentrate on a single person's low doses. That being the case, the person himself is his best radiation protection man, and the only one to take the whole responsibility for his own safety. Let us make it possible for all nuclear power workers to take care of their own radiation protection. This will take a lot of radiation protection training.

TRAINING

A refuelling outage involves about 1000 workers from some 100 different contractor companies. These workers receive about 70 - 80 % of the total annual dose. If the number of companies were reduced to 20 - 30, arranging company-specific radiation protection training would be more practical. With company-specific training we can concentrate on radiation protection matters that are important to that specific company. Electricians have different problems than mechanicians.

Training alone is not enough to keep the contractor companies' knowledge of radiation protection on a high level. Each company should nominate a person who is responsible for the communication between the power company and the contractor company on radiation protection questions. He would be responsible for disseminating all information which is sent to the company to all its employees. He would thus act as a company's own radiation protection manager.

VERSATILITY OF SKILLS

One way of reducing doses is to reduce the number of people working in a controlled area. By teaching people to do a series of operations rather than just one specialist task, the number of people can be reduced. For example, a mechanician can insulate components, make simple scaffoldings and take care of the cleanliness of the work site in addition to his mechanical work. Doing the work in this way, it will become more flexible and also more interesting and more challenging to the employee. A motivated employee also takes good care of his own radiation protection.

GENERAL CLEANLINESS AND ORDER

Cleanliness and order go hand in hand with good radiation protection. That is why the responsibility for the cleanliness of the working environment should also be passed more towards the individual. Contamination cannot be seen by eyes but by keeping surfaces clean and the work site in order, so that there are no unnecessary objects lying around, you can be quite sure that there is no contamination. A high level of cleanliness and order also makes the work site pleasant and safe. Working in such environment is faster and more fluent.

DEVELOPMENT OF RADIATION INSTRUMENTS

As responsibility for radiation protection is given to those who do the work, new demands will be placed on the measuring instruments. They have to be light and simple to use. One push button (on/off) is enough. All other buttons are unnecessary and make using the instrument too difficult. The accuracy of the instrument does not need to be very good; 1 mSv/h is enough. Analogical display is better than digital. The rough range of dose rate is more important than the exact value in numbers. Besides the dose rate instrument, the employee has to have an electronic dosimeter with a digital display and sound alarm to be able to monitor his doses.

ONLY BY MEASURING CAN YOU FIND OUT WHICH DOSES YOU SHOULD CONCENTRATE ON REDUCING

COMPUTER AIDED RADIATION PROTECTION SYSTEM AT TOKAI REPROCESSING PLANT

Jun-ichiro ISHIDA, Jun-ichi SARUTA, Rika YONEZAWA
Power Reactor and Nuclear Fuel Development Corporation, Tokai, Japan

INTRODUCTION

Radiation control for workers and workforce has been carried out strictly and effectively taking into account ALARA principle at Tokai Reprocessing Plant(TRP) which has treated about 860 tons of irradiated fuels by now since 1977. The outline of radiation control method at TRP has already been described in (1), (2) and (3). This paper briefly describes our experiences and the capabilities of Radiological Information Management System (RIMS) for the safety operation of TRP, followed by radiation exposure control and activity discharge control as examples .

OBJECTIVES AND SCOPE

The main plant construction started in 1971 and was finished in 1974, since then waste treatment facilities and waste storage facilities were successively constructed together with locating the safety control rooms at several facilities separately. On the other hand various kinds and levels of radioactive materials are treated in TRP and the radiation fields are monitored for the purpose of avoiding excessive exposure of workers and of confirming that working environment is satisfactory for operations. Therefore all the data are to be centralized in the central safety control room for the effective radiation protection.

SYSTEM DESCRIPTION AND CAPABILITIES

The RIMS, which consists of several functions such as a radiological monitoring at workplaces, a radiological data base of past experience, a management of radiological work, etc., was designed and set up at the safety control rooms to reduce exposures associated with routine and special repetitive maintenance operations in TRP. The schematic diagram of RIMS is shown in Fig.1.

(1) Radiological Monitoring at Workplaces

The radiological monitoring at workplaces of TRP is conducted by using about 400 channels of continuous on-line monitoring equipment such as area monitors for gamma-ray and neutrons, dust monitors for alpha and beta particles, exhaust monitors for krypton-85, iodine-129,131, etc. which are located at each spot. The signals of all the detectors are centralized to the health physics panels in each safety control room and then are linked to the computer system of RIMS through the panels of the central safety control room. And to support these on-line monitors, manual radiation monitoring such as area survey of external radiation, airborne radioactive materials and surface contamination is carried out periodically. Dose equivalent rates at fixed points in each facility are measured with survey meters daily, weekly and monthly. Airborne radioactive materials in workplaces are weekly sampled by the air sampling system and then measured by low background proportional counters to estimate the concentration of radioactive materials in workplaces. Surface contaminations at fixed points in the workplaces are estimated by smear sampling daily and weekly. All these data except surface contamination are input to the computer of RIMS. There is no need to record surface contamination which is normally less than the detection limits except for the special maintenance period because the restricted area of TRP is essentially well controlled based on the principle of "Non-contamination". The off-line survey data are input to the RIMS through handy-terminals or radioactive measurement instruments.

By using the RIMS, each data is displayed in case of need, for example, every minute, hour, day or week.

The data are easily compared to the authorized limits to confirm the state of the facilities. If dose equivalent rate or concentration of airborne radioactive materials were raised over the control levels, they warn workers to evacuate from the room immediately.

(2) The Radiological Management System and Radiological Data Base of the Past Experiences

In case of the work done under high dose rate or in contaminated area such as the work in a cell, a special radiological work plan needs to be authorized by the director of TRP after checking by the staffs of radiation protection section and the safety superintendent. Advice on radiation protection is given to the plan in consideration of minimization and optimization of exposure to workers. On this occasion the staffs of radiation protection section refer to the past similar experiences from view points of the working process, the radiation monitoring programme, the choice of radiation protection apparatus, the education and training, the maximum individual dose, the total collective dose, the emergency planning etc.. Especially the prior check of the radiation levels and the procedures of the work is very important. So far these performance checkings have been done by the human sea tactics, and so it takes a lot of time and the products of the past experiences have not always been put to practical use. The RIMS includes many experiences of the past special radiological works, and the required data are gained quickly as factors of date, working room number, working unit, working group's name, species serial number and so on. During the work the exposure doses to workers are collected and added by every individuals and are compared with the planned exposure dose by using the alarmed personnel dosimeters and the RIMS. After the work the analysis report of the work is written and is input to the RIMS for the next similar works.

(3) Information on the Present Conditions of Plant Operation

The RIMS includes operational conditions such as shearing, dissolution, clarification, extraction, Pu purification, Pu concentration, acid recovery distillation, and so on which are needed now and then.

CONSEQUENCES OF RADIATION CONTROL

The number of workers have increased in keeping with increase of facilities. Higher collective dose equivalents, by way of example, 1.7 man-Sv in 1983, 2.0 man-Sv in 1984 and 4.5 man-Sv in 1988 were resulted from the large maintenance works such as the repair of dissolvers, the replace of acid recovery evaporator and so on. Under normal plant operation the average collective dose equivalent is about 0.5 man-Sv in a year and the average exposure of an individual is about 0.1 mSv recently. These values are mainly the external exposure because the internal exposure have rarely occurred.

CONCLUSION

By operating the RIMS, the conditions of workplace such as dose equivalent rate and air contamination are easily and rapidly grasped to take prompt countermeasures for radiological protection, localization and elimination of contamination, and also the past experience data are properly applied to new radiological works to reduce exposures associated with routine and special repetitive maintenance operations at TRP. Finally, authors would like to emphasize that the form and system for radiological control of reprocessing plant has been established throughout our 15-year-experience at TRP.

TREND OF COLLECTIVE DOSE AND DOSE REDUCTION MEASURES OF MITSUBISHI ELECTRIC CORPORATION WORKERS IN NUCLEAR POWER PLANTS

Ichiro Yamato, Taesuke Nakayama, Fumio Shimokawa, Toshiki Yamamoto

Mitsubishi Electric Corporation, Kobe, Japan
("MELCO" hereafter)

ABSTRACT

MELCO has supplied the reactor instrumentation control system, reactor coolant pump motors, turbine generator and central control system for the pressurized water type nuclear power plant. For the legal periodical inspection and repair work, MELCO has also received orders for the periodical inspection for 23 power plants (including 4 plants under construction) of 5 electric power companies, and executed the inspection work from the view point of preventive maintenance.

The annual dose for MELCO's workers is liable to be decreased in spite of increased number of plants. The dose for new plant in particular is 50% or less as compared with that for conventional plant. This is because the measures taken for the conventional plant against the dose reduction is reflected upon the new plant.

The dose reduction measures are taken for each system for which order was received. Such measures are mainly intended to improve the work procedures and equipment for reduction of work time in the radioactive area and to arrange the working process, so as to perform the work in such period when the dose level at the working environment is low.

To enhance the workers' consciousness for reduction of dose, MELCO provided the workers with dose predictive training, and let them aware of such items known at the tool box briefing(TBM), which could realize the dose reduction for workers. MELCO has been positively promoting the activity to arrange the desirable work environment for extermination of 3Ks (*Kiken, Kitsui, Kitanai*) or 3Ds(dangerous, difficult, dirty) including protection against radiation in corporation with electric power companies.

INTRODUCTION

The number of workers engaging in nuclear facilities for MELCO's nuclear work to talled to approx. 300 (net) annually, and the number of workers engaging in such work, including the employees of cooperative companies totalled to approx. 1,500 (net) annually.

The paper is intended to report the results of investigation/analysis on the annual dose(1983~1994) for employees of MELCO at time of periodical inspection from the view point of dose reduction, and to introduce the technical method for dose reduction and contents of education/training for workers.

TRENDS

1. The annual collective dose(PWR) for MELCO's workers(including workers of cooperative company) during period from 1983 to 1994 tends to be decreased inspite of increased number of power plants.
   1) The annual dose for MELCO's worker per each periodical inspection of PWR plant is liable to be decreased.
   2) The reason why the dose for MELCO's worker was increased in 1993 is that the

attached work (replacement of steam generator) was executed.
(dose for work concerned: 443 man.mSv)

2. The main exposure for MELCO's workers is that received during periodical inspection, or from the replacement work of reactor coolant pump motor. The transition of dose during latest 5 years is liable to be decreased.

METHODS

The basic principles for dose reduction measure are to secure the proper distance from the radiation source, to reduce the time required for work, to shield and remove the radiation source. The effect of dose reduction is depending on how these four principles are fulfilled by the electric power company, contractor(who plans the work) and workers in cooperation. As a result of such activities, the dose for MELCO's workers during periodical inspection of nuclear power plant is liable to be decreased.

1. The methods for those who plan the dose reduction measures will include the improvement of equipment/facility, adjustment of work implementation process, and improvement, education and training of work procedures, etc.
   1) The improvement of equipment/facility will include the modification of power cable connection from conventional type to plug-in type, installation of lube oil filling and drainage equipment for lube oil, installation of lifting device for motor terminal box, and is intended to shorten the time required for work.
   2) The adjustment of work implementation process, for instance, is so planned as to be performed when the water is filled in the secondary side of steam generator within the loop room as much as possible.
   (When the water has already been filled in the secondary side of S/G, the water will serve as shielding substance, causing the environmental dose rate to be decreased by more than 50%.)
   3) The education/training is an essential item from the view point of radiation protection, as it helps to enhance the worker's consciousness against dose reduction.
   For the education/training, MELCO provides the basic education/practical education on the radiation for 7 hours, to learn the knowledge on radiation, influence of exposure, dose limit, etc.
   For dose reduction, MELCO provides the dose prediction training(HYT), using the illustrations, to minimize unnecessary radiation exposure.
   Such training was evaluated for effect in accordance with the result of questionnaire conducted on the workers, which proved that some effect was brought about, though it was difficult to evaluate it quantitatively.
   For dose prediction training, MELCO gathered the workers in charge and selected the leader to make up a small-member group, to provide the dose prediction training, using the illustrations simulating the site for each group
   In addition, MELCO provides a reading-out of instruction manuals prior to the work, or the TBM on the very day of work.

2. The measures to be taken by the electric power companies will include the purification of primary cooling material stained due to oxidation operation of

plant, removal of high dose rate piping, etc.
When the radiation source is removed, the dose rate for entire plant is decreased, causing the dose against the worker of contractor to be decreased.
Such measures are expected to provide the greatest dose reduction effect.

3. The education/training discussed above is intended to allow the workers to learn the knowledge on the basic principles for dose reduction, to be conscious of dose reduction,
and further to utilize such knowledge during the process of work.
Enhancing the consciousness of worker against the dose reduction will help to eliminate unnecessary radiation exposure of each worker, and repeated practice will reduce exposure.
The attitude of each worker concerned with the radiation protection will be an essential item to secure the radiation safety.
It is also essential for each worker to take the dose reduction activity as his own activity, and to let him have such consciousness as to be taking part in the activity.
Although it is difficult to calculate the dose reduction quantitatively for trial, the dose reduction of 30% is thought to be an effect of such activity.

CONCLUSION

The paper mainly discussed the dose reduction measures from the standing point of a contractor.
It is thought that the great effect will be assured for dose reduction by through the work by three parties of electric power company, contractor(who plans the work) and workers in cooperation.

It is also necessary to minimize the exposure risk of workers by reflecting the ALARA spirit(which ICRP recommends), upon the local equipment/facility design/layout and workers, to minimize exposure risk of workers.
It is important to enhance the consciousness of workers against the dose reduction as well as to study the technical dose reduction measures.
Each nuclear power plant takes the radiation as a main factor of countermeasure against 3Ks, and has been carrying on the dose reduction measures together with the electric power company.

The dose reduction will be an important problem to be settled, for those who are engaged in the radiation protection. The authors are intended to positively promoting the subject in the future.

MAJOR SCIENTIFIC TOPIC NUMBER 5.2. (see page 7)

ABSTRACT (See instructions overleaf)

This year the new Slovak legislation on radiation protection, based on ICRP 60 recommendations, has been prepared. The individual dose trends for different professional groups of nuclear power plant workers for last few years are sumarised. In this conection the attention has been given to the professional groups and activities with potential high radiation risks. The results show that some problems with new dose concepts complying can arise.

FIELD MEASUREMENTS OF BETA-RAY SPECTRA INSIDE NUCLEAR GENERATING STATIONS USING A SILICON DETECTOR COINCIDENCE TELESCOPE

Y. S. Horowitz[1], Y. Weizman[1] and C.R. Hirning[2]

[1] Physics Department, Ben Gurion University of the Negev, Beersheva, Israel
[2] Health Physics Department, Ontario Hydro, Whitby, Ontario, Canada

INTRODUCTION

Beta radiation is now recognized as a significant radiation safety problem in the personal dosimetry of weakly penetrating radiations. The use of "thick" dosimeters (eg., typically 100 mg cm^{-2}) for beta dosimetry requires, therefore, the application of beta correction factors which correct for the under-response of these dosemeters to low-energy betas. The estimation of these beta correction factors requires in-turn some knowledge of the beta-ray energy spectrum impinging on the dosemeter. In acknowledgement of this requirement, and to improve the accuracy of beta ray personal dosimetry in their nuclear power installations, Ontario Hydro initiated a study in the 1990s aimed at the characterization of beta radiation fields in CANDU reactor typical working conditions.

In the first stage of this effort, a two-detector coincidence telescope, based on a thin (97 μm) silicon detector (dE detector) and a thick (2 cm) plastic scintillator (E detector), was used (1). The use of a 97 μm thick silicon detector allowed us to achieve a lower energy coincidence threshold of 125 keV. This telescope was used to measure approximately thirty beta radiation fields in CANDU nuclear generating stations (2). Monte Carlo calculations were then used to estimate beta correction factors for the LiF-TLD elements in the Ontario Hydro TL dosimeters (3). Due to the poor energy resolution and noise characteristics of the plastic scintillator, the spectrometer coincidence efficiency decreased rapidly below 500 keV reaching a value of only approximately 15% at 125 keV. These low energy characteristics were judged insufficient, since the Monte Carlo calculations (3) showed that it is exactly the energy region below 500 keV for which the electron depth-dose distributions vary extremely rapidly, thereby contributing to the large and uncertain values of the beta correction factor. Furthermore, the measured beta spectra, corrected crudely for the loss in coincidence efficiency below 500 keV, showed an approximately exponential electron fluence intensity that increased with decreasing electron energy, implying that the deduced beta correction factors could be very significantly underestimated due to the uncharted electron energy region between 60 keV (the minimum electron energy which penetrates to a skin depth of 7 mg cm^{-2}) and 125 keV. Other serious difficulties arose when measurements were attempted in areas, for example a reactor containment vault, which required encapsulation of the spectrometer in plastic to prevent radioactive contamination. The encapsulation in plastic without adequate ventilation or cooling led to an increase in the temperature and leakage current of the front silicon detector, resulting in a rapid increase in noise level and consequently to an uncontrolled increase in the chance coincidence rate.

Based on these considerations a two- or three-element detector coincidence telescope based exclusively on silicon detectors, and cooled thermoelectrically when encapsulated was constructed and tested with the following significant advantages.

SYSTEM PERFORMANCE

1. The lower energy coincidence threshold (front dE detector, A = 40 μm) is 70 keV (60% efficiency) compared to 125 keV (15% efficiency) for the silicon/plastic

spectrometer. Slightly higher but still improved coincidence thresholds are obtainable with 72-μm and 97-μm thick detectors.

2. The coincidence efficiency decreases from 100% for electron energies below 100 keV to 250 keV depending on the choice of thickness for the front detector A compared to 500 keV for the plastic spectrometer. For the 40-μm detector the coincidence efficiency is 100% over the entire range of energies above 100 keV. For the thicker dE detectors the loss in coincidence efficiency is far more moderate below 250 keV than the loss in coincidence efficiency for the plastic spectrometer.

3. An important figure of merit (FOM) of the spectrometer is the rejection factor against photons, R_p, where

$$Rp = N_1/(N_t - N_c). \qquad (1)$$

N_1 is the singles counting rate in the thick energy detector , N_t is the total coincidence counting rate, and N_c is the chance coincidence rate. R_p is defined in this manner for a pure incident photon fluence and is essentially a measure of the reduction in the photon count rate due to operation of the coincidence requirement.

The photon rejection ratios are also significantly improved compared to the silicon/plastic spectrometer. For ^{133}Ba, in the two-element mode, the photon rejection ratio is 1600:1 compared to 360:1 for the silicon plastic spectrometer. In the three-element mode, the photon rejection ratio for ^{60}Co photons is approximately 2000:1 compared to 225:1 for the plastic spectrometer.

The beta-ray spectrometer described herein, incorporating photon rejection ratios of up to 2000:1, represents a significant improvement in the "state-of-the-art" in beta ray spectroscopy in the intense photon fields often encountered in reactor radiation environments. The spectrometer has been used to measure over 40 field spectra in CANDU reactors (5) ands the details of these measurements and the calculated beta factors using depth dose distributions based on Monte Carlo calculations for these spectra are described in the following.

BETA-RAY MEASUREMENTS

A total of forty two measurements were carried at three sites operated by Ontario Hydro, the Pickering, Bruce B and Darlington Nuclear Generation Stations. The measurements were carried out on various fuelling machine and boiler room components and smears from various working areas, in various detector configurations and at various source-detector distances. These sources are representative of components that working personnel come into direct contact during clean-up and maintainance procedures. The spectra are generally featureless with the relative intensity of the electron fluence increasing roughly exponentially with decreasing electron energy. The maximum energy varies between 1200 keV and 3500 keV, with an average energy of approximately 550 keV. This behaviour is apparently typical of a mixed fission-product spectrum. The threshold energy of the various spectra varies between 70 keV and 150 keV. Filtered spectra, through various layers of protective clothing, show no significant changes in shape in the important low-energy region, the main effect of the filtration being a reduction in the maximum energy of the spectra. Thus, although low-energy betas in the primary spectrum are absorbed by the protective clothing, multiple scattering and attenuation of the higher-energy electrons replenishes the supply of low-energy electrons, resulting in an essentially unaltered spectrum in the low-energy region. This observation goes against the common dogma that protective clothing reduces superficial dose via absorption/removal of low-energy electrons. This will be true only in the absence of high-energy electrons which continually replenish the supply of low-energy electrons.

CALCULATION OF BETA CORRECTION FACTOR

Beta correction factors were calculated for all the measured beta-energy spevctra, for both the 100 mg cm-2 and 240 mg cm-2 skin and extremity dosimeters, in both perpendicular and isotropic geometries. It is interesting to compare the average beta correction factors obtained using the silicon spectrometer with those obtained using the plastic spectrometer. The beta factors are increased by 19% for the skin chip and by 11% for the extremity dosimeter respectively, indicating that low-energy electrons (between 60-125 keV and not detected by the plastic spectrometer) lead to a measureable, but not dramatic, increase in the beta correction factors.

Averaging over all the beta correction factors for the skin dosemeter yields 2.33 ± 0.83 compared to the current value of 1.74 used by Ontario Hydro. Averaging over all the beta correction factors for the extremity dosemeter yields 3.73 ± 1.38, compared to the current value of 2.0 used by Ontario Hydro. Our measured values are, therefore, 34% (skin chip) and 87% (extremity dosemeter) higher than the current beta correction factors used by Ontario Hydro in their dosimetry program. It is intuitively more reasonable to expect that the working place environment (and averaged over the movements of the radiation worker) produces an effective near-isotropic radiation field for a "chest-worn" or an extremity dosimeter. In this case the more appropriate beta correction factor for the "skin" chip would be 2.73 ± 0.77 and for the extremity dosimeter 4.42 ± 1.17. These values are 57% and 120% greater, respectively, than the current values used by Ontario Hydro.

CONCLUSIONS

The very large spread in beta correction factors clearly indicates the need for a dosimetry system based on thinner detectors for both the "skin" chip and the extremity dosemeters. With the currently used thickness of 100 mg cm^{-2} and 240 mg cm^{-2} used by Ontario Hydro, the appropriate beta correction factors vary by approximately one order of magnitude depending on the source of the radiation field, the angular distribution of the radiation field, the source - TLD distance, etc.... The only practical method to reduce these large uncertainties is to adopt detector thicknesses as low as possible and still consistent with other dosimetric requirements such as minimum detectable dose, ruggedness, etc... To demonstrate the benefits of decreased thickness we have calculated the beta correction factors for representative and extreme spectra for 40 and 20 mg cm^{-2} chips. These particular thicknesses were chosen to correspond to commercially available LiF-TLDs. The benefits of decreased thickness are dramatic. The average value of the beta correction factor decreases from 4.80 for a 240 mg cm^{-2} chip to 1.29 for a 20 mg cm^{-2} chip. In addition, the spread in beta correction factors also dramatically decreases, from 4.80 ± 2.1 (44%) for the 240 mg cm^{-2} chip to 1.29 ± 0.1 (8%) for the 20 mg cm^{-2} chip. Clearly a 20 mg cm^{-2} chip of high sensitivity is the optimum choice for superficial dose estimation due to beta rays.

DOSIMO

A NATIONAL COMPUTERIZED SYSTEM FOR MONITORING OPERATIONAL RADIATION EXPOSURE

André D. CANIPELLE
GIIN General Secretary

INTRODUCTION

In parallel to the expansion of the number of French nuclear power plant units in operation, maintenance actions have multiplied, which has meant calling upon the services of a growing number of increasingly specialized workers. It has therefore proved necessary to reinforce the radiation dose rate surveillance of these workers.

As a result, certain companies decided to set up their own occupational radiation dose monitoring system, in addition to mandatory monitoring by the OPRI[1], using dosimeters, generally electronic or thermoluminescent film badges, supplied by the subcontractor companies or nuclear facility operators. This enables acquiring fast and accurate knowledge of the radiation doses received by the workers.

For this type of surveillance to be fully efficient, a data centralization system was required, able to provide frequent, even daily readings if necessary, of the dose received during the current month or for any period of time, up to the sum of the doses accumulated over five years.

A first step forward has already been taken by EDF with the implementation of the Dosinat computer application, which centralizes data on the occupational radiation exposure of EDF agents and subcontractor company personnel in all French nuclear power plants.

The difficulties encountered in monitoring transient workers confirmed that a monitoring system not restricted to nuclear power plants alone was necessary (see the Birraux report, the CSSIN working group, etc.).

This is why EDF and the GIIN, joined by the CEA, Cogema and the DGA[2], decided to set up a system covering all subcontractor company personnel in the nuclear field. This system, called Dosimo, is managed by the GIIN.

The regulations in force reinforce the interest of the Dosimo system, which is expected to extend throughout Europe, then worldwide.

Euratom directive No. 90/641, published in December 1990, specified the responsibilities of nuclear facility operators and companies employing personnel in the nuclear field, with respect to radiation dose rate monitoring. The draft revisions of Euratom directives Nos. 80/836 and 84/467, which set basic radiological protection standards, confirms these responsibilities and integrates the recommendations of CIPR publication No. 60, leading to a decrease in the

allowable dose rate limits applicable to workers, and the implementation of measures to reduce workers' individual doses in accordance with the ALARA[3] optimization principle.

This evolution makes it necessary for both nuclear facility operators and subcontractor companies to have rapid, accurate, and complete knowledge of the doses received by personnel. The Dosimo system fits perfectly into the framework of these new requirements.

OBJECTIVE

The objective of the Dosimo system is to provide a close follow-up of workers' occupational dose rates.

To do so, Dosimo gathers the readings of occupational dose rates:

- Measured by nuclear facility operators using the Dosimo system during operations performed by subcontractor company personnel,
- Transmitted by the subcontractor companies employing the personnel in other cases.

Via Dosimo, this information is at the disposal of:

- Subcontractor companies, as concerns their own employees,
- The employees themselves, and
- Nuclear plant operators, for all subcontractor company personnel.

It will be made available as needed to company doctors, via employers.

FUNCTIONALITIES

Management of non-dose rate related data:
A set of functions managed by the Dosimo system enables identifying all personnel, nuclear facility operators, and subcontractor companies.

Management of dose rate data:
A set of functions enables:

- Manually or automatically downloading of the doses received by workers,
- Preserving monthly readings for five years for each worker,
- Reading the dose rate received by each worker for the current month, up to the dose accumulated over five years,
- Guaranteeing that confidentiality rules are respected.

ORGANIZATION

Dosimo inputs:
Subcontractor companies transmit identifying data on their companies and personnel concerned, and notify the departure of the latter from these companies.

---

3. ALARA: As Low As Reasonably Achievable.

Nuclear facility operators enter the readings of individual workers' occupational dose rates into the system; they are responsible for the data they enter and they alone are authorized to make changes. If need be, the sucontracting companies complete these data with readings of doses received offsite, or abroad.

USE OF THE DATA

The information gathered can be used:

- By the representative of the company holding the password. The password only gives access to data concerning company personnel. The company is thus informed of the doses received by its personnel, and can compare the results with set objectives, estimate the efficiency of its radiological protection measures, and use this experience feedback to prepare subsequent operations.

- By persons designated by the nuclear facility operator, holding the password. These persons have access only to data on fully identified workers.
  The data enables the operator, in collaboration with the subcontractor company, to implement preventive measures for the operation envisaged, taking into account the occupational dose situation of the workers, and thus optimize radiological protection (ALARA).

- By the GIIN, which manages the system. The GIIN:

  - Receives requests for connection to the system,
  - Issues the passwords,
  - Ensures data consistency and contributes to solving anomalies,
  - Ensures proper operation of the system, and
  - Is authorized to answer any request concerning Dosimo.

CONFIDENTIALITY RULES

Approval of the Dosimo system was received from the CNIL (National Committee on Information Systems and Personal Freedom) on December 21, 1993. In this framework, a worker, on request from the GIIN, can obtain information concerning himself.

Employers are bound by a charter to respect the rules concerning the confidentiality and use of the data supplied by Dosimo.

Nuclear facility operators and subcontractor companies undertake to limit access to Dosimo data to specifically designated persons, on a "need to know" basis.

COMPARISON OF NEUTRON DOSE MEASURED BY ALBEDO TLD AND ETCHED TRACKS DETECTOR AT PNC PLUTONIUM FUEL FACILITIES

N.Tsujimura[1], T.Momose[1], K.Shinohara[1] and H.Ishiguro[1]

[1] Power Reactor and Nuclear Fuel Development Corporation, Tokai ,Ibakaki, Japan

INTRODUCTION

Power Reactor and Nuclear Fuel Development Corporation(PNC) has fabricated Plutonium and Uranium Mixed OXide(MOX) fuel for FBR MONJU at Tokai works. In this site, PNC/Panasonic albedo TLDs/1/ are used for personal neutron monitoring. And a part of workers wore Etched Tracks Detector (ETD) combined with TLD in order to check the accuracy of the neutron dose estimated by albedo TLD. In this paper, the neutron dose measured by TLD and ETD in the routine monitoring is compared at PNC plutonium fuel facilities.

DOSEMETER DESIGNS

Figure 1 shows a cross-sectional view of PNC/Panasonic albedo TLD. This dosemeter consists of eight TLD elements, four of them for beta/gamma ray and the other for neutron. Element 1 is $^{7}Li_2{}^{11}B_4O_7(Cu)$ for compensation of gamma component, element 2 and 4 is $^{6}Li_2{}^{10}B_4O_7(Cu)$ to mainly measure thermal neutrons of the external fields and albedo neutrons respectively. Neutron dose H is given by the next equation,

$$H=Kn \cdot Tn=Kn \cdot (T4-T1-C \cdot (T2-T3)) \quad (1)$$

where T1,T2,T3 and T4 are thermoluminescence readings in unit R, calibrated to ^{137}Cs exposure, and Kn is the conversion factor from albedo neutron reading, Tn, to neutron dose. Energy and angular response of this dosemeter has been investigated by mono-energetic neutron fields/2/, moderated neutron fields, and also calculated by Monte-Carlo method. The conversion factor Kn is very energy dependent and appropriate value must be used to application areas. Default value of Kn for routine monitoring was determined experimentally by the comparison between TLD and neutron dose equivalent detector, "rem counter", in the typical workplace.

In this comparison study, we used Neutrak badge commercially available from Nagase- Landauer Ltd. as Etched Tracks Detector(ETD). This detector material is poly-allyl diglicol carbonate (trade name CR-39) and has a dimension size 10 x 5 x 1mm and high density polyethylene film(1mm) is attached in front of etched layer. Neutron dose is assessed by counted etch-pits N multiplied by conversion factor.

RADIATION FIELDS

The dominant nuclides which cause external exposure in the plutonium facility are ^{238}Pu,^{240}Pu and ^{241}Am. These emit gamma-ray(low energy X-ray), spontaneous fission neutrons and (alpha,n) reaction neutrons. Glove-box is shielded by polymethyl methacrylate(PMMA) and/or lead-contained PMMA, total thickness is about 50mm. Neutron energy spectra at various points in the workplace are measured by INS type multi-moderator ^{3}He detector/3/ and calculated by unfolding method. Average neutron energy in the typical workplace is about 1MeV, and the neutrons with energies above 100keV dominates approximately 90% of total neutron dose.

COMPARISON OF THE NEUTRON DOSE

Total 1,200 workers wore albedo TLD combined ETD at the fabrication process of MOX fuel from April, 1993 to March, 1994, and significant neutron dose were measured by TLD and/or ETD of 413

workers. Figure 2 shows the comparison between the albedo neutron reading Tn and counted etch-pits N. Superimposed lines present the maximum/minimum ratio obtained by the in-the-field experiments, in which albedo TLD and ETD are mounted on the water phantom installed in the typical workplace. The relation between N and Tn obtained by the combined dosemeter worn by workers agrees very well to that by experiments. Number of etch-pits is proportional to albedo reading and the average of N/Tn ratio is 0.3 with a standard deviation of 30% except the low dose range(below the detection limit, 0.2mSv). Figure 3 shows frequency of the quotients of the neutron dose measured by ETD and TLD, and the ratio are centered about 1.0 and almost within a margin of factor 2.

Though these dosemeters have a quite different energy response(TLD is sensitive to slow neutron, ETD fast neutron only), N/Tn ratio is constant. This results mean that the neutron has a uniform energy distribution in the typical workplace and TLD doesn't need any corrections, i.e. energy dependence at different workplace, for assessment of neutron dose.

CONVENTIONAL CALIBRATION METHOD

We have investigated the relation between N/Tn ratio and Kn at various neutron fields. Figure 4 shows the relation between the N/Tn and Kn. Though N/Tn ratio is observed in the range 0.3 to 10 over the average neutron energy range 0.5 to 5MeV, Kn is proportional to N/Tn with the next relation.

$$Kn=Ka\cdot 13.7\cdot(N/Tn)^{0.92} \qquad (2)$$

where Ka is the angular dependence correction factor since these two dosemeter has a different angular response. Factor Ka varies from 1.0(perpendicular) to about 2.0, depending on incident angle, but the appropriate value of Ka is found to be fixed as 1.5 not to underestimate the neutron dose in the stray neutron fields encountered in ordinary work.

Therefore we propose the conventional calibration method for albedo TLD corresponding to the ratio of measured value by TLD and ETD. Using ETD as relative neutron monitor to study average N/Tn ratio in the typical workplaces, we can classify the types of neutron fields, where special Kn value is needed, and easily get appropriate Kn. As example, if the average neutron energy in the workplace is lowered by additional shielding around glove-boxes and N/Tn ratio changes remarkably, we may re-evaluate Kn value using equation (2).

CONCLUSION

The summary of this comparison study of TLD and ETD in the PNC plutonium fuel facilities are as follows.

(1) Neutron dose measured by albedo TLD has a good agreement with that by ETD.

(2) The ratio of N/Tn ratio obtained from two dosemeters worn by workers is almost constant in the workplace. Any location-dependent variations of N/Tn ratio are negligible except for special work conditions.

(3) The ratio of N/Tn ratio is an ideal index for Kn and we can easily get appropriate value of Kn using that ratio.

(4) Use of ETD as relative neutron monitor for personal monitoring, we can easily re-evaluate Kn.

ABSTRACT (See instructions overleaf)

The aerosol samples from ventilation stack of NPP V1 Jaslovské Bohunice have been collected for the long time. The sampling is carried out by aerosol sampler (Model Sierra Misco 8080) with a flow control system. The device is placed at the bottom of the stack, where the air from all ventilation ducts is already mixed. The air volume throughput for one filter is several thousands of m^3. Sensitive gamma spectrometric analysis of aerosol samples is performed using germanium detectors. Radiochemical analysis followed by beta, resp. alpha spectrometry has been carried out, too. About 20 radionuclides with activities in the range 10^{1}-10^{-5} Bq/m^3 was studied. The essential part of total volume activity of evaluated radionuclides is connected with ^{110m}Ag, ^{58}Co, ^{60}Co, ^{54}Mn and ^{51}Cr.

From the large file of experimental data obtained in the years 1985-1995 correlation between individual radionuclides was performed. The aim of the study is to find out easily measurable "marker" radionuclides which will enable either to estimate the contribution to the dose from not easily measurable radionuclides or to perform more sensitive analysis of samples indicated by higher activity of marker radionuclides. The correlation coefficients were determined for the all combinations of evaluated radionuclides and they were compared with critical values of correlation coefficient for selected level of significance. Correlation was studied from the point of view of reactors' operation mode. Its variation in time was studied, too.

EXPERIENCE ON STATISTICAL ANALYSES OF OCCUPATIONAL DOSE DISTRIBUTIONS IN NPP EBO JASLOVSKE BOHUNICE

M. Vladár,[1] D. Nikodémová,[1] J.Hutta,[2] S.Mocko[2]

[1] Institute of Preventive and Cilnical Medicine, Bratislava, Slovakia
[2] Nuclear Power Plants a.s., Jaslovské Bohunice, Slovakia

INTRODUCTION

We analysed the basic characteristics of occupational effective doses, that are:

- the average annual effective dose. E,
- the annual collective effective dose, S,
- the fraction of workers exposed to annual dose exceeding 5 mSv, NR_E,
- the collective dose distribution ratio, SR_E, for E exceeding 5 mSv,

collected ad NPP A1, V1, V2 and EBO, (as the whole), in the site Jaslovske Bohunice, by several statistical methods of dose distribution [1]. The doses were summarized during the years 1990 to 1994.

For the assessment of above mentioned parameters three different dose distribution models were used:

a) direct method (DIR), using the distribution of workers by dose ranges. The midpoint of each interval has been used as **geometric mean** of dose ranges [2],

b) log-normal distribution of doses (LN), with parameters α, β estimated by regression analysis of the function:

$$\nu_i = \alpha + \beta \ln(E_i),$$

where ν_i is the quantil and E_i is the upper bound of i-th dose range.

c) hybrid log-normal distribution (HLN) with parameters α, β, γ, estimated by regression analysis of the function:

$$\nu_i = \alpha \ln(E_i) + \beta E_i + \gamma$$

Values of quantils, ν_i were calculated by standarts statistical methods [3]

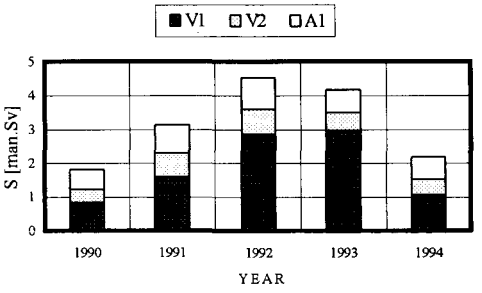

Figure 1. Collective doses in the NPP V1, V2 and A1 (1990-94).

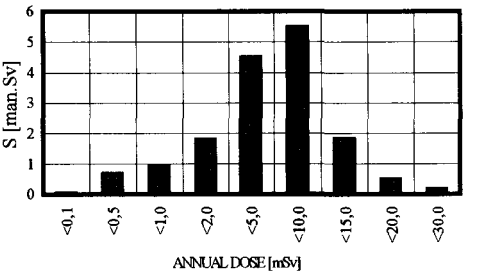

Figure 2. Distribution of collective doses according to the range of individual dose(1990-94).

CONCLUSION

Our experience with the statstical analyses of occupational doses in NPP EBO confirmed that:

- The assessment of annual individual and collective doses by using three methods of dose distributions shows small differences. The average values of annual effective doses for monitored persons are in the range of 1.4 to 2.0 mSv. LN distribution show lower values.
- The LN distribution method gives significantly lower values of NR_E and SR_E ,
- Direct method and HLN distribution model provides practically the same results.

According to Basic Safety Standards [4] we suppose that 5 mSv could be an investigation level (instead of until now used three tenths of the basic limit, that is 15 mSv). This value is exceeded by less than ten percent of workers.

The fraction of collective doses due to the effective doses higher than 5 mSv, reaches the value of about 50%..

In the light of the given results one can see that the introduction of the reduced basic annual limits of effective dose (20 mSv/a), will not create a serious problem by organizing the work in NPP EBO.

The fraction of the ''lost'' collective efffective doses, with respect to the chosen recording level of 0.1 mSv , does not exceed 2%.

SAFETY CULTURE ASPECTS OF MANAGING FOR SAFETY - EXPERIENCE OF A LARGE NUCLEAR REPROCESSING SITE

Helen S Rycraft Head Human Factors, BNFL, Sellafield.

INTRODUCTION

The Nuclear Industry is going through turbulent times both in terms of public acceptance and business issues. Safety is one area which impacts on whether the business is allowed to continue, and how an organisation organises itself. The need to cut costs to make nuclear power a viable energy resource, has forced the Nuclear Utilities to review manning policies, and management style, and in particular how to maintain safety standards during a period of change, and ultimately support continuing improvement of standards.

The shrinking workforce requires a new style of management, one that depends more on the people of the organisation taking responsibility for safety at all levels of the organisation. Not only personal safety but the safety of their colleagues, general public and the environment. With reduced number of people, and 'delayering' of an organisation, managers have to switch to a facilitating or co-ordinating role, as the controlling role e.g. close supervision, is no longer possible or effective. This often requires a culture change. In the case of BNFL the changes were not confined to the recent past, but began in the 1970's with the civil service culture, moving to a project culture in the 1980's with the building and commissioning of major projects, and needing to change to an business/operations culture to secure work for the company into the 21 Century.

The safety culture of an organisation is indivisible from the company culture, each aspect of a culture influences the whole and so the balance between business, safety and quality, has to be managed.

BNFL provides a full fuel cycle service to nuclear power plants, and associated services to many national and international organisations. The following notes are taken from the work carried out in the company, and mostly at the Nuclear Reprocessing and Waste storage Site at Sellafield, based in the North West of England. Following the recent re-organisation, the site now employs 6,200 people and has a further 1,500 contractors working on construction activities on the site. Activities on the site range from remote handling to hands on tasks, involving highly active materials to low level waste. These activities take place in old plant (> 30 years old) and new plant, and within the full life cycle of plants i.e. design, build, commission, operate, modify, decommission/re deploy, care and maintenance. Multiple types of tasks under many different conditions.

JUDGING IMPROVEMENT IN SAFETY CULTURE

In order to measure or judge improvement in anything, the starting point has to be determined. The two questions "What have we got?" and "Where are we ?" have to be answered before sensible major programmes for improvement can be formed and implemented. Without these answers, any action will be blind and some may cause the opposite effect to that desired. Any technique(s) used for judging Safety Culture must be able to identify :

1. *Perceptions - What are the work force's opinions on the safety of their plant? Do they feel safe?*
2. *Attitudes- how do the workforce see their and others responsibility for safety? Are they proactive or are they passive? Is safety at work somebody else's job?*
3. *Strengths and Weaknesses - What do they do well? How do they compare with companies with 'good' safety performance?*
4. *Beliefs vs. Behaviours -Is what they say what they do?*

Once these factors have been identified management can then plan for change and monitor any change. At BNFL Sellafield, two methods were developed to identify "What have we got?" and "Where are we now?" .

Sellafield Safety Attitude Survey

This was designed to identify the Safety Culture on the Sellafield Site and was planned in 3 stages.

1. *Focus group- 50 people were brought together as a discussion group to identify the topics and issues of main importance to safety on the Sellafield Site. A questionnaire for a much larger sample of people was developed.*
2. *Pilot Study - 161 people answered the questionnaire, and the technical validity of the questions, and the administration logistics were tested and improved.*
3. *Full Survey -During Autumn 1991, 5295 questionnaires 172 attitude questions were completed. These were analysed by Professor T Lee of St Andrews University.*

There were many detailed findings giving the strengths and weaknesses of the work force's safety attitude, and the results also gave indication where effort should be targeted. The survey also identified attitudes helping BNFL to develop its safety culture and contributing to improving safety performance, and those that were not.

Sellafield Safety Culture Review

A complementary method for judging safety culture was developed by BNFL using the foundation of IAEA's INSAG -4 *(ref. 1)* and the UK Government's Advisory Committee on Human Factors 3rd Report "Organising for Safety" *(ref. 2)*. The review was developed and applied for the managers of 3 plants who were uncertain as to the true state of safety attitude on their plants, and how they influenced their workforce's safety culture.

Targeted interviews using a question framework developed from the above texts were used by the interviewers as a guideline to structure the interviews. Selection of personnel interviewed (both individuals/groups, shifts/days) were based on the role of the personnel within the plants, and included service groups, the plant's independent safety advisors and the Government Nuclear Installation (NII) inspectors directly involved in the inspection of the plant. The latter were included, as some measure of behaviour modification became apparent as the perceived result of contact with the inspectors.

The interviews identified the perceptions and attitudes associated with the plant's safety culture, which were then analysed to identify where they matched, conflicted, or were discontinuous. This process identified dominant attitudes and areas of conflict, along with the strengths and weaknesses forming their Safety Culture. From this, the plant developed a programme, building on their strengths to eliminate or neutralise their weaknesses, using participative team methods to engender ownership of plant and performance.

Attitude Survey and Safety Culture Review are complementary. They can be used selectively to address different aspects of a organisation's Safety Culture. The Safety Attitude survey, once developed, is easy to apply, and the analysis has a statistical basis so that confidence in the results can be judged readily. It gives a good overview of the dominant safety culture present in a population, and identifies the sections or profile of the workforce holding a dominant attitude. The Safety Culture Review looks at Safety Culture within a Plant's management system. Trained and experienced interviewers are required, and the analysis of the data is more complex. However it is able to follow the issues through and identify root causes of difficulties, and identify the possible root of the attitudes expressed. Judgement of behaviour is also able to be incorporated.

THE BUSINESS CASE FOR PRO-ACTIVE SAFETY MANAGEMENT

For an organisation to use resources to develop or improve their safety culture, tangible benefits must be evident. Traditional benefits of a good safety culture are : **Reduction of costs** - *e.g. associated with waste, accidents, staff turnover, equipment* and **Legal Imperatives**- *e.g. costs of insurance, civil action, prosecution.*

However, a more positive business case for a good safety culture can also be made with:

The Enhancement of Business Opportunities

A good safety culture can gain a company advantages when bidding for work. The improvement of quality and reliability, and associated gains in efficiency and effectiveness, can be directly related to having a good safety culture within an open management system.

A good safety performance is also an assisting factor for good industrial relations, and for promoting a culture of excellence. A company who wish to recruit quality personnel also require a good image. This in turn will assist the company to maintain a high public and business profile as a quality company. Potential customers prefer to do business with a non-controversial company.

The moral imperative

All industry has a responsibility to the people they employ, the general public, and the environment they can affect. Without this sense of responsibility there would be no control over actions by companies or individuals within the company. Damage due to irresponsibility cannot be totally quantified, and society places a value on morality. A good safety culture is one way of promoting and maintaining the sense of responsibility within a company's workforce, without the need for restrictive, punitive and costly management systems.

SHAPING AND CHANGING A SAFETY CULTURE

BNFL had to identify what culture they needed to develop a successful and smaller workforce for operating or decommissioning their existing plants, and for the new workforce that was to operate their new Thermal Oxide Reprocessing Plant (THORP). Workforce reorganisation required a clear statement of values and behaviours before team building could commence. The shaping action was developed and installed locally, for experience had shown that Central or HQ 'initiatives' can be forced through and led by the senior management, but eventually the initiatives can fail due to lack of local support. In a large organisation different sub-cultures require different shaping processes to move towards the desired culture. Within BNFL, the common theme was participation and involvement of all the workforce, led and supported by senior management. By promoting ownership of locally developed and installed shaping processes, the resultant improvements are normally faster and are more likely to endure.

All of the shaping processes identified to the workforce the behaviour demanded by the company. Once benefits to the individual are identified e.g. dose reduction, job security, attitudes are more likely to change. These shaped attitudes however, require commitment by management, consistency of application of behaviour demands and the benefits to individual and peer group identified and publicised.

One immediate benefit is that once an attitude change has been achieved, peer group pressure becomes a strong reinforcer i.e. "the way we do things around here" which then sustains the behaviours you require. This is a lot more effective and cost effective than continuous managerial pressure and policing.

Involving all persons in the workforce uses all the skills and ideas of the workforce, and improves communication allowing a quicker response to circumstances. There is a need to develop management to be receptive to workforce ideas, and comments, so that ideas are freely offered. Management in this environment are also more likely to be told of problems and their consequences earlier, before damage to people, plant or organisation occurs.

In summary, development of safety culture has a lot to offer an organisation in terms of safety, quality and productivity. The final step of 'empowerment' can only be achieved by trust in fellow worker's attitudes, and abilities, and sustained by continued empowerment even under difficult conditions. Improvement of the safety culture has to build on the existing strengths of the organisation and recognise the associated weaknesses. Once an improvement programme has been derived, management and workers must have patience with the process, and aim to monitor movement at regular intervals. In a large organisation progress will not be uniform across all departments, and actions successful in one sub-culture may be unsuccessful in another. Identifying visible successes and publicising them will encourage management and workers, and serve to silence persons in the organisation who wish to maintain the status quo. For an existing organisation, a step by step approach is a less painful method for change but ultimately an organisation cannot afford to carry 'passengers'. By involvement, the workforce can start to participate, by participation ownership develops, and finally by true empowerment, actions involving safety, production and quality are put in place at all levels of the organisation, naturally, efficiently and continuously.

Radiation Protection Experience during Active Commissioning of the Thorp Reprocessing Plant; Karen Spour and Euan Hutton, Radiation Protection Advisers, Thorp Division

1 Introduction

BNFL's Thermal Oxide Reprocessing Plant (Thorp) reprocesses uranium oxide fuel assemblies which have been irradiated in thermal reactors in the UK and overseas. Plans for the plant were first announced in 1974. Application for planning permission was submitted in 1977, and government permission to construct the plant was granted after the Windscale enquiry in 1977. The plant was given the license to start active commissioning in Head End in early 1994, and then in Chemical Plants in late 1994. Presently the whole of the process is being challenged in a planned commissioning strategy which will last into 1996.
Thorp is designed to reprocess the spent oxide fuel into uranium trioxide (UO_3) and plutonium dioxide (PuO_2).
The Thorp complex can be essentially broken down into three distinct areas:
Thorp Receipt and Storage
Provides pond storage for fuel awaiting reprocessing in Thorp.
Head End
Fuel is transferred from Receipt and Storage into the Feed Pond where it is monitored to check fissile content, burn up and cooling time. The individual fuel assemblies for LWR fuel, or cans in the case of AGR fuel, are transferred onto the shear elevator and carried up to the shear cave. The fuel is sheared into small lengths to optimise the dissolution of the fuel inside the cladding. The sheared fuel and cladding debris is directed via a chute into one of three dissolvers, each with a nominal 1.8 teU capacity and dissolved in 8M nitric acid for approximately 16 hours. The cladding hulls are retained in a removable basket and sent for encapsulation. Insoluble fission products and fine particles of cladding are removed by centrifugation. Clarified dissolver solution is then accounted for by measurements taken for volume, mass and isotopic composition. Following this, the solution is transferred to buffer storage tanks and fed onto the Chemical Separation area.
Chemical Separation
The liquor is transferred to the Chemical Separation area where it undergoes first cycle separation in pulsed columns to separate out uranium, plutonium and highly active fission products. After product removal, the remaining liquor is stripped of solvent and sent for evaporation and thereafter vitrification. Separated plutonium and uranium streams then undergo purification and product finishing to PuO_2 and UO_3 respectively prior to containerisation and storage in dedicated facilities.

This paper will discuss Radiation Protection Experience during the commissioning of Thorp Head End and Chemical Plants, and will look at issues such as plant design and its effect on contamination control, the routine survey philosophy, the commissioning strategy, dose control and environmental discharges.

2 Plant Design

The Thorp design relies on biological shielding in the form of bulk concrete for the protection of personnel from radiation exposure. All shielding assessments for Thorp Head End and Chemical Plants have been based on PWR fuel with an irradiation period of 40 Gwd/t, a rating of 40 Mw/t and a cooling period of 5 years.
Many other factors have been built into the shielding design of Thorp, eg all walls are much thicker than required purely for shielding purposes because of structural and seismic requirements, all shielding calculations have assumed that vessels and pipework are full of active liquor, and all sources of potential radiation exposure have been diverted away from main occupancy areas as far as practicable.
Unrestricted access areas such as corridors and offices, are designed to a target dose rate of 1 μSv/hr, as compared with the legal limit for these areas of 7.5 uSv/hr. (See Fig 1 *Classification of Areas*).
The Thorp design has also aimed to reduce radiation exposure and occupancy times in higher potential radiation areas, by use of remote control, remote manipulators, remote reading of instruments and gamma interlocks.
Processes requiring direct operator intervention have been eliminated as far as practicable, by such measures as the installation of ejection systems instead of pumps, automatic liquor sampling, pneumatic transfers of samples to areas for analysis and remote filter changing within filter caves.
As an aid to the design of localised shielding, and to control radiation exposure, a system of area classification has been adopted in Thorp, according to expected/potential radiation and contamination levels in each area.
The classification system is comprised of 5 zones, R1-R5 radiation and C1-C5 contamination. (See Fig 1 - *Classification of Areas*).
The radiation and contamination classifications of an area are carried out independently of each other, against such criteria as expected and potential radiation and contamination levels in the area, occupancy time in the area and the type of work to be undertaken in the area.
Thorp is designed so as to restrict the maximum individual whole body dose, ie the sum of effective dose equivalent from external radiation, and committed effective dose equivalent from internal radiation, to less than 15 mSv/year, (the legal limit being 50 mSv/year), with the worker group average dose not exceeding 5 mSv/year.
Whole body dose in Thorp is comprised almost entirely of external radiation exposure. The effect of internal exposure is minimal due to the design of the plant in terms of contamination control, ie Ventilation, C1-C5, Sub-changerooms, Containment etc. Internal exposure therefore, is not routinely assessed on Thorp, but carried out on a campaign basis only.
The Thorp design target for extremity dose is that any individual should not exceed 300 mSv/year, (the legal limit being 500 mSv/year) with a worker group average not exceeding 200 mSv/year.
The integrity of plant shielding, confirmation that the plant is operating within target radiation and contamination levels, and that operational radiation exposure is minimised, as well as multitudinous operational parameters, will be tested throughout the period of Level 5 commissioning.

3 Commissioning Strategy

The overall strategy for the commissioning of Thorp, defined the need for 5 levels of commissioning, where the plant and process were challenged with water, simulants, chemicals and following the designation of the plant as a controlled area, uranium and ultimately irradiated fuel in 'bands' of increasing irradiation, band 1 being the least irradiated and band 4 being similar to reference fuel. (See Fig 2 - Fuel Bands).

The objectives of Level 5 active commissioning are to demonstrate the safety and technical acceptability of Thorp operations, test all related and supporting systems, and confirm radiation and contamination control are as per design targets.

Commissioning is undertaken using System Performance Demonstration Definition Documents (SPDDDs), which identify the intent, objectives, pre-requisites, resources, material and sequencing of activities associated with the performance of a particular test.

Some radiological Level 5 commissioning tests include; trend monitoring of aerial discharges, routine monitoring of plant radiation, contamination and airborne activity levels and confirmation that they are within design targets, and demonstration that occupational exposure to personnel is within design targets.

To date, all radiological SPDs carried out have confirmed that the plant is functioning well within design targets, and no anomalies have been reported.

4 Contamination Control Philosophy

The contamination control philosophy for Thorp is based on controlling contamination in such a way as to keep the normal operating areas free from loose surface contamination. This philosophy was adopted to ensure that the routine issue of personal air samplers, for the assessment of internal dose, was not required. In order to achieve this position, the average surface contamination levels must not exceed about 0.004 Bq/cm^2 (alpha) which is two orders of magnitude more restrictive than the traditional "non-active area target".

To this aim, the plant has been designed into segregated areas C1 to C5 (see Fig 1 *Classification of Areas*). Where C1 is the lowest, ie inactive and C2 areas (operating areas) are comparable with these, up to C5 where there is the greatest possibility of contamination to be generated. The plant has been designed so that the air flows throughout the building from C1 through to C5, with the ventilation, filtering and extract systems becoming more involved the closer they are to the sources of contamination.

For management purposes, the whole of the plant has been classified as a Controlled Area. Entry to the plant is via a main changeroom, which contains lockers, change facilities, showers and monitoring facilities. Plant personnel wear factory basic clothing and shoes which are removed on exit at the barrier in the main changeroom.

The barrier against the spread of contamination is defined at the C2/C3 sub change facility, where there is provision for a change of outer clothing, ie C3 coveralls, gloves, boots and monitoring facilities. As the "C" category is increased so the protective clothing and respiratory requirements are increased.

Appropriate engineering consideration has been given at the workplace to contain both alpha and beta contamination both during design and operation of facilities. The operating philosophy has been to engineer out contamination hazards, via containment such as gloveboxes, ventilation and local barriers at the job.

Activity-In-Air Monitoring

In order to constantly monitor the working area breathing zone for the presence of airborne activity, Thorp has a system of approximately 750 installed activity in air monitors. These instruments are all connected via the Radiological Protection System (RPS) to the Central Control Room (CCR). If an instrument detects airborne activity it alarms locally to warn the local area operators, and in the CCR to enable a response to the alarm to be formulated. There are 3 levels of alarm which are dependant on the amount of activity present in the air.

There are specific monitors which are designated as zonal evacuation monitors. Certain combinations of these monitors in alarm will instigate a zone or plant evacuation.

5 Routine Survey Philosophy

In order to maintain the long term operability of Thorp, it is essential to ensure that radiation and contamination levels of the plant remain within the Thorp target levels as discussed previously (See Fig 1 *Classification of Areas*).

A routine survey schedule was implemented both during Level 4 and Level 5 commissioning which covers every area of Thorp, and identifies the type of radiological survey to be undertaken, ie radiation and/or contamination, the survey frequency (based on occupancy time), the radiological classification and the activities undertaken in the area.

The routine survey philosophy for Thorp defines four main survey types;

Control Monitoring - These general radiation and surface contamination surveys are undertaken in all unrestricted access areas such as corridors, offices and workshops, ie C2 areas.

First Level Plant Status Surveys - are undertaken to warn plant operators of any significant increase in radiation and contamination levels that require immediate remedial action. These surveys focus on areas where radiological problems would be readily detected, such as sub changerooms.

Second Level Plant Status Surveys - are carried out in an audit capacity in all unrestricted access areas, at least once a year.

Audit surveys - are carried out in all key operating areas at least once a year to confirm that radiological control is being maintained, and also to identify any trends in radiological conditions.

6 **Dose Control Philosophy**

The Thorp target for whole body dose is 15 mSv per year for an individual, and 5 mSv for a worker group average.
Personnel working within the Thorp controlled area are designated classified persons in accordance with the Ionising Radiation Regulations 1985, and as such must wear a personal dosemeter as approved by an authorised dosimetry service.
The routine dosemeter for Thorp is currently the film badge, issued on a monthly basis, with quarterly issue being considered for some itinerant worker groups. In addition to routine dose monitoring, dose control is required to run in parallel to ensure that dose targets are not exceeded and that exposure is ALARP. Dose control is carried out by the issue of Merlin Gerin Personal Alarmed Dosemeters (PADs). These PADs are issued on an individual or job specific basis, where there is the potential for enhanced radiation exposure. These are normally issued where gamma doserates are expected to exceed 25 μSv/hr. A guide dose of 50 μSv per day has been adopted in Thorp to maintain dose targets, however, higher doses can be authorised by management on a case by case basis.

Extremity doses are measured in Thorp using Thermoluminescent Dosemeter (TLDs), which are issued when doserates exceed 75 μSv/hr beta gamma. Plant and Operations have been designed such that extremity, internal and neutron exposures are less than one tenth of the relevant dose limit, and therefore, routine assessment is not required.

7 **Environmental Impact of Thorp Discharges**

At the Windscale enquiry (1977), BNFL stated a strategy for the management of effluents, placing specific limits on Thorp discharges:-

1 No member of the most highly exposed (critical) group(s) should receive an annual committed effective dose equivalent >50 μSv from aerial *or* marine discharge routes.
2 By the time of Thorp operations, the sum total of annual exposure (CEDE) from the whole of Sellafield (including historical effects) operations should be less than 500 μSv pa.
3 Radiation exposure to the public should be ALARP (As Low As Reasonably Practicable).

During normal operating conditions (ie design flowsheet 1200 tonnes PWR pa) annual discharges have been calculated to result in critical group doses of ~20 μSv via the aerial pathway and ~24 μSv via the marine pathway. Both are clearly within the 50 μSv limit.
Recent calculations also show that mid way through the base load period (ie Thorp maximum throughput at design flowsheet) total site discharges, including Thorp, will result in critical group doses of ~60 μSv (aerial pathway) and ~190 μSv (liquid pathway). Again, these are clearly within the 500 μSv limit.
Figure 3 shows the aerial discharge authorisation limits for the most significant isotopes for a reprocessing rate of up to 100 tonnes pa and the actual aerial discharges Jan-Dec 94.
The environmental impact of the 1994 discharges is 0.38 μSv, predominantly due to the Isotope I129.
The total annual liquid discharges (Jan-Dec '94) are presented in Fig 4. *Annual Liquid Discharges Jan - Dec 1996.*
The impact of the 1994 liquid discharges is 1.54 μSv, dominated by Co60 and Cs137.
Discussion
To date, the arrangements implemented in Thorp to ensure contamination control and dose reduction, have proven to be successful.
There have been no indication of any contamination migrating from C3/5 areas into the C2 operating areas, with all operating areas remaining at the Thorp target levels. This implies that contamination control measures at the sub changeroom barrier, and the ventilation system are functioning correctly and efficiently.
Only 1% of the total number of routine surveys undertaken in 1994 were found to be above the Thorp target levels, however these were exclusively in sub changerooms, where potentially contamination items, eg coveralls and boots would not be unexpected. These contamination levels were quickly returned below action level by decontamination, or removing the source. No areas of gross surface contamination, or high radiation areas have been found whilst carrying out routine surveys in operations areas.
The shielding of the plant has been tested both routinely by way of regular radiation surveys, and also in support of SPD commissioning checks upon the first challenge to an area with irradiated fuel.
No shielding weaknesses have been discovered, and all operating areas are well below the target of 1 μSv/hr. These SPD checks will be repeated as commissioning progresses to the next fuel band.
The average whole body dose in Thorp during 1994 was 0.93 mSv, well below the Thorp worker group average of 5 mSv. No single individual who had been employed exclusively in Head End or Chemical plants received a whole body dose greater than 2 mSv, again well below the 15 mSv whole body dose limit for an individual in Thorp.
The Thorp extremity dose target for an individual is 300 mSv. No individual exceeded 1% of this target, an indication that remote working and decontamination prior to commencing a task, are both common practices.
All dosimetry campaigns to date, internal, neutron and extremity, have shown no need for systematic assessment of these doses.
During 1994, the aerial discharges from Thorp were well below the authorised levels, with liquid discharges also being very low.
As commissioning progresses towards irradiated fuel of a similar magnitude to reference fuel, aerial and liquid discharges, as well as radiation and contamination levels on the plant will be continually monitored. Shielding checks will continue and dose reduction will be an ongoing trend.
The engineered design of Thorp, together with the Radiological Protection Systems and promotion of good working practices will successfully support the operation of Thorp into the 21st century.

RADIOACTIVE GASEOUS EFFLUENTS MONITOR UPGRADE AT THE BRUCE A NUCLEAR GENERATING STATION

N. Sion

Ontario Hydro, Toronto, M5G 1X6, Canada

INTRODUCTION

Ontario Hydro is committed to the effective management and control of the radioactive gaseous effluents from the ventilation pathways within the limits established by the Atomic Energy Control Board (AECB), and within the design and operating targets associated with the ALARA (As Low As Reasonably Achievable) policy.

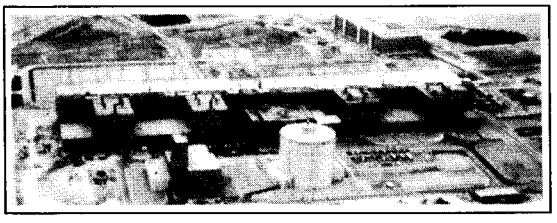

Fig. 1 Aerial View of Bruce A Nuclear Generating Station

The Bruce A nuclear generating station, fig. 1, is located on Lake Huron and is a 4-reactor power plant of 740 MW(e) net each. A major overhaul and upgrade of the radiation monitoring system has just been completed resulting in a system that effectively complies with current Canadian regulatory requirements.

THE MONITORING SYSTEM

Fig. 2 is a much simplified schematic of the Stack Monitoring flow diagram. In essence, the monitor draws a representative isokinetic sample conforming to ANSI 13.1 by a probe located in the stack above the station roof to minimize non-uniformity of the flow profile. The flow is maintained isokinetic and the sampling lines above the station roof are heat traced to forestall potential condensation.

The sampling stream then divides into two. The smaller stream passes through a desiccant which removes any water vapour for subsequent analysis for the presence of tritium. The larger stream is filtered to remove airborne particles and is monitored with a beta detector. The flow continues through a charcoal filter to remove gaseous halogen aerosols in the presence of an energy window to detect the presence of Iodine-131 photopeak. The sample is then pumped through a 7.5 litre Marinelli chamber where it is monitored for noble gas by a 2 channel NaI detector. The Marinelli chamber has a second port through which a germanium detector can be inserted for isotopic identification. Periodic purging of the chamber is performed to obtain updated background.

The monitoring system was supplied by Sorrento Electronics of San Diego whose microprocessor would continuously collect data and transmits hourly to the Control Room. Local data storage, with local alarms and displays are in place should communication between the microprocessor and the Control Room be disrupted.

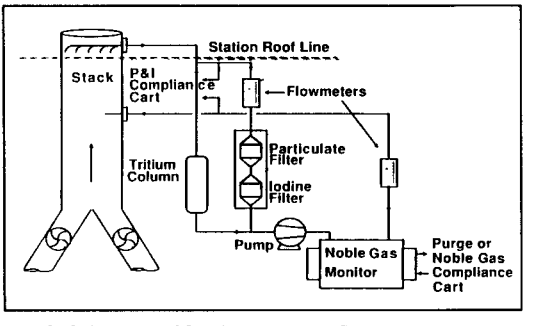

Fig. 2 Schematic of Stack Monitoring System

FUNCTIONAL REQUIREMENTS

The monitoring of the gaseous effluents is based on the most restrictive radionuclides via I-131 for radioiodines, Sr-90 for particulates both measured in curies and predominant matrix of noble gas mixture measured in γCi-MeV, Ref. 1 as well as tritium in water vapour form, measured in Ci.

The monitoring objectives are

For Compliance: where the continuous monitoring demonstrates compliance with regulatory limits and operational targets - by laboratory analysis

$$\text{Lower Limit} = \frac{\text{Concentration of 1\% Weekly Operating Target (WOT)}}{\text{Mean Weekly Flow at the Sample Point}}$$

Upper Limit = Concentration of $\frac{\text{100\% Weekly DEL}}{\text{Mean Weekly Flow at the Sample Point}}$

For Control monitoring: where on-line detectors continuously monitor the sample so that an operator can take corrective action to ensure limits are not exceeded.

Lower Limit = Concentration of $\frac{\text{0.1 Weekly Operating Target (WOT)}}{\text{Mean Weekly Flow at the Sample Point}}$

Upper Limit = Concentration of $\frac{\text{25 Weekly Operating Target (WOT)}}{\text{Mean Weekly Flow at the Sample Point}}$

Radiological releases are reported in Derived Emission Limits (DEL), or fractions thereof. The DEL is the amount of a radionuclide, or group of, which if released from the entire station in one year, would result in a member of the public at the station boundary receiving a whole body maximum permissible dose (500 mR/yr - 5 mSv/yr). The Ontario Hydro self-imposed target limit is 1% DEL (5 mR/yr - 50 μSv/yr).

Fig. 3 The Stack Ventilation Exhaust Fans

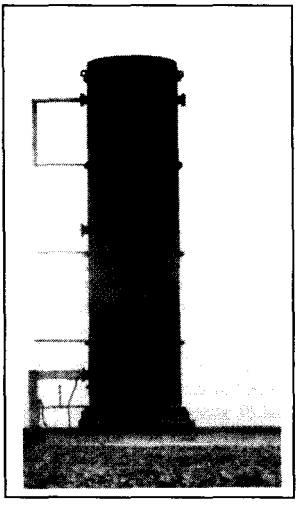

Fig. 4 Stack Probe Location Above Roof

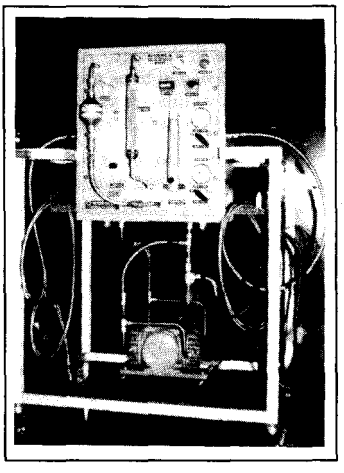

Fig. 5 The Particulates, Iodine and Tritium Compliance Monitoring Cart

For Bruce A the above translates to releases in table 1.

RADIONUCLIDE	1 DEL Ci/week regulatory compliance upper limit	1% DEL = WOT Ci/week Weekly Operating Target	1% WOT Ci/week compliance lower limit	0.1 WOT Ci/week control lower limit	25 WOT Ci/week control upper limit
H^3	$1.95\ E^{+5}$	$1.95\ E^{+3}$	$1.95\ E^{+1}$	1.95^{+2}	$48.75\ E^{+3}$
I-131	0.618	$0.618\ E^{-2}$	$0.618\ E^{-4}$	$0.618\ E^{-3}$	$15.45\ E^{-2}$
NG (Ci-MeV)	$1.29\ E^{+5}$	$1.29\ E^{+3}$	$1.29\ E^{+1}$	$1.29\ E^{+2}$	$32.25\ E^{+3}$
Particulates	1.38	$1.38\ E^{-2}$	$1.38\ E^{-4}$	$1.38\ E^{-3}$	$34.5\ E^{-2}$

Table 1: Regulatory and Target Release Rates

Out of Bruce A's nine stacks, the stack having the lowest activity concentration is shown in Table 2 which becomes the Minimum Detectable (MDA) to be measured.

STACK	RADIONUCLIDE	COMPLIANCE		CONTROL	
		Lower Limit	Upper Limit	Lower Limit	Upper Limit
Non Contaminated	H^3	0.418 $\mu Ci/m^3$	4.18 $\mu Ci/m^3$	4.182 $\mu Ci/m^3$	1.05 mCi/m^3
Stack	I-131	1.33 pCi/m^3	13.25 nCi/m^3	13.3 pCi/m^3	3.31 nCi/m^3
Reactor	NG	0.277 $\mu Ci/m^3$	2.77 mCi/m^3	2.766 $\mu Ci/m^3$	0.692 mCi/m^3
Building	Particulates (Sr-90)	2.96 pCi/m^3	29.59 nCi/m^3	29.6 pCi/m^3	7.40 nCi/m^3

Table 2: Target Minimum Detectable Activities

AREAS OF IMPROVEMENT

Stacks, fig. 3: The original regtangular ducts were replaced with circular stacks, the flow profile improved and the velocity probe was located to give an accurate average of stack velocity.

Relocation of Sampling Probe and Velocity Probe, fig. 4: The original sampling probe was some 8m above the roof and close to the edge. Any maintenance to be done required scaffolding and was hazardous to staff. The probes were lowered to be about 1.53m (5 ft) above the roof. This was about 3 stack diameters above the last confluence of ventilation streams. This was accepted since the flow profile was steady; representative sampling and averaged flow velocity were attainable, Ref. 2.

Leak Detection: Two mass flowmeters were added to the inlet and outlet of the sampling line to the Sorrento monitoring system; and usually read the same for no in-leakage or out-leakage. Useful for after cartridges are changed, and for pressurization/vacuum tests of the sampling system.

The Particulates and Iodine Compliance Monitoring Carts, fig. 5: Two mobile carts, each of which can be plugged into the sampling line as needed when the installed system was down for maintenance or during equipment failure, enhanced the reliability and availability requirements.

The Noble Gas Compliance Monitoring Carts, fig. 6: Each of the two carts has a High Purity Germanium (HPGe) detector; its liquid nitrogen cryostat, power supply, multi-channel analyzer, PC with screen display, printer, and software for data collection and analyses, isotope identification, quantification and trending. Its HPGe detector can easily fit the installed Marinelli chamber's second port. They are used when the installed noble gas system is unavailable, or when isotope identification is required.

Meeting Unavailability Requirements: A reliability of >99% as specified in Ref 3 is being met by the ongoing availability of the mobile carts figs. 5 & 6.

Interfacing with the Control Room: The installed monitoring system alarms in the Control Room on high release rates and on system malfunction. Emissions in %DEL rate/h are also displayed. This accelerating trend gives an operator advance warning of a potential problem before the alarm limit is reached.

AN IMPROVED SAFETY SYSTEM OF A RADIATION FACILITY FOR INDUSTRIAL STERILIZATION

Vujo Drndarević, Danko Djurić, Aleksandar Koturović, Miroljub Arandjelović, Ratko Mikić
Institute of Nuclear Sciences "Vinča", P.O Box 522, 11001 Belgrade, Yugoslavia

Abstract - Modernization of the original safety system of the radiation facility for industrial sterilisation at the "Vinča" Institute of nuclear science is described. In order to improve radiation safety of the facility, the latest recommendations and requirements of IAEA have been implemented. The concept and design of the modernised system are presented. The new elements of the safety system are described and the improvements achieved by means of this modernisation are pointed out.
Key words: safety system, radiation facility, ^{60}Co.

1. INTRODUCTION

The gamma irradiator of the Institute of nuclear sciences "Vinča" performs the industrial process of sterilization of single use medical appliances, food, pharmaceutical, cosmetic or other products or raw materials. The sterilization is carried out by ionizing radiation from a ^{60}Co source. Currently a $9.25 \cdot 10^{15}$Bq (250,000 Ci) source is being used. The facility has been designed to accommodate safely the source of maximum activity of $3.7 \cdot 10^{16}$Bq (1,000,000 Ci). When the facility is not operating, the source is submerged into a water storage pool 6.5 m deep. The design of the facility and the principle of laying down the source classify it as the IV group of facilities for industrial sterilization [1].

In order to ensure a high level of radiation safety the facility is equipped with an autonomous safety system. In accidental situations, or in cases of failures of some of its elements, this system discontinues the irradiation process and returns the source to fully shielded position.

The original safety system has been ensuring a safe operation of the facility both for the personnel and for the environment since 1978. Having in mind this long period of intensive use of the facility, with the aim of increasing the radiation safety, and to upgrade the properties of the safety system to meet the latest requirements and recommendations of the IAEA [1,2], a modernization of the original safety system has been undertaken.

The accidental conditions causing the trip of the safety system could be due to either radiation or radiation-free events. The original safety system is activated by a power failure as a radiation-free event or by a fall out of the ^{60}Co source from its container or by inadvertent entry of a person through the product entry or exit ports as radiation events. The reaction of the safety system to any system malfunction or to a detection of accidental conditions is returning the source to the fully shielded position.

2. THE MODERNIZATION OF THE SAFETY SYSTEM

The original safety system consisted of: two ionization chamber measuring channels for the measurements of radiations in the irradiation chamber and in the maze, pressure mats at each product entry or exit ports of the maze, one emergency cable and emergency stop buttons located in the irradiation chamber, a safety delay timer allowing the irradiation chamber inspection in the course of preparations for start-up, and an electromagnetic lock on the door of the chamber.

The ionization chamber situated in the irradiation chamber serves to detect the position of the source. While the source is in the exposed position no person can have access to the irradiation chamber. The other ionization chamber situated in the maze serves to detect accidental carrying the source out of the irradiation chamber. A failure of either of the two channels will cause a safety system trip and return of the source to the fully shielded position.

Through the product entry and exit ports the products are transported to and out of the irradiation chamber by the product conveyor placed in aluminium containers called tote boxes. At both entry and exit ports pressure mats have been installed in order to register any inadvertent entry of personnel. Any excitation of these pressure mats will discontinue the irradiation process and the source will be returned to the fully shielded position.

In the course of preparations for the start-up the operator inspects the irradiation chamber during the time allowed by the safety delay timer and locks the door of this chamber by the key A. Once the safety system has been activated, this key is used to initiate the irradiation procedure. In case that during preparations someone was left behind in the irradiation chamber or in the maze, an emergency stop cable located around the walls of the irradiation chamber and of the maze and emergency stop buttons are available for stopping the process and returning the source to the fully shielded position. The key X is in possession of the manager of the facility and it is used for disabling parts of the safety system in the process of reconfiguration or replacement of the source. These processes are carried out following the written administrative procedure.

For the purpose of routine controls of radiation levels on the premises a portable radiation monitor is available

to the personnel. Despite the written procedures and requirements set for the use of this monitor, in the accidents that have occurred in similar installations throughout the world the portable monitor was out of order or had not been used at all [3].

The basic requirements set to the modernization of the safety system were related to the extension of the detection capabilities of both radiation and non-radiation causes of accidental states retaining, at the same time, the concept, operating modes, and all elements of the original safety system. In addition, a better presentation was required of the state of the system, of the causes of its operation, and the possibility of connecting this system to a cental computer was required.

The modernized system was extended to include detection of fire in any part of the installation and detection of earthquakes. The extension also covered the detection of a rupture of the encapsulation of the source ^{60}Co and the addition of a photoelectric system for controlling the product entry and exit ports. These extensions have been materialized by introducing into the safety system the following elements [4]:

- the electronic control system of the product entry and exit ports,
- detector of contamination of the storage pool water,
- detector of fire,
- seismic detector,
- the portable radiation monitor indirectly incorporated into the safety system,
- the central unit for displaying status and signalization.

All elements, original and new, of the safety system have been connected to a central unit for the purpose of presentation of the state of the system and for the corresponding signalization. This unit, as listed above, is another new element introduced into the structure of the safety system. Block diagram of the modernized safety system of the gamma irradiator is shown in Fig.1.

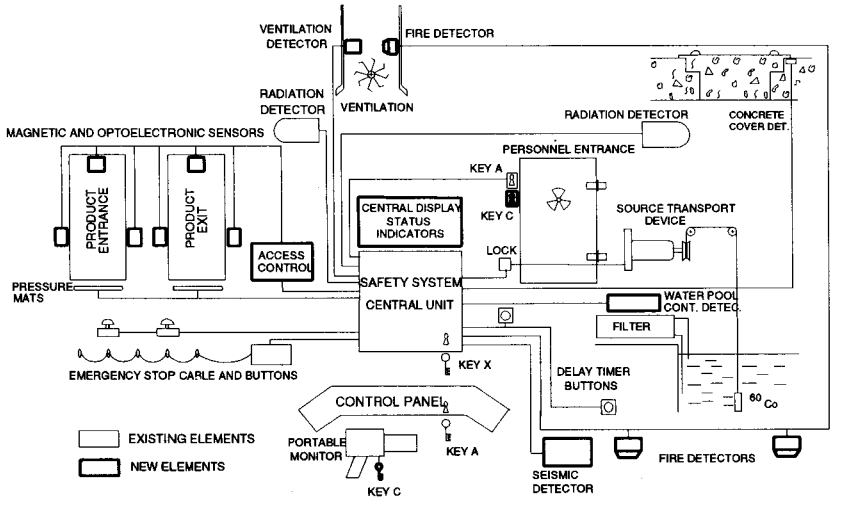

Fig. 1 Modernized safety system of the facility for industrial sterilization in the Institute "Vinca"

3. NEW ELEMENTS OF THE SAFETY SYSTEM

Some of the more interesting new elements of the safety system will be described in more detail. First of all is the central unit for the presentation of the state of the system and signalization. This unit provides the operator with a complete information of the state of the installation and clearly indicates the cause of any trip of the safety system. All data are presented on an LCD alphanumeric display containing 2x20 characters. The messages shown on this display are of the type:

NO ENTRY	AUTHORIZED PERSONS ONLY	SAFETY SYSTEM TRIP
IRRADIATION IN PROGRESS	SPECIAL REQUIREMENTS	MEASURING CHANNEL FAILURE

All possible states of the system have been included in the corresponding set of messages. Each change of the

display is accompanied by a short sound signal in order to draw operator's attention that a change has occurred.

The central unit is provided by an RS-232 interface thus it can be connected to a PC. Fig.2 shows the block diagram (a) and a simplified flow chart (b) of the central unit.

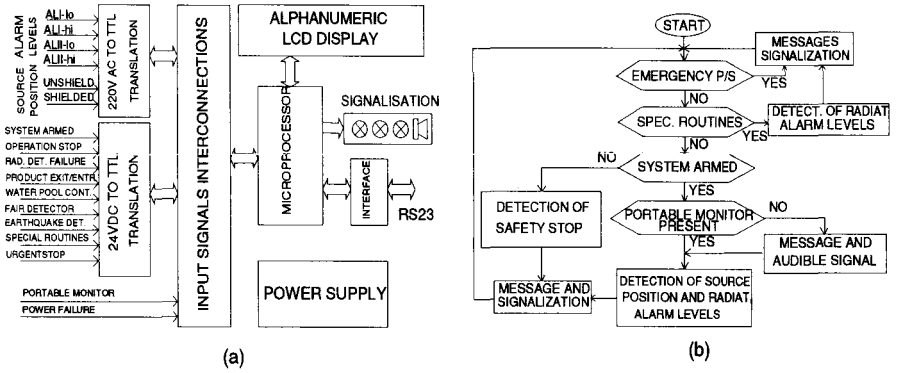

Fig. 2 shows the block diagram (a) and a simplified flow chart (b) of the central unit

The portable radiation monitor, has also been incorporated into the safety system. This has been done indirectly, i.e. the key of the electronic lock C is fixed to the monitor there fore the operator has to carry the monitor when entering or leaving the radiation chamber, thus has to meet the requirement that the chamber should not be entered without this monitor.

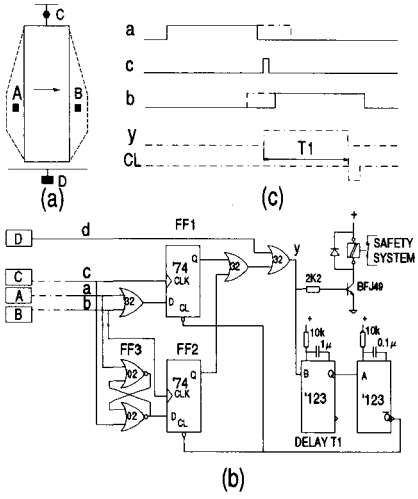

Fig. 3 Detectors position (a), block diagram (b) and signal timing (c) of the electronic control system at the product entry and exit ports

With the original safety system it was possible to enter deliberately the irradiation chamber by stepping over the pressure mats at the product entry and exit ports or by hanging on the conveyor belt. In order to prevent this type of entry into the high radiation area a new, additional, electronic control system has been designed, Fig.3.

The additional electronic protection system "recognizes" the tote boxes and permits only their entry to the maze. This system detects both direct entry or an entry of a person hung on the conveyor belt. The detection is performed by two pairs of photoelectric sensors (A and B) and by one inductive proximity switch (C), shown in Fig. 3. Micro switch D, shown in Fig.3a, registers any activation of the original pressure mat. The electric circuit controlling the product entry and exit ports in shown in Fig. 3b. The timing diagram of the corresponding signals is shown in Fig. 3c.

ENVIRONMENTAL DOSIMETRY LOW DOSES

Michel Espagnan
Cogema Marcoule Nuclear center, France

The COGEBADGE® , COGEMA Dosimeter, equipped with a 4 dosimeter thermoluminescent card, is used for environmental dosimetry.

The capacities and limits of the thermoluminescent dosimetry system, allow, in routine operations, the measurement of very low dose levels, including natural radiation background.

For the photon thermoluminescence dosimetry system :

- the critical level (L_C), representing the signal that provides a confidence level 1-α that the result is not due solely to a fluctuation of the background, is equal to 4 μGy.

- the detection limit (L_D) representing the lowest value of dose which can be measured with a given confidence level (95 %) is equal to 10 μGy

- the determination limit (L_Q) representing the lowest value of dose which can be measured with a given precision (10 %) is equal to 120 μGy

The variation of the determination limit L_Q with precision is given in the figure 1.

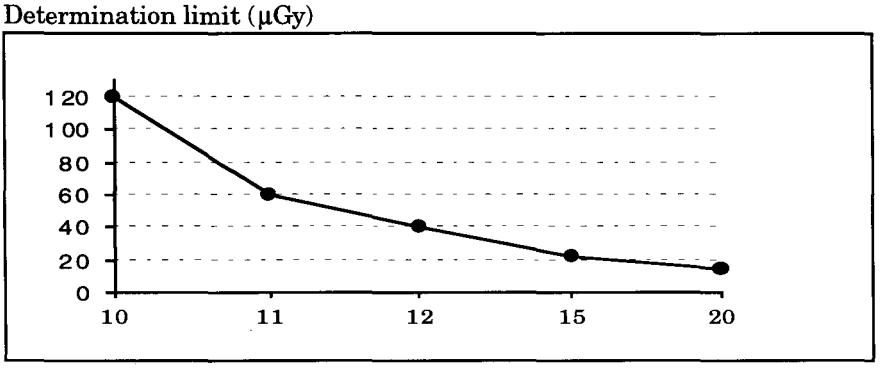

Fig. 1 Variation of the determination limit with precision

THE DEVELOPMENT OF AN EFFECTIVE SAFETY MANAGEMENT SYSTEM

R W Davies

Amersham International plc, Little Chalfont, HP7 9NA, England

Abstract

In UK law the responsibility for making arrangements to minimise risk and secure safe operations rests with the employer who in practice delegates this down through line management.

The paper describes a novel approach to assisting managers in meeting their responsibilities and explains how the system operates in a company producing radioactive materials for use in healthcare, life science research and industry.

Introduction

The essence of UK safety law is that businesses must make arrangements to minimise risk and secure safe operations, and that individuals have a responsibility for ensuring that their actions do not endanger colleagues. The responsibility for making the arrangements rests with the Chief Executive and, by inference and common practice, is delegated down through line management.

In the past safe operational practice was achieved within the company through instructions devised by the central safety group and issued to line managers. The safety group had the responsibility to ensure that the company complied with all relevant laws and licenses while the majority of line managers assumed or expected that 'safety' was taken care of centrally and thus had little proactive influence on the safety of their operations. There was also little in the way of formal audit.

Company Safety Arrangements

In 1990, the company safety policy was revised to emphasise the safety responsibilities of line management and included the phrase "managers at all levels are responsible for the safety of operations under their control". The central safety group became responsible for providing a safety management system to enable line managers to demonstrate that they were undertaking the required actions.

The key regulatory requirements and company standards are given to managers through the Company Safety Arrangements. This document tells managers what arrangements they must make to comply with the law fully, without the need for the managers to be familiar with the detail of the legislation. In the UK the regulatory framework is complex with over 30 Acts of Parliament and 80 sets of Regulations applying in the safety field.

The Company Safety Arrangements comprise 25 single pages, each covering a specific topic (for example : safety instructions; safety training; supervision; assessment and control of hazards; audits and corrective action). Each arrangement identifies who is responsible for the action and what the minimum requirements are. Generally the line manager or the site manager (the senior individual responsible for the operations of a complete site) are the focus of the actions. The arrangements are supported by more detailed safety guidance notes which can be referred to by relevant managers when they are determining their actions.

The responsibility for interpreting new and existing legislation for all aspects of safety and for ensuring that it is covered by the requirements laid down in the Company Safety Arrangements lies firmly with the central safety group. Managers can therefore expect that if they comply with the company arrangements that they will be in compliance with the relevant laws.

Manager's Safety Files

The execution of the company safety arrangements requires each manger to issue to staff rules, instructions and procedures appropriate to the nature of the operations under his or her control. The proper recording and review of these provides adequate evidence of compliance with the arrangements (and hence compliance with the laws). Managers were encouraged to collect the documents together or keep references to them in a "safety file" which was to be regarded as a "living system". It represents a simple documented management system. In order to ensure an acceptable and reasonably uniform content in an auditable format the central safety group imposed a quality assurance dimension onto the system. The system must comply with the QA requirements of ISO 9000 where these are relevant to the operations. Essentially, the manager must establish a safety organisation, identify and control all documents, conduct regular reviews and internal audits and have an effective corrective action procedure. Some of the details of ISO 9000 such as the requirement for a manual and, particularly, a management representative, were an inappropriate fit with "arrangements" and with the paramount need for the manger to "own" the safety file. The least prescriptive standard offering safe performance must be the preferred option. However, recent experience has shown that when a management unit has fully embraced ISO 9001, the existing safety file components which are common to both the safety and quality assurance systems also are in full compliance with the quality assurance system.

The basic components of the manager's safety file are shown below :

Manager's Safety File

- Policy
- Organisation
- Appointments
- Instructions
- Training
- Hazard Assessment
- Accident Investigation
- Audit
- Review

Audit

A key area where the current practice differs from the past is in auditing. The present arrangements require three tiers of audit. The first is 'self audit' carried out by the managers to enable them to know where they do or do not comply with laws or company standards and to satisfy themselves that their instructions and systems are being followed by their staff. The second tier is at the site manager level and involves reviewing the manager's self audits and checking the quality of the manager's audits. The third tier is at the corporate level and combines the aim of the site manager's audits with in-depth technical audits carried out in reaction to audit observations, legislative changes etc. In practice the site manager's and corporate audits are either combined or alternated.

Audits have been carried out over the past five years by formally trained auditors to ensure that managers have evidence to demonstrate compliance with each and every detail required by the company safety arrangements, using the arrangements themselves as an audit checklist. The adequacy of implementation has been checked by sampling procedures and questioning staff in the workplace. It is accepted that the likelihood of the auditor uncovering an isolated incidence of bad practice is small, because most operating units will have more than 100 practical procedures each and behaviour of staff is influenced by the presence of the auditor. It is this detail of the operating procedures that must be checked locally (and systematically) by the local audit arrangements.

The Arrangements in Practice

The system was implemented by all technical managers on Amersham's UK sites and effective management was generally achieved within two years. An important benefit was the recognition by managers that the safety file, when completed, offered a useful source of information and enabled them to understand their safety responsibilities and liabilities. There were two main problem areas. The requirement for internal audit was largely ignored and a few managers tried to abdicate their safety responsibilities to a safety specialist. Suitable counselling has now ensured that all direct appointments and instructions are those of the manager, and that a management signature indicates absolute ownership of any consequences arising from the signed document.

The manager's safety file includes as a minimum a statement of policy, organisation chart, key appointments, and references to all required rules, procedures and records. A series of unsupported compliance statements is insufficient unless there is a clear indication of how compliance is achieved. The depth and coverage of the information is tailored to the complexity of the organisation and tasks involved. When a radical change in organisation has occurred, the file has been found to be inadequate and significant changes, for example to supervisory procedures, have been necessary. On the other hand, when management has changed but the organisation remained constant, the documentation has required little alteration. There is, however, a need to train a new manager formally in the whole safety management system.

Conclusions

Experience over five years indicates that the safety management system coupled with audit and review can provide managers with confidence that their operations are adequately controlled and regulators with an auditable trail of evidence to confirm this.

AN INTEGRATED APPROACH TO PLANT SAFETY

T J George
Amersham International plc, Amersham, Bucks, HP7 9LL, England

Abstract
An innovative safety approach to the design of plant used in the manufacture of a wide range of radioactive products for healthcare, life science research and industrial applications at Amersham International is described.

The paper also describes how the techniques for reviewing the design of new plant have been adapted to the review of operational facilities and the decontamination and decommissioning of facilities at the end of their production life.

Introduction
Over the last five years safety review arrangements have been developed consistent with those applied in the nuclear industry but adapted in an innovative way to reflect the requirements of a commercial manufacturing environment. These arrangements have been applied to the design of new facilities; reviews of operating facilities; and the decontamination and decommissioning of redundant plant.

Classification and Project Phases
A multistage procedure for safety approval is applied to all new facility projects. At the start, the project is classified by a senior health physicist into one of four categories, depending on its safety significance. Higher significance construction projects are split into 4 stages - Concept, Final Design, Pre-Operational Commissioning and Operational Commissioning.

Hazard Identification/Hazard and Operability Study
A Hazard Identification review is carried out at the Concept stage by a small team using a check list. This early review ensures that the designer is aware of the main safety issues and can take account of them in the facility design.

The developed plant design and process are subjected to a Hazard and Operability Study (HAZOP) to identify all possible deviations from the way the design is expected to work and all the issues associated with these deviations. The group performing the study are selected from the Safety, Manufacturing and Engineering functions. The Manufacturing representative is a supervisor or operator with experience of the type of plant and process being designed.

The technique uses a structured approach for the identification of hazards by the generation of deviations from design intentions using guide words. Many of Amersham's operations are 'hands on' and the guide words may be applied to operator actions as well as plant components.

The HAZOP sessions have become an integral part of the design process and, although when initially introduced were viewed with some suspicion, they are now welcomed as a thorough vetting of the design before potential errors and omissions prove more costly. Having carried out the HAZOP it is possible to quantify the risk of the plant/process to operating staff or the general public by using techniques such as Fault Tree Analysis. The HAZOP is as much a review of quality as it is of safety issues and the technique has been successfully applied to manufacturing operations where the quality of the product is the principal objective.

Peer Review
The HAZOP provides an excellent basis for writing the 'Final Design' Safety Clearance document. This is then subjected to a review by a Peer Group which brings together the design team and an independent group of experienced staff selected from Site and Corporate Safety, Engineering and Manufacturing. The proposals are presented by the design team and subjected to challenge by the Peer Group. All points of view can be balanced at this session and it has proved to be much more effective than using individuals to review a document in isolation. Following this review the 'Final

Design' Safety Clearance is formally approved by the relevant Manufacturing Manager, the Site Engineering Manager and the Site Radiological Safety Officer. Peer Reviews may be held at other stages of the project if deemed necessary by the Peer Review Group Chairman.

The Arrangements in Practice

Amersham is currently investing in new pharmaceutical manufacturing facilities. Two semi-automated production suites situated in a clean-room complex carry out the final stages of radiopharmaceutical manufacturing. They will handle stock dilution, vial filling, sealing and labelling operations and waste management. Nine radionuclides, including Sr-89, Ga-67 and In-111, will pass through the plant which has been constructed and is currently undergoing pre-operational commissioning tests. This was a particularly challenging project to marry the stringent requirements of pharmaceutical regulators where Good Manufacturing Practice guidelines must be observed and radiological protection requirements for protection of operators from radiation exposure. The principal pharmaceutical and radiological design issues and identified solutions are shown in the Table below:

Pharmaceutical design requirement	Radiological design requirement	Solution
Operate pharmaceutical clean rooms at slight overpressure to protect product from particulate	Handle radioactive products in rooms at slight underpressure to prevent escape of product following a spill	Clean room surrounding radioactive handling area at positive pressure. Radioactive material handling room/ enclosures at negative pressure
Deliver air to product to pharmaceutical standards and ensure flow is away from product	Direct air away from operators and towards interior of enclosures containing the radioactive product	Pharmaceutical requirements at point of vial filling and stock bottle emptying. Enclosures at negative pressure to protect operator
Provide minimum disturbance to laminar air flow close to vial filling	Surround the vials with lead shielding as they are filled	Provide some shielding local to the vials but supplement with full shielding on face of enclosure
Label vials after dispensing with product to prevent errors	Label vials before dispensing to reduce operator dose	Label vials after dispensing but automate and provide shielding local to vial location
Provide easy accessibility to dispensing line for full line clearance at end of product run	Provide shielding and remote operation to control operator dose	Bulk stock separated from dispensing line and heavily shielded. Filled vials lightly shielded and shielding designed for easy removal at end of run
Remove radioactive waste after each product run	Store radioactive waste in facility until decayed	Highest activity liquid waste stored. Bulky solid waste removed by remote transfer

Periodic Reviews of Safety

Formal major reviews of safety are carried out for all facilities on a 5 year rolling programme. The plant, process and safety management arrangements are considered in each review which covers normal operating conditions and also reasonably foreseeable fault conditions arising from plant failures, operating failures and external hazards. The HAZOP technique is used as a tool for fault identification.

A report with recommendations for improvements is submitted to a Peer Review in the same way as a new plant safety clearance. The Manager is then required to prepare an Action Plan for improvements which is monitored through to completion.

Examples of areas where improvements have been required are: radiation shielding; fire detection; fire compartmentation; transfers of radioactive material; containment; extract filtration/traps; safety management; barrier monitoring arrangements; activity in air alarm monitoring.

Decontamination and Decommissioning Projects

The main distinction between new plant projects and decontamination and decommissioning projects is the amount of 'on the ground' operational safety issues to be resolved. A round-the-table HAZOP is first carried out on the proposed approach, in order to identify the main protective features required to control contamination and radiation dose and to test the operability of the method. The HAZOP may also identify the need for a 'mock up' and trial operation to be carried out prior to the actual job to confirm its practicability and this enables operating times to be measured where dose control is critical. Detailed Method Statements are produced by the staff who are going to undertake the work. These Method Statements are subjected to a HAZOP approach in the workplace in order to identify potential safety problems before the task is undertaken. A system for ensuring that the significance of deviations from Method Statements are assessed has been developed. The whole process is overseen by the operational Health Physicist.

Conclusion

The integrated approach to plant safety responds effectively to rapidly changing manufacturing requirements and has resulted in real improvements to 'on the ground' operational safety without imposing unacceptable bureaucratic restrictions.

UK IONISING RADIATIONS INCIDENT DATABASE (IRID)

G O Thomas[1], J R Croft[1] and M K Williams[2]

[1] National Radiological Protection Board, Chilton, Didcot, Oxon, UK
[2] Health and Safety Executive (HSE), Nuclear Safety Division, London, UK

ABSTRACT

The widespread use of ionising radiations carries with it the potential for incidents and accidents. Their severity can vary from the trivial to the fatal and may involve substantial economic penalties. In order to assist in learning the lessons from events that have occurred, the NRPB, HSE and Her Majesty's Inspectorate of Pollution (HMIP) have established a national Ionising Radiations Incident Database (IRID). This paper provides details of the specification and operation of the database together with the proposed feedback mechanisms.

INTRODUCTION

A fundamental part of any assessment of, and plans for the prevention and mitigation of reasonably foreseeable radiological incidents, is to learn the lessons from accidents that have occurred and to feed this back through training and guidance to users. The efficiency with which this happens depends on the collective experience of individuals. Each may have direct experience of some types of accident, but will almost certainly have to rely on data from publications, conferences and possibly anecdotal information. There is a natural tendency for organisations not to publicise their own accidents, especially if the accident was a 'near miss' that fortuitously did not have serious consequences - this time! As a result our feedback experience from accidents both nationally and internationally can be limited, fragmented and difficult to pass on to the next generation of workers. Thus there is a need for a more coherent means of feedback.

DEVELOPMENT AND OBJECTIVES

UK legislation requires that accidents, incidents and occurrences which satisfy specified criteria are reported to the regulators, HSE and/or HMIP. The regulations also require an employer working with ionising radiations to appoint a Radiation Protection Adviser (RPA) and to involve that person in investigations of incidents and accidents. NRPB acts as RPA to some 800 organisations and provides technical services to many others. As a result, NRPB is involved in the investigation of a wide range of incidents and accidents, including many 'near misses' which would not be legally reportable. An NRPB/HSE feasibility study (1990) on improving feedback concluded that mechanisms were in place in the nuclear and transport sectors, but that there would be significant benefits from a national incident database to cover the non-nuclear sector ie. industry, research, teaching and health care. However it also highlighted some crucial practical problems related to the confidentiality of information; the resolution of which took some time. Impetus to the work was provided by the Commission of the European Communities (CEC), both in supporting work in this area and as a result of their 4th European Seminar on Optimisation of Radiation Protection in April 1993 (1) which concluded that a principal challenge for the future is ".... to improve our feedback from past experiences by developing databases".

As a result of subsequent work the NRPB, HSE and HMIP have entered into a partnership to combine incident and accident data in a confidential form in the Ionising Radiations Incident Database (IRID). The objectives are:

(a) to establish and operate a database that will act as a national focus on radiation incidents primarily in the non-nuclear sector, ie. industry, research, teaching and medicine;

(b) through appropriate publications, to provide feedback and guidance to users of ionising radiations on preventing or limiting the consequences of radiation incidents; and

(c) to provide regulatory bodies and others with advisory responsibilities, analyses of relevant data that help in assessing priorities in resource allocation.

SCOPE

The database is designed to cover radiological incidents including near misses and occurrences involving actual or potential occupational and public exposure. However, some types of incident are excluded from IRID since they are already covered by existing arrangements. Those excluded are:

(a) **Nuclear incidents:** these would include nuclear (as opposed to radiological) incidents that involve criticality or events related to the safety of reactors or nuclear processing plants.

(b) **Transport incidents:** the NRPB runs, under contract to HSE and the Department of Transport (DTp), a database (2) of incidents involving the transport of radioactive material.

(c) **Patient exposure:** The HSE (3) and Medical Devices Agency have systems for reporting and dissemination of relevant data. In addition at a European level the European Federation of Organisations for Medical Physics (EFOMP) are in the process of establishing a database for radiotherapy accidents in Europe (4).

Included are:

(a) **Radiological incidents occurring on nuclear sites:** eg. an incident involving a radiography source being used on a nuclear site.

(b) **Occupational and public exposure in the medical sector:** eg. a radiotherapy source left implanted in a patient discharged from hospital.

(c) **Incidents involving radioactive material in the public domain not arising from discharges authorised by regulatory bodies:** these would include incidents which required the National Arrangement for Incidents involving Radioactivity (NAIR) to be invoked.

(d) **Radiological incidents in the defence sector:** the unattributable nature of the database may now allow such incidents to be reported, without the origins being obvious.

(e) **Unintentional and/or unauthorised discharges of radioactive materials into the environment:** these would include discharges from nuclear and non-nuclear licenced sites.

NRPB are responsible for the management of the database and together with HSE and HMIP are reviewing their files to provide historical data. This will be generally limited to the last decade, although some earlier incidents will be included because of their value in 'learning the lesson'. It is recognised that this data is incomplete and that any retrospective analyses would need to be used with caution.

DATABASE STRUCTURE

The database operates on a Personal Computer (PC) using DBASE V software and consists of 24 fields including one text field. These are defined in a Data Element Dictionary and are summarised below:

1	Case number	13	Occupation of worker(s)
2	Area	14	Type of equipment
3	Incident Date	15	Isotope(s) involved
4	Incident Level	16	Activity
5	Exposure Level	17	Kilovoltage of radiation generator
6	Site Level	18	Cause of incident
7	Nature of accident	19	Availability and effectiveness of contingency plans
8	Number exposed: occupational	20	RPA: appointed, involved in investigation
9	Number exposed: public	21	RPS: appointed, involved in investigation
10	Whole body dose(s)	22	Follow up action (eg improvements)
11	Extremity dose(s)	23	Date of entry in database
12	Internal organ dose(s)	24	Description: text field

Fields 1 to 23 contain either numeric data (eg. dose in mSv) or one or more codes that categorise the incident and have been designed to permit useful analyses of the database; for example searching for incidents over a specified period of time involving industrial radiography and resulting in doses in excess of the dose limit. In defining the fields, a balance has had to be made between the level of detail, its usefulness and the effort involved by those submitting incident data. To maximise the overall benefit it was felt important to achieve a high reporting percentage and that this would only be achieved if the reporting system was not

onerous on the contributors. Therefore the number of data fields has been minimised to that consistent with categorisation and analysis requirements. Field 24 is a text field that contains descriptions of the incidents, the causes, the consequences, follow up actions and lessons to be learned. The format has been designed to allow it to be directly reproduced in publications to provide feedback to the users.

CONFIDENTIALITY AND QUALITY ASSURANCE

The information entered into the database will not contain any names or addresses of organisations or individuals. Only the originator of the incident entry will know the names of the organisations or individuals concerned and all data presented to NRPB will be in a sanitised format. NRPB has undertaken not to divulge any privileged information to a third party. HSE and HMIP are well aware of the natural wariness that potential contributors may have in respect of the involvement of regulatory bodies. Therefore they have given assurances that they will not seek to obtain further information from the other partners (or the contributing organisation, if different) about any incident recorded on the database which was not reported to regulators.

Simple reporting proformas and guidance has been developed to help obtain consistency in the reporting of incidents. To try and minimise the degree of variation in the categorisation of incidents the Database Co-ordinator at NRPB will independently code the data (from the text description) and discuss any discrepancies with the contributor prior to data entry and entry validation. Checks have been devised to identify duplicate reports by automatically cross referencing a number of fields.

FEEDBACK

Undoubtedly the value of IRID will be judged on the quality and accessibility of feedback to users and regulators. Equally this will be a crucial factor in maintaining the flow of contributions from various organisations. Initially the primary feedback route will be through publications:

(a) NRPB/HSE/HMIP will publish periodic review documents that reproduce the text descriptions of incidents, where appropriate enhanced by diagrams or drawings of accident scenes, and analyses of the distribution and trends in incidents.

(b) Incidents that are of particular relevance will be published in NRPB's 'Radiological Protection Bulletin' HSE's 'RPA Newsletter' and HMIP's Bulletin.

A key use of the feedback from IRID should be in the training of all those involved in the use of ionising radiation. Therefore a number of short joint publications (with slides) that can be used as training material targeted at specific work groups will be produced.

FUTURE DEVELOPMENTS

Although initiated by NRPB and HSE and joined by HMIP, it is intended that IRID is made as wide a collaborative effort as possible, involving others in the partnership or as contributors.

There are also valuable lessons to be learned from incidents outside the UK and it is envisaged that one future development will be to add a module covering such incidents. This may be influenced by the development of comparable databases in other countries and international organisations such as IAEA and the European Union (EU). Undoubtedly each country or international organisation will have a need for specific data fields but it should be possible to agree on core data fields and formats - a challenge for the future.

In a Tritium facility the measurement of Tritium surface contamination is required to insure :

- The radiation protection of workers at different work places,
- the sorting, disposal and storage of wastes and materials.

The most common way to measure surface contamination is to quantify the removable surface contamination by liquid scintillation counting. However this process is unaccurate since the removal efficiency has not been quantified so far. There are very few scientific reports about this issue. Some studies related to stainless steel has been carried out, nevertheless data about organic compounds are still missing.

Our experiments were carried out using the smear technique on four types of specific materials belonging to Valduc Tritium utilities :

- Stainless steel,
- waste containers (steel + painter),
- vinyl,
- floor coating.

Results are gathered on the paper. They highlight we must introduce in the relationship used to evaluate the surface activity a coefficient which depends on the type of material and on the surface state. On another way we can observe a good agreement between our values and those from the theoritical model proposed for stainless steel (1).

ASSESSMENT OF THE EFFICIENCY OF PERSONAL PROTECTIVE EQUIPMENT FOR USE IN RADIOACTIVE CONTAMINATED ENVIRONMENT - RECENT IPSN CONTRIBUTION

Gilbert BRUHL ; J. CORBIÈRE ; J. CL. LABORDE ; J. VENDEL
Institut de Protection et de Sûreté Nucléaire , 92265 Fontenay-aux-Roses, France

Abstract

In all industrialized countries important studies have been accomplished with the aim of improving the personal protective equipment (PPE) performances, i. e. of minimizing the exposure to hazardous environment and other risks for workers attending to operate in a contamined area and, at the same time, to increase their physiological comfort.

In the same field, IPSN, in collaboration with other European laboratories, has achieved in the last four years, an important research program, in order :

- to determine the efficiency of protection of the different categories of PPE,
- to improve the design and to develop new material of construction of special type of PPE (e.g. ventilated-pressurized protective clothing, ventilated hoods,...),
- to optimize the time of use during routine operation or emergency situations, by considering both technical performances and physiological aspects such as heat constraints and health effects.

After a brief review of the main characteristics required for the different categories of PPE, the present communication will present the directions of research which were preferred in order to achieve the objectives specified here above. Then it will conclude with a review of the instructions of use, maintenance and wearer training, which are the essential factors to be considered by every responsible of operational health of the employers in a nuclear facility, in relationship with the PPE management program.

1 - PERFORMANCE LEVELS OF THE DIFFERENT CATEGORIES OF PPE

In order to evaluate the level of protection offered by a particular PPE, the following definitions are used :

- **Nominal Protection Factor (NPF)**

The ratio of the average concentrations of contaminant measured in the ambient atmosphere and inside the PPE, at the point where the wearer draws breath. The concentrations taken into account are the average concentrations recorded during a standardized test.

$$NPF = \frac{C\ ambient}{C\ inhaled}$$

- **Permeance or Total Inward Leakage (TIL)**

Quantity corresponding to the reciprocal value of the NPF. It is expressed in %.

$$TIL = \frac{1}{NPF}$$

According to these definitions and as usually admitted in the literature [1], [2], the efficiency of the different categories of PPE can be classified in accordance with table 1.

Categories of PPE / Definitions	Range of Nominal Protection Factor	Range of average leakage into the PPE (in %) during standardized test (Permeance)
Ventilated-pressurized protective clothing (Air feed impermeable suit)	10 000 - 100 000	0.001 - 0.01
Ventilated hood (Air feed impermeable hood)	5 000 - 50 000	0.002 - 0.02
Filter type respirator (Full face mask with filter)	2 000 - 10 000	0.005 - 0.01
Non ventilated protective clothing (Blouse or impermeable suit)	2 - 20	5 - 50

Table 1 : Efficiency of different categories of PPE

2 - MAIN RESEARCH DIRECTIONS

2.1 - Ventilated-pressurized protective clothing or hoods

- Improvement of the protection factor

For air feed protective clothing the protection factor level mainly depends on :

- the **static leaktightness** which in term depends on the intrinsic tightness of the clothing during normal working conditions; the studies have been focused on the improvement of the welding or seams and fasteners quality.
- the **dynamic leaktightness**, which is essentially dependant on the efficiency of the exhaust device(s) and on the aeraulic performances of the protective equipment.

Concerning this last field, both investigations have permit to increase namely the NPFs by a factor of 4 (i.e. from 20 000 to 80 000) by developing special high efficiency exhaust devices, and by increasing the internal air flow rate inside the equipment (see figures 1 and 2).

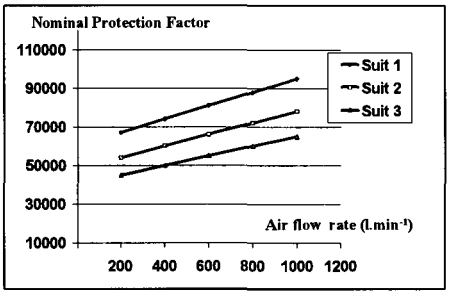

Figure 1 : Variation of NPFs by increasing air flow rate in ventilated-pressurized clothing

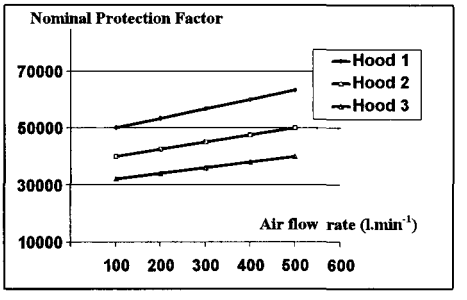

Figure 2 : Variation of NPFs by increasing air flow rate in ventilated-pressurized hoods.

- **Improvement of physiological comfort (new concept of ventilation of suits)**

The studies were carried out in cooperation with occupational physicians to the definition of a system of "direct skin or body ventilation" which allows a better thermal regulation of the wearers, particularly in case of intervention in hot environments.

The results have proved that for the same ventilation rate and the same physical work rate, the acceptability duration may be improved by 50 % by means of the refreshing due to the direct skin ventilation, in comparison with the traditional clothing in which the ventilation is fed into the suit, i.e. only over the underwear.

- **Studies concerning new material of construction of PPE**

In addition with efficiency against particle penetration, design of PPE must comply with other typical requirements, such as mechanical resistance, flexibility, flammability behaviour, suitability to disposal (by incineration), gas permeation, etc. Table 2 here after presents the compared performance of principal materials, replacing PVC, which has been so far the most common one.

PVC (standard or non flammable)	Low cost Easy welding Non flammable	Non incinerable High Cl content (36 %)
POLYURETHANE (standard or non flammable)	Incinerable Good mechanical & chemical resistance	High cost Difficult to weld
POLYETHYLENE (standard or non flammable)	Low cost No Cl content Incinerable	Flammable Mechanical resistance lower than PVC
PVC coated with polyester	Low permeability to gas (e.g. tritium), Excellent mechanical & chemical resistance	High cost Heavy material Non flammable
Polyethylene - Vinyl Acetate (EVA)	No Cl content Incinerable Acceptable mechanical & chemical resistance	Flammable, Difficult to weld and assembly, Higher cost than PVC
Non woven tissue (TYVEK) (polyethylene standard or non flammable)	Low weight, Incinerable Flammability depends on (Cl, Br, ...) content	Higher cost than PVC Mechanical & chemical resistance lower than for the previous material

Table 2 : Comparison between different material of construction of PPE

Airborne concentration	Recommended personal protective equipment	
	Continuous use	Short duration use in special circumstances
Less than 0.3 DAC	No requirements. Half face respiratory may be appropriate	No requirements. Half face respiratory may be appropriate
Greater than 0.3 DAC Less than 30 DAC	Full face respirator with particulate filter	Full face respirator with particulate filter
Greater than 30 DAC Less than 150 DAC	Air fed respirator, hood, blouse or impermeable suit	Full face respirator with filter, or air fed respirator, or impermeable suit
Greater than 150 DAC Less than 300 DAC	Air fed impermeable suit	Air fed respirator or impermeable suit
Greater than 300 DAC	Air fed impermeable suit	Air fed impermeable suit

Table 3 : Guidance for the selection of PPE (particulate hazard) for normal operations or emergency situations (IAEA Recommendations)

2.2 - Non ventilated-non pressurized protective clothing

Due to the fact that this kind of protective clothing does not provide the entire protection of the respiratory tract of the wearer, it was interesting to assess the different kinds of equipment in use (blouses, coveralls, 2 pieces suits,...) in order to determine the protection factor given by the protective suit without any additional respiratory protective device.

Two kinds of particle permeation test, using Na Cl agent test, with different particle sizes (respectively 0,6 µm and 1,4 µm of aerodynamic mass median diameter), have been successively performed :

- at first, the efficiency of the material of construction has been implemented. Figure 3 here after gives the results obtained for several types of non wowed materials.
- at second, the efficiency of the complete suit has been implemented (this test is called "whole suit test"). Figure 4 here after shows the results obtained on different types of protective clothing.

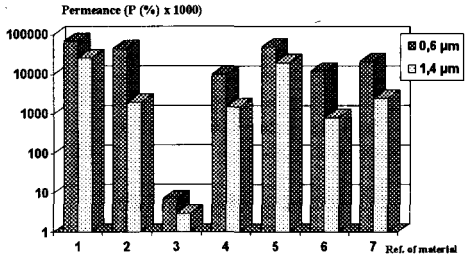

Figure 3 : Particle penetration test for material of construction of protective suits

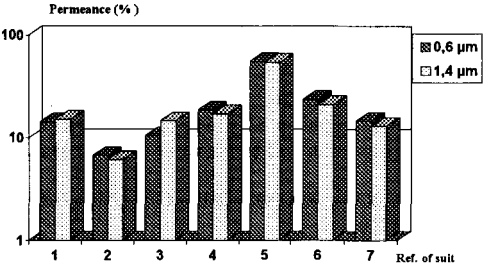

Figure 4 : Particle penetration test for protective clothing ("Whole suit test")

The conclusion of these tests are :

- Figure 1 : results depend on both particle sizes and permeability of material,
- Figure 2 : results depend only on the design of the suit (position of openings, straps on legs, neck, arms,...) and very little on material of construction. Total Inward Leakage can vary from 5 to 50 %.

These results have been confirmed by several European laboratories using the same test procedures, during intercomparison exercises [3], [4]. This means that the use of non ventilated protective clothing must be limited for very low contamined environment or combined with appropriate respiratory protective equipment in case of high or medium contamined environment for routine or emergency operations.

3 - CONCLUSION

Due to the different levels of efficiency, PPE should be chosen in accordance with the risk analysis. Table 3 here above could be a good help for the selection of the appropriate PPE. In addition other parameters should be taken into account, such as :

- examination of the means for removal or reduction of the sources of internal/external other than individual contamination or exposure (constructive provisions, confinement, ventilation or preferential extractions,...);
- evaluation of environmental parameters (toxic gases presence, fire risk, temperature, etc.) and of human factors (training and experience of operators);
- preparation of working protected areas (mobile or fixed tents with appropriate ventilation joined to equipment for radiological surveillance);
- choice of the most appropriate PPE for the intervention : reusable or disposable (disposal problems procedures);
- economics factors : equipment cost + decontamination cost/disposal cost (related to wastes volume);
- personal training, control and maintenance of equipment, etc.

ACCIDENTAL INTERNAL EXPOSURE OF ALL GROUPS OF CHERNOBYL NUCLEAR POWER PLANT EMPLOYEES

Igor A. Goussev, Alex A. Moiseev, Vladimir I. Evtichiev
Scientific Research Center of Russian Federation - Institute of Biophysics, Jivopisnaya, 46, Moscow, Russia

INTRODUCTION

Accidental internal exposure of Chernobyl NPP employees has started from April, 1986 and it was found to be decreased to pre-accident level at the end of 1987. Significant number of people from all groups of staff and temporary employees were measured using whole body counters situated in Clinical Department of the Institute of Biophysics, which has represented the main body for medical assistance and expertise in these people including those, who suffered from acute radiation syndrome as well as the people engaged in all kinds of works at Chernobyl NPP site. Technical characteristics of the equipment and techniques used to assess the internal exposure are given in [1].

INTERNAL EXPOSURE OF PEOPLE DIED FROM COMBINED RADIATION INJURIES

Internal exposure doses did not exceed 12 Gy (thyroid gland), 1 Gy (lungs) and 0.25 Gy (whole body) for all mortal cases excluding two patients (Reg. Nos.: 24, 25). Internal exposure doses for these two cases are given in Table 1.

Table 1 Internal exposure of staff members died due to the Chernobyl accident (maximum levels)

Reg. Number	Internal exposure dose, Gy		
	whole body	lungs	thyroid gland
24	1.8	2.2	23
25	0.8	1.1	21

INTERNAL EXPOSURE OF STAFF WORKED AT THE SITE OF CHERNOBYL NPP DURING THE EXPLOSION AND FIRE AT UNIT 4

Table 2 demonstrates thyroid dose distribution in 204 persons including 143 acute radiation syndrome victims. Maximum thyroid doses are about 20 Gy, average thyroid dose is (1.5±0.2) Gy, 95% percentile is 1.8 Gy.

Table 2 Thyroid dose of staff worked at the site of Chernobyl NPP during the explosion and fire at Unit 4

Dose range, Gy	Number of people
0 - 1.23	173
1.23 - 3.67	18
3.67 - 6.11	4
6.11 - 8.55	4
8.55 - 10.99	2
10.99 - 13.43	2
13.43 - 15.87	0
15.87 - 18.31	1

According to whole body counter measurements the lung doses for these people did not exceed 1.2 Gy, where the average lung dose was found to be (0.15±0.07) Gy and 95% percentile is 0.7 Gy. Whole body internal doses did not exceed 0.1 Gy.
Radionuclides provided internal exposures are: Zr-95, Nb-95, Ce-141,-144, Cs-134,-137, I-131.

INTERNAL EXPOSURE OF PEOPLE EMPLOYED FOR ACCIDENT CONSEQUENCES ELIMINATION IN 1986

The described contingent includes persons employed from May to December, 1986 within 11 consequent periods. Table 3 gives the characteristics of these groups.

Table 3 Employee groups observed in 1986 ã.

Group Number→	1	2	3	4
Period of work→	26.04-01.05	01.05-10.05	10.05-20.05	20.05-1.06
Number of people→	178	31	20	25

Group Number→	5	6	7	8	9	10	11
Period of work→ (months of 1986)	VI	VII	VIII	IX	X	XI	XII
Number of people→	56	52	50	48	41	23	18

Total number of observed people is 542.

Table 4 Average values of radionuclide intake (nCi) in Chernobyl employees (1986)

Radionuclide	Number of group										
	1	2	3	4	5	6	7	8	9	10	11
Cs-134	195	52	29	36	35	36	30	20	21	22	14
Cs-137	410	96	58	73	67	78	67	44	48	51	37
Ru-103	218	N/M	102*	N/M	N/M	N/M	N/M	N/M	N/M	N/M	N/M
Zr-95 + Nb-95	784	N/M	22*	N/M	N/M	N/M	N/M	N/M	N/M	N/M	N/M

*Average for groups 1,2,3 (i.e. in May, 1986). N/M - not measured (below detection limit).
Table 4 shows that inhalation of radionuclides was practically finished in the second half of May, 1986, which is certified by the absence of "inhalation radionuclides" (Zr-95, Nb-95, Ru-103). Total incorporated activity was stabilized on the level of 50 nCi, which is typical for local population burdens found after the Chernobyl accident in urban population of Kiev and Gomel and corresponded to the foodstuff radioactive intake.

Table 5 gives the comparison between NPP staff and temporary employed workforce ("liquidators").

Table 5 Comparison of the internal contamination between NPP staff and "liquidators" (April, 1986), nCi

Radionuclide	Staff	"Liquidators"	Total Average
Cs-134	229	96	195
Cs-137	505	229	410
Ru-103	279	198	218

We did not calculate individual doses for 542 persons, which majority had internal doses below 0.0015 Gy. Maximum observed internal doses were equal to 1.16 Gy (lungs) and 0.03 Gy (whole body). Average individual whole body internal exposure dose of Chernobyl NPP employees did not exceed 0.003 Gy in 1986. Persons with lung doses above 0.05 Gy represents 2.4% of all measured employees and lung dose groups correspondingly are of the following percentage: 1.7% (>0.15 Gy), 0.9% (>0.75 Gy), 0.2% (> 1 Gy). All these lung doses are completely accumulated within 1986.

INTERNAL EXPOSURE OF PERSONS EMPLOYED IN 1987

Total number of Chernobyl NPP employees measured by our whole body counter in 1987 is 1192. 10 occupational groups and one group of people whose occupation was not exactly identified were selected. 56% of measured people represents "pure" nuclear power plant staff and about 44% are temporary workforce.

Cs-134,-137 were found in all measured persons. The low contents of Ru-106 (3-5% of total radiocaesium activity) and Co-60 (less than 3-5% of MPBB) were found in 43 persons. No other nuclides were measured in 1987.

Average radiocaesium activity is (122±6) nCi, 97% percentile is 500 nCi and 90% percentile is 200 nCi. No correlations between occupations and incorporated activity burdens were revealed (0.008, p=0.2%). Weak correlation was found between age and incorporated activity (correlation coefficient=0.15, regression coefficient=(31±6)).

Thus, the internal exposure of Chernobyl NPP employees does not corresponds to the occupational activities and their average internal exposure whole body doses were calculated to be equal to 0.6 mGy.

CONCLUSIONS

1. Internal exposure of thyroid, lungs and whole body of persons died from combined radiation exposure could not make effect in clinical outcomes excluding 2 patients (7% of whole lethality).
2. Internal exposure whole body doses in two aforementioned mortal cases represented less than 15-30% of total whole body dose at the moment of death.
3. Lung doses of died patients did not exceed 0.5 Gy.
4. Thyroid doses of died patients did not exceed 25 Gy.
5. Whole body doses of the internal exposure of died patients were less than 3-4% of external exposure doses given in [2].
6. Accidental exposure doses of thyroid in Chernobyl NPP employees did not exceed 20 Gy, where average dose was (1.5±0.2) Gy and 90% percentile is equal to 1.8 Gy.
7. Accidental internal exposure of Chernobyl NPP employees was finished at the end of May, 1986 (1 month after the accident).

ABSTRACT (See instructions overleaf)

The experience of medical provision of the personnel, suffered during nuclear installations accidents on the nuclear-powered submarines shows, that during such accidents personnel is exposed to Gamma-radiation in doses, which cause acute radiation syndrom (ARS), up to the extremly grave degree of heaviness. Besides, Betta-radiation of radioactive gases, penetrating into nuclear-powered submarine accomodations during severe accidents of nuclear installations, gives rise to acute radiation injuries of skin (ARI) of the personnel.

Gamma-radiation collective doses, intercepted by nuclear-powered submarines personnel during nuclear accidents ranged from 17 up to 74 people/Gy, and average individual doses - from 0.16-0.38 Gy up to 0.57-0.22 Gy. Collective dose of Betta-radiation on the skin was equal to 218.9-816.6 people/Gy, and average individual dose on skin was from 2.3-4.8 to 5.7-4.0 Gy. Individual dose on thyorid at the cost of summary iodine radionuclides inhalation averages between 1.9-2.8 and 2.4-10.3 Gy.

Death as a result of acute radiation syndrom determines the average risk for nuclear-powered submarines personnel equal to 0.5-0.8E(-4) per year. Risk of acute exposure stochastic effects comprise 9-14% of the risk of acute radiation syndrom fatal results.

Harm index expressed in years of expected life expentancy reduction for 1000 people accounts for 2.3-3.9. Probability of exposure fatal consequences comprise 10-15% of the total risk magnitude of the death for various reasons (fires, explosions, sections flood etc.) Thus, total magnitude of the death risk accounts to amount of the order of E(-3).

ABSTRACT (See instructions overleaf)

One of most important problem for radiation monitoring procedure at IHEP is to create and investigate the reference radiation fields, which adequately simulate the accelerator radiation conditions, for the goals of correct dosemeters calibration It is assumed that the IHEP reference fields set has to include the following groups of reference fields: 1) based on neutron radionuclide sources, 2) behind the biological accelerator shield (including high-energy fields), 3) creating by charged particles such as muons

The results of dose characteristics investigation of the IHEP reference fields based on radionuclide sources ^{239}Pu-Be and ^{252}Cf are presented in the paper The neutron ambient dose equivalents measured in these fields are compared with those calculated from the neutron spectra measured by multysphere spectrometer and monocrystal stylbene spectrometer

The instruments being used in the dose characteristics measurement as well as the calibration procedure of these instruments on the primary National Standard neutron and proton fields at VNIIFTRI (State Standard of Russia) are discribed

Neutron response functions of the instruments are calculated in energy range up to 1 GeV in order to analyze the systematical errors arising when the instruments could be applied in the high-energy reference fields Configuration of a set of dosimetric and spectrometric instruments requiring for high-energy reference fields investigation is discussed Preliminary measured dose characteristics of the IHEP high-energy reference radiation fields are given

ABSTRACT

The calculational investigation of the high-energy neutron and proton absorbed dose distributions in the tissue-equivalent plate phantom was carried out. The calculations were performed with the ROZ6H/SADCO-2 program package.The ROZ6H discrete ordinates code is based on the solution of the Boltzmann equation for neutral and charged particles in the 1-D geometry by numerical schemes of second-to-fourth order of accuracy. The SADCO-2 nuclear data library contains cross-sections for neutrons (with energy 0.02 eV–10 TeV), photons (0.1–20 MeV), protons, pions, kaons (20 MeV–10 TeV) as well as a stropping power for all charged particles. The ROZ6H/SADCO-2 package allows one to calculate particle spectra with error about 5–10%. The absorbed dose (D) was calculated as follows : $D = \int F_i(E) k_i'(E) dE$, where $F_i(E)$ is the spectrum of particle of the i^{th} type; $k_i'(E)$ is the total kerma factor for neutrons and photons at energies below 20 MeV and it is the partial one for neutrons, protons, pions and kaons at energies E>20 MeV. (The partial kerma factor is the sum of energy transferred to charged particles excluding fast (E>20 MeV) charged hadrons.) The calculated absorbed dose distributions on the phantom depth for normal and isotropic incident neutrons and protons with energies 20 MeV–100 GeV are presented in the report. The presented data are assigned both for specialists in the radiation therapy and for working up recommendation of acceptable levels of irradiations.

ABSTRACT

The calculational investigation of radiation fields formed by high-energy neutrons and protons behind iron and concrete shielding was carried out with the ROZ6H/SADCO package. The ROZ6 discrete ordinates code with SADCO-produced multigroup data sets provides a high accuracy of the high-energy hadron transport calculations. The dependencies of the following components of radiation on the shielding thickness and source energy were determined: thermal neutrons; fast neutrons; neutrons with E>20 MeV; photons with E<20 MeV; charged particles. The formula for approximation of dose equivalent (H) attenuation in the transition range of shielding thickness (t) was proposed : $H_i(t) = exp(a_i^0 + a_i^1 t + a_i^2 t^2)$.
For the range of equilibrium attenuation the calculated data were described by the 'length of relaxation' method: $H_i(t) = H_{i0}(E) exp^{-t/\lambda}$. The absence of equilibrium between high-energy (E>20 MeV) and low-energy (E<20 MeV) radiation components in the iron shielding was taken in account : $H(t) = H_o^{(E>20)} exp^{-t/\lambda_h} + H_o^{(E<20)} exp^{-t/\lambda_l}$. The following designations in the above relations are used: a_i^0, a_i^1, a_i^2 are the parameters; λ_i is the attenuation length of radiation component of the i^th type; H_{i0} is the dose build-up factor of the i^{th} type radiation. Calculated approximation parameters for all mentioned components are presented in the paper. The uncertainty of presented data is about 5–10%. The comprehensive comparison of calculated attenuation lengths with numerous experimental data shows a high reliability of the proposed approximation. Presented data are assigned for the practical radiation problems solution on high-energy proton accelerators at energies 20 MeV–300 GeV.

ABSTRACT

A much used for absorbed dose calculations at neutron energies E<20 MeV kerma approximation $D_i = \int F_i(E) k_i(E) dE$, can not be extended to a high-energy range, because there is not the charged particle equilibrium. It was proposed to calculate the hadron (n, p, π, K) absorbed dose at energies 20 MeV–10 GeV by presented equation using partial kerma factors (k'_i(E)) instead the total one (k_i(E)). The partial kerma factor may be calculated as $k'_i(E) = \sigma_i \gamma \sum_j E_j + (dE_i/dx)/\rho$ for p, π, K; $k'_i(E) = \sigma_i \gamma \sum_j E_j$ for n. In the above relations F_i(E) is the spectrum of hadron of the i^{th} type; σ_i is the microscopic total cross section of hA-interaction; γ is the number of target atoms per unit mass; dE_i/dx is the stopping power of primary charged particle; ρ is the mass density; E_j is the energy of produced in hA-interaction heavy charged particle (A>1) or the energy of proton with E<20 MeV. Thus, the partial hadron kerma factor is defined as the sum of energy transferred in a reaction to charged particles with high stopping power only: d, t, ^{3}He, α, residual nuclei and low-energy protons. The equilibrium conditions for those particles exist always in a practice. The total and partial kerma factors calculated with hybrid (at E<100 MeV) and cascade-evaporation (at 100 MeV<E<10 GeV) models are presented. Good agreement of calculated total kerma factors with the experimental one at energies E<70 MeV and with calculational literature data at E<1 GeV was shown. Calculated partial kerma factors for the energy range 20 MeV–10 GeV are assigned to solve the practical problems of hadron absorbed dose calculation.

ABSTRACT (See instructions overleaf)

Neutrons have been considered created in beryllium, copper and lead targets bombarded by 660 MeV protons from phasotron of Joint Institute for Nuclear Research, Dubna. Mean neutron energies in the beams formed at zero degree respectively to the direction of proton beams equal approximately to 350 MeV, 280 MeV and 200 MeV, respectively. Recombination index (RIQ) has been taken as a parameter describing the radiation quality.

Measurements performed using a 3,8 cm^3 recombination chamber filled with TE gas up to 500 kPa. Two voltage values : U_R =30v and U_S =800v applied to the chamber electrodes sequentially. The recombination index of radiation quality (Q_R) derived from measured currents of the recombination chamber using the following relation :

$Q_R = (1/R) [1-i(U_R)/i(U_S)]$ where i - are the ionisation currents of irradiated recombination chamber related to the monitor reading; U_S - is the voltage applied to the chamber ensuring nearly saturation conditions; U_R - is the recombination voltage chosen during the calibration in a reference gamma field, such that : $i(U_R)/ i(U_S) = 1 - R = 0.96$

All result agree within experimental and calculation uncertainties (10%) The RIQ values practically do not differ also with values of quality factor defined in ICRP -21

It is shown only minor difference of RIQ for three beams considered.

RIQ decreases with depth in the phantom water 5 at 1cm depth to approximately 3.2 at the depth of 12 cm, where a broad maximum of depth dose distribution taken place. The radial distribution of RIQ are similar for three beams too.

It can be concluded that there is no essential differences radiation quality of the beam. The beam with energy of 350 MeV is preferable, because of higher beam intensity.

ABSTRACT (See instructions overleaf)

The multisphere neutron spectrometer detectors (commonly referred to as Bonner Spheres), augmented with threshold neutron detectors, were exposed to well characterized beams of neutrons generated by striking either a thick tungsten target with a beam of 800 MeV protons or a thin lithium target with 800 MeV protons at the Los Alamos Weapons Neutron Research facility. The experiments were performed in the 15° flight path from the tungsten target and in the 0° flight path from the lithium target. The purpose of these experiments was to compare the neutron energy spectra determined from unfolding the sphere and threshold detector data with the energy spectra determined by time of flight measurements for the neutron beam. The Bonner sphere set, including 5.08cm, 7.62cm, 12.70cm, 20.32cm, 25.40cm, 30.48cm, and 45.72cm diameter moderators, plus a Bare and a Cd covered detector was augmented with a $^{12}C(n,2n)^{11}$ threshold detector and a Bismuth fission counter to provide data for the energy regions above 20 and 50 MeV respectively. Paired sets of ^{6}LiF and ^{7}LiF TLD chips were used as the neutron sensitive elements at the center of the moderator spheres. Several different average energy neutron beams were obtained from the tungsten target by inserting various thickness of polyethylene filters in the beam upstream of the detector location. The integrated beam intensity during each exposure was monitored by a small plastic scintillation counter inserted in the beam, which provided a count proportional to the dose equivalent, calculated for each filter thickness. The average energies for the beam spectra from the tungsten target ranged up to approximately 400 MeV, and peaked near 800 MeV from the lithium target. The data from the detectors larger than the beam diameter were corrected using Monte Carlo calculations. The corrected data were analyzed using four different spectrum unfolding computer codes to determine which technique would give the best results, ie. the best match with the time of flight measurements. The results indicated that all of the unfolding codes were reasonably good in determining the gross neutron field parameters of dose, dose equivalent, and average energy. The conclusion can be made that the multi-detector neutron spectrometer will give sufficiently accurate spectral information for neutron energies up to 800 MeV for dosimetry and shielding evaluation purposes.

ABSTRACT

Measured spectra for 8 neutron fields and superposition method for dosimetric apparatus calibration with the help of these neutron fields are presented. 7 of these fields are based on ^{252}Cf and Pu-α-Be sources and the 8th one is the field of high energy leakage neutrons behind the biological shielding of proton synchrotron on 70 GeV. Mean energy of the neutron spectra of these fields are from 0.11 MeV to 3.0 MeV and 79 MeV, correspondently. The neutron spectra of the first 7 fields have been measured with the help of Bonner spectrometer and scintillation spectrometer, based on single crystal of stilbene. The 8th spectrum have been measured with the help of Bonner spectrometer supplemented by modified detector with 5 cm copper converter and by scintillation detector which detected an inelastic reactions ^{12}C(n,α) ^{9}Be and ^{12}C(n,n)3α. It has been shown that the superposition method allows one to calibrate dosimetric detectors more correctly than commonly used techniques.

TRANSMISSION FACTORS FOR THE NEUTRONS FROM SOME RADIOISOTOPE PRODUCTION REACTIONS FOR PET

Daniel G. Hernández and Juan A. Cruzate
ENTE NACIONAL REGULADOR NUCLEAR
REPUBLICA ARGENTINA

INTRODUCTION

The purpose of this work is to present the dose transmission factors of ordinary concrete, for neutrons originated during the production of some radioisotopes used in positron emission tomography (PET). PET is a technique used in nuclear medicine which use in image diagnostics is in permanent increasing, because of two unique characteristics : the spatial resolution is independent of depth, and, it is possibly to make absolute corrections to tissue attenuation. These characteristics make it possible to determine the real concentration levels of the radioactive tracer in tissues, as well as the parameters related to the functioning and metabolism of tissues and organs.

The availability of adequate positron emissors is one of the restrictions for the use of this technique in nuclear medicine Because of the short half lives of these isotopes (from 1 minute to 2 hours approximately), it is a common practice to install a particle accelerator capable to produce them in the surroundings of the PET. The positron producer isotopes commonly used are: ^{11}C, ^{13}N, ^{15}O, and ^{18}F, which are produced by means of the reactions $^{16}N(p,\alpha)^{11}C$, $^{16}O(p,\alpha)^{13}N$, $^{13}C(p,n)^{13}N$, $^{15}N(p,n)^{15}O$, $^{14}N(d,n)^{15}O$ and $^{18}O(p,n)^{18}F$.

This work is only related to the shielding necessities of cyclotrons with accelerating protons up to energies from 10 to 13 MeV, and for the reactions $^{18}O(p,n)^{18}F$ and. $^{13}C(p,n)^{13}N$ This is so, because some recent studies indicate that the optimum energy for these types of cyclotrons is around 11 MeV. As well, the reactions $^{18}O(p,n)^{18}F$ and. $^{13}C(p,n)^{13}N$ generate the most restrictive conditions for the shields [1].

The main requirement for shielding arise from rapid neutrons, coming from the nuclear reactions that are produced in the target, which have a high penetration and a high quality factor. The gamma radiation produced in the target normally is not relevant for the dimensioning of the shields, because the last ones must be capable to attenuate photon radiation originated in them, in particular by capture of thermal neutrons in hydrogen.

DETERMINATION OF THE SPECTRUM OF INCIDENT RADIATION

The spectrum of incident radiation was estimated supposing that the projectiles are fully stopped in the thick target, and that it may be neglected the lost of particles in nuclear reactions. The calculation of neutron spectrum was made using the cross sections for thin target , $\sigma(E)$ [2-7], and the number of incident particles interacting between the beam energy and the reaction threshold energy.

The number of neutrons produced by protons with energies between E and dE is $\sigma(E)$ N dE/(dE/dx), where N is the atomic density of the isotope considered in the target, and dE/dx is the lost of energy per unit length travelled by the particle [8].

The energy scale of the neutrons emitted is determined by analysing the energy distribution of the reaction, taking into account the masses of the intervening particles, the energy of the incident particle, and the angle between the velocity vectors of incident and emitted particles.

For neutrons emitted at 0°, when exist only one open reaction channel that produce a residual nucleus in ground state, the energy of the incident proton (E_p) and the emitted neutron (E_n) are related by $E_n=E_p+Q$, where Q represents the energy balance of the reaction. In the case that the residual nucleus remains in an excited state with energy W, the energy of the emitted particle will be $E_n=E_p+Q-W$. In both cases, the recoil energy of the residual nucleus was neglected, which is essentially valid if the mass of residual nucleus is much more than the mass of the emitted particle. Using this calculating method, it was possible to estimate the spectrum of neutrons emitted at 0° in the reactions $^{18}O(p,n)^{18}F$ and. $^{13}C(p,n)^{13}N$, in thick target condition, and for protons with energies between 10 and 13 MeV.

DETERMINATION OF THE TRANSMISSION FACTORS

It was used the discrete coordinates code ANISN[9] for obtaining the neutron spectra in the output of infinite slabs of ordinary concrete This code applies the method of discrete coordinates, or S_n, which is a numerical technique of finite differences, for solving the Boltzmann transport equation for steady state.

Because of the great variation of concrete compositions, we selected the TSF 5.5 concrete [10], with a density of 2.3 g/cm^3 and 15.5% by weight of water, as representative of ordinary concrete.

The source used was a parallel beam of neutrons, of unitary fluence, incident in almost right angle ($\cos\theta$= 0.9894) over the shield. The energy distribution of the beam was the estimated, in the form already described, for the reactions $^{18}O(p,n)^{18}F$ and. $^{13}C(p,n)^{13}N$. The calculations were made in xy (slab) geometry, with quadrature order 16 and Legendre polynomial expansion of order 3 (S_{16} P_3).

We used the cross sections corresponding to the coupled library VITAMIN C [11], with 171 neutron groups and 36 photon groups. That the library is coupled means that the secondary photons generated by the neutron interactions appear as sources for the gamma groups, which are subsequently transported by the ANISN code.

The neutron and photon spectra obtained outside the shield were converted to effective dose by means of the factors conversion presented in a publication based in the publication 60 of ICRP [12], for anterior-posterior (AP) irradiation geometry.

RESULTS

In figures 1 and 2 we present the transmission factors for effective equivalent dose (Sv cm^2), obtained for neutrons generated in the reactions $^{18}O(p,n)^{18}F$ and. $^{13}C(p,n)^{13}N$, with protons of 10, 11, 12 and 13 MeV, inciding almost normally on ordinary concrete. These factors take into account the primary radiation and the secondary gamma radiation generated in the shield.

CONCLUSIONS

The data presented are a suitable tool for making, in simple form, the approximated dimensioning of primary shielding, required for cyclotrons commonly used in the production of radioisotopes for positron emission tomography. It must be pointed that, the transmission factors obtained are slightly conservative in relation to real shielding, because they were calculated using a parallel beam of neutrons, inciding in almost right angle on the shield.

REDUCTION OF EXPOSURES TO CYCLOTRON PERSONNEL INVOLVED IN THE MANUFACTURE OF RADIOPHARMACEUTICAL PRODUCTS

M. A. Doruff[1] and R. W. Davies[2]

Abstract

The management of the radiation exposure of cyclotron operators is particularly challenging in a commercial environment where the production cycle, from the onset of bombardment to the shipment of finished radiopharmaceutical products, can be as little as six hours.

This paper addresses the components of the radiation protection program - from management commitment and support, through policies and practical procedures to engineering provisions - which have successfully delivered significant reductions in personnel doses over the past five years.

Introduction

Amersham Healthcare/Medi-Physics currently operates five variable energy cyclotrons in the United States for the production of radioactive materials for the formulation of radiopharmaceuticals for use in diagnostic nuclear medicine. Cyclotrons accelerate positive or negative ions to bombard specific enriched targets either inside the machine or externally in a vault. The energy and current of the ion beam is adjusted to maximize production yields from specific nuclear reactions for specific product nuclides. Nuclides produced by bombardment are typically short half-life photon emitters such as I-123, Ga-67, Tl-201, In-111 and Rb-81.

Radiation Protection Issues

There is a need to provide reliable delivery of product to health care professionals for scheduled administration to patients. Due to the short half-life of these products, the time from the onset of bombardment to administration of the product to the patient may be less than 24 hours. This tight scheduling allows little time for unplanned delays or machine failures. In this context, it is essential to maintain effective radiation protection practices while meeting the needs of customers.

The main sources of radiation exposure associated with cyclotrons are activated targets, internal machine components associated with targets and beam production, and external components activated by recoil neutrons. Positive ion machines produce more activation. Machine operators are exposed to these sources of radiation during day-to-day operation of the machines including installation and retrieval of targets and routine maintenance. They are also exposed during repairs and major maintenance which includes rebuilding of machine elements.

Management Arrangements for Dose Reduction

For an operator dose reduction programme to be effective it must be supported directly by senior management through a clear statement of policy, through the setting of firm and aggressive limits on permissible exposure, and through provision of necessary resources. A culture must be established where it is unacceptable to receive dose for the sake of the product without proper regard for radiation protection.

Careful day to day management of procedures for cyclotron operation and routine maintenance is a major contributing factor in the reduction of dose. This effort is enhanced through daily accountability for operator exposures by cyclotron management; close cooperation with radiation protection staff; mandatory survey of radiation levels prior to any vault entry; and strict compliance with decay time requirements prior to vault entry. An effective preventive maintenance programme needs to be planned and implemented, and preparation made for contingencies for backup production in the event of a major machine breakdown. Regularly scheduled routine maintenance has resulted in improved production yields and reduced breakdowns, both significant in reduction of operator dose. Exposure of highly skilled technical staff should be limited during routine operations to ensure their availability during critical repairs in potential high dose rate situations.

The management of dose in the course of repair and major maintenance or rebuilds needs to be a cooperative effort between cyclotron management and the radiation protection staff. This effort is initiated by a meeting to review the type and scope of work to be done in advance. A plan is developed which specifies what work is to be done at what time and by which operator(s). Each operator is allocated an individual dose limit for the course of the project with an additional limit on collective dose. The commitment to observe all limits, policies and procedures is confirmed prior to the initiation of work. An agreement is reached to ensure that significant changes in the type or scope of work will be conducted only after additional review and discussion. One individual assumes a supervisory role in cyclotron operations and one in the radiation protection group.

The commencement of major repair and rebuilding operations is typically scheduled at least 48 hours following the end of the most recent bombardment. The optimum decay period has been determined by comprehensive radiation level profiles conducted during previous post-bombardment time intervals. Once the work is initiated, it is critical that radiation protection staff maintain vigilance in the area with the single objective of ensuring all practices are conducted in the interests of keeping doses as low as reasonably achievable without becoming involved in actual repair operations. It is necessary to maintain this independent role in the overall operation to repair the machine and restore operation as quickly as possible.

Engineering Provisions for Dose Reduction

Routine exposures received during normal cyclotron operations are usually limited by provisions which limit operations in relatively high radiation areas. These provisions include local shielding of components in proximity of targets; construction of external machine components from materials with minimal neutron activation or activation to short half-life or low activity nuclides; installation of external components outside primary neutron flux; carefully designed target

transport systems; automated post-bombardment target delivery; and effective instrumentation for measurement of radiation levels in appropriate locations. There has been a recent trend towards the use of negative ion machines which produce far less secondary machine component activation.

Additional provisions are available to enhance dose reduction in repair and major maintenance situations. These include the use of power tools to reduce the time spent in high radiation areas; the use of remote direct reading dosimeter systems to monitor operator dose in real time without interruption; availability of inactive replacement parts for rehearsal of repair operations; careful planning and use of localized shielding without increasing job time; proper handling and storage of radioactive machine parts with a means of easy identification of the location of smaller parts; and the avoidance of performing work on external components with internal components exposed.

Results

Amersham Healthcare/Medi-Physics implemented the measures described in this paper beginning in 1990 with the objective of reducing doses in the cyclotron facilities to less than the ICRP 60 recommended level of 20 mSv per year by 1996. The results of this initiative are provided in the following table of annual doses for the years 1989 - 1994. All doses are effective dose equivalents in mSv.

Year	Maximum Individual Dose	Collective Dose	Average
1989	63.1	2211	15.8
1990	49.5	2315	11.9
1991	33.0	1592	9.3
1992	30.1	1450	8.0
1993	31.8	1550	8.6
1994	21.3	1242	7.2

In five years following 1989, the maximum dose received by an individual was reduced by 66%, while the collective and average doses decreased by 44% and 55%, respectively. Results for the year 1995 are not available at the time of writing this paper, yet projections indicate that this trend has continued and additional reductions are expected. It is noteworthy that the significant reduction in the maximum dose received by an individual was not achieved by distributing the dose among more individuals.

Conclusions

The approach described has been very effective in reducing radiation doses to staff in a commercial environment where increased regular production has been required from predominantly positive ion cyclotrons.

Comparison between calculated and measured equivalent doses caused by heavy ions

Johannes Georg Festag

Gesellschaft für Schwerionenforschung mbH, Darmstadt, Germany

Ambient equivalent doses behind thick shields are calculated using the data derived by Weise (1). These data include neutron yields, estimated by using measured differential neutron and proton production cross sections of heavy ion reactions, and effective neutron dose transmission factors for ordinary concrete.

The ambient neutron doses are measured by normal REM-counters during the course of high energy physics experiments. Accelerated ions of carbon, nickel and gold are stopped in an iron beam dump. The specific energies (energy per nucleon) are between 1 and 2 GeV/n. The ambient doses at the location of the REM-counter are calculated using data for the reaction Ne $\rightarrow$ Fe at 2 GeV/n. The results are

accelerated ion	specific energy (Gev/n)	accelerated ions per second	calculated dose (µSv/h)	measured dose (µSv/h)
C	2.0	2.7 E+07	4.7 E-01	3.7 E-01
Ni	1.9	9.2 E+05	1.6 E-02	8.5 E-02
Au	1.0	1.8 E+06	1.9 E-01	3.5 E-01

For the carbon and gold ions the measured doses match well to the calculated doses. In the case of the nickel ions there is a discrepancy, the measured results are a factor of about 5 higher than the calculated results. These differences may be caused by beam losses outside the beam stop.

ABSTRACT (See instructions overleaf)

The mixed radiation fields behind shielding of the 70-Gev proton synchrotron is composed of thermal and fast neutrons; high energy particles, pnotons and charged particles. One of the major techniques for direct dose equivalent measurements in such mixed radiation fields is based on low-pressure tissue-equivalent proportional counters (TEPC). The TEPC has been designed in collaboration with Institute of Biophysics (Moscow). The main technical data of TEPC are presented The instrument allows us to measure kerma and dose equivalent for photons and neutrons simultaneously in a single measurement. The separation technique in treatment of the pulse height spectrum with threshold in terms of linear energy is used to obtain the neutron dose equivalent. Calibration of the TEPC in terms of neutron and photon kerma are presented. The problem conserned with TEPC calibration in terms of ambient dose equivalent have been solved by the calibration in the National primary standard neutron fields of VNIIFTRI (State Standard Committee of Russia, Mendeleevo). TEPC are used for metrological ensurance of radiation protection at IHEP. The results of a simple routine neutron dosimeters calibration by TEPC in a mixed accelerator radiation fields are presented. Experimental results of dose characteristics measurements are presented for the reference fields of IHEP and JINR (Dubna, Russia). The results are compared with the other dosimetric systems ones.

VARIATION OF RADIATION DOSES ESTIMATED ON TIME RESOLVED PHOTON ENERGY SPECTRA OF PULSED RADIATION FIELDS

INTRODUCTION

Since the dose and dose rate effectiveness for low LET radiations became evident by experimental results in animals as well as theoretical considerations, determination of radiation dose due to time resolved energy spectra of low dose and high dose rate radiation fields such as pulsed radiation fields has become important for radiation protection practice(1). From this point of view, scintillation spectrometer that can be used for analysis of photon energy spectra in the energy region from 0.1 MeV to 100 MeV has been developed for estimation of radiation doses due to X- or gamma-rays induced by operation of nuclear facilities. The main purposes of this paper are: to determine the time resolved photon energy spectra of pulsed radiation fields and to describe the differences between the mean dose rates averaged over total measuring times and the dose rates averaged over pulse duration periods during which radiations are emitted by the accelerator.

EXPERIMENTAL

1.Scintillation detector and its response function

Scintillation detector was constructed with a 7.6 cmϕ x 7.6cm$l$ BaF_2 crystal and a HTV R594 photomultiplier tube with breeder resistances. A 30 x 30 response matrix of the detector was constructed by modifying energy deposition spectra calculated by the EGS4 Monte Carlo code(2) into response functions whose energy resolution was experimentally determined by using radioactive sources. Fundamental properties of the spectrometer and an accuracy of unfolded spectra were investigated by using mono-energetic gamma-rays from radioactive sources and neutron capture gamma-rays from the E-3 beam facility of the Kyoto University Research Reactor. Photon energy spectra could be estimated within an error of about 8 % of the incident photons(3).

2.Measurements

Measurements of the time resolved photon energy spectra were carried out in the workplace around the electron linac facility of the Kyoto University Research Reactor Institute. A measuring point in the experimental room was about 1.1 m away from the wall of 2.7 m in thickness which was situated between the target room and the experimental room. A Ta target of the linac was placed in the target room at 2.6 m away from the wall and, as a result, the total distance between the target and the detector was about 6.4 m. The measurements was also performed outside the experimental room near the entrance for sending in experimental equipments. The second point was situated at about 8 m away from the first measuring point.

The linac was operated with the beam energy of about 30 MeV and the beam width of about 10 ns. The repetition frequency of a bunch of electrons(an electron pulse) was 300 pulses s^{-1}. Photon energy spectra were measured in the two time regions of time interval between

successive electron bunches, from 0 to 10 μs and 10 μs to 3.3 ms, by coincidence counting method using a ORTEC Digital Delay & Gate.

RESULTS AND DISCUSSION

1.Time resolved photon energy spectra

A time spectrum of photons (time series variation of photon counting rate) observed by the scintillation detector was shown in Fig.1. The abscissa of the figure shows the elapsed time (62.5ns /channel) from the incidence of a bunch of electrons into the Ta target. As is evident from the figure, most of photons were observed within a few microsecond and the maximum counting rate was approximately 10 counts s^{-1} and the total counting rate during 0 to 10 μs was almost 30 counts s^{-1}. This means that approximately one photon/ 10 electron bunches could be detected in this time period and that the distortion of energy spectrum due to chance coincidence of incident photons would be scarcely occurred here.

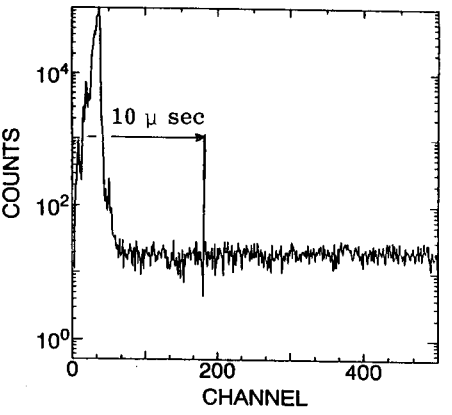

Figure 1. Time spectrum of photons observed by BaF_2 spectrometer.

Examples of photon energy spectra observed in the experimental room are shown in Fig.2. The solid and the broken histograms in Fig.2 represent the spectra measured during the former and the latter periods of the time interval between electron bunches from the linac, respectively. Since high energy photons and neutrons are considered to be generated in a few tens of nanosecond after incidence of electron bunches into the target, the photon energy spectrum shown by solid histogram seems to be mainly originated in high energy photons and their scattered ones and partly due to photons generated by neutron inelastic scattering in the wall. On the other hand, the result by broken histogram in the figure shows the energy distribution up to the energy of about 8 MeV. The higher energy part of this spectrum seems

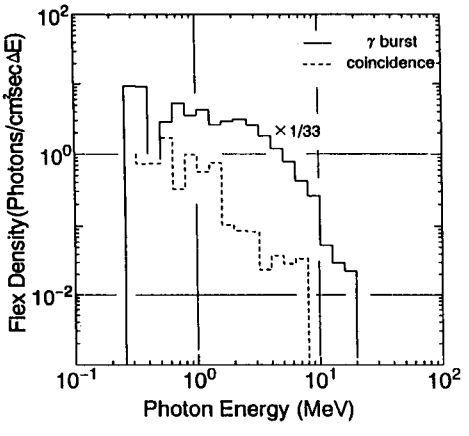

Figure 2. Time resolved photon energy spectra in the experimental room.

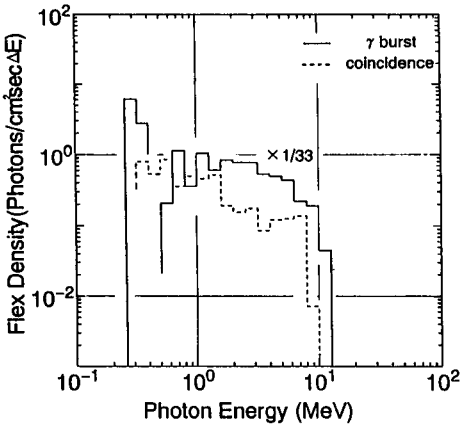

Figure 3. Time resolved photon energy spectra near the entrance of ex. room.

to be caused by neutron capture gamma-rays emitted from the surroundings of the spectrometer.

Photon energy spectra observed near the entrance to the experimental room are shown in Fig.3. It is evident from the solid histogram that the intensity of photons below 5 MeV becomes weak compared with that shown in Fig.2 and the photons more than 15 MeV do not have enough intensity to be detected by the present method. On the contrary, the broken histogram reveals us that the energy spectrum around 7 MeV which would be caused by neutron capture by the iron shutter of the entrance becomes more intensive than that in the experimental room.

2. Variation of dose rates within the interval of electron pulses

Air absorbed dose rates calculated on the energy spectra illustrated in Figs.2 and 3 are shown in table 1. The second and the third columns of the table show the absorbed dose rates given by the first intensive high energy photons and fast neutrons and those by gamma-rays from naturally occurring radionuclides and photons by slow neutron capture reactions, respectively. The mean dose rates during measurements are shown in the last column of the table. As is evident from the table, the dose rates in the former period (0 to 10μs of the pulse spacing time) are more than hundreds of times than those obtained in the later period (10μs to 3.3ms of the pulse spacing time). And, furthermore, the dose rates in the former period will show values by several times as much if the realistic high intensity pulse duration time shown in Fig.1 is taken into consideration.

Table 1. Variation of dose rates within the interval of electron pulses.

(unit:nGy/h)

time interval	0 to 10 μs	10 μs to 3.3 ms	mean
inside exp room	2.7×10^4	7.8×10^1	1.7×10^2
near entrance	8.3×10^3	8.5×10^1	1.1×10^2

In radiation protection practice, total doses are usually determined using personal dosimeters and dose rates are often interpreted as the mean doses illustrated in the last column of the table. But it is to be noted that the total doses are originated in repeated irradiation of extremely high intensity photons momentary emitted. So it may be concluded that dose rate effectiveness for irradiation by pulsed radiations with a duration less than a few nanoseconds must be investigated to get definitive information on the DDREF, though the ICRP has already recommend that the value 2 be used for the factor.

CONCLUSIONS

From the investigation stated above, conclusions are as follows:

(1) Energy spectra of pulsed photons determined by using the BaF_2 spectrometer changed remarkably with time. High intensity and high energy photons were observed within a few nanosecond after incidence of electron bunches into the target.

(2) The maximum dose rate caused by pulsed radiations became more than a thousand of times the mean dose rate averaged over the total measuring period.

SHIELDING DESIGN CALCULATION FOR SPring-8 INSERTION DEVICE BEAMLINE

Yoshihiro Asano and Nobuo Sasamoto

Department of Snchrotron Radiation Project

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken 319-11, Japan

1. INTRODUCTION

SPring-8, an 8 GeV class synchrotron radiation facility of Japan, is now under construction and the beamlines are in the design stage. The first beam will be emmited by October in 1997. The SPring-8 is composed of an electron/positron linear accelerator (linac), a booster synchrotron injector, and a storage ring (Fig.1). The linac is about 140 m long and accelerates electrons (meaning electrons and positrons) to 1 GeV. The booster synchrotron of which circumference is about 400 m, accelerates the electrons from the linac up to 8 GeV. The electrons are then injected into the storage ring, which is capable of storing circulating currents up to 100 mA at 8 GeV. The circumference of the storage ring is about 1500 m with 38 straight sections including 34 standard ones of 19 m in length and the 4 long ones of 40 m in length. The electrons emit synchrotron radiation while they are being deflected in the fields of the ring bending magnets or specially arranged magnets called insertion devices which are placed in the straight sections. The synchrotron radiation is introduced to an experimental floor by a beamline through ratchet-shaped bulk shielding walls of the storage ring as illustrated in Fig.1. Synchrotron radiation extremely high brilliance and high power density is available at the SPring-8 and

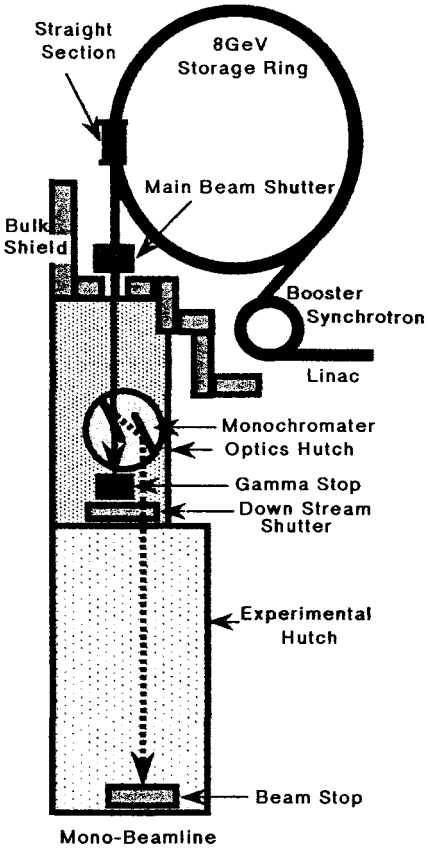

Fig.1 Illustration of the Spring-8 insertion device beamline for monochromatic beams.

therefore the shield of the beamlines for radiation safety must be designed under severe conditions.

The design criteria of 6.67μSv/h and 2.0 μSv/h are employed in occupied areas and at the boundary of controlled area.

Main shielding components for the beamline safety are a main beam shutter, down stream shutter, gamma stop, beam stop, and optics and experimental hutches. In the present paper, we will focus on the calculation for the beam shutter, the gas bremsstrahlung gamma stop and the hutch wall. In the calculation, the following 4 kinds of radiation sources were considered; (a) neutrons, photons and muons due to electron beam loss, (b)synchrotron radiation, (c)bremsstrahlung from the residual-gas molecules in the straight section of the storage ring and (d) photoneutrons generated at the gamma stop struck by gas bremsstrahlung. In this paper, we consider the monochromatic beamline as illustrated in Fig.1.

2. SHUTTER

Optimum thickness of the main beam shutter was calculated by using a modified Jenkin's formula(1) for neutrons and photons and a Swanson's formula(2) for muons. Gas bremsstrahlung calculation was also performed with tabulated data(3). As a results, we found that the tungsten of 18 cm thick or more are necessary on the standard sections. For the down stream shutter, the thickness was calculated by using STAC8, a shielding design code for synchrotron radiation(4). The beam stops are the same as the down stream shutter except for the mechanical movement.

3. HUTCH

One of the functions of the hutch is to shield the scattered photons of synchrotron radiation. Therefore, the structure of hutch depends strongly on the source. The thickness was calculated by using STAC8 as functions of a scattering angle and polarization.

In case of a high-energy inelastic scattering wiggler beamline(5), the key parameters are as fallows; the total power of 18.0 kW, the period length of 12 cm, the peak magnetic fields of 1 T, the period of 37 and the critical energy of 42.7 keV. The shield wall composed of a lead plate of 30 mm thick and an iron plate of 10 mm thick were found to be required for the side wall of the optics hutch including a local shield at 2 m distance from the beam.

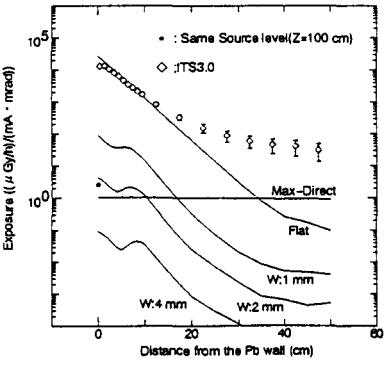

Fig.2 Dose distribution due to ground shine on the floor outside the hutch. (Photon source is scattered photons in 90 ° direction by Cu at 2m from scattered point. W denotes width)

The ground shine which is caused by the scattering photons from the concrete ground were also considered. For the purpose, another type of hutch wall composed of lead plate of 10mm thick sandwiched by iron plates of 5 mm thick was employed. The calculation was performed with ITS3.0(6) and G33-GP(7), assuming synchrotron radiation

perpendicularly scattered by Cu scatterer. As shown in Fig.2, the calculational result shows that the lead band of 30 cm or more in width and 2 mm thick is required along the foot of the hutch for attaining the dose which is equal to that at 1 m high from the floor.

4. GAMMA STOP

Gas bremsstrahlung is generated by the interaction of the stored electrons or positrons with residual gas molecules or ions in the storage ring vacuum chamber, which becomes important especially in the straight section because of an invasion into the beamline. Gamma stop made of lead is a standard beamline component of the SPring-8 to prevent bremsstrahlung from expanding to the down stream of the beamline.

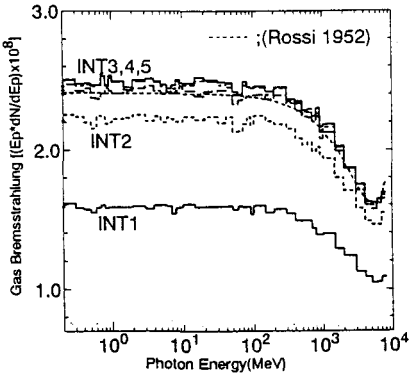

Fig.3 Gas bremsstrahlung spectra depending on the number of the interactions generated by EGS4 resulting from 0.1A 8GeV electron and interacting with 0.1205g/cm^2 air. (INT1;single interactions, INT2;double interactions, INT3.4.5; triple or more interactions, ---;theoretical data[8][9])

The residual gas pressure is designed to be below 0.133 μPa(10^{-9} torr). The EGS4(10) calculated gas bremsstrahlung spectra are shown in Fig.3. As shown in the figure, the gas bremsstrahlung generated within single interactions between the electrons and 0.1205 g/cm^2 air molecules is about 60% of that generated within multi-interactions. The bremsstrahlung is nearly saturated within triple or more interactions. In case of the interactions with 0.01205 g/cm^2 air molecules, the gas bremsstrahlung generated within single interactions is almost saturated. Most of the bremsstrahlung is emitted within 0.1 mradian.

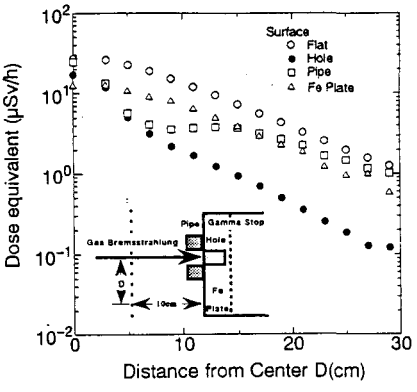

Fig. 4 Dose distribution due to back scattering by the gamma stops of various shapes. (Doses are at the point D(cm) from the center of the beam on the plane set at 10 cm in distance. Hole size;1cm in radius and 3cm in depth, Pipe size; 4cm in outer radius,3cm in thickness and 3cm in length, Iron plate; 5cm in thickness).

On the basis of the results of the EGS4 calculations, together with tabulated data(3), the gamma stop of 30 cm in thickness and 26 cm in diameter is recommended. Dose distribution due to the back scattering that depends on the shape of the gamma stop was calculated. As shown in Fig.4, the gamma stop with a hole is found to be beneficial to reduce the dose due to the back scattering.

The photoneutrons are produced through the interactions of gas brems-

ABOUT THE RADIATION ENVIRONMENT AND SHIELDING OF THE HEAVY ION ACCELERATORS

L.G.Beskrovnaia, M.M.Komochkov

Joint Institute for Nuclear Research, 141980 Dubna, Russia

INTRODUCTION

The aim of this work is to develop the semiempirical method of the radiation environment and shielding prediction in wide range of energy and mass numbers of accelerated ions (nuclei) on base of works having been published early /1-5/ in the light of contemporary information. The algorithm is based on some approximations, one of which permits to use accumulated information about parameters of radiation fields formed in proton-nuclei reactions. The major components of radiation field of proton and ion accelerators are neutrons and photons, as it is known. Therefore, only these components are considered. Energy range of the proposed algorithm is between Coulomb barrier and 10 GeV/nucleon.

RADIATION ENVIRONMENT ESTIMATION

The main quantities of radiation environment are neutron yield Y and radionuclides activity, Q, which depend on mass number of nucleus-projectile A_c, its atomic number and energy per mass unit E_c and also on flux of nuclei-projectiles (ions) F. With the aim of radiation environment prediction, it is suggested to use the following expression as a basis of neutron yield, Y_{ns}, estimation from stopping-length (thick) target :

$$Y_{ns} = \frac{L}{A_t} \sum_j \int_{R_{jth}}^{R_j} F_j \sigma_j dR \tag{1}$$

where R_j are the ranges of incident and secondary ions, R_{jth} is the range of ion j with the energy of the threshold of neutron production, A_t is the mass number of nucleus-target, L is Avogadro number, σ_j is the neutron production cross section in nucleus (j) with nucleus - target (t) interaction. At the ions energy more than 60 MeV/nucleon Y_{ns} was calculated by semiempirical formula

$$Y_{ns} = N\left(\sigma_{ns}\eta_{ns} / \sigma_p\eta_p\right) \tag{2}$$

where N is the number of protons equivalents /1/, σ_{ns} and σ_p are the cross sections nucleus - nucleus and proton - nucleus inelastic interactions, respectively, η_{ns} and η_p are the numbers of inelastic interactions of nuclei and protons incident on target, respectively. The function f takes into account fragmentation of nucleus-projectiles.

$$f = 1 + 0.19\,\eta_{ns}\sqrt{A_c} \tag{3}$$

Figure 1 shows the neutron yield from stopping-length target; the results have been obtained by (1),(2) and experiments which have been compiled in /5/. Radiation environment can be estimated by Y_{ns} in the first approximation /5/. It is worth while to consider residual activity at ion accelerators consisted of two components: induced by ions (or nuclei) Q_{ns} and neutrons Q_{nns}. The activity Q_{ns} can be represented as

$$Q_{ns} = N\frac{\eta_{ns}}{\eta_p} f Q_p \tag{4}$$

where Q_p is the activity induced by protons with energy $E_p = E_c\ A_c$ /6/. The activity Q_{nns} can be represented as

$$Q_{nns} = Y_{ns}Q_{np} / Y_p = N\sigma_{ns}\eta_{ns} f Q_{np} / \sigma_p\eta_p \tag{5}$$

where Q_{np} is the activity induced by neutrons at proton accelerator with the energy $E_p = E_c\ A_c$. On the data /6/ base it may expect that

$$Q_{ns} / Q_p = D_{ns} / D_p \tag{6}$$

$$Q_{ns} / Q_{np} = D_{nns} / D_{np} \tag{7}$$

where D_{ns} and D_p are the γ -radiation dose rates conditioned by Q_{ns} and Q_p respectively, D_{nns} and D_{np} are the γ - radiation dose rate conditioned by Q_{nns} and Q_{np} respectively. The results of measurements and calculations are compared in the table.

Table. The ratio of γ - dose rates measured /7/ and calculated with formulas (4)-(7) for Cu target irradiated by protons, ^{4}He and ^{12}C with energy 3.65 GeV/nucleon at other equal conditions.

Quantity	Measured	Calculated
$D_{^4He} / D_p$	3.4 ± 0.9	$3.2^{a)}$ $(4.8)^{b)}$
$D_{^{12}C} / D_p$	8.8 ± 2.4	$6.1^{a)}$ $(14)^{b)}$

a) Calculated with expressions (4) and (6); b) Calculated with expressions (5) and (7).
The formulas (4)-(7) gives possibility to estimate dose rates near of the ions accelerator.

DIFFERENTIAL DISTRIBUTION

Phenomenological model with using simple formulas for calculation of double differential cross sections of neutron production $d^2\sigma / dEd\Omega$ in order to predict of the radiation environment and shielding from neutrons has been developed in /2-5/. The basic regularities of the neutrons production in nucleus-nucleus interactions have been obtained by analysis of data /6,10,27-35/ from ref. /5/ and were used for development of the model. Analysis has been showed that there is the similarity in differential cross sections of neutron production for different collided nucleus at different energy. The neutron production cross section is presented in the form of the sum of four components:

$$d^2\sigma / dEd\Omega = \sum_{i=1}^{4} (d^2\sigma / dEd\Omega)_i \qquad (8)$$

The first component of the sum describes high energy part of neutrons spectrum. The second component describes neutrons generated in single nucleon collisions of the nucleus-projectile with nucleus-target. The third component is presented as the product of nucleus-nucleus interaction inelastic cross section σ_{ns}, number N and the double differential distribution of cascade neutrons in proton-nucleus interactions. The fourth component describes the distribution of the evaporation neutrons. The description of these components is given in /5/.

The information about $d^2\sigma / dEd\Omega$ permits to determine double differential neutrons yield from thick target, that lets to estimate the radiation environment both before and outside the shield. The dose of neutrons with the energy more then E_t emitted from the thick target at the distance r, outside the shield with the thickness x can be calculated as:

$$Hr^2 = \int_{E_t}^{\infty} (d^2Y / dEd\Omega) Bh \exp(-x/\lambda) dE \qquad (9)$$

The neutrons flux emitted from thick target with energy more then E_t outside the shielding for various angles can be expressed as:

$$\frac{dY}{d\Omega}(x) = \int_{E_t}^{\infty} \frac{d^2Y}{dEd\Omega} B \exp(-x/\lambda) dE \qquad (10)$$

where B and λ is buildup factor and attenuation length of neutrons fluence (dose), respectively, at the ordinary concrete, h is a conversion factor from the fluence of neutrons to the dose.

Neutrons flux distribution from thick Cu target bombarded by 86 MeV/nucleon ^{12}C ions with the intensity of 10^{11} s^{-1} in the heavy concrete measured /8/ and calculated by the algorithm is presented in Fig.2. The difference of data in Fig. 2 at the concrete thickness x=0 can be explained due to detection by carbon detector of the charges-fragment nucleus-projectiles emitted from the target. Comparison of the experimental data /9/ and calculated data obtained by the expression (8) is plotted in Fig.3. This comparison was carried out for energy spectrum of neutrons emitted from the thin gold target at $\theta = 0^0$ at the interaction the gold nucleus at 800 MeV/nucleon energy with it.

CONCLUSIONS

The phenomenological model for the radiation environment and shielding prediction has been examined by the experimental data. Comparison of calculated and measured data shows the reasonable agreement. Thus, the algorithm allows to estimate quickly the radiation environment and shielding of heavy ion accelerators in the energy range from tenth MeV/nucleon to tenth GeV/nucleon with atomic mass of nucleus projectiles and nucleus-target from Helium to Uranium.

INTORDUCTION

Concrete is one of the widely used shielding materials, but has only moderate shielding properties for neutrons and gamma rays. Its hydrogen content, an element most effective for fast neutron shielding, is very low (~0.56 % by weight). Enriching concrete with hydrogen-containing materials would enhance its neutron shielding properties, while its gamma ray shielding properties as well as its mechanical strength would be improved by using heavy aggregates. Polyethelene $[(CH_2)_n]$ and polyvinyl chloride (PVC) $[(CH2\text{-}CH\text{-}Cl)_n]$ were introduced as part of concrete constituents to improve its neutron attenuation properties. Both of these compounds are rich in hydrogen atoms. Although PVC has less hydrogen density than polyethelene, the chlorine atoms in the polymer have a higher atomic number and a higher neutron absorption cross-section than either hydrogen or carbon atoms.

In order to improve the gamma ray attenuation properties, pyrite (FeS_2) heavy aggregate ore was selected, which has higher density and higher effective atomic number over ordinary concrete. The attenuation properties of Barite heavy aggregates were presented elsewhere(1).

In a radiation field of neutrons and gamma rays, the appropriate concentration of polymer and heavy aggregate can be selected to give the optimum total dose attenuation.

MATERIALS AND METHODS

The polyethelene used was in the form of small balls 3.3 mm in diameter and their specific gravity was 0.95. The PVC was in the form of cylindrical pellets, 3.3 mm in diameter, 3 mm in height, with a specific gravity of up to 1.4. The heavy aggregate ore consisted of up to 90% Pyrite and Pyrrhotite, up to 5% Chalcopyrite, some sphalerite and traces of other minerals. The fine aggregate which was basically feldspar and quartz has apparent, saturated surface dry and bulk specific gravities of 2.706, 2.661 and 2.642, respectively.

Type-1 Portland cement was used. The weight ratios of cement, of fine aggregates:course aggregate:polymer were, 1:1:1:1 (denoted as Py-PVC-1 and Py-Poly-1 for PVC and polyethelene concrete respectively), 1:1:1:1.4 (denoted as Py-PVC-1.4 and Py-Poly-1.4 for the two types respectively) and pyrite polymer free concrete (pyrite conc.). The water to cement ratio was 0.5.

A neutron dosimeter that approximates human body dose-equivalent over a wide neutron energy was utilized (type NM2-NE Technology). The gamma ray exposure was measured by a portable ionization chamber (model 660, Victoreen), with accuracy better than 5% at ^{137}Cs gamma ray energy. The neutron source was ^{241}Am-Be with a neutron emission rate of $6.6x10^6$ n/s and a tolerance of 10%. Its neutron dose-equivalent rate at 1 m was 66 μSv/h. The gamma ray source used was ^{60}Co, of $1.4X10^8$ Bq activity.
Broad-beam geometry was used, where, in most practical situation, the narrow beam conditions for neutrons do not prevail. The distance between the point source and the detector

was kept constant at 1m. The Lateral dimension of the specimen was selected to give maximum scattering towards the detector. A 60 cm. Lateral dimension was enough to scatter most neutrons and gamma rays.

RESULTS AND DISCUSSION

The natural log of relative neutron dose versus shield thickness is shown in Fig.1. The slope of the lines would be the neutron linear removal coefficient. Clearly the concrete type with higher polymer concentration shows higher attenuation and that polyethylene type exhibits higher attenuation over PVC type. The value of the neutron removal coefficient for Py-Poly-1.4 was approximately twice that of the Pyrite Polymer-free type. The natural log of relative gamma ray exposure rates are shown in fig.2. Unlike neutron attenuation, in this case the pyrite concrete of no polymer shows the highest attenuation followed by ordinary concrete and PVC concrete. The least attenuator was the polyethylene type. This is attributed, mainly, to the high density and the higher effective atomic number of pyrite ore over the rest types. The attenuation coefficients data presented here for pyrite-polymer concrete is close to that of barite-polymer type (1).

It may be concluded that in a mixed field of neutron and gamma rays, the appropriate concentration of polymer or heavy aggregate can be selected to give the highest attenuation of the total dose.

SHIELDING CALCULATION ON THE "TESLA" ACCELERATOR INSTALLATION IN THE INSTITUTE OF NUCLEAR SCIENCES "VINČA"

Radojko Pavlović[1], V. Aleinikov[2], L. Beskrovnaja[2]
[1]Institute of Nuclear Sciences "VINČA", Belgrade, FR YUGOSLAVIA
[2]Joint Institute for Nuclear Research, Dubna, Russia

Introduction

The TESLA Accelerator Installation is planned to be an ion accelerator facility consisting of an isochronous cyclotron - the VINCY Cyclotron, a heavy ion source - the mVINIS, a D^- and H^- ion source - the pVINIS, three low energy experimental channels, and five high energy experimental channels. The principal schema of the TESLA Accelerator installation is shown in Figure 1.

In creating its concept the main aim was to obtain a multipurpose machine, i.e. to enable the acceleration of ions in a wide range of specific charges. The first requirement was to obtain heavy ions with energies well above the Coulomb barrier, i.e. well above 5 MeV per nucleon, and make the machine a good instrument for research in nuclear physics. The second requirement was to obtain sufficiently hight intensities of protons and deuterons with energies above $\approx$ 60 MeV, and make the machine a sufficiently good instrument for applications in medicine.

The low energy experimental channels of the TESLA Accelerator Installation are the channels for experiments with the ions from the mVINIS Ion Source. These channels are: the channel for physics of multiply charged ions - L_1, the channel for surface physics - L_2, and the channel for materials science with medium energy heavy ions - L_3.

The high energy experimental channels of the TESLA Accelerator Installation are the channels for experiments with the ions from the VINCY Cyclotron. These channels are: the channel for nuclear spectroscopy and hyperfine interactions - H_1, the channel for heavy ion nuclear reactions - H_2, the channel for physics of very thin crystals and material science with high energy heavy ions - H_3, the channel for radionuclides production and research with high energy neutrons - H_4, and the channel for proton beam therapy - H_5.

High-energy heavy-ions are planed also in use for in-situ analysis of the elementary process in the materials exposed, including research on microdosimetry and track structure and energy deposition of accelerated particles.

The VINCY cyclotron will be able to deliver $\approx$ 1 μA of 36 MeV per nucleon O^{8+} ions, $\approx$ 100 nA of 23 MeV per nucleon Ar^{16+} ions and $\approx$ 700 nA of 7 MeV per nucleon Xe^{28+} ions. It will be able to deliver also heavy ions of lower energies - above $\approx$ 3 MeV per nucleon. This machine will be able to give $\approx$ 20 μA of 73 MeV deuterons, and $\approx$ 2 μA of 66 MeV protons. It will be able to give also deuterons of lower energies - above $\approx$ 43 MeV, and protons in the energy region of 22 - 36 MeV.

Shielding criteria for medium energy particle accelerators

Full understanding of the prompt radiation field generated requires knowledge of the primary interaction in the target material and the subsequent progression of the interaction products through the structure and surrounding experimental material and shielding.

All existing medium and high energy accelerators require some shielding for two reasons:

- to limit the biological effects on occupationally exposed persons and population exposure to acceptably values, according to basic radiation protection principle (ALARA - As Low As Reasonable Achievable (ICR 91, BSS 94)),
- to reduce experimental background conditions to tolerant values.

The design of a practical shielding arrangement for medium and high energy accelerator is in general a rather complex task for which no simple hand-book formulae are adequate. Nevertheless, it is possible by using a series of methods to make reasonably precise design in many instances and to allow for an adequate

range of design in many other cases (KOM 86).

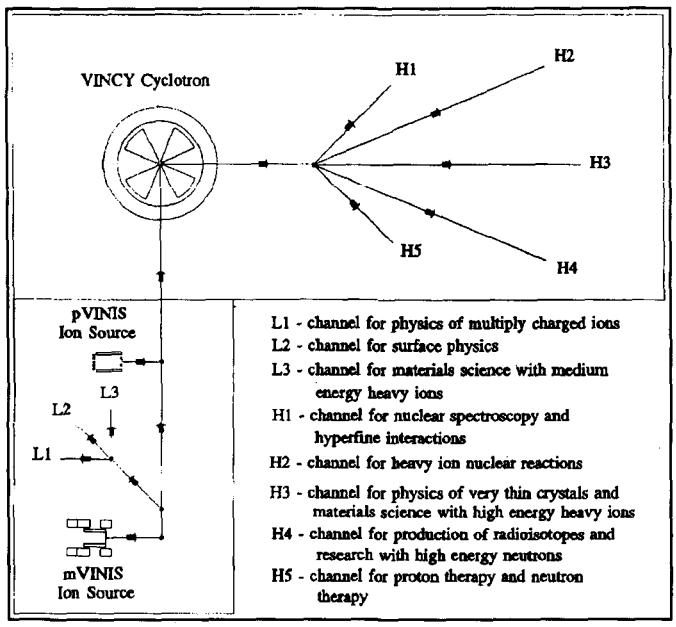

Figure 1. The principal scheme of the TESLA Accelerator Installation (TAI 93)

At its best the calculation for the shielding of a medium, as well as high energy accelerators involves, many simplifying assumption to make the problem tractable. Nevertheless the magnitude of the cost at stake and the engineering problems of support and handling forbid the casual use of large margins of safety, and require an attempt at precision compatible with the knowledge of the basic factors of production and propagation of radiation (PAT 73, TRS 88).

It is a fact familiar to all who have considered the shielding of a heavy particle accelerators that the radiation component that dominate in the prompt radiation field and the shielding problem, on the accelerator with performances like the TESLA Accelerator Installation have, is neutron radiation.

The beam losses interacting with components of accelerator structure, as well as beam of accelerated particles interacting with experimental targets, irradiated specimen or patient will give rise to high neutron fluxes, for which shielding must be provided, and also lead to component damage and induced radioactivity, with the attendant risk of increased radiation exposure of maintenance personnel.

Health physics problems at heavy-ion accelerators, with exception of accidental exposure close to or directly in the accelerator beam, are largely due to their neutron production. Thus an understanding of neutron production by charged particles is an essential weapon for the armoury of the health physicist, who must design shielding for such accelerators, estimate their production of radioactivity, and measure the radiation field they produce.

Experimental data on neutron yields and spectra from stopping protons are available at proton energies above 100 MeV; however, there is much less data for protons and for deuterons in the energy range between 50 and 100 MeV, where inelastic cross sections change rapidly with energy (BRO 83, FAS 76).

Shielding calculation

The first goal of all efficient accelerator shielding design is to attenuate the high radiation intensities produced by the accelerator and its associated equipment to levels that are acceptable outside the shielding, at minimum cost and without compromising the utility of the particle accelerator for its designed purposes. The

first and the most important and the most complicated step is determination of radiation sources, i.e. the space, time, particle and energy distribution of radiation fields (NCR 77). It is, therefore the most complicated step in solving radiation protection and shielding problems also in TESLA Accelerator Installation, especially due to the substantial lack of information about interaction cross section for the most important accelerated particles - protons and deuterons, in the energy range of interest (BRO 83).

In order to make critical analysis of existing project for cyclotron room we were used a simple exponential function to calculate ambient dose equivalent rate on the outer side of cyclotron shielding room, at working places for occupationally exposed workers and in the environment and working places occupied with other workers and member of the public.

According to planned characteristic of accelerated ion beams, their energies intensities, mass and charge of ions, we decided that the biggest problem for cyclotron shielding will be with deuteron acceleration. As a source of secondary neutrons we assumed will be sides of vacuum chamber, due to interaction of deuterons with average energy about 30 MeV/nucleon lost from acceleration. We were assume that the number of deuterons lost from acceleration, J, will be about 10^{13}, and that emitted neutron spectrum will be with average energy in the range from 5 to 20 MeV. On the basis of these assumptions we were calculate ambient dose equivalent rate, $\dot{H}$, out of the shield walls from equation (ALE 95):

$$\dot{H} = J \cdot f \frac{Y \cdot B \cdot h}{4 \cdot \pi \cdot R^2} e^{-x/\lambda} \qquad (1)$$

where Y - neutron yields per one deuteron lost from acceleration, B - buildup factor, λ - ambient dose equivalent attenuation length, h - neutron dose conversion factor far neutrons penetrated through shielding wall, x - shielding wall thickness, and R - distance from neutron source to the point of interest.

Conclusion

On the basis of this strongly approximated calculations we concluded that thickness of 150 cm of the side walls of accelerator room is not enough to perform safe radiation environment outside cyclotron room. We also concluded that in order to be able to use large basement area it is necessary to shield the space just under accelerator shielding room.

INDUCED RADIOACTIVITY OF THICK COPPER TARGET IRRADIATED BY 3.65 GEV PROTONS

A.A.Astapov*, V.P.Bamblevsky

Joint Institute for Nuclear Research, Dubna, Moscow Region, 141980, Russia

INTRODUCTION

In recent years it is discussed the applications of the high energy proton accelerators in industry and medicine (for electrical energy production, radioactive waste transmutation, proton therapy etc.) (1,2). For these purposes it are necessary the machines with high intensity beams that may lead to complex radiation problems. Major such problem is γ-radiation induced radioactivity in accelerator equipment, which brings the main contribution to the personal total dose as rule more than 60%.

The present study deals with the induced radioactivity of the thick copper target irradiated by 3.65 GeV protons.

EXPERIMENTAL

The copper target of $\varnothing 100\times 130$ mm^2 dimensions is irradiated with beam of protons of 3.65 GeV energy and $7\cdot 10^{10}$ protons/cycle during 4 hours approximately. The experimental and monitoring conditions are the same as those described in (3). The irradiation control is performed with an ionization chamber. The total number of incident protons G is determined using the reactions of activation $^{27}Al(p,x)^{18}F$ and $^{27}Al(p,x)^{24}Na$. The values of the reaction cross sections are taken from paper (3). The number G determined with the activation detectors agrees with that one obtained with the ionization chamber within the measurement error (the chamber miscounts have been corrected). The following value is determined: $G=(5.0\pm 0.4)\,10^{13}$ protons.

The dose rate was measured with the use of the scintillation detector with NaJ(Tl) crystal of $\varnothing 63\times 63$ mm^2 dimensions and the multi-channel amplitude analyzer. Figure 1 illustrates the experiment configuration.

SIMULATION

The code package is developed for the calculation of the radioactivity induced by high energy protons. It allows :

1) To get the information about the stable elements and it nature abundance and the gamma radioactive nuclides with the half-life more than 5 minutes on the flight.

2) To calculate the spallation cross sections by using semiempirical Silberberg-Tsao's (4) and Rudstam's (5) formulae for protons and also to estimate the spallation cross sections for the nuclei. The peripheral reactions are also accounted in the this code.

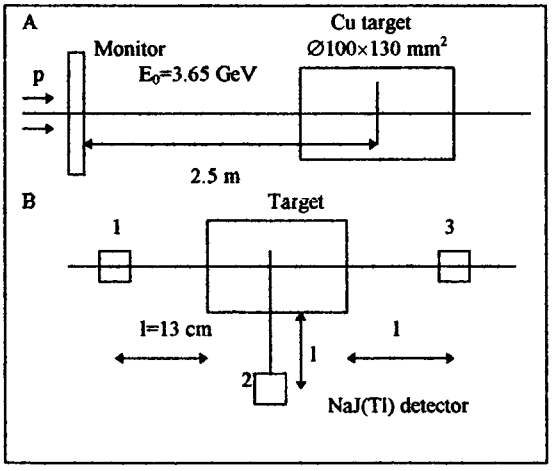

Figure 1. Geometry: (A) - target irradiation; (B) - dose rate measurement from the: 1 - beam inlet, 2 - side, 3 - beam outlet.

3) To calculate the induced gamma radioactivity with Silberberg-Tsao's formulae for the protons and nuclei. The data are equivalent to Barbier's ones (6) and are the dose rate existing at 1 cm of a supposed point source of 1 gram of target material, the dose rate existing in front of an infinite radioactive wall of great thickness, the specific activity and the total activation cross section.

4) To simulate the dose rate distributions around the thick targets irradiated by the high energy protons. The hadron inelastic interaction distributions over the targets are calculated by Monte-Carlo method using SHIELD code (7).

Below, the several comparisons of the numerical and experimental results are presented to demonstrate the capabilities of

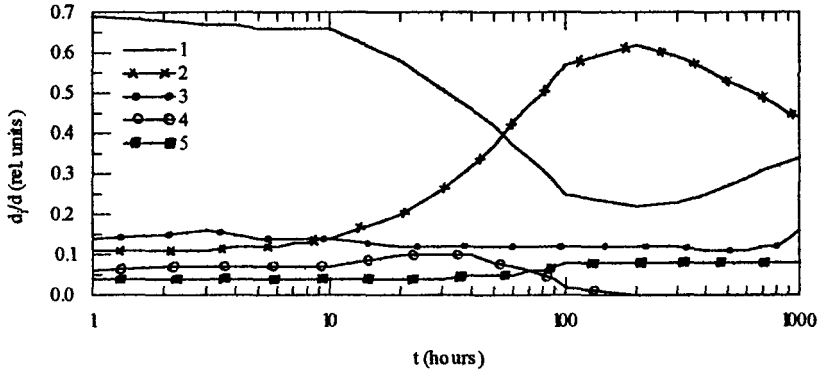
←↑Figure 2. Dose rates per one incident proton d at various detector positions, t is cooling time.

↓Figure 3. Relative contributions to dose rate d_i/d by various type hadrons at position #1: 1 - neutrons with E_n>10 MeV, 2 - primary protons, 3 - secondary protons with E_p>10 MeV, 4 - neutrons with E_n<10 MeV, 5 - $\pi^{\pm}$ with E_π>10 MeV; t is cooling time.



this code package. There are presented the simulation results of the dose rates in dependence on the time for the cylindrical Ø100×130 mm^2 thick copper target irradiated by 3.65 GeV protons. Relative contributions in the dose rate from radioactivity for the primary beam and the secondary particles (of neutrons with energy lower than 10 MeV and different types of the hadrons with energy more than 10 MeV) are obtained for the proton irradiation.

RESULTS AND DISCUSSION

Figure 2 shows the experimental data and simulation results of the dose rates per one incident proton d in dependence on the time at l=13 cm and various points for our target irradiated by 3.65 GeV protons. The indicated error is the monitoring inaccuracy that does not exceed 10%. The additive error of the γ-radiation dose rate has the systematic nature and is less than 15%. The exponential law $d=d_0+A\exp(-(t-t_0)/B)$ was used for the fitting by χ^2 criterion (8). The velocity of decay of this target induced radioactivity decreases with t increasing and is in good qualitative agreement with formulae by A.Sullivan (9). The calculated values d are obtained with Monte-Carlo method. The difference between calculation and experimental values of γ-radiation dose rate does not exceed 30% that it is allows to use our package for analysis of the induced radioactivity of thick targets.

Simulation data presented at figure 3 are the time-dependent relative contributions in the dose rates d_i/d from induced activity by the primary beam and secondary particles - neutrons n with energy $E_n<10$ MeV and different types of hadrons (i=p, n, $\pi^{\pm}$) with energy $E_i>10$ MeV. The induced activity is mainly produced by the primary protons and secondary neutrons with $E_n>10$ MeV. At the cooling beginning the secondary neutron contribution nature is the radioactive copper isotope production by the peripheral reactions. For this reason it is very important to account the single isotope production reaction channels. The approximations (4) may lead to the large inaccuracy for energies less than ~100 MeV (for the threshold region) and light nuclides, produced in spallation reactions (10). Therefor it is necessary to use experimental isotope production data libraries for the low energy hadrons, for example (11).

Also the package allows us to get of spatial distribution of radionuclides in thick target and other additional information to predict correctly the radiation danger levels for high energy proton accelerators.

ESTIMATION AND MEASUREMENT OF Fe-55 AND Ni-63 IN HARDWARE ACTIVATED AT HIGH ENERGY ACCELERATOR FACILITIES

Yuichi Oki,Takenori Suzuki,Masaharu Numajiri,
Taichi Miura and Kenjiro Kondo

National Laboratory for High Energy Physics,
Oho 1-1,Tsukuba-shi,Ibaraki-ken,305,Japan

1,Introduction

At high energy accelerator facilities, accelerator components are exposed to primary and secondary particles with energy spectra from thermal to high energy,and as a result,they become radioactive through various types of nuclear reactions including spallation reactions[1, 2]. From a viewpoint of accelerator radiation protection, evaluation and measurement of radioactivities in these hardware is one of the most important things. Most radioisotopes produced are γ-emitters, and their radioactivities can be readily determined with a conventional radiation detector. While ^{55}Fe(EC decay,half-life:2.7y) and ^{63}Ni(β^- decay,half-life:100.1y) ,which are formed in accelerator components composed of iron and steel, emit no γ-ray, and from their nuclear properties, chemical separation of these radioisotopes from the irradiated samples is unavoidable prior to the measurement. These long-lived radioactivities accumulate in proportion to the machine operation time and become dominant in the residual activities several years after beam-off. These isotopes are conceivable to be produced abundantly because of the large cross-sections leading to their formation. Therefore,measurement and evaluation of these radioactivities are very important for safe handling of these accelerator components, and no report however is available on the measurement of ^{55}Fe and ^{63}Ni formed in the bulk hardware.

This paper is concerned with the development of measurement methods and the evaluation of ^{55}Fe and ^{63}Ni activities formed in iron and steel commonly used in accelerator hardware. The chemical separation of these radioisotopes from the irradiated materials was studied extensively. The ^{55}Fe and ^{63}Ni radioactivities were also estimated on the basis of the neutron fluxes measured by using a set of Au foils and Cu threshold detectors and compared with those experimentally obtained by a liquid scintillation counting method.

2,Experimental

In order to measure the integrated hadron fluxes(mostly neutrons),an activation method was adopted: a set of Au foils(about 1g) and Au foils wrapped with 1mm-thick Cd and copper discs(about 6g and/or 3.4g) were placed at various positions in the beam-line tunnel(EP2) of the National Laboratory for High Energy Physics(KEK) 12-GeV proton synchrotron. Iron and steel discs were placed at the same positions. Table 1 shows the cross-sections and effective threshold energies used for the calculation of integrated hadron fluxes in a copper threshold detector. The beam line tunnel is about 40m long, 6m wide and 4m high,being enclosed by heavy concrete blocks. The average intensity of primary protons was $(0.5\text{-}1.3)\times10^{12}$ protons per second, which was continuously monitored with SEC(secondary emission chamber). After the irradiation of a certain term,the radioactivities formed in the activation detectors and samples were measured with a high resolution Ge-detector connected to 4k PHA. To avoid the intereferences of short-lived radioisotopes,their radioactivities were measured about two weeks after the end of irradiation.

The ^{55}Fe and ^{63}Ni were measured with a liquid scintillation counter(LSC)(Packard Tri-Card 200CA/LL). Fig.1 shows the chemical separation procedures of iron and nickel from the irradiated discs and the preparation for the counting samples for LSC. 16mL of EX-H emulsfier was added to the iron or nickel solution thus separated in a glass counting vial of 20 mL and shaken vigorously. The milky gel-samples for LSC thus

prepared were allowed to stand for about one day and then measured several times for 30 min. A window of 0-70 keV was set to cover the entire energy region of β^--rays from ^{63}Ni(E_{max}=65.9keV), whereas for the measurement of ^{55}Fe radioactivity, three window widths of 0-7 keV,7-1200 keV and 0-1200 keV were set to measure the X-rays of 5.8 keV(K_α) and 6.4 keV(K_β) and Auger electrons of 5.2-5.8 keV. The extent of quenching was determined by the external standard method using a ^{137}Cs source.

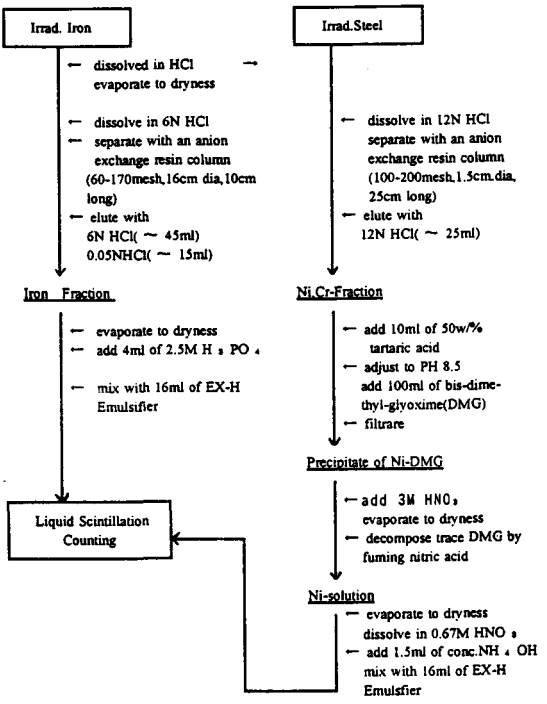

Fig.1 Procedures for chemical separation of ^{55}Fe and ^{63}Ni from irradiated iron and steel samples and preparation of counting samples for LSC

3, Results and Discussion

The chemical yields for the whole procedures shown in Fig.1 were about 91% for ^{55}Fe and 94% for ^{63}Ni. Both γ-ray and liquid scintillation spectrometries showed no contamination in the samples thus prepared. The counting sample preparations for LSC were simple and applicable to the ^{55}Fe and ^{63}Ni measurement with high sensitivity. For iron and steel samples. the detection limits were 0.82 Bq/g(Fe) and 0.035 Bq/g(SUS,Ni content of 15%) by assuming the counting time of 100 min. and 95% confident level(2 σ).

Thermal neutron fluxes were $(2.0\text{-}5.2)\times10^5 cm^{-2}s^{-1}$, and almost the same at any places in the EP2 tunnel. ^{63}Ni is primarily produced in steel discs through thermal neutron capture reactions of ^{62}Ni with natural abundance of 3.66%; its cross-section is 14.6 b. The steel samples used were all SUS discs with nickel content of 15%. As Table 2 shows, the ^{63}Ni radioactivities calculated from the thermal neutron fluxes were relatively good agreement with those obtained experimentally. On the other hand,the ^{55}Fe mainly formed through the thermal neutron capture of ^{54}Fe and (n,2n) reaction of ^{56}Fe, which have large cross-sections of 2.25 b and about 600 mb for the neutrons of thermal and 18 MeV, respectively. In order to calculate the ^{55}Fe activity, the cross-sections for the (n,2n) reaction were taken from ENDF/HE-VI library. Fig.2 shows the relation between the radioactivities calculated and exprimentally obtained at six different positions. The calculated values for the two positions downstream from beam-loss points and close to the beam line were considerably overestimated, indicating that the (p,pn) reaction of ^{56}Fe is

Table 1. Cross sections and effective threshold energies for calculating the integrated hadron fluxes using a Cu threshold detector

Nuclide	Threshold * energy(MeV)	Cross-section ** (mb)	Half-life
^{60}Co	13	7.8	5.27y
^{58}Co	23	18	70.9d
^{56}Co	35	3.7	77.1d
^{54}Mn	50	13	312d
^{48}V	72	5.5	16.0d
^{46}Sc	85	4.7	83.8d

*Routti(1974) [3] , **Asano et al.(1983) [4] ,

considered to contribute somewhat the ^{55}Fe formation at the positions close to the beam line. This disagreement can be explained in terms of coexisting high energy protons in the measured fluxes and the difference of the excitation functions of the (n,2n) and (p,pn) reactions. ^{55}Fe and ^{63}Ni survive for long time after beam-off and emit no γ-ray. Therefore no radiation level does not necessarily mean that all radioactivity had decayed out. From a viewpoint of radiation safety, it is very important to evaluate their radioactivities prior to an actual handling of radioactive accelerator components. The present study indicated that a rough estimation of ^{55}Fe and ^{63}Ni activities is possible by measuring the neutron fluxes by a set of Au foils and Cu threshold detectors.

INTERCOMPARISON OF PERSONAL DOSIMETERS USED IN U.S. DEPARTMENT OF ENERGY ACCELERATOR FACILITIES

J.C. McDonald[1], G. Akabani[1], R.M. Loesch[2], M. Höfert[3] and C. Vaerman[3]

[1] Pacific Northwest National Laboratory, Richland, Washington 99352 U.S.A.
[2] U.S. Department of Energy, Washington, D.C. 20585 U.S.A.
[3] European Laboratory for Particle Physics, CH1211 Geneva 23, Switzerland

An intercomparison of the dose equivalent response of personal dosimeters in use at U.S. Department of Energy (DOE) accelerator facilities took place at the European Laboratory for Particle Physics (CERN). This is the third such intercomparison sponsored by the DOE. The two previous intercomparisons were performed in a U.S. laboratory using a source of high energy neutrons. In this intercomparison dosimeters were exposed at CERN in two shielded positions relative to a production target that was hit by a positive hadron beam of 205 GeV/c. The neutron energy spectra present at these two locations had been calculated earlier using Monte Carlo methods and agreed well with those that had been determined experimentally using Bonner sphere spectrometer systems. The dose equivalents at these two positions were measured by CERN personnel using a tissue equivalent proportional counter system. For exposure, the dosimeters were mounted onto spherical phantoms made of polyethylene at several angular positions. The DOE dosimeters were mailed to CERN and following exposure returned for readout. The results of this intercomparison are relatively consistent with the two others previously performed in the U.S. The relative dose equivalent responses of neutron dosimeter types such as: albedo, nuclear emulsion and track etch plastics were found to have variations relative to the mean value responses of up to a factor of three. The possible causes for such large variations will be discussed.

INTRODUCTION

The U.S. Department of Energy (DOE) currently administers 12 laboratories that perform high-energy accelerator-based research. The accelerators at these laboratories produce radiations having energies ranging from a few MeV to the TeV range. The high-energy neutrons produced by these accelerators present a difficult radiation protection problem, because they can penetrate large thicknesses of shielding (1,2).

The DOE operates a program to accredit suppliers of personnel dosimetry for DOE facilities. This program is entitled the Department of Energy Laboratory Accreditation Program (DOELAP)(3). The two neutron sources used for DOELAP proficiency testing are unmoderated and D_2O-moderated ^{252}Cf. The unmoderated ^{252}Cf source has a mean energy of about 2.3 MeV with a high-energy tail extending to approximately 10 MeV. However, this source is not appropriate for testing personal dosimeters that are expected to measure dose equivalents produced by neutrons with energies of several hundred MeV.

The intercomparison of dose equivalents determined with personal dosimeters used at DOE high-energy accelerator facilities was intended to show the degree of consistency in high-energy neutron dosimetry at the participating laboratories. The high-energy neutron fields generated at CERN provided a more realistic approximation to the actual fields encountered at DOE high-energy accelerator facilities than could be provided by the two neutron sources used in the DOELAP program.

MATERIALS AND METHODS

The neutron fields used for this intercomparison were generated at CERN by bombarding a copper target with a beam of positive hadrons (protons and pions) with a momentum of 205 GeV/c. The secondary radiation produced by this interaction at 90° passes through shields of either concrete or iron (4). The radiation fields outside these shields contains a large portion of high-energy neutrons that can be used to irradiate personal dosimeters or area survey meters. Determinations of the neutron energy spectra for the two experimental conditions were carried out using Monte Carlo methods and Bonner sphere spectrometer systems (4). Good agreement was found between these two methods.

Personal dosimeters from participating DOE facilities were mailed to CERN from the Pacific Northwest National Laboratory. Appropriate numbers of control dosimeters were not irradiated, so that the background and transit doses could be evaluated. At CERN, the dosimeters were irradiated on two types of plastic phantoms.

Calibration exposures were performed using a rectangular solid phantom measuring 40 x 40 x 15-cm and an irradiation distance of 2 m from a ^{238}Pu-Be neutron source. For exposures at the accelerator experimental positions, dosimeters were mounted on spherical polyethylene phantoms at several angular positions. Following exposures at CERN, the dosimeters were mailed back to the participants for readout.

RESULTS AND DISCUSSION

Dose equivalents determined from the readings of the personal dosimeters used in this study were compared to the mean of all values determined by all of the participants. The dose equivalents determined by the participants were also compared to the values determined by CERN. The ratios of average readings to the mean for the participants are shown in Figure 1, for the concrete shielding configuration and 2, for the iron shielding configuration.

It can be seen from this plot that the extremes of average readings for dosimeters used by different participants vary from the mean by up to a factor of 3. The variations are in both directions and do not appear to correlate to dosimeter type or participant. The results for the concrete shielding configuration seem to be somewhat more consistent.

The dosimeter types used in this study had different dose equivalent responses as a function of neutron energy. In addition, the dosimeters were calibrated using different reference neutron sources. Therefore, it is not surprising that their responses to this high-energy neutron field varied by large amounts. In order to determine whether the inherent dose equivalent response of the dosimeters as a function of energy, the reference calibration source or other uncertainties were responsible for these differences, it would be necessary to design a specific experiment to test the effect of each influence quantity. It is expected that future intercomparison exercises will include such tests.

RADIATION MONITORING SYSTEM FOR ELECTRON ACCELERATORS AT ATOMINSTITUTE VIENNA

H.Aiginger, M.Fugger, E.Unfried

Atominstitute of the Austrian Universities, Schuettelstr. 115, 1020 Wien

INTRODUCTION

The Atominstitute Vienna has two Van de Graaff accelerators installed, with a maximum voltage of 2 MV and 400 kV respectively. Both accelerators are used only in electron mode, therefore the affect of X-rays produced by the electron beam on adjacent rooms and the operators area has to be monitored and limited. This is of great importance all the more than both accelerators are installed in rather normal laboratory rooms in the basement of the building. There is no special shelter as it is usual for such radiation facilities. To determine the maximum permissible beam current and/or to prescribe restricions in adjecent rooms hitherto it was necessery to make tedious measurements of the dose rate in areas affected by radiation from the accelerator. Whereas the dose rate at the workplace of the operator and the experimental area was monitored continuos, there was no possibility to do this for the neighbouring rooms, especially above the accelerator. It was in the responsibility of the operator to operate the accelerator within prescribed limits. For the 2 MV accelerator, when operated with external beam, the dose rate due to scattered electrons had to bee considered too.

As the accelerator area must not been accessed during operation, an interlock system with redundancy 2 and video monitoring of the area is provided. This is not described in detail here.

By official order it was neccessary to update the complete monitoring system for both accelerators. This system is nearly identical for both accelerators (no electron doserate to consider for 400 KV because of distance) and is described in brief for the 2 MV accelerator. In a second step of the project it is planned to use the acquired parameters of the accelerator system for automatic operation of the accelerator.

REQUIREMENTS and DRAFT

The absolute dose rate limit by official order was fixed to 25 μSv/h for all locations in the vicinity of the accelerator area. The first step was to find out the critical locations to decide how many detectors are required and where they have to be positioned.

In the operator area the maximum dose rate occurs at the barrier between accelerator area and operator area. This position requires 3 detectors. One is a filtered GM-detector for the X-ray doserate, the others are identical proportional ß-detectors with thin entrance windows, but one of them with a ß-absorber of perspex and therefor sensitive only for X-rays. The difference of the proportional detectors is a good measure for the electron dose rate. By comparison of the three detectors malfunctions can be detected. The reading of the proportional detector should not be lower then that of the unfiltered one. The reading of the filtered one should be equal to that of the GM-detector. A function test by natural radiation is self evident.

The maximum dose rate in adjacent rooms is found above the accelerator, at a position depending on the experimental arrangement. Extensive investigations for different cases showed that the position on the ceiling of the accelerator area exactly above the standard position of the X-ray target (gold) is a sufficient worst case approximation for all arrangements used and all electron energies from 0.5 to 2.2 MeV. As there is no practical possibility to locate detectors on the floor of the room above (this is the experimental area of the research reactor Triga Mark II) it was decided to mount a GM-detector at this position on the ceiling. To get a measure for the dose rate on the floor above the GM-detector is mounted inside a filter of lead and aluminium which simulates the absorption of the ceiling. This method would work perfect for a concrete filter but lack of space prevented this. Therefor a correction with an experimental determined function depending on the voltage of the accelerator is necessary.

Beside the accelerator voltage it is neccessary at least for plausibility tests to acquire the beam current. For external beam this may be difficult or impossible in a direct way. Acquiring all partial currents in the accelerator allows by balance-sheet of this currents to get the beam current without direct measurement. Considering the planned second step of the project it is useful to acquire all data which are normally displayed on the control panel and all logical states of switches and relays. This allows the simulation of the control panel on the computer screen.

The data acquisition applays therefore to several analog and digital signals as inputs. The only output at present is a failsafe logical output to shut down the accelerator. When acquiring data one has to keep in mind the possibility of transient signals everywhere in the accelerator wiring. They occure during voltage break downs in the accelerator tube or tank. Isolating amplifiers and isolating logical modules are therefor a must for each signal line. Data acquisition and evaluation is done on an intelligent board independent of the host computer which is free for other jobs such as operating the accelerator as planned for the future. Beside the main task of the program that is monitoring the radioation levels, giving warnings or shutting down the accelerator there are also a lot of routines watching the technical status of the accelerator and giving hints to the technical service personal.

OPERATION

Switching on the main power switch of the accelerator powers the computer. When ready the program ACMOS (**AC**celerator **MO**nitoring **S**ystem)is loaded from the disk and starts with a selftest. After a detector test with background radiation a login screen is displayed and a floppy disk is requested for the logfile and a log file on the disk is created and/or opened if it exists already for this day. Each day has its logfile which is stored on the disk. When starting the system another day the logfile is transfered to floppy disk. The login requires a password which is given by the master user which decides also the different permissions connected to this password (external beam, warning light in the accelerator area off, part of the interlock system off for service purposes, etc.). Only the master user can alter the warning and shut off levels, the permissions and several calibration factors. When a key switch on the operating panel is activated the power up procedure of the accelerator is continued via the computer and the actual status is stored in the log file and also printed. The computer screen shows all the acquired data after some averaging. The actual dose rate for display is measured in time preset mode with sliding averaging, whereas for limit evaluation and for the logfile this is done in preset count mode to speed up the response. Each time any of the acquired data differs significant from that of the last entry in the log file a new actual data set of all operating parameters and acquired data is added to the log file. If necessary this entry contains also messages for the technical service personal or the reason for shut down if this happened. This messages are always displayed on the screen and printed. Depending on the relevance some messages on the screen are accompanied by an acoustic signal and some messages have to be quit by the operator.

Shut down can be initiated by the operator, by a limit condition or if a fatal error in the system is detected. It causes another entry in the log file and closes it. When the shut down is caused by main power off the computer power is switched off with time delay to allow correct saving of the log file. The operation of the computer is monitored by a watchdog system which also causes a shutdown in the case of a hangup of the program.

The system is in use with only minor modifications since January 1996.

SOME ASPECTS OF IMPLICATION OF NEW ICRP RECOMMENDATIONS INTO NEUTRON RADIATION MONITORING AT IHEP

A.G. Alekseev, V.N. Lebedev, S.A. Kharlampiev

Institute for High Energy Physics, Protvino, 142284, Russia

INTRODUCTION

New Radiation Safety Standards developing by National Commission on Radiation Protection of Russian Federation (NCRP) will base on the ICRP Recommendations given in the ICRP Publication 60 [1]. It changes the approach to exposure reglamentation realized in actual Russian radiation safety standards and requires to estimate consequences of this reconsideration for radiation monitoring practice of the Institute for High Energy Physics (IHEP).

PROBLEMS OF TRANSITION TO ICRP-60 RECOMMENDATIONS

Present Radiation Safety Standards and the ICRP Recommendations (ICRP-60) differ in:
— the recommended quality factor dependence on linear energy transfer (LET);
— the basic and operational quantities for radiation risk evaluation for external exposure;
— occupational and public dose limitation.
The effective dose concept adopted by Russian NCRP instead of the critical organ concept requires from radiation safety services to use in their activity new ICRP operational quantities as well as new dose limits. When the ICRP-60 Recommendation will be introduced into neutron radiation monitoring practice, correspondent changes can be in:
— procedure of metrological maintenance;
— instruments used in the neutron radiation monitoring;
— organizational and limitational base of neutron radiation monitoring.

METROLOGICAL BASE OF THE IHEP RADIATION MONITORING

The metrological base of the IHEP radiation monitoring have been revised recently when the neutron reference fields [2] used for metrological maintenance of routine dosemeters have been certified [3] in terms of the neutron ambient dose equivalent rate. These neutron reference fields are:
— standard commercial calibration system UKPN-1M with ^{252}Cf and $^{239}Pu-Be$ radionuclide sources and a collimator made of polyethylene with 3% of ^{10}B;
— ^{252}Cf and $^{239}Pu-Be$ radionuclide sources in free air;
— ^{252}Cf in 30-cm diameter iron or polyethylene moderator.
The $Q(L)$ dependence recommended in ICRP Publication 21 [4] has been put on the basis of the certification. So, for IHEP radiation monitoring practice where new operational quantities are already used, implication of the ICRP-60 recommendations will be reduced to re-certification of the reference fields in terms of $H^*(10)$ based on new $Q(L)$ dependence.

ACCURACY OF AREA MONITORING

Possible changes in routine dose measurements accuracy concerned with implication of the ICRP-60 recommendations have been estimated for routine instruments most widely used in IHEP area monitoring such as rhodium monitors (RM) and passive monitors (PMS) usually calibrated in $^{239}Pu-Be$ field. RM is a counter with rhodium foil converter in polyethylene moderator of 10-inch diameter and is usually used in controlled areas. PMS is a $^{6}LiF - {}^{7}LiF$ pair in polyethylene moderator of the same diameter and is used in supervised areas.

The systematic errors of ambient dose equivalent measurements have been calculated for RM and PMS in the IHEP radiation fields where neutron spectra have been measured [2,5,6]. The energy dependences of ambient dose equivalent factor $h^*(10)$ of [7] based on the $Q(L)$ dependence of ICRP-21 and of [8], where $h^*(10)$ has been recalculated on base of the $Q(L)$ dependence of ICRP-60, are used for calculating H_0 — neutron ambient dose equivalent in a radiation field. The energy dependences of detector response to neutrons, $R(E)$, for RM and PMS, under the condition of their calibration in the $^{239}Pu-Be$ reference field are used for calculating H_{RM}, H_{PMS} — responses of the dosemeters in terms of ambient dose equivalent for both $Q(L)$ dependences.

Table 1. Mean ratios of H_{RM}/H_0, H_{PMS}/H_0 , and H_0^{60}/H_0^{21} calculated for three groups involving most available neutron spectra of IHEP radiation fields.

Ratio	$Q(L)$ dependence	Pu-Be	Behind upper and side shielding at exp. hall [5]	Behind side shielding and far from it , [6]	Reference fields on base of ^{252}Cf [2]
H_{RM}/H_0	ICRP-21	1	0.75	1.26	1.21
	ICRP-60	1	0.79	1.17	1.13
H_{PMS}/H_0	ICRP-21	1	0.72	1.11	1.15
	ICRP-60	1	0.75	1.04	1.04
H_0^{60}/H_0^{21}		1.26	1.18±0.05	1.34±0.04	1.38±0.06

The RM and PMS measurement systematic error is given by deviation of ratio H_{RM}/H_0 or H_{PMS}/H_0 from 1. Mean values of this ratio for three groups of neutron spectra are presented in Table 1. One can see that systematic error will reduce with transition to ICRP-60 recommendations in case of considered dosemeters and neutron spectra.

The difference in absolute values of ambient dose equivalents of ICRP-21 and ICRP-60 in IHEP workplace fields can be also found in Table 1 where the ratios H^{60}/H^{21} of these values calculated for the three neutron spectra groups are given. Transition to ICRP-60 will lead to dose increase up to 1.4 times while the neutron fluence remains the same.

APPLICABILITY OF EXISTING RADIATION MONITORING INSTRUMENTS

ICRP-60 recommends the occupational dose limit to be equal 100 mSv per 5-year period. The annual occupational dose limit of 20 mSv will be in this case in 2.5 times lower than the former one. It can lead to correspondent reduction of working range of dosemeters used in radiation monitoring and can result in impossibility of further application of some dosemeters. When transit to ICRP-60 recommendations, there are two factors working in the same direction: 1) dose limit changes and 2) the increase of ambient dose equivalent up to 40 percents mentioned above. The administrative control dose levels established in IHEP are recalculated in Table 2 for new dose limits in simplest way, i.e. divided by 2.5 (except supervised area where ICRP-60 recommended annual dose level is directly applied).

In Table 2 we have estimated the possibility of application of available monitoring instruments in case of adopted ICRP-60 recommendations by comparison of minimal doses measured by the instruments with new levels, so Table 2 contains ratios of minimal measurable doses to new levels. The values of minimal measurable dose have been recalculated by multiplying by a factor of 1.4, reflecting with some conservatism the fact of the ambient dose equivalent factor increase after transition to ICRP-60 recommendations. According to ICRP-35 Recommendations [9], an instrument could be still used in radiation monitoring if its minimal measurable dose less than new value of control dose level in 10 times and over.

As it is seen from Table 2, all the instruments will preserve their applicability in case of simple decrease of dose levels as recommended by ICRP-60.

PERSONNEL MONITORING

Brief analysis of personal exposure on base of personnel monitoring data for 1990–1993 years has shown that annual personnel doses greater than 20 mSv had occured in approximately 1% cases (10–12 cases per year instead of about one case for 50-mSv limit), while the mean annual personnel dose was about 3 mSv. Since new ICRP-60 Recommendations allows to exceed 20-mSv annual limit in case when mean dose over a 5-year period does not exceed 20 mSv, such low mean annual doses and overexposure frequency allow us to meet to new requirements without considerable changes in personnel radiation monitoring procedure. Reconsideration of administrative classification of workplaces seems to be enough to optimize personal exposure.

Table 2. Ratio of minimal measurable dose to established control dose level recalculated according to ICRP-60 requirements on dose limits, for basic IHEP dosimetric instruments

Established for:	Area 1	Area 2	Supervised	Individual
Control level, H_{est}	91 μSv/h	17 μSv/h	1 mSv/year	2.8 mSv/run
Dosemeter	H_{min}/H_{est}			
Active

CONCLUSIONS

The transition to ICRP-60 recommendations will not involve any changes in instruments used in the IHEP routine neutron radiation monitoring. Modification of the IHEP metrological base will be not nesessive too, but we shall need in new certification of the instruments used for metrological maintenance.

The decrease of the annual dose limits will require optimization in the monitoring instruments application at some supervised areas and new classification of workplaces in controlled areas.

It has been shown, for most widely used in IHEP neutron radiation monitoring dosemeters such as RM and PMS, that transition to ICRP-60 recommendations concerned with operational quantities will not increase systematic error of the IHEP neutron dose measurements if the calibration procedure remains the same. The mean absolute values of measured doses will increase on 18% in radiation fields behind the upper and the side accelerator shielding, and on 30–40% — in other available IHEP radiation fields.

ABSTRACT

A brief description and characteristics of some radiation monitors designed in IHEP for a real-time radiation monitoring system for UNK project are presented. The radiation monitors output the information about radiations on coaxial cables using 16-bits digital signals. On these cables the power supply of radiation monitors is provided. A transmission of signals on distance up to 1.5 km is possible. Most attention has been concentrated on informative reliability. Monitors make the autodiagnostics of some their own parameters and the results of the autodiagnostics are passed in signals.Data and experience received in the tests of radiation monitors in radiation fields at experimental area of 70 GeV IHEP's accelerator and at start-up of a UNK injection channel are analyzed.

ABSTRACT

The set of neutron reference fields with the mean energies from thermal up to 4 Mev were created at IHEP on the base of the radionuclides sources (Cf-252, PuBe) and special systems for neutron spectra degradation. These reference fields are a system of common usage and research directions in framework of Metrological Council on Charged Particle Accelerators (MCCPA). MCCPA is consist of authorities from IHEP (Protvino), JINR (Dubna), INP(Gatchina), Mendeleev's Metrological Institute (S.Petersburg).

IHEP reference fields:

- are supplied by instruments and methods of sertification, that include Russian State Standarts;
- serve for calibration of measurement instruments for radiation control systems at the charged particles accelerators;
- are used for intercomparisons of various measurement instruments (dosemeters, ratemeters, spectrometers).

These works are carring out during 10 years in framework of MCCPA and provide the quality assurace of radiation control at charged particle accelerators in Russia.

ABSTRACT (See instructions overleaf)

Recently in many scientific centers conceptual study of Accelerator Driven System (ADS) various versions, i.e.subcritical reactors with a external source of neutrons as a proton accelerator and neutron-producing target is carried out. Conducted in SSC RF ITEP study shows about the serious problems, connected with provision of ADS radiation safety, in some aspects distinguished from similar problems for existing nuclear reactors. Following problems on maintenance of ADS radiation protection are formulated.

1.Calculation of a system shield of target-blanket in view of interaction with 4 type of radiation: a protons with energy 1-1,5 Gev, a neutrons of different energy from target and blanket, mesons and γ-radiation.

2. Study of changes of the radiating characteristics of a target under action of protons and neutron flux, formed in target and blanket, and processes of formation volatile of products of spallation-reactions in a target and their influence to a radiation conditions in the system of the proton transportation and on process of regeneration of a target.

3. Calculation of activation level and biological shield of high-power proton accelerator design (with a proton current up to 300mA), magnets of a system of a beam formation and transportation to a target in connection with possible losses of protons during acceleration at normal operation of a accelerator.

4. Study of emergency beam deposition consequences in designs and systems, specified in items 3, in particular, in a system of a beam reception at failure of magnets of a system of proton transportation and other.

Results of the experts ITEP investigations on separate aspects of ADS radiation safety and protection are given.

RADIATION PROTECTION AND THE NATURALLY OCCURRING RADIOACTIVE MATERIALS (NORM)

There are many industries dealing with naturally occurring radioactive materials (NORM), some of them without knowing that their industrial processes and/or their regular wastes involve radioactivity. However, an increasing number of industries that produce NORM wastes are being sued, wherever there is a legal framework to do so. In particular, NORM wastes produced for a long time by the oil industry became foci of legal battles in the United States and elsewhere. The ripple effect of these judicial battles will influence the decision making processes of NORM wastes producing industries, mostly because of the costs incurred by remedial and preventive actions concerning NORM contamination. The regulation of NORM will occur sooner or later, and such actions may become mandatory. A foreseeable consequence of such regulation is a change in attitude concerning the sources and materials associated with NORM. Among those industries likely to be affected one can mention: niobium; rare earth processing; oil production; phosphate; uranium mining and milling; zircon; water treatment; and waste water treatment. The paper will briefly review data on exempt concentration activities, as suggested by the Basic Safety Standards based on realistic environmental and dosimetric models. These activity concentrations are compared with those found in a number of extractive industries, and may be used to establish derived limits from a pre-established dose limit.

INTRODUCTION

When one reads sections **1.4** (14) and (15) of the 1990 Recommendations of the International Commission on Radiological Protection, better known as ICRP Publication 60 (1), one can reasonably interpret that, according with the ICRP, the main goal of radiation protection is to protect human beings from unnecessary exposure by establishing standard of protection which takes into proper account the beneficial aspects of the practices leading to radiation exposure. In addition, there is concern with the environment to the extent that transfer of radionuclides through environmental compartments may affect the radiological protection of humans. In so being, the practices leading to releases of naturally occurring radioactive materias (NORM) into the environment can be easily justifiable, by and large, from the view point of taking into proper account the beneficial aspects of most such practices. However, because one needs to be concerned with the environment in which NORM releases may affect the radiological protection of humans, one cannot just ignore such releases.

A number of well respected international organizations — the Food and Agriculture Organization (FAO), the International Atomic Energy Agency (IAEA), the International Labour Organization (ILO), the Nuclear Energy Agency of the Organization for Economic Co-operation and Development (OECD/NEA), the Pan American Health Organization (PAHO) and the World Health Organization (WHO) — recently sponsored the International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources (BSS) (2). The BSS was approved by the IAEA's Board of Governors in 1994. The NORM issue was not specifically contemplated in the BSS, however, exempt activity concentrations and exempt activities of radionuclides were established based on the following general principles (2,3):

"(a) the *radiation risks* to individuals caused by the *exempted practice* or *source* be sufficiently low as to be of no regulatory concern;

(b) the collective radiological impact of the *exempted practice* or *source* be sufficiently low as not to warrant regulatory control under the prevailing circumstances; and

(c) the *exempted practices* and *sources* be inherently safe, with no appreciable likelihood of scenarios that could lead to a failure to meet the criteria in (a) and (b)."

Table 1 lists the exempt activitiy concentrations established in the BSS for ^{222}Rn (plus ^{218}Po, ^{214}Pb, ^{214}Bi, ^{214}Po), ^{224}Ra (plus ^{220}Rn, ^{216}Po, ^{212}Pb, ^{208}Tl -36%-, ^{212}Po -64%), ^{226}Ra (plus ^{222}Rn, ^{218}Po, ^{214}Pb, ^{214}Bi, ^{214}Po, ^{210}Pb, ^{210}Po, ^{210}Pb), ^{228}Ra (plus ^{228}Ac), ^{228}Th (plus ^{224}Ra, ^{220}Rn, ^{216}Po, ^{212}Pb, ^{208}Tl - 36%-, ^{212}Po -64%), Th-nat (including ^{232}Th and progeny), ^{230}U (plus ^{226}Ra, ^{222}Rn, ^{218}Po, ^{214}Po), and U-nat (including the ^{238}U progeny), which are the most relevant radionuclides in the case of NORM releases, and activity concentrations found in some selected extractive industries..

Table 1. Exempt activity concentrations for the most relevant radionuclides (plus their progeny) in the case of NORM releases, as established in the Basic Safety Standards and activity concentrations found in selected extractive industries.

RADIONUCLIDE	ACTIVITY CONCENTRATION (kBq/kg)	
	Exempt (3)*	Extractive industries
Rn-222	10	
Ra-224	10	
Ra-226	10	2.7 (zircon sand - 4) — 658 (radioactive scale - 5)
Ra-228	10	368 (radioactive scale - 6)
Th-228	1	1.1 (zircon sand - 4) — 200 (radioactive scale - 6)
Th-natural	1	0.7 — 111(zircon sand - 4,7)
U-230	10	
U-natural	1	3 — 30 (zircon sand - 4,7)

*Reference numbers are within parenthesis.

EXTRACTIVE INDUSTRIES

As an anticipated consequence of the 1991 ICRP recommendations (1) and the adoption by national authorities of any one version of the rules suggested in the BSS (2) , many extractive industries will have to adjust their practices to more stringent limits to take care of NORM releases and the exposure of individuals in the workplace. The heavy fraction of rutile, ilmenite, zircon or monazite rich mineral sands usually have high ^{232}Th and ^{238}U, resulting not only in exposure of individuals in the workplace, but also in NORM releases.

The radioactive scales in oilfield tubulars can be considered unwanted byproducts of some operations in the petroleum industry. The concentration levels found in some radioactive scales can be much higher than the exempt activity concentrations listed in Table 1. As an example, ^{226}Ra and ^{228}Ra activity concentrations as high as 1 x 10^3 kBq/kg have been reported in the literature (5,6,8,9). Inhalation of ^{222}Rn and ^{220}Rn plus exposure to other alpha emitting natural radionuclides occur in

workplaces of the petroleum industries, as well as discharge into the environment of huge amounts of NORM wastes.

The phosphate fertilizer industry is another example of industry that produce NORM with enriched levels of ^{238}U and ^{226}Ra (10,11). Exposure of individuals in the workplace and environmental effects due to NORM occur also in the phosphate fertilizer industry.

There are many other industries that produce NORM wastes and expose individuals in the workplace. In some cases the exposed individuals and their managers are unaware of NORM . Radiation protection needs to be urgently implemented in such places. Because litigation tends sometimes to precede regulation strict liability claims concerning NORM have been on trial in the United States

CONCLUSIONS

1. The BSS does not contemplate the NORM issue directly, but can be used as a guidance for establishing rules to be adopted at national and international levels.
2. Individual exposure in the workplace and environmental effects resulting from NORM should be taken into proper account by the international radiation protection community.
3. The license of an extractive industry containing NORM should contain radiation protection and radioactive waste management plans to be approved based on well established rules adopted by the competent national authority.

MAJOR SCIENTIFIC TOPIC NUMBER 5.6. (see page 7)

ABSTRACT (See instructions overleaf)

In 1990 we got the order from the Bavarian Government to carry out a research project with the title "Man-Modified Materials Containing Natural Radionuclides". First of all, there had to be found exposure pathways, which are relevant in Bavaria, regarding to the radiation exposure of population and working persons. By means of a literature study and own calculations, we found relevant subjects and proposed to investigate them more intensively [1]. One of these topics was the handling with thoriated tungsten welding rods.

The properties of the tungsten rods are improved through the addition of radioactive thorium. In 1991 - 1993, as well as in 1995, we investigated the radiation exposure by handling with thoriated tungsten welding rods. We investigated the different exposure pathways and determined the spezific activity in dependence to the different types of welding rods. By carrying out surveys with the users, we determined the exposure pathways for the individual exposed persons: TIG-"hand-welders", TIG "machine-welders", labourers, other persons. We measured the activity concentration of the breathing air while welding, at grinding the electrodes and by staying in the rooms where usually it's welded. The size distribution of the aerosol-attached activity was determined with cascade impactors. The main emphasis was the comparison of the different sampling systems at the measuring of the activity concentration of the breathing air.

For the various exposed persons, at the extern irradiation with gamma- and beta-radiation and the inhalation of radioactive aerosoles, the radiation exposure was calculated by means of experimentelly determined data. And so, a maximum dose about 20 mSv per year was estimated.

THORIUM EXPOSURE DURING WELDING AND GRINDING WITH THORIATED TUNGSTEN ELECTRODES

T. Ludwig, G. Seitz

Berufsgenossenschaft der Feinmechanik und Elektrotechnik, Köln, Germany

ABSTRACT

Applying Tungsten Inert Gas (TIG) shielded welding process, often thoriated tungsten electrodes are used. Thorium is added to facilitate arc starting and to increase the arc's stability. If the electrode is touched down on the workpiece - not standing for a proper use but not always to avoid - a part of it will be vaporised. In the course of this, Thorium will be emitted. Only a sharp electrode will guaranty the wanted quality. Therefore the welder had to grind the electrode from time to time, also emitting Thorium in breathable form.
The presented contribution gives an overview about the results of numerous personal measurements of airborne activity concentration during grinding and welding.
Under proper use of thoriated electrodes at welding airborne activity (Th-232) of up to 2.6 mBq/m³ were found. This leads to an maximum annual body burden of 1.5 Bq. This is far below the limits of German regulations of non radiation workers. During grinding activity concentrations up to 0.5 Bq/m³ were measured. Even taking realistic annual working time into account limit may be exceeded. Radiation protection measures are to be enhanced, suggestions are made.

MATERIALS AND METHODS

Breath samplings had been taken in 19 plants under realistic conditions. Samplings during grinding were taken near breath openings of the patient (fig. 1/2). For the welding measurements a modified protective shield had been used, so that samplings could be taken beyond the shield in welders breath area (fig. 3). With the known volume rate and the sampling time the sampled volume could be calculated.

Fig. 1: Dust sampling during grinding

Fig. 2: Personal dust sampler

Fig. 3: Dust sampling during welding

ANALYSING FILTER SAMPLINGS

Expecting enough activity on that samplings, taken during grinding, these filter samplings were analysed by direct alpha spectrometry. The detection limit of this method (10 mBq Th-232 per Filter) was low enough therefore. These samplings were analysed by BIA.[1)]

The total activity on the welding filter samplings were far below the detection limit of alpha spectrometry. Therefore these samplings were analysed by gamma spectrometry after neutron activation. With this method a detection limit of about 0.1 mBq Th-232 per filter could be reached.

RESULTS

In table 1 the results of welding measurements are presented. The mean value (without measurement no. 1) of activity concentration is about 0.5 mBq/m³. The result of measurement no. 1 does not fit the other values. In this case, the welder continual touched down the electrode on the workpiece not in proper use.

The average of yearly inhaled activity by welding - based on realistic working time in the involved plants - is nearly 500 mBq/y.

measure no.	working time per year [h]	volume (m³)	Th-232 activity per filter (mBq)	activity concentration mBq/m³	yearly inhaled activity (Bq/a)

Tab. 1: Results of measurements during welding with thoriated tungsten electrodes

Table 2 shows the preliminary results - for the influence of some parameters the discussion is still going on - of the measurements during grinding the electrodes. The alpha spectrometry analyses shows, that the Th-230 activity of the used electrodes was clear below 20 % of the Th-232 activity.

In most cases no technical ventilation is used on the wheel stand. The mean value of inhaled activity per single grinding is 4.5 mBq (measurement no. 3 and no. 19 omitted).

Tab. 2: Selected results of measurements during grinding of thoriated tungsten electrodes, no. 3 and no. 19 were sampled with technical ventilation in use, all others without ventilation

DISCUSSION

Welding: While recently a possible hazard through inhaled Thorium during welding is reported [1], this mesurements seem to confirm with other literature [2,3] which show Thorium exposure during welding well below of the anual limit of intake. The estimated maximum value of yearly inhaled activity (1.5 Bq/y) is below the German limit for non radiation workers (6 Bq/y). Of course a longer yearly welding time could lead to an exposure reaching the limit. Improper use of the electrodes (measurement no. 1) could exceed the limit. So the ALARA principle should taken into account and the possible incorporation should be reduced through technical ventilation during welding.

Grinding: Two of the grinding results are above the limit. With the determined average value of inhaled activity per grinding (4.5 mBq) more than 1350 grindings per year - corresponding to 6 grindings per day - could lead to an intake above the limit. Especially if one person grinds the electrodes for a number of welders (case no. 19 e. g.) this could be a problem if no technical ventilation is used.

For grinding thoriated tungsten electrodes the use of technical ventilation on the wheel stand is therefore always recommended. When cleaning the waste box of the wheel stand, breath protective equipment should be used.

ACKNOWLEDGEMENTS

The authors would like to thank the involved industrial injuries insurance institutes, the Norddeutsche Metall BG and the Maschinenbau und Metall BG for additional samplings. They also are grateful to the BIA for alpha spectrometry measurements of the grinding samplings.

A TWO YEAR STUDY OF NORM LEVELS IN THE FACILITIES OF A MAJOR MALAYSIAN OIL AND GAS EXPLORATION AND PRODUCTION COMPANY

D.A. Bradley
Asia Lab (M) Sdn Bhd, No 6, Jalan 4/91, Taman Shamelin Perkasa,
56100 Kuala Lumpur, Malaysia

ABSTRACT

Four comprehensive surveys of offshore and onshore facilities of a major Malaysian Oil and Gas E and P Company have been completed in the two year period since March 1993. Data include measurements of external gamma doserate, surface contamination, Rn and Tn progeny levels, particulate radioactivity in ambient air and radium in liquid effluent and sludge. Monitored quantities have yielded values which are for the most part in accord with those of undisturbed environments although limited occurrence of elevation of doserate, and of radium concentration in sludge have been observed. In the latter instance measured concentrations of ^{226}Ra and ^{228}Ac have been within values of less than 1Bq g^{-1}, being in general very much less than this. Comparison with reported oil and gas facility NORM levels in other parts of the world indicate present levels to be relatively low.

INTRODUCTION

The Malaysian Atomic Energy Licencing Board (AELB) have developed radiological monitoring guidelines in response to an established potential for inadvertent technological enhancement of Naturally Occurring Radioactive Material (NORM) in oil and gas facilities (1-12). AELB document LEM/TEK/30 (1) calls for establishment of oil and gas baseline data for a wide range of radiological parameters, also listing conservative levels above which AELB notification is required. These parameters and notification levels, comprise of external gamma doserate (0.5μSv h^{-1} inclusive of background), surface contamination (0.04 Bq cm^{-2} for alpha emissions, 0.04 Bq cm^{-2} for other emissions), Rn and Tn progeny levels (0.01WL and 0.02WL respectively), airborne ^{238}U, ^{232}Th, ^{226}Ra, ^{228}Ac and gross alpha and beta contaminants in dusty working environments (0.01 Bq m^{-3} for ^{238}U, 0.002 Bq m^{-3} for ^{232}Th, notification levels not specified for other parameters) and in addition the monitoring of total specific activity (TSA) of scale and sludge (0.1 Bq g^{-1} above prevailing background). As with regulatory authorities elsewhere (5) the AELB requires TSA to be quoted assuming secular equilibrium, viz TSA = (6 x specific activity of ^{226}Ra) + (8 x specific activity of ^{228}Ac), ^{226}Ra and ^{228}Ac characterising the presence of ^{226}Ra and ^{228}Ra progeny in the ^{238}U and ^{232}Th chains respectively. The associated gamma emissions of ^{226}Ra and ^{228}Ac are generally of sufficient prominence to facilitate their detection. Note that account is only taken of those progeny contributing significantly to the total activity following the elapse of several half-lives. Present results are from the accumulated data of an on-going comprehensive study of the facilities of a major Malaysian Oil and Gas E and P company. The results have been obtained over a period of two years (March 1993 to April 1995) and are associated with the routine operations of oil production.The study comprised of four separate surveys, each of three months duration, with two monitoring exercises per year, these being conducted in the second and fourth quarters. The even spacing of surveys provided for the elucidation of possible trends in recorded values of the parameters.

METHODS

The currently reported study encompassed 9 installations sited off the east coast of Peninsular Malaysia and 57 installations sited off the coasts of Sabah and Sarawak. Also included in the study were two Peninsular Malaysia onshore installations (one gas terminal and one supply base) and two East Malaysian onshore installations (one crude oil terminal and one supply base). None of the offshore platforms currently surveyed use injected seawater for artificial lift. This is relevant since incompatibility between the chemistry of injected seawater and formation water is known to promote deposition of NORM throughout the process line. The measuring equipment used in the conduct of these surveys comprised of: (i) field equipment which allowed *in situ* assessments and; (ii) laboratory-based facilities for gamma spectrometry and gross alpha and beta analyses. Table 1 lists the main items of equipment and the lower limits of detection typically achievable using standard practices for the levels which prevail.

RESULTS AND DISCUSSION

For many of the parameters a significant fraction of monitorings have been found to be within background. As an example, from a total of 3509 surface contamination measurements performed in areas where production fluids potentially come into contact with exterior surfaces (eg in vicinity of metering packages, launchers and receivers) less than 10 measurements were statistically above background (eight at the limit of detection, one at a value of between 0.04 - 0.05 Bq cm^{-2} and one at the level of 0.40 - 0.41 Bq cm^{-2}). Similar findings have been obtained for Rn and Tn progeny. For parameters with sufficient numbers of data recording above minimum detection levels the associated distributions display a strong positive skew best characterised by geometric means and geometric standard deviations. Particular examples are *in situ* measurements and TLD evaluations of external gross gamma doserate (Figures 1 and

2 respectively). The broader distribution of values observed for TLD evaluations was due to the positioning of TLD chips (3 chips per packet) at points which *in situ* measurements indicated to provide elevations of prevailing background (eg at the base of first stage separators). Elevation of above twice background were of highly limited occurrence. Figure 3 provides results for gross β levels measured in air, displaying the characteristic positive skew and indicating the majority of measurements to be below minimum detectable activities (11). Figure 4 shows the distribution of TSA in sludge, computed from measured values of ^{226}Ra and ^{228}Ac (each being less than 1Bq g^{-1}) as discussed above. A significant fraction of the samples of sludge indicated TSA's of below 1.0 Bq g^{-1} while more than 95% of the sludge samples showed levels in excess of the conservative AELB notification level of 0.1 Bq g^{-1}. Present results indicate considerable consistency with lower or typical values for routine operations in other parts of the world, including the North Sea, USA, Italy, Tunisia and the Congo (2,3,6), being much lower than the upper range values quoted for doserates, and for radium activities in scale, sludge and other precipitates. The majority of presently reported data are either consistent with prevailing levels of the undisturbed local environment or represent subtle elevations from this. No current evidence exists for the presence of trends in any of the monitored parameters. Current data provide a firm basis from which future changes might be identified. The results of this study add to a more extensive survey currently being conducted by this E and P Company.

RADIATION PROTECTION IN THE OFFSHORE PETROLEUM INDUSTRY

Jiri Kvasnicka

Radiation Dosimetry Systems
7 Stewart Court, Leanyer, N.T. 0812
Darwin, Australia

ABSTRACT

Radium and barium are normally dissolved in the formation water of oil reservoirs. After sea water, which contains sulfates, is injected to the reservoir to maintain production pressure radium can precipitate with barium as barium(radium)sulfate (1). This salt plates out on internal surfaces of pipes, valves and vessels and highly radioactive scale is formed. The specific activity of ^{226}Ra and ^{228}Ra in scale formed on some internal surfaces of an offshore oil production facility was measured as 250,000 Bq/kg and 300,000 Bq/kg respectively. About ten times lower specific activity of radium was measured in sludge. Naturally occurring radioactive materials in petroleum facilities are referred to as NORMs. To manage occupational radiation exposures contaminated pipes and vessels were visibly marked, all personnel on the facility attend regular training and a radiation protection monitoring program was implemented. Even though the external dose rate on external surfaces of some pipes and vessels contaminated with scale already reached 60 μSv/h it was possible to manage the maximum personal annual effective dose equivalent below 1 mSv. During shutdowns external dose rates inside contaminated vessels may reach more than 150 μSv/h and the potential alpha energy concentration of radon and thoron daughters in non-ventilated vessels may reach several WLs. Therefore, all entries of vessels contaminated by scale and protection of employees must be planned and breathing protection provided in order to keep personal doses at low levels. The paper summarized practical experience in assessment of personal doses and management of personal exposures which involve job planning and exposure scenario modelling.

INTRODUCTION

Specific activities of natural radionuclides in some NORMs may be extremely high and their build up increases with the depletion of oil in the reservoir. Therefore, the following exposure pathways are considered: a) External exposures due to radionuclides in pipes, valves and vessels containing radioactive scale, sand and sludge and external exposures inside vessels; b) Internal exposures to inhaled particles of resuspended scale; and c) Internal exposures to inhaled radon and thoron daughters inside vessels.

It early stages of NORMs build up operational occupational radiation exposures are below the public limit of 1 mSv per year. To estimate such a low average annual occupational effective dose equivalent requires to use a combination of experimental and modelling assessments methods which are similar to assessment methods used in the uranium industry.

EXTERNAL EXPOSURES

Occupational external exposures in the petroleum industry are mainly due to external gamma-rays of short-lived decay products of ^{228}Ra and ^{226}Ra which are contained in scale,

sludge and sand (Table 1). The exposure rate at surfaces of pipes and vessels, which internal surfaces are in contact with a mixture of oil and water or in contact with the produced water, were measured as high as 8 mR/h. Considering that NORMs are under normal operational conditions confined inside pipes, valves and at the bottom of vessels the external exposure rate decreases sharply with the distance from relatively small but intensive sources of radiation.

Table 1

Specific activities, a (kBq kg^{-1}), of natural radionuclides in samples of scale, sludge and sand from an off-shore oil producing facility

Sample description	Specific activity (kBq kg^{-1})					
	^{238}U	^{226}Ra	^{210}Pb	^{232}Th	^{228}Th	^{228}Ra
Scale	0.5	250	12	0.5	25	300
Sludge	-	25.0	-	-	2.6	29.5
Sand	-	8.9	0.06	-	2.28	9.60
Sand	-	0.75	-	-	0.20	0.85

Radioactive barium(radium)sulfate scale is a very brittle material. During shut downs when pipes and vessels are empty and the temperature drops scale cracks and peals from pipes surfaces. Subsequently, scale debris often cumulate in large quantities inside oil separators where the external dose rate was measured in excess of 150 μSv/h.

INTERNAL EXPOSURES

The most important radionuclides from internal dosimetry point of view, which are present in radioactive scale, sludge and sand in more significant activities, are ^{228}Th, ^{228}Ra, ^{226}Ra and ^{210}Pb. Internal exposures due to inhalation of airborne radioactive dust containing these radionuclides and due to inhalation of decay products of both radon isotopes had to be considered to cover potentially the most important occupational exposure scenarios. The effective dose equivalents per unit activity intake are presented for NORMs with several activity mean aerodynamic diameters (AMADs) in Table 2 (2). Considering that the specific radium activity in scale is about thirty times higher than the specific activity of material in Table 2 the effective dose equivalent of 1 mSv is equivalent to inhalation of approximately 300 mg of fine scale particles.

Table 2

The effective dose equivalent per unit activity intake, $h_{50,dust}$ (mSv Bq^{-1}), and amounts, m (g mSv^{-1}), of inhaled NORM dust with the specific activity of 12000 Bq kg^{-1} of ^{228}Ra, 1000 Bq kg^{-1} of ^{228}Th, 10000 Bq kg^{-1} of ^{226}Ra and 1500 Bq kg^{-1} of ^{210}Pb that give the effective dose equivalent of 1 mSv as a function of AMAD

AMAD (μm)	$h_{50,dust}$ (mSv Bq^{-1})	m (g mSv^{-1})
1	0.0041	10.0
5	0.0033	12.4
10	0.0031	13.2
20	0.0026	15.7

Internal exposures due to inhalation of radon and thoron daughters are equally important as exposures to inhaled airborne scale particles. Even though the radon emanation coefficient of scale was measured to be very low (3.5%) (3) the potential alpha energy concentrations of both radon and thoron daughters may reach in non ventilated vessels several WLs.

PERSONAL EXPOSURE MANAGEMENT

Routine operations on offshore petroleum production facilities include only a few vessel entries per year and therefore personnel are exposed more frequently to external radiation than to inhaled radionuclides. To manage external exposures at low levels was achieved through periodic training of all personnel in radiation protection. All pipes and vessels, which contain NORMs, were marked and all personnel were instructed to plan routine procedures so the occupancy time and the distance from marked components are as low as practicable. Thus, it was possible to keep annual external exposures below 1 mSv. Vessel entries are planned and special work procedures are adopted. During entries of vessels contaminated by scale all personnel use respiratory protection (supplied air is used in vessels contaminated with scale), disposable overalls, rubber boots and rubber gloves. The external exposures of personnel involved in vessel entries are measured by electronic pocket dosimeters and vessels are ventilated.

Vessel ventilation is more important in large tanks contaminated by sludge where it is difficult to use supplied air. Modelling was used to estimate the effect of ventilation on the potential alpha energy concentration of radon and thoron daughters inside large tanks. Provided the air in a tank is replaced by the outside air five times per hour the original potential alpha energy concentration of radon daughters and thoron daughters is decreased by a factor of 240 times and 45 times respectively. The results of the computer modelling were supported experimentally.

CONCLUSIONS

It is very important to be aware that NORMs may be present in production components of offshore petroleum production facilities as personnel who are unaware of their existence will receive high external and internal doses which could exceed the annual limit of 20 mSv.

The NORM detection programs should be enforced by national regulatory bodies so radiation protection monitoring programs could be implemented soon after NORMs are detected. Such monitoring programs ought to be periodically reviewed as NORMs build up faster at the end of the life of oil reservoirs.

Provided the radiation protection monitoring program is implemented it is possible to manage personal radiation exposures in the offshore petroleum industry so personal doses are at low levels.

RADIATION SAFETY ASPECTS

IN THE OIL AND GAS PRODUCTION FACILITIES IN EGYPT

G.M. HASSIB

National Centre for Nuclear Safety and Radiation Control,
Atomic Energy Authority,
P.O. Box: 7551, Nasr City, Cairo, Egypt

ABSTRACT

The applications of radiation sources of various types in the oil and gas industry became an essential part in the prodution and expansion programmes in the production companies. Among these applications, oil well logging with gamma and neutron sources and tube weld radiography with gamma sources are well known.

On the other hand, naturally - occurring radioactive materials (NORM) have been detected in varying concentrations in hydrocarbon reservoirs in different areas of the world. Such materials may induce radioactive scales, sludges or gases in the production lines.

In this report, radiation safety guidelines are proposed to be implemented in the oil and gas production facilities in Egypt.

These guidelines are based mainly on the international safety standards such as the ICRP recommendations as well as the guidelines set by other countries of well recognized radiological health practices such as USA, UK and Europian Commnunity.

LEVELS OF RADIOACTIVITY IN GRIT BLASTING MATERIALS

Brian Heaton [1] and John Lambley [2]

[1] University of Aberdeen, Aberdeen AB9 2ZD
[2] ICI Tracerco, Aberdeen AB23 8GY

Introduction:

The problems of the build up of naturally occurring radioactive materials within the scales and silts accumulating in gas and oil production and processing plants are well known. (1) Whilst surveying for these materials it became apparent that very occasionally high survey readings were being produced which could not be associated with elevated levels in scales or silts in the plant being investigated. Further measurements established that the source of these elevated levels was in fact grit from recent cleaning operations which had not been properly cleaned away. It was therefore decided to look at the activity levels in grits more systematically to see if a real problem did or could exist.

Method:

Grits were obtained from a variety of commercial sources. In the UK. silica and sand are prohibited with regard to their use in blasting materials (ground quartz type rocks) Most industrialised countries have similar regulations UK (2), Belgium (3), Netherlands (4), France (5) and Germany (6)

Grits are therefore generally manufactured from slag from copper or steel processing, chilled iron particles or cast iron particles. The commercial name of some would however still indicate a direct mineral source. Unfortunately it was not always possible to obtain information as to which type a given sample was and chemical analysis results at this point are not available. Samples were subject to γ spectral analysis, generally in two centres to ensure reproducible results.

Results:

The results from the γ spectral analysis of the various samples are given in table 1.

Table 1. Activities in representative Grit Samples

Grit Number	Type of Grit	Ra-226 Bq/g	Ac-228 Bq/g	Cs-137 Bq/g	Am-241 Bq/g
1	Copper Slag	0.09 ± 0.02	0.01 ± 0.05	0.003 ± 0.001	0.003 ± 0.001
2	Cast Iron	less than 0.005	less than 0.005	less than 0.002	less than 0.002
3	Iron Slag	0.05 ± 0.02	less than 0.005	less than 0.002	less than 0.002
4		less than 0.03	0.05 ± 0.01	less than 0.003	less than 0.002
5		less than 0.05	0.10 ± 0.01	less than 0.002	less than 0.002

The samples which have been obtained from the slag arising from one of the refractory processes can all be seen to contain some of the naturally occurring nuclides. Only the activities of Radium 226 from the Uranium 238 series and Actinium 228 from the Thorium 232 series are recorded. Although measurements have not currently been made it is thought more than likely that these isotopes are in equilibrium with the respective parent radionuclides. The radionuclides lower down the series exhibited different levels of equilibrium. One sample can also be seen to contain very small amounts of both Cs-

137 and Am-241. This trapping of the natural and artificial radioactive cations by the slag is not surprising. Work carried out for other purposes shows that in practice slag is an exceedingly efficient method of fixing radionuclides and the results in table 2. show the ability of slag to trap the naturally occurring radionuclides present on scrap iron in radioactive barium sulphate scale. Over 95 % of the activity put into an electric arc furnace was trapped and immobilised into the slag produced (7). By varying the amount of slag produced it was possible to vary the activity per gramme indicating the an approximately uniform distribution was occurring.

Table 2. Uptake of Radium-226 and Actinium-228 (Radium-228) from scale contaminated iron melted in an induction furnace. From data provided by Clyde Shaw Ltd.

Melt Wt. kg	Input Ra-226 kBq	Activity Ac-228 kBq	Slag Wt. kg	Slag Ra-226 kBq	Activity Ac-228 kBq	Output Ra-226 kBq	Activity Ac-228 kBq
12,900	199	130	1310	0.15	0.11	197	138
9700	149	98	1820	0.10	0.05	182	91
8700	134	88	1320	0.12	0.03	158	40
5000	77	51	1620	0.08	0.03	130	49
4800	74	49	1540	0.08	0.03	123	46
6000	92	60	1700	0.08	0.03	136	51
6800	105	69	1500	0.08	0.03	120	45

Similar work carried out by Boynton and Lambley (8) and Gomer and Lambley (9) looking at the ability of slag to trap the radioactive cations on contaminated steel again showed that some of the cations present could be successfully moved into the slag leaving the now decontaminated steel behind. The technique removed virtually all the caesium isotopes into the slag, but the Cobalt-60 all went into the steel. From all the experiments, once the slag cooled the trapped cations were exceedingly stable and the leach rate was immeasurably small.

Discussion:

It would seem likely therefore that naturally occurring radionuclides present in the source ores or other materials present in the kiln are likely to be accumulated in the slag. Likewise many artificial radionuclides which deliberately or inadvertently find themselves in the furnace are also going to accumulate in the slag.

The activity levels at which the legislation in various countries classifies materials containing naturally occurring radioactivity as radioactive varies enormously. Some levels are given in table 3. As can be seen compared to the levels measured in the grit samples in most countries none of the grits would be considered as being radioactive. However in some the levels could be approached and in Germany the level for radium -226 would actually be exceeded by some of the grits measured.

Table 3. Brief Summary of some activity levels at which different countries consider material radioactive.

United Kingdom	0.37 Bq/g of Ra-226 (RSA 93) but under " Rare Earths" Exemption Order 14.8 Bq/g of Radium
Holland	100 Bq (total)/g
Germany	0.05 Bq/g for Ra-226
Malaysia	0.1 Bq/g (total)
Australia (South Australia)	35 Bq/g and 5 x 10^3 Bq (Ra-226)

The very use of the grits is going to produce an aerosol of fine powder. The people actually doing the blasting should be wearing sufficient protective equipment to ensure that the inhalation of the material is minimal. None of the levels measured approach the 10 Bq/g Radium-228 or 1 Bq/g Radium-226 levels the NRPB (10) recommend as operational level below which no one is likely to exceed a dose of above 1 mSv/y. Air monitoring measurements have not been made to confirm this.

Recommendations:

Our experience would indicate that non-slag type grits from smelting processes will not present any problems at all and can be used without any further tests being made. Copper or iron slag based grits may cause a problem depending on the national definition of what is classed as radioactive. Likewise mineral based grits may also cause a problem in some countries. If national limits are low then suitable analysis should be carried out on a representative sample of the grits prior to use. The levels of activity detected would indicate that the normal precautions taken during grit blasting operations are sufficient to ensure that no exposure limits for non-classified workers will ever be approached.

RESULTS OF DECOMMISSIONING WORK UNDERTAKEN AT THE RADIOMETALLURGIY LABORATORY OF THE CEA CENTRE IN FONTENAY-AUX-ROSES

C. Dieudonné,[1] F. Legée,[1] J. Llopis,[1]

[1] Commissariat à l'Énergie Atomique , Fontenay-aux-Roses, France

Since 1990, CEA has been undertaking decommissioning work of the radiometallurgy laboratory for plutonium based fuels at the Fontenay-aux-Roses centre, which has been operational since 1963

The protection survey put in place on the Centre's Radiation Protection Department has enable dosimetric figures to be produced for this decommisioning operation, which generates high doses.

The collective dose of the worksite amounted to 1772 men.mSv, which makes one of the major CEA decomissioning worksites.

Doses received whilst work was in progress came from two main sources (picture 1):

- work undertaken within cells, which generated the highest dose rates
- nuclear waste stored in the premises adjacent to the cells. These doses are called "passive doses"

The dosimetric indicators used by the Radiation Protection Department are presented for each year. In particular, these are collective doses for the whole worksite, average dose and the dose received by the most exposed employee (picture 1 and 2)

One notice a significant increase in activity in 1993 and 1994 (increase in terms of work force, collective dose and even average dose)

Besides the normal correlation between work force and overall dose, the increase in the average dose results from a high passive dose in the order of 30 μSv per day and per man, since irradiating waste couldn't be evacuated fast enough and was stored on the premises.

Picture 3 compares the average dose received per employee with that received if the passive dose for 1993 and 1994

A 60% reduction in the dose resulting from the use of remote control robots was assessed for an initially estimated dose of 300 men.mSv.

The expansion of ALARA initiative on such worksites has led to the use of remote-controlled equipment to decommission cells, automatic carriers to scrape floors and walls, cutting out internal cell protection panels by remote-control and γ-camera to make maps.

Evolution of the collective dose and the work force during work in progress

CLASSIFICATION OF WORKERS USING OPEN/SEALED SOURCES OF RADIOACTIVE MATERIALS

A G RICHARDS

Radiation Protection Service
The University of Leeds
LEEDS LS2 9JT

The finalisation of the European Directive on basic safety standards now means that member states of the EC must introduce legislation to implement the Directive. In the nuclear industry criteria for classification of areas could be related to the Annual Dose receive by workers in the industry.

In research laboratories, and hospital and higher education research laboratories the doses measured by workers are of the order of 2mSv per year. Therefore criteria (based on a different parameter) than dose received, needs to be considered.

The International Commission Radiological Protection[1] uses two designation of areas, controlled and supervised. Supervised areas require less administrative control but some control is necessary to ensure the doses outside the boundary are suitable for members of the general public. The ICRP in publication 68[2] recommends the use of dose coefficients e(50) which corresponds to the committed effective does E(50) resulting from an intake of 1Bq of the radionuclide.

For internal exposure it is recommended that the Annual Limit on intake should be based on a committed effective dose of 20mSv

so $$ALI = \frac{0.02}{e(50)}$$

Designation of Workers Using Open Sources

Most of the establishments above tend to designated the area and then classify the worker accordingly. Contamination is rarely present and some indication of the activity which could be handled in a supervised area would help the administrative requirements and help also to remove anomalies different establishments.

Previous papers[3] have indicated that of the total activity handled, allowing for some difference in volatilities, that of the total activity handled the fraction inhaled.

Hence allowing a factor of 3/10 for non classified workers.

Activity handled $= 10^4 \times 3/10 \text{ ALI} = 3 \times 10^3 \text{ ALI}$

$$= 3 \times 10^3 \frac{0.02}{e(50)}$$

$$= \frac{60}{e(50)}$$

where e(50) = dose coefficient

Using the dose coefficients given in ICRP8 to derive the ALI for inhalation. The table indicates the activity which may be handled, before the need for imposing greater administrative controls.

	Activity Handled Bq	e(50)	ALI Bq
$^{3}H_20$	3.3×10^{12}	1.8E-11	1.1×10^{9}
$^{3}H(OBT)$†	1.4×10^{12}	4.IE-11	4.8×10^{8}
$^{14}C_{dioxide}$	9.3×10^{12}	6.5E-12	3.1×10^{9}
^{32}P	7.5×10^{10}	8.0E-10	2.5×10^{7}
^{33}P	6.3×10^{11}	9.6E-11	2.1×10^{8}
^{35}S(vapour)	5.0×10^{11}	1.2E-10	1.7×10^{8}
^{125}I(vapour)	1.1×10^{10}	5.3E-09	3.8×10^{6}

* Dose due to the activity not absorbed through the skin is not included
† gaseous form

The administrative controls which can be relaxed include the use of Approved Dosimetry Services (UK)[4] for dosimetry purposes, rigid laboratory procedures and regulations relating to movement of radiation workers between member states[5,6].

Use of one or more radionuclide.

The activity handled would need to be reduced if more than one radionuclide is used. This is frequently the case in the type of laboratory referred to above.

The activity handled of each radionuclide can be derived quite simply by estimating the fraction of the ALI to be used.

		activity handled
^{32}P	1/10 ALI	7.5×10^{9}
^{35}S	1/5 ALI	1.0×10^{11}
^{3}H	7.10 ALI	1.0×10^{12}

Figure 2 Activities Handled in Multiple Use

The sum of the ALI's must not be greater than 1.

In the case of radionuclides with a high beta, or gamma dose rate it may be necessary to use additional shielding to reduce the workers occupational exposure. This may be a limiting factor in the activity handled.

External Exposure

The revised European Directive[7] will probably set a level of 6mSv above which workers should be designated as Category A or classified workers under UK legislation. Existing UK legislation[8] sets a dose rate of $7.5 mSvh^{-1}$ as the level above which a worker should normally be classified. The use of a time average dose rate over an 8 hour period, so as not to exceed $7.5 \mu Svh^{-1}$, allows some flexibility.

If the new European Legislation requires the designation level to be set at $6mSvy^{-1}$ corresponding to $3\mu Svh^{-1}$ the time average dose rate could be changed to $100\mu Sv$ over a 40 hour period. This would then give an average dose rate of $2.5\mu Svh^{-1}$ which would satisfy a 6mSV designation level.

This would also help reduce the potential for over classification using open sources as discussed earlier.

Conclusion

The classification of workers using open sources need to be considered in the implementation of the Directive the above could use.

EVALUATION OF THE ENVIRONMENTAL DOSE AND THE ^{131}I CONCENTRATION IN A LABORATORY OF RADIOACTIVE MATERIALS PRODUCTION

Juan Azorín[1] and Jesús de la Torre[2]

[1]Universidad Autónoma Metropolitana-Iztapalapa, México, D.F. 09340, Mexico,
[2]Instituto Nacional de Investigaciones Nucleares, Salazar, Mex. 52045, Mexico

INTRODUCTION

Among the radioactive materials produced at the Department of Radioactive Materials Production of Instituto Nacional de Investigaciones Nucleares to be used in nuclear diagnosis and therapy in Mexico, ^{131}I which emits approximately equal numbers of medium-energy beta particles and gamma rays, has special importance notwithstanding its short half-life due its affinity with vital glands (1). Therefore, the air must be monitored because significant levels of airborne contaminators can occur in working areas (2).

In this laboratory there are working 10 workers making the dilution of $Na^{131}I$ to be used in Nuclear Medicine for medical examination and treatment of thyroid condition.

The aim of this work is to determine the ^{131}I annual incorporation levels as well as the personal and environmental dosimetry in the working area. Concentration of ^{131}I in the laboratory of radioactive materials production atmosphere and the absorbed dose produced for this concentration are determined. External dosimetry both personal and environmental were obtained with locally made thermoluminescent dosimeters.

PERSONAL MONITORING

a) Air monitoring for intake.

The inhalation route of the personal subject to potential intake of ^{131}I was monitored at the breathing zone (3). This was done with personal air samplers Victoreen 08-430 consisting of a charcoal filter and a small battery-driven pump that draws air though it. The filter was fastened to the lapel of the worker's lab coat to be located near the breathing zone. The pump were operated at a pumping rate of 6.99 liters /min.

Air samplers were used by the workers along six months. Filters were evaluated every day at the end of the work's day by means of gamma spectroscopy considering sampling times in the range of 120 to 150 minutes. Iodine-131 concentration was determined at room temperature (20°C) and at atmospheric pressure of 532 mmHg.

Radioactive concentration (Bq/liter) of ^{131}I was evaluated by means of gamma spectroscopy of the filters by dividing the net counts (counts - background) by the product of the detector efficiency (counts/gamma-ray) by the counting time (s) and by the sample volume (liters) (4):

$$C = \frac{counts - background}{E\, t_c\, Y\, V_c}$$

Dose equivalent values were calculated by multiplying the ICRP dose conversion factor, 2.9×10^{-4} mSv/Bq, by the air derived concentration in Bq/m^3, and by the volume of air breathed in over the working period under conditions of "light activity", 1.2 m^3/h x 5 h (5). In equation form this is expressed as follows:

$$D(mSv) = ADC(Bq/m^3) x 1.2(m^3/h) x 5(h) x 2.9 x 10^{-4}(mSv/Bq)$$

b) External dosimetry

Personal monitoring of the workers was performed using locally made thermoluminescence dosimenters. Personal dosimeters were constituted by four LiF:Mg,Ti+PTFE pellets placed in plastic badges of the thickness required to fulfil electronic equilibrium conditions. Monitoring devices were worn on the trunk, between waist and shoulder level at the site of the highest exposure level to which the body is subjected. Personal thermoluminescence dosimeters were worn by the workers for a month between changes because the risk of excessive exposure is low.

Environmental monitoring of the working area was performed using $CaSO_4$:Dy+PTFE locally made thermoluminescence dosimeters. Environmental dosimeters were placed at 1.60 m floor level to be exposed along one month.

Thermoluminescence readings were made in a Harshaw 4000 TL analyzer at a heating rate of 10°C/s integrating the signal from 30°C to 300°C during 30 seconds. All readings were made in N_2 atmosphere.

Previous to be used and reused, the dosimeters were submitted to an specific thermal annealing. Thermal annealing consisted in heating at 400°C during 1 hour followed by 100°C during two hours for LiF dosimeters and 300°C during 30 minutes for $CaSO_4$ dosimeters.

Doses were evaluated interpolating in a calibration curve previously elaborated by irradiating a batch of dosimeters at given doses using a Victoreen 64-764 (12.79 GBq) ^{137}Cs irradiator.

RESULTS AND DISCUSSION

Results showed that ^{131}I derived air concentrations received by occupationally exposed personal and the absorbed doses resulting from these concentrations were lower than the limit established by the ICRP, except that obtained for a worker, labouring during two months at the radiopharmaceuticals packing area, which received a dose three fold the established limit.

Personal dosimetry revealed that two workers received an absorbed dose two fold higher than the limit due that these workers were labouring at the radiopharmaceutical packing area.

Environmental monitoring results showed that two points, located at the packing area and at the labelled radiopharmaceuticals area, registered radiation levels 5 times higher than the typical environmental values.

CONCLUSIONS

These results suggested that the hot cells in the radiopharmaceuticals packing area could have any radiation leakage which was corrected immediately reducing these radiation levels until admissible values. However, these areas must be classified as controlled areas.

ACKNOWLEDGEMENTS

The authors express their gratitude to E. Quintero of Environmental Radiation Protection Laboratory, ININ for her technical assistance in the gamma spectroscopy measurements and to J. Lezama of Radioactive Materials Production Department, ININ for providing facilities to make the field measurements.

The on-line operationnal dosimetry of workers as a key issue for neutron radioprotection optimisation.

J.Y. HERVE, J.M. ESCHENBRENNER, P. VALIER and J. CHEVALLIER
Commissariat à l'énergie atomique/VALDUC
21120 Is sur Tille (FRANCE).

Handling and processing of various chemical forms of Plutonium leads to neutron irradiation, for example due to (α,n) reactions. Under some circumstances, workers are therefore subject to occupationnal exposures.

Regulation regarding individual dosimetry is very stringent to implement. Furthermore, individual dosimetry is not well adapted for operationnal measurement because of the overwhelming response time, specially in case of on-line neutron monitoring on the spot. R.T.L. dosimetry , P.G.P.-D.I.N. type, carried out by differential measurements using ^{6}LiF and ^{7}LiF detectors, was the first achievement. Since then we have been using BD 100R bubble dosimeters. These detectors are located nearly the most critical work places as far as neutron radiation is concerned.

This paper deals with neutron characteristics of the different work places in term of spectrum and intensity. It focuses on bubble dosimeter operation : calibration, drift of the sensibility and reading frequency, function of reset operations, etc... Our main goal is to use in the near futur this dosimeter for the on-line monitoring of neutron. This approach will enable us to optimize the neutron doses delivered to the most critical work places and to make workers sensitive to health physics issues.

Preliminary results are reported as well as our health physics policy in respect to the A.L.A.R.A. principle.

RADIATION PROTECTION AT A RADWASTE TREATMENT AND STORAGE FACILITY IN THE NETHERLANDS

Jeroen Welbergen
COVRA, Vlissingen, The Netherlands

1 INTRODUCTION

Since 1984 the radioactive waste produced in the Netherlands is managed by COVRA, the Central Organisation for Radioactive Waste. This dedicated organisation has been set up as a joint venture between the three major radwaste producers in the country and the government.
All kinds of radwaste (LLW, ILW and HLW) that will be generated in the next 100 years will be treated and stored in an above ground facility.
At this moment COVRA's activities are collection, treatment and storage of LLW and ILW. The conditioned HLW is expected to arrive in the year 2001.
The treatment and storage facility for LLW and ILW is located in the south-west corner of the Netherlands near the town of Vlissingen (Flushing).
The construction of a storage building for HLW in Vlissingen will start in 1997.
The methods of radwaste treatment are chemical cleaning by means of a precipitation technique of liquids, incineration of organic liquids, supercompaction of solids, reducing large items and conditioning treated radwaste by cementation.
At this moment, in the storage facility there are approximately 20,000 drums of conditioned LLW stored with a total volume of 7500 m^3 and a total activity of 0,5 PBq. This waste has been collected in the period 1982 - 1995.
The new facility is in operation since 1992.
Radiation protection during 1992 - 1995 is quantified by monitoring the radiation during treatment and storage, dosimetry of the work preformed by radwaste workers and measuring radiation levels at the fence of the facility.
In the facility near Vlissingen there are some 45 employees working of which 30 are radiological worker.

1.1 Producers of radwaste

In the Netherlands the radwaste producers are research institutes, hospitals, ore-processing and manufacturing industry, and nuclear facilities (two nuclear power plants and two nuclear research reactors).
The annual amount of LLW produced by the users of radioactive materials in research, medicine and industry equals roughly the amount of ILW produced by the nuclear facilities. This amount is after treatment, conditioning and packaging some 500 m^3.

1.2 Radwaste management organisation and facilities

In general terms the task of COVRA is to manage all Dutch radwaste, in order to protect man and the environment against the hazardous effect that could be caused by this radwaste. This means more specifically:

- collection and shipment of radwaste
- treatment and conditioning of radwaste
- storage of all kinds and categories of conditioned radwaste
- conventional and radiological protection

- monitoring the radwaste before treatment
- monitoring the radwaste after conditioning
- monitoring the environmental impact of treatment and storage

2 ACCOUNTANCY OF RADWASTE TREATMENT AND RADIOLOGICAL ASPECTS

Before shipment an administrative and radiological control of the radwaste is preformed by radiation protection monitors (RPM's) of the Health Physics department of COVRA. These measurements are executed to check if there is compliance with COVRA's standards of LLW and ILW.
After shipment there is an extra administrative and radiological check of the radwaste at the receptionbay of COVRA and after agreement the radwaste is transported into a bufferstorageroom in the treatment building.
During treatment and storage of the radwaste there is a daily and a weekly program of monitoring preformed by the RPM's. They measure the doserate and the level of contamination in the treatment- and storage buildings.
The results of these measurements should be in accordance with the radiological zone classification of IAEA.
The emission of aerosols and gasses (α, ß, γ, SO_2, NO_2 and CO) in the ventilation air is accounted for by sampling and analyzing airfilters from the ventilation systems and the ventilation stack.
The emission of radioactivity in the wastewater is accounted for by analyzing the radionuclides and the emission of chemical substances (heavy metals, MAC, EOX and COD) in the treated wastewater.
The limits of emission in air per year permitted by the Dutch authorities are for α-emitting nuclids: $2.5*10^4$ Bq, for ß/γ-emitting nuclids: $2.5*10^{10}$ Bq, non-ionising gasses SO_2: 40 mg/Nm^3, NO_x: 70 mg/Nm^3 and CO: 50 mg/Nm^3.
The limits of emission in water per year permitted by the Dutch authorities are for α-emitting nuclids: $1.5*10^7$ Bq, for ß/γ-emitting nuclids: 10^{11} Bq, non-ionising heavy metals: 0,5 mg/l, MAC: 0,5 mg/l, EOX: 0,1 mg/l and COD: 1100 mg/l.
These limits were during the years 1992 - 1995 never exceeded.
The doserates at the fence of the COVRA-facility are monitored. These measurements are used for the accountancy of the dose caused by COVRA's activities. The contribution to the doses at the fence of the facility (figure 1) was in **1992** ; 0,01 μSv, in **1993** ; 6 μSv, in **1994** ; 8 μSv and in **1995** 6 μSv (**1991** is used as a referencepoint).
The radiological protection of the workers, contractors and visitors of the treatment and storage facility at COVRA are monitored by electronical dosimeters. The doses of the workers of COVRA are also monitored by thermoluminescence dosimeters (TLD). These TLD's are once a month controlled by an Approved Dosemetry Service and the results are reported back to COVRA and the results are also stored in a centralized databank system (NDRIS).
The collective doses of the radiological workers of COVRA in 1992 was 10,5 manmSv (32 man), in 1993 it was 7 manmSv, in 1994 it was 7 manmSv and in 1995 it was 16 manmSv (figure 2).
The collective doses of contractors in 1992 was 4,6 manmSv (3 man) and in 1993 it was 0,7 manmSv (3 man). COVRA made no use of contractors in the

period 1994 and 1995.
During the period 1993 - 1995 approximately 2000 people visited the facility and during those visits a personaldose of 6 μSv was never exceeded (mostly however 1 - 2 μSv).
The radiation protection during collection and transportation of radwaste from the producers is preformed by RPM's of the Health Physics department.
The operators are accompanied by a RPM during treatment and storage of radwaste. The RPM preforms the radiological measurements of the radwaste and is responsible for the radiation protection.
Persons leaving the controlled zone are controlled on α/ß contamination and on γ contamination.
A reading device for the electronical dosemeters gives the person a read-out of his personal dose collected during that day.
Twice a year the workers in the controlled zone of COVRA are informed by the radiation protection officer (RPO) of their personal dose .
The RPO is mandated by the license holder COVRA and is responsible for the radiation protection at COVRA.

METHODOLOGY FOR RISK ASSESSMENT FOR WORKERS HANDLING UNSEALED RADIOACTIVE SOURCES

T. Klaver, Y. Franken and Chr J. Huyskens

Centre for Radiation Protection, Eindhoven University of Technology,
P.O. Box 513, 5600 MB Eindhoven, The Netherlands

INTRODUCTION

Occupational handling of unsealed radioactive substances may result in internal or external contamination of the worker or in releases to the environment.
We developed a methodology for risk assessment for workers who handle unsealed sources and for the estimation of releases to the environment. Results of risk assessments are helpful to establish derived limits regarding the quantities of radioactive substances that can be handled within defined dose constraints, appropriate for the actual working scenarios.
This study is supported by the Dutch Department of Labour, with the special objective to develop constraints on the source activities in laboratory work and other fields of application. In this paper, we give some highlights of the study, focussed on the dose consequences for the worker.

MODEL ANALYSIS

In essence our study is concerned with the model analysis of the relationship between the quantities of the unsealed radioactive substances that are handled in a particular practice and the potential dose consequences for the workers. A major factor in this modelling is the description of the characteristics of these scenarios, in particular the working techniques, the physical and chemical properties of the material and the protective measures that are taken.
As regards the working conditions we distinguish regular working conditions, which indicate that the progress of work is as it was planned, and incidents that are perceived as small mishaps which can occur and for which it is reasonable to assume that they will occur every now and then.
The model analysis that we developed also provides the option to calculate dose consequences in accident situations. In accident situations, however, the dose consequences for the worker are not the only factor that should be considered. The probability of accidental events plays an important role as well. Therefore, the risk assessment for accidents is beyond the scope of this paper.

The dose consequence for the worker in terms of committed effective dose can be described as a function of the activity intake and the dose coefficient DC for the pathway under consideration. The intake can be described as the product of the source activity ACT and the fraction of this activity, which is transferred to the worker – the transfer fraction to the worker – TFW:

$$\text{DOSE CONSEQUENCES} = \text{INTAKE} \times \text{DC} = \text{TFW} \times \text{ACT} \times \text{DC}$$

From this expression, it is clear that the transfer fraction for the worker TFW is an unambiguous measure for the consequences for the worker. In principle, this transfer fraction should be determined for all relevant pathways. However, some pathways cannot be described in a simple way with a mathematical model. Furthermore, the practical importance of the various pathways is different. Exposure of the worker due to the air pathway can happen under normal working conditions and as a result of incidents or accidents. Exposure of the worker due to contamination of the skin, ingestion or injection is always an incident or accident.
Therefore, we developed a mathematical model for the air pathway. This mathematical model is based on a general algorithm that solves first order compartment models, including recycling. Our model makes calculations of transfer fractions possible, not only under regular working conditions

but for incident and accident scenarios as well. After calculating the transfer fractions for the air pathway, the other relevant pathways are judged retrospectively.

Restrictions to the activity of radioactive substances can be described in terms of restrictions to the product of activity and dose coefficient. In actual situations, an upper bound for this product (ACT × DC) can be derived from the dose constraint for a certain kind of practice.

$$TFW \times (ACT \times DC) \leq DOSE\ CONSTRAINT$$

The product (ACT × DC) is a very elegant way of describing the upper bound for the activity, because it is a measure for the 'radiotoxicity' of the activity handled. When the transfer fraction and the dose constaint are known, the product (ACT × DC) is the same for all radionuclides.

The transfer fraction and the dose constraint are different for regular working conditions and for incidents. If we want to derive guidelines for constraints of activity, it is necessary to choose a dose constraint for regular working conditions and for incidents. Developing dose constraints was not the objective of this study. However, the study can provide insight into the meaning of dose constraints.

The mutual difference in consequences for the worker in different scenarios can be expressed by the ratio of respective transfer fractions. Assuming that the consequences in a certain actual scenario A and in a so-called *reference scenario* R are identical, it follows that:

$$TFW_R \times (ACT \times DC)_R = TFW_A \times (ACT \times DC)_A$$

Once an upper bound of (ACT × DC) for the refence scenario has been derived (or chosen), the upper bound of (ACT × DC) in the actual scenario can be derived, assuming identical consequences for the reference scenario and the actual scenario:

$$(ACT \times DC)_A = \frac{(ACT \times DC)_R}{TFW_A / TFW_R}$$

The ratio of the transfer fractions TFW_A/TFW_R can be regarded as the correction factor needed to derive the upper bound of (ACT × DC) for the actual scenario.

RESULTS: ABSOLUTE MEANING OF TRANSFER FRACTIONS

We calculated transfer fractions for a variety of scenarios. In this paper, we present a summary of the results for a 'standard' laboratory. The results are given for working in a fume hood, for one month of regular working conditions and for the 'maximum reasonable incident', respectively.
The maximum reasonable incident is failure of the fume hood. The transfer fraction for one month of regular working conditions is calculated by multiplying the transfer fraction for a full working day by 20. The transfer fraction for the incident is calculated over a period of one hour after the incident.
From this summary of results it can be shown that the transfer fraction for the worker during one month of regular working conditions is always less than the transfer fraction for the maximum incident. Furthermore, it may be expected that the dose constraints for regular working conditions and for incidents, although numerically unequal, are in the same order of magnitude. Taking into account that it is prudent to assume that an incident will occur once a month for planning purposes, this means that the transfer fraction for the incident situation is dominant in the risk evaluation. Therefore, derived limits should be based on the incident circumstances. An adequate level of protection under regular working conditions then is implicitly guaranteed.

A very important conclusion from this study is that it is not effective to improve the ventilation qualities of a fume hood beyond a certain level. Provided that a certain level of protection by the fume hood is guaranteed, the upper bound of (ACT × DC) is determined by the incident situation, in which the fume hood is not working at all. On the other hand, it is advantageous to improve the operational safety of the fume hood in order to prevent incidents.

RESULTS: RELATIVE MEANING OF TRANSFER FRACTIONS

We compared the calculated transfer fractions for a number of actual scenarios (for working in a fume hood) to the transfer fraction in a chosen reference scenario. This ratio of transfer fractions can be taken as the correction factor TFW_A/TFW_R for determining the upper level of $(ACT \times DC)_A$ in the actual scenario, once the upper level of $(ACT \times DC)_R$ for the reference scenario is known.

The comparison refers to incidents, because the incident circumstances determine the maximum activity that can be handled in a certain scenario.

We have chosen the *handling of an aqueous solution in a fume hood in a standard laboratory* as the reference scenario.

SUMMARY OF RESULTS FOR WORKING IN A FUME HOOD IN A STANDARD LABORATORY

TFW – one month regular working conditions	*TFW – maximum incident*	*SCENARIO*	*TFW_A / TFW_R for incidents (rounded)*
4,6 E-3	1,4 E-1	Boiling of a volatile or an aqueous solution*	2000
4,4 E-3	8,1 E-2	Boiling of a moderately volatile solution*	1000
1,7 E-3	1,1 E-2	Working with very fine dust	150
4,4 E-5	1,4 E-3	Spattering processing of a volatile solution*	15
2,2 E-4	1,2 E-3	Gas or vapour in a holder or working with dust	15
4,4 E-5	8,1 E-4	Spattering processing of an aqueous solution*	10
4,4 E-6	1,4 E-4	Working with a volatile solution*	2
1,7 E-5	1,2 E-4	Spattering processing of a moderately volatile solution*	2
4,4 E-6	8,1 E-5	Working with an aqueous solution* (reference scenario)	1 (by definition)
1,7 E-6	1,2 E-5	Working with a moderately volatile solution*	0,2
4,4 E-7	8,1 E-6	Preparation of syringes with an aqueous solution*	0,1
2,2 E-9	1,2 E-8	Solution of a non-volatile material	0,0002

*It is assumed that the radionuclide in the solution is equally volatile as the solvent

OTHER IMPORTANT RESULTS

The methodology for calculating transfer fractions allows us to derive upper bounds for the activity handled, and not only for working in laboratories, but for other situations as well (nuclear medicine, working with animals, radionuclide production and other industrial applications).

The method provides an insight into the differences between the consequences of different working conditions, different physical properties of the material handled and different protective measures.

The methodology is also a useful tool in optimisation studies, because it can provide insight into the effect of additional protective measures (e.g. an extra containment).

The method also gives us an opportunity to derive transfer fractions to the environment for the air pathway. This makes it possible to derive upper levels of activity for unsealed radioactive sources, based on upper bounds for the emissions of activity.

RADIOACTIVE CONTAMINATION CONTROL PROGRAMS IN RADIOACTIVE INSTALLATIONS OF BIOLOGICAL RESEARCH

INTRODUCTION

Radioactive compounds are nowadays widely used in Biological Research. There is a great quantity of analytic radioisotopic techniques since they yield evident advantages like specificity, versatility and sensitivity in comparison with non radioactive protocols. Nevertheless, it is obvious that manipulation of radioactive unsealed sources may generate risks for exposed workers.

The aim of our work has been to evaluate the probability and incidence of several contamination types that can occur. In order to achieve this purpose, we have make an exhaustive analysis of the most common radioisotopic techniques (table I) used in our Research Centers. Also, we have taken into account physical characteristics and radiotoxicity of the radioisotopes used in such techniques.

Type of mollecule	Most Common techniques	Labeled compouns mainly used
Nucleic acids	Northern, Southern, "in situ" hybridization	nucleotids-^{32}P, -^{33}P
	Sequencing	nucleotids-^{35}S, -^{32}P, -^{33}P
	Activity RNA-polimerase based methods	nucleotids-^{32}P, -^{33}P
	Footprinting, bandshift	nucleotids-^{32}P, -^{33}P
	Activity of genetic promoters	chloramphenicol, acetyl CoA-^{14}C
	DNA synthesis	Thyimidine-^{3}H
Proteins	Western blot, radioimmunoassays	Na^{125}I
	Binding hormone-receptor assays	ligands-^{32}P, -^{35}S, -^{125}I, Na^{125}I

Table I: Radioisotopic techniques most commonly used in Biological Research

The main factors that we have considered in relation to the probability and incidence of possible contamination are: maximum activity used per assay (assays carry out "in vivo" or "in vitro"), physicochemical characteristics of radioactive compounds used, and of his main and residual compounds; technical complexity (manipulation type and equipment needed). This information has been quite useful to set up the contamination control program that we expose below.

MATERIALS AND METHODS

In order to determine contamination levels in the different techniques indicated below, we have performed the following measures:

-Surface contamination: surfaces and diverse material.

-Enviromental contamination: coal filter, coal samples used during the manipulation of volatile compounds (labeled with S-35 or I-125 and/or I-131), liquid effluents.

-Personal contamination: external (protection clothes and skin) and internal (these measures haven't been done because of not having the necessary resources).

The measuring time depends on the kind of equipment or surface to measure. The distance between the monitor and the surface or equipment has been about 1 cm.

In the radioisotopic techniques using P-32, I-131 and/or I-125 the measures have always been directly taken.

In the case of S-35, C-14 and P-33, the measures have been both direct and indirect, and always indirect measurement in case of H-3.

The equipments used in the direct measurements were:

-BERTHOLD:LB-122 and 123.

-ROTEM: Ram-Gene1, Ram-Surf, Ram DA-3 with PM-10 ang GM-10 probes

-MINI-INSTRUMENTS: E, EP-15 and 44A.

The indirect measurements have been performed by smearing with filter paper wet in decontaminant solution are afterwards counting in a liquid scintillation counter.

We have evaluated the factors considerated in the introduction and according to them, we have been able to provide the specific hazards of each technique .All these data together with bibliographic references,have decided the necessary protection protocols.

* Radiolabelling of biological molecules with I-125 or I-131

* *Asociated risk.*

Volatility of radioactive iodo during the labelling experiment. This can produce personal, external and internal, contamination and superficial contamination.

* *Protection measures.*

- Storing the labelling compounds at room temperature.
- Avoid the use of strong oxidants.
- Work always into a fume hood with charcoal filters.
- Use the Hamilton syringes for dispense the radioactive compounds.
- Take advice to put the plates or filters of active charcoal into the fume hood and into the work place to prevent airborne contamination.

* Radiolabelling of proteins with S-35 amino-acids.

**Asociated risk..*

Releasing of ^{35}S--labeled volatile sub-products. Although this compounds have not yet been identified, likely candidates are methyl-mercaptan (CH_3-^{35}SH) as the major volatile product of radiolytic decay of methionine, with hydrogen sulfide H_2S and sulfur dioxide as minor components. Netherless, some authors suggest that less volatile sub-products are released from ^{35}S-cysteine than from ^{35}S-methionine.

Release of volatile radioactive compounds from ^{35}S-amino acids happens during storage, protein-labelling experiments and incubations.

These compounds are readily soluble in water, for this reason the incubators used in cell culture could become highly contaminated.

* *Protection measures*.

- Stored at -80º the 35S-aminoacids in dry ice
- Traw the products in a fume hood with charcoal filters
- Place the filters of activated charcoal in the incubator (this filter does not affect the CO_2 equilibrium in the incubator).
- The water inside incubator should be changed after each labelling.
- Use a sufficient volumen of tissue culture media (75µCi/ml).
- Add an effective stabilizer agent to the tissue culture media (tricina 50 mM). This agent should not be toxic.

*Radiolabelling of biological molecules with H-3

** Asociated risk.*

- The tritiated compounds used for biological research wiith high risk of contamination are tritiated water, tritiated thymidine and some organic compounds .
- The biological risk highly depends of the tritiated compounds used. Tritiated thymidine presents a high risk of internal contamination because these compounds are quickly metabolized into the genetic material .
- The tritiated water (especially in high specific activity) causes contamination of the frost in freezers when this compounds is stored.
- Tritium gas, tritiated water and some tritiated organic solvents pass through the walls of plastic containes easily.
- Compounds stored in aqueous solution may give rise to tritiated water by exchange which can then result in contamination of the frost in freezers.

** Protection measures .*

- Experiments with tritiated water or tritiated compounds must be carried on in a fume cupboards (with charcoal filters) to prevent airborne contamination.
- The refrigerators and incubators where tritiated compounds are stored should be checked to detect possible contaminations .
- Sealed glass vials in wich labelled compounds have been stored for long periods should be opened with great care, preferably in a fume cupboard or glove box.
- Tritiated water should be stored at room temperature in sealed containers.
- Wear two pairs of gloves.

CONCLUSIONS

Due to the analysis carried out on the application of radionuclides in biological research we have established a program for contamination control and surveillance and we have set up contamination Reference Levels in these radioactive installations:

REFERENCE LEVELS	Bq/cm^2
Surface contamination	1
Skin	0,37

RADIATION PROTECTION IN THE RADIOACTIVE INSTALLATIONS OF THE AUTONOMOUS UNIVERSITY OF BARCELONA

Carmen Baixeras,[1] J. Molero,[2] and F. Pérez[1]

[1]SPR Autonomous University of Barcelona, 08193 Bellaterra, Spain,
[2]Germans Trias i Pujol University Hospital, 08916 Badalona, Spain

INTRODUCTION

In the Autonomous University of Barcelona (UAB) there are numerous investigation and teaching activities that imply the use of equipment generating ionizing radiations or the manipulation of radioactive isotopes. The existence of disciplines so different as medicine, veterinary, biology, physics or chemistry gives rise to a broad diversity of applications, concerning the techniques carried out as well as to the equipment and radioactive isotopes that are used. Other notable characteristic of the university radioactive facilities is its spatial dissemination, being located in different faculties and departments distributed all over the campus.

The Spanish legislation (1) establishes the regulation on the protection against ionizing radiations according to the guidelines of the EU (2). Furthermore, it exists a regulatory organization in radiological safety matter that it is the Spanish Nuclear Security Council (Consejo de Seguridad Nuclear: CSN) (3). This organization checks and authorizes the performance protocols of all the nuclear and radioactive facilities of Spain. In order to coordinate the inherent activities to the management of the ionizing radiations in the UAB, it was necessary to create a Radiological Protection Service (RPS). Its most important task is to remind of the risks limitation principles in the use of the ionizing radiations to the involved professionals and to control the fulfillment of the radiological protection regulations in use.

The basic document of the RPS is the Radiological Protection Handbook that must be approved and authorized by the CSN. All the procedures and guidelines concerning the organization and safety management of the ionizing radiations used in the UAB investigation and teaching activities are written in this document. Between these procedures are emphasized those which are referred to the environmental radiological vigilance, concerning radiation levels and contamination both inside and outside of the installations, and also to the control of the radioactive waste management. Within this last, one way to manage the liquid radioactive waste is dilute it and make a controlled evacuation through the sewer that guarantee that the activity levels are below the limits authorized by the CSN (1). The activity limits authorized for release in a controlled way the liquid radioactive effluents are found explicitly collected in the Radiological Protection Handbook of the UAB (4).

The RPS of the UAB periodically carry out radiological controls in the different radioactive installations of the campus. Such controls envisage the environmental radiation level measurement and the detection of the radioactive contamination in the different work surfaces. Furthermore, it has been performed a campaign to control the liquid waste release in the sewer net of the campus in order to verify that the limits established for the controlled liquid waste pouring away are sufficient to assure a good radiological quality of the residual waters. The knowledge of the radiation and contamination levels will permit the optimization of the techniques used, specially in view of the next incorporation of the new recommendations of the ICRP (5) to the Spanish legislation. Furthermore setting up a liquid waste sampling and measurement method results indispensable for the evaluation of the impact of a hypothetical accident that could happen in any installation of the university campus. The methodology used and the results obtained from these controls are described in the present paper.

INSTALLATIONS, EQUIPMENT AND RADIOISOTOPES

The UAB holds 9 radioactive installations that develop investigation and teaching activities. The denomination of these facilities and the radioactive sources used are detailed in Table 1.

Table 1. Denomination and radioisotopes used in the UAB installations

Code	Denomination	Faculty	Radioisotope
BQ-C	Biochemistry	Sciences	^{32}P, ^{35}S, ^{125}I
BQ-V	Biochemistry	Veterinary	^{3}H, ^{14}C, ^{32}P, ^{35}S, ^{125}I
GFR-C	Radiation Physics	Sciences	enclosed sources
G-C	Genetic	Sciences	^{32}P, ^{35}S
IBF	Biochemistry	Institute	^{3}H, ^{14}C, ^{32}P, ^{35}S, ^{45}Ca, ^{125}I
SRE-C	RIA Service	Sciences	^{3}H, ^{32}P, ^{125}I
UB-M	Biochemistry	Medicine	^{3}H, ^{14}C, ^{22}Na, ^{32}P, ^{45}Ca, ^{86}Rb
UF-V	Physiology	Veterinary	^{3}H, ^{14}C

The nature and characteristic of the radioactive isotope used by the personnel of the UAB installations are related in Table 2. Furthermore, the faculty of veterinary counts on one installation of radiodiagnostic equipped with an X-rays device (maximum characteristics: 100 kVp, 100 mA and 1000 ms). The RPS gives coverage to a total of 140 persons including students and professionally exposed personnel. These persons are subject to the corresponding medical and dosimetric control. The medical control is performed at the UAB in a center authorized by the CSN. The Spanish legislation establishes that the professionally exposed personnel of the radioactive facilities must accredit a license for working with ionizing radiations and at present there are 17 Supervisor licenses and 6 Operator licenses in the UAB campus. In each installation, the Supervisor is responsible of the radiological safety routine controls without prejudice of the RPS actions.

Table 2. Characteristics of the radioisotopes used in the UAB.

Radioisotope	Radiation Type	Maximum Energy (MeV)	Half Life
^{3}H	β	0.0186	12.3 years
^{14}C	β	0.156	5730 years
^{22}Na	γ	1.28	2.6 years
^{32}P	β	1.71	14.3 days
^{35}S	β	0.167	87.4 days
^{45}Ca	β	0.083	163 days
^{86}Rb	β	1.77	18.66 days
^{125}I	γ	0.035	60 days

METHOD AND MEASURING SYSTEMS

The environmental radiological vigilance that carries out the RPS with a semiannual periodicity include the control of the environmental radiation levels and the detection of the surface contamination in the different installations. The radiation levels are determined using an ionization chamber ROTEM RAM ION connected to a portable computer that stores in a data base the levels of each controlled installation. The detection of the contamination in the surfaces is carried out with the same counter and, in the case of being detected a level significantly higher than the background, the activity by surface unit is determined with the counter FAG CONTAMAT. This counter is provided with a proportional probe for beta-gamma radiation, that is calibrated according to a library of 25 different radioisotopes. When the access to the surface is difficult, as for example drain, the measure is carried out by rubbing the surfaces with an absorbent paper that is after measured. The efficiency of the ionizing chamber RAM ION is 30% for energy of 600 keV and its response is compensated for a range of 10 to 1000 keV. For the superficial contamination counter the manufacturer indicates an efficiency of 34% for the ^{90}Sr ^{90}Y. The ionization chamber is calibrated each two years by an official metrological laboratory and the counting response of surface contamination probes is verified annually using a set of calibration sources by the own RPS.

The control of the liquid waste activity levels has been carried out through a specific campaign that have take in account the most meaningful installations concerning the use of radioisotopes. The selected installations have been: the SRE-C, the UB-M, the UF-V and the IBF. In each installation has been taken residual water samples in points of the sewer corresponding to the drain of the facility. This sampling has been accomplished during the controlled pouring of the liquid wastes previously diluted according to the protocol established by the RPS (4). For each installation were taken five samples of a liter, the first before beginning the release and the remainders each ten minutes. Beta-emitters were measured by WALLAC 1220 QUANTULLUS low background liquid scintillation counter. For counting by means of liquid scintillation system, the samples were conditioned following the preparation method established for the environmental samples measurement by our Group (6). The determination of ^{125}I activities was accomplished in a WALLAC 1271 CLINIGAMMA solid scintillation counter (7). The ^{22}Na level was measured using a ORTEC GMX high resolution gamma spectrometer provided by a HPGe detector linked to a 8k multichanel analyzer (8).

RESULTS

The periodic controls carried out by the RPS of the UAB have shown levels not significantly different from the environmental background value, namely 0.1 μSvh^{-1} for irradiation and 13 cps (beta-gamma average) for surface contamination. Higher irradiation levels, up to 0.5 μSvh^{-1}, have been observed only in a few occasions, corresponding to situations in which wastes or radioactive material in use were found inside the working zone. Furthermore, in one control over the working surfaces, contamination was detected in the absorbent cover paper reaching levels of 5.5 $Bqcm^{-2}$ of ^{32}P. The obtained results confirm the need of hold the wastes and radioactive material always outside of the working zone and prove the effectiveness of the periodic radiological controls. In the other hand, the control of liquid radioactive wastes poured through the drain has involved ^{125}I, ^{22}Na and beta total determination from samples taken from the sewers. In the case of the ^{125}I activities slightly higher than the background level have been observed just in the middle of the sampling decreasing to the background value in ten minutes approximately. These values must be investigated using a counter with a lower detection limit in view to determinate the activity as far as the ^{125}I has the lowest authorized limit of the radioisotopes analyzed. In the case of the ^{22}Na, the levels of the samples from the UB-M were below the minimum detectable activity of the detection system, namely 10 $mBql^{-1}$. With respect to the beta total determination, samples analyzed were found to have activities below the minimum detectable activity of the counting system, namely 0.1 Bql^{-1}. This result shows the goodness of the beta liquid effluent release protocol. Radiological survey in the radiodiagnostic installation has showed the following levels of irradiation: 0.1 μSvh^{-1} in the vicinity of the operator console and 0.7 $mSvh^{-1}$ for the leakage radiation test (placing the detector at 1 m from the X-ray tube and working with maximum generator parameters). The results prove that the installation was well-designed and the leakage radiation verify the legal prescription, i.e. < 1 $mSvh^{-1}$.

EVALUATION OF OCCUPATIONAL EXPOSURES IN THE CZECH REPUBLIC

Ing.Zdenek PROUZA,CSc.[1], Ing.Karla PETROVÁ[2]

[1] State Office for Nuclear Safety, Slezská 9, 120 29 Prague 2, Czech Republic
[2] National Radiation Protection Institute, Šrobarova 48, 100 00 Prague 10, Czech Republic

ABSTRACT - The recent situation in the Czech Republic (CZ) concerning the evaluation and recording of occupational radiation exposures is described. The individual monitoring is based on the interpretation of the personal dosemeters responses and the evaluation of the other special dosimetric methods (measurement of excreta, whole body counting, etc.). The evaluation of occupational radiation exposures is carried out by five approved dosimetric services, which control about 20,000 workers. Record keeping of overexposures is based on two systems, which principles are explained. Based on long time analysis of occupational radiation exposures in CZ it can be present that the average values and trends of individual and collective effective dose equivalents are comparable with those in developed countries. The distributions of the radiation exposures for the important occupational groups of workers are presented.

INTRODUCTION

The individual monitoring of workers with sources of ionizing radiation (SIR) in CZ is based on measurement, evaluation and registration of occupational radiation exposures (ORE) using personal dosimeters or the other special methods (measurements of organ doses, of excreta, the whole body counting, etc.). The licensee's duty, covered by law in CZ[1], is to secure the control, monitoring and recording of ORE of its workers.

Recent legislation in CZ, in accordance with political and economical changes in the country, is going through an extensive reconstruction. A proposal of the Law on Peaceful Use of Nuclear Energy and Ionizing Radiation (new "Atomic Act") [2] has been already elaborated (it is assumed to come into force during 1996). The Atomic Act and related regulations are based on ICRP Report 60 [3] and New International Basic Safety Standards [4], i.e. licensees will be responsible not only to designate controlled areas where specific protective measures are required for:

* control of ORE and prevention of the spread of contamination during normal working conditions,
* prevention and limitation of the extent of potential exposures,

but shall maintain exposure records for each worker for whom an assessment of ORE is required. Simultaneously, licensees will be responsible for the communication with the Central Registry of Occupational Exposures (CROE). CROE is created [5] by the State Office for Nuclear Safety (SONS) for the registration and evaluation of ORE on the national level.

The evaluation of ORE is carried out by five approved dosimetric services in CZ - National Personal Dosimetric Service, two Dosimetric Services of NPP at Dukovany and Temelin, Dosimetric Service of Uranium Industry and Dosimetric Service of Nuclear Research Institute in REZ. Recently these services control about 20,000 workers (Table 1).

METHODOLOGY

The film dosemeter is a basic type of dosimeter for the evaluation of ORE from external irradiation. All services proceed from filtration analysis for the estimation of dosimetric quantities. A qualitative estimate of contamination of worker and of individual (surface and penetrating) dose equivalents (with recording level 0.2 mSv for one month period of control)

are made by the evaluation of dosemeter. The estimated value of individual penetrating dose equivalent H_p is considered to be an acceptable (usually overestimating) estimate of the effective dose equivalent from external irradiation. Further dosimetric investigations (from H_p > 1.25 mSv) are carried out, considering the presumed geometry of irradiation , if an overexposure is suspected.

Since 1976 personal neutron dosemeters (based on plastic track detectors Malyar with the couple of fission foils, enriched uranium and natural thorium [6]) are used (recording level H_p > 1.25 mSv for month as well as for year control periods is used at the selected workplaces (about 600 workers) with significant neutron sources (industrial radiographers, well-loggers, etc.).

Some workplaces, especially NPP's, are equipped with additional, operational dosimeters (mostly TLD, now different types of electronic detectors) for evaluation of ORE in the course of special tasks, somewhere finger TLD are used.

As far as the internal contamination is concerned, the licensees are responsible for securing of monitoring of workers or workplaces and recording of the results. When individual monitoring is inappropriate, inadequate or not feasible, ORE are assessed on the base of the monitoring of the workplaces, information about given location and duration of exposure. CROE registers ORE from internal contamination exceeding the recording level (0.1 of annual limit of intake).

The evaluation of annual ORE and their recording in dependence on different factors (occupational group, working time, sex, age, etc.) are introduced into practice of dosimetric services a fter a revision of their methodology of ORE evaluation (implementation of the new ICRP and ICRU recommendation) during 1990-91 years.

OVEREXPOSURES RECORDING

Record keeping of overexposures is based on two systems:

- if there is suspicion on overexposure at a workplace, licensee is obligated to estimate of the severity of given event; an investigation shall be conducted with the aim to identify the circumstances and assess and record the relevant doses and their distribution in the body. In the case that the annual limit of the effective dose equivalent $H_{E,L}$ (for internal contamination - 1/10 of ALI), the event must be reported to CROE. For serious incident (with possible medical consequences) National Radiation Protection Institute in Prague is involved in evaluation of incident consequences;
- the second system is based on co-operation of CROE with dosimetric services; these services report directly to CROE immediately after the evaluation of dosimeters for given control period any excess of the $H_{E,L}$ (or determined investigation levels). Identified events are then investigated by inspectors of SONS directly at the workplace where the event occurred.

183 persons were involved in 65 minor accidents and in indicated events detected in CZ (and former CSSR) during the 1954 - 1994 years. 102 of them were exposed by external and 81 by internal radiation. Only 15 from these events have led into health consequences (dermatitis with skin defects, cataracts). In some events surgical interventions - amputation of fingers, removal of a local deposit were used. In the period 1975-94 years 107 dosemeter readings were reported by the second system as exceeding the value 50 mSv ($H_{E,L}$). Following reinvestigation it appeared that in most cases the primary evaluation was falsely positive; it was concluded that only in 45 of indicated findings, the values of $H_{E,L}$ were exceeded.

DISTRIBUTIONS OF ORE, CONCLUSIONS

The long term evaluation of ORE in CZ covering period 1975-1990 has undertaken in 1993 year [6]. Several basic characteristics are illustrated in Table 1.

Based on mentioned analysis and recent results of ORE evaluation, we can present that:

- the average values and trends of individual effective dose equivalent (H_E) are comparable with those in developed countries (only 20-30 % of values ORE were higher than 0.2 mSv, the recording level),
- the significant part of the annual collective dose equivalent (S) arises form operations in the nuclear industry, when values of H_E from radon, its daughters and from ore dust constituted about (60-80)% of its total value in the uranium industry (UI);
- average individual values of H_E in NPP Dukovany are lower or comparable with those in the other NPP s PWR - type. In period 1985-94 (operational time of NPP Dukovany) the H_E values have been registered in the interval (0.55 - 0.82) mSv.

ABSTRACT (See instructions overleaf)

An optimization study of the total gamma shield mass requirements for a space nuclear power system is presented. The minimization of the mass of the gamma shield for a space nuclear power system is of interest because it represents a large fraction of the overall spacecraft mass, typically between 20% and 40%. Optimization of the shield mass can thus result in significant mass savings which translate into reductions in launch costs.

The gamma radiation source and reference dimensions were based on the Russian TOPAZ-II nuclear electric power-generating reactor. The potential shield materials analyzed were aluminum, steel, lead, tungsten, depleted uranium, lithium hydride, and concrete. The required shield masses were normalized to the lowest value, providing a "mass index" that was used as a basis of comparison for the different shield materials. A gamma source of 10^{16} γ/sec originating from a thin disk-source model of the reactor, provided a uniform beam of monoenergetic gamma rays incident on the cone shield. A value of 50 mSv/hr (5 mrem/hr) was chosen as the desired dose equivalent at the reference dose point. The computations were performed with QAD-CGGP, a three-dimensional, point-kernel gamma shielding code. Depleted uranium had a mass index of 1.0 and provided the required shielding with the lowest mass requirement. Mass indices between 1.2 and 1.7 were characteristic of tungsten and lead, making them potential substitutes for depleted uranium in the case of smaller reactor power levels.

REENTRAINMENT OF $^{239}PuO_2$ PARTICLES CAPTURED ON HEPA FILTER FIBERS

Yuji Yamada, Akira Koizumi and Katsuhiro Miyamoto

National Institute of Radiological Sciences, Chiba, Japan

ABSTRACT

The collection efficiency of the air filter is the most important parameter for removing of radioactive aerosols. At the same time, retention of the captured particles is very important for contamination control not only during use but also after use. Reentrainment of $^{239}PuO_2$ particles collected on HEPA filter fibers was investigated under various conditions of air flow direction, air flow rate, air flow pattern and dust loading. Activity median aerodynamic diameter (AMAD) of Pu aerosols was about 0.45μm, and the geometric standard deviation (GSD) was 2. Collected activity on the filters ranged from 10^7 to 10^8 Bq/m^2. Dispersal rate under nominal direction flow was measured as less than 2 x 10^{-7} /hr. Under the inverse direction flow, higher dispersal rates were observed, but dispersal basically decreased with increasing sampling run. High air flow rate increased the dispersion. There was no significant differences among air flow patterns, continuous flow, intermittent flow and mechanical shock flow. Dispersal rate strongly depended on the dust loading. For example, three times loading of atmospheric airborne particles against the initial pressure drop was found to increase the dispersal rate by over 300 times to 10^2 /hr at maximum. Even if experimental conditions were considered extremely severe, it makes us to take reentrainment from a high loading filter more seriously, since it indicates that there is a possibility of air contamination due to handling of the spent HEPA filter.

INTRODUCTION

Reentrainment of particles collected by the air filter as well as a filtration mechanism has been a very important subject. The recoil phenomenon of alpha-emitting nuclides such as plutonium(Pu) has been recognized to affect retention of alpha active particulate on filters. There are many papers on the recoil of radon progeny from a substrate from the perspective of basic science and in practical application. However, there are few studies on the recoil of Pu particles. Fleischer and Raabe noted the possibility that recoiling fragments of Pu particles due to alpha decay relates to dissolution in liquids[1]. McDowell et al. investigated the effects of recoil on penetration through HEPA filters and reported that alpha-emitting particulate matter does indeed penetrate high efficiency filter media much more effectively than nonradioactive or beta-gamma-active aerosols[2),3)]. However, Wen and Kasper investigated the kinetics of reentrainment from surfaces for nonradioactive particles and explained particle reentrainment as a result of a competition between adhesion forces and fluid dynamic lift forces[4)].

In our previous studies[5),6)] on HEPA filter, decontamination factors against Pu aerosol particles were almost the same or higher than the levels expected from experiments using nonradioactive aerosol particles, but these studies did not clarify retention efficiency. For filters in long-term use and spent filters containing such plutonium-containing dust, retention efficiency is very important along with collection efficiency. In this work, we focused on the retention of alpha active particulate, distinguishing from apparent retention with re-collection and net retention.

MATERIALS AND METHODS

Experiments were performed with filter media not in-place HEPA filters. The filters used in this work had an effective diameter of 37 mm. Basic collection performance was examined in our previous studies[6)]. Two types of test filters with and without dust loading were prepared prior to loading of radioactivity for dispersion experiments. Atmospheric dust was loaded up to 1.7 and 3.0 times the initial pressure drops of the filter. Radioactive source filters were prepared by collecting plutonium oxide ($^{239}PuO_2$) aerosol particles[5)] at an air flow face velocity of 7.8 mm/s, which corresponds to about one-third of the nominal flow velocity of HEPA filters. The particles were polydisperse aerosols with AMAD (Activity Median Aerodynamic Diameter) ranging from 0.4 to 0.5 μm and GSD (Geometric Standard Deviation) ranging from 1.9 to 2.1. Activity densities on the source filter surface ranged from 10^7 to 10^8 Bq/m^2.

Reentrainment of Pu particles captured on HEPA filter fibers was examined under dynamic conditions with air flow rather than static conditions. Source filters and

clean filters for sampling of the dispersed particles were mounted in a multistage filter holder as shown in Fig.1. Experimental parameters on air flow through the source filter consisted of two air flow directions, two air flow velocities and three air flow patterns. The air flow directions were a nominal direction from front to back and an inverse direction from back to front. The air flow velocities were a nominal velocity of 23 mm/s and high velocity of 1.2×10^2 mm/s. The air flow patterns were (1) continuous flow, (2) intermittent flow that stopped for five seconds per half minute and (3) mechanical shock flow by free fall from a height of 50 mm. Three runs of five minutes sampling were repeated every ten days so that nine samples were obtained for each source filter.

SSD for alpha counting and phoswich detector for LX-rays of ^{239}Pu counting were used for activity measurements of filter samples. The minimal detectable activity during 2.5×10^5 sec counting was 1.2×10^{-2} Bq.

RESULTS AND DISCUSSION

Effects of air flow directions through the source filter on reentrainment of Pu particles were examined by intermittent flow at high air flow velocity. In the case of nominal direction flow, no significant activities in sampling filters were detected except one measurement among total 27 sampling runs. The dispersal rate per hour was very small and was estimated to be 2.3×10^{-7}. However, dispersed activities were observed in most runs with inverse flow from back to front. This indicates that particle reentrainment with nominal direction flow is not denied. Dispersed particles would be re-collected by fibers before penetrating a filter. The maximal dispersal rate per hour reached 2.4×10^{-5}. Dispersal rates scattered among source filter samples and even among successional runs using the same samples. Overall tendency showed a decreasing trend with the sampling runs. Next, effects of air flow patterns through the source filter on reentrainment of Pu particles were examined with inverse direction flow at high air flow velocity. Three source filter samples for each air flow pattern, continuous flow, intermittent flow and mechanical shock flow, were used for dispersion experiments. As shown in Fig.2, the measured dispersal rates ranged from 4×10^{-5} to 10^{-7} /hr. There were no differences in dispersal rates among air flow patterns. Thirdly, effects of air flow rates through the source filter on reentrainment of Pu particles were examined with intermittent flow in an inverse direction. The dispersal

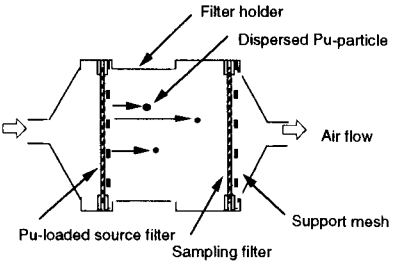

Fig.1 Structure of filter holder with multistage for sampling the dispersed Pu particles

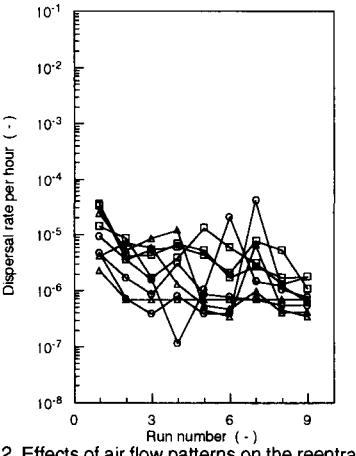

Fig.2 Effects of air flow patterns on the reentrainment of Pu particles at inverse flow of 1.2×10^2 mm/s (○: continuous flow, △: intermittent flow, □: mechanical shock flow)

rate depended on the air flow velocity. The measured dispersal rates at nominal velocity were smaller than those at high velocity. The maximal dispersal rate was 3.1×10^{-6} /hr and it was approximately one-tenth that at high velocity.

For source filters loaded with atmospheric aerosols, reentrainment was examined in the same way as for the pre-loaded source filters described above. The experiments were made in the inverse direction flow through the source filters at high flow velocity. Air flow patterns were continuous flow, intermittent flow and mechanical shock flow. As shown in Fig.3, high dispersal rates were observed for the source filters with dust loading. The maximal dispersal rates were 5.6×10^{-4} /hr with low dust loading and 1.0×10^{-2} /hr in high dust loading. These were 23 - 4.2×10^2 times higher than the rate for the filter without dust loading. There were no differences of the dispersal rates among the three air flow patterns. The dispersal rate decreased with increases in sampling run number. The dependency was

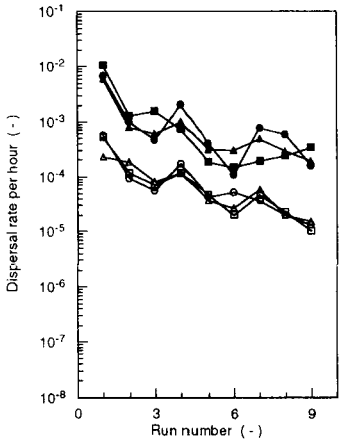

Fig.3 Effects of low and high dust loading on reentrainment of Pu particles at inverse flow of 1.2 x 10^2 mm/s (○ : continuous flow, △ : intermittent flow, □ : mechanical shock flow, open symbol: low loading, solid symbol: high loading)

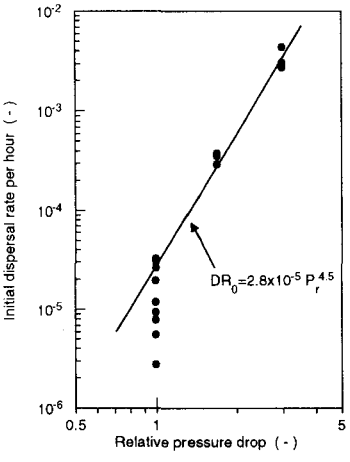

Fig.4 Dependency of the initial dispersal rate on the dust loading level of the source filter

relatively more clear than that for filters without dust loading. The fitted curves were expressed as an exponential function defined by

$$DR = a \exp(b N)$$

where DR is the dispersal rate per hour, N is the number of sampling runs, and a and b are the constants. b in the low and high loading filters were estimated as 0.36 and 0.34, respectively. The difference between these two was very small, so that factor b was assumed to be common (b = 0.35) for all experiments including those using filters without dust loading. Initial dispersal rate, DR_0, is defined by extrapolating to the point where the sampling run number is zero. The DR_0s for filters with low and high dust loading and those for filters without dust loading were estimated and plotted against the relative pressure drop, P_r, of the source filter to initial pressure, where the P_r is one of the indices indicating the dust loading levels. The DR_0 linearly increased with the P_r in a semi-logarithmic graph as shown in Fig.4. The relationship was expressed by

$$DR_0 = 2.8 \times 10^{-5} P_r^{4.5}.$$

For example, the dispersal rate at two times dust loading is calculated to have increased by 23 times. It was confirmed that the reentrainment was strongly affected by dust loading. The loaded dust particles play the role of a Pu carrier in radioactive particle reentrainment.

CONCLUSIONS

The reentrainment of submicron-sized Pu particles captured on HEPA filter fibers was experimentally investigated, and the results are summarized as follows:

(1) With nominal direction flow from front to back, the dispersal rate was estimated to be below 2.3 x 10^{-7} /hr at a high velocity of 1.2 x 10^2 mm/s. This dispersal rate was much lower than the maximal penetration of the HEPA filter with a minimal collection efficiency of 99.97 % for 0.3 μm sized particles. Therefore, it was concluded that Pu particles captured on filter fibers near the front surface hardly penetrate the filter.

(2) With inverse direction flow from back to front, reentrainment phenomena of Pu particles were observed in most experiments. The dispersal rate increased with air flow velocity and dust loading to the order of 1 x 10^2 /hr. In handling of a spent filter contaminated by Pu, marked attention should be paid to preventing air contamination.

(3) Dispersal rates were not constant in the succeeding sampling runs and decreased with large scattering. The fitted curves were expressed as an exponential function for all experiments.

IMPROVEMENT OF RADON SUPPRESSING AEROSOL MONITORING TECHNIQUES

T. M. Ibach, R. Scheuer, P. Guglhör

Technical Inspectorate of Bavaria (TÜV Bayern Sachsen, München)

ABSTRACT

Subject of this presentation is the improvement of the effectiveness of different radon-suppressing techniques for Alpha aerosol monitoring in working areas.

Due to the very high dose factors of Uranium and Transuranium Aerosols the limit of detection for airborne concentrations derived from statistical considerations has to be very low, i. e. about 100 mBq/m³ after a few hours.

ABPD (Alpha/Beta Pseudo Coincidence Discrimination)- and AERD (Alpha Energy Range Discrimination)- techniques can reach that goal when the Alpha emitting radon decay products do not change their equilibrium. When measuring continuously in real conditions, this is disturbed by systematic errors, such as the influence of Po 214, which sometimes changes its equilibrium with the suppressible Po 218.

As a result of our investigation we changed the ABPD- and the AERD- method by stopping the air flow through the measuring filter for a short time and watching the decay and build up of Po 214 by means of an on-line least squares fit.

INTRODUCTION

The implementation of the newer findings about the high biological effectiveness of Alpha-radiation, mainly of Uranium and Thorium, resulted in lower limits of intake and lower limits of airborne radioactivity concentration.

The permanent presence of an airborne Alpha concentration of 0.2 Bq/m³ would be equivalent to the yearly limit of intake, as it is given by the German Radiation Protection Ordinance of 1989. Accordingly high are the demands on aerosol-monitoring, which should detect the presence of such an airborne Alpha concentration as early as possible. In that case continuous monitoring is the appropriate method.

When monitoring Aerosols, it is an unwelcome side effect that the radon-followers give a varying contribution to the Beta-signal as well as to the Alpha-signal. This varying contribution presents the essential restriction to the lower limits of detection, mainly when measuring continuously.

Apart from continuous Alpha-spectrometry the most important measuring techniques to minimise such a restriction are the ABPD (Alpha/Beta Pseudo Coincidence Discrimination)-technique (1) and the AERD (Alpha Energy Range Discrimination)-technique (2). These methods can also be combined (3).

Both these techniques use the specific detectability of Po 214 of the Radon decay chain (resp. Po 212 of the Thoron decay chain). Po 214 (resp. Po 212) is representative for the natural activity (including e.g. Po 218 resp. Po 216), which can then be deducted from the total activity to get the artificial (Uranium, Transuranium) Alpha activity as a result.

This presentation was developed in the course of the research project: Room Air Monitoring of Uranium and Transuranium, supported by the Ministry of Environment (Bundesministerium für Umwelt) of the Federal Republic of Germany with the Project Number StSch 4055

The ABPD-technique uses the short lived succession of the decay of Bi 214 and Po 214 in the Radon decay chain (resp. of Bi 212 and Po 212 in the Thoron decay chain) whereas the AERD-technique takes advantage of the range of the Alphas of Po 214 (resp. Po 212), which is high compared to the case of long lived Alpha-Emitters, like Uranium or Transuranium nuclides.

The following simplified part of the nuclide chart explains it:

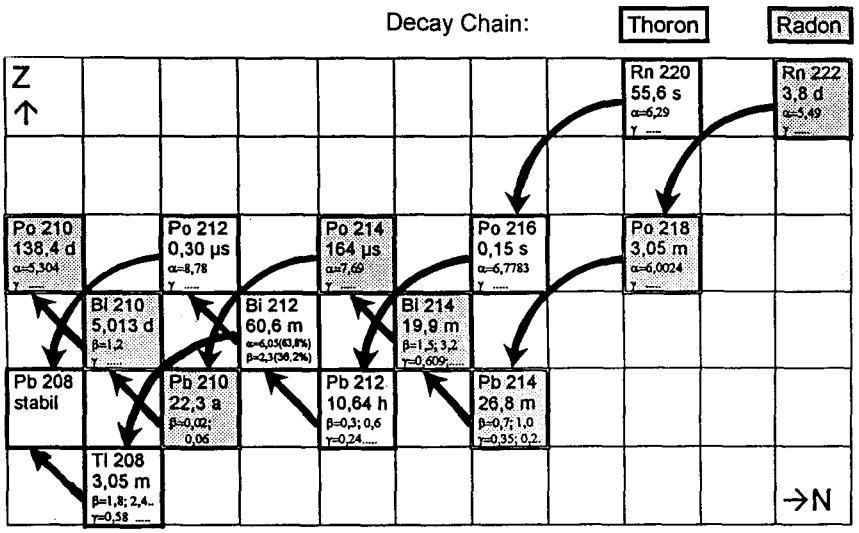

Figure 1: Extract of the Karlsruhe Nuclide Chart with the Radon and Thoron decay.

INTERFERENCES

The theoretical detection limits of these radon-suppressing techniques are about 0.2 Bq/m³ when that concentration is present for at least 1 hr in an atmosphere of 10 Bq/m³ Radon Gas in the state of equilibrium of the Radon daughters (4). When comparing these theoretical detection limits with the ones achievable in real cases, it shows that there are systematic interferences due to the disturbances of the equilibrium of the radon decay products. One example should explain this:

If there is a system for circulating and filtering air, that works optionally, the long-lived radon decay product Po 214, which is the basis for the compensation, is filtered out, while the short-lived Po 218 is rebuilding quickly. So switching on that system leads to an undercompensation of the Radon daughters, if the monitor's compensation was adjusted before - or, even worse - switching off that system leads to an overcompensation of the adjusted system.

It is obvious that similar effects appear, after doors of monitored rooms are opened ore closed.

SOLUTION

We have tried to separate the influence of Po 218 by stopping the air flow through the measuring filter of an ABPD-monitor regularly for a short time and watching the Alpha-signal. The part of the signal due to Po 218 falls exponentially with a half-life-time of 3.05 min. The count rate, collected every 10 seconds, is fitted by a least squares fit using a transputer system to get the Po 218 concentration. The same method,

but using the rebuild of Po 218 is also used, when the air flow is started again. The Po 214 concentration is known by the pseudo coincidence rate.

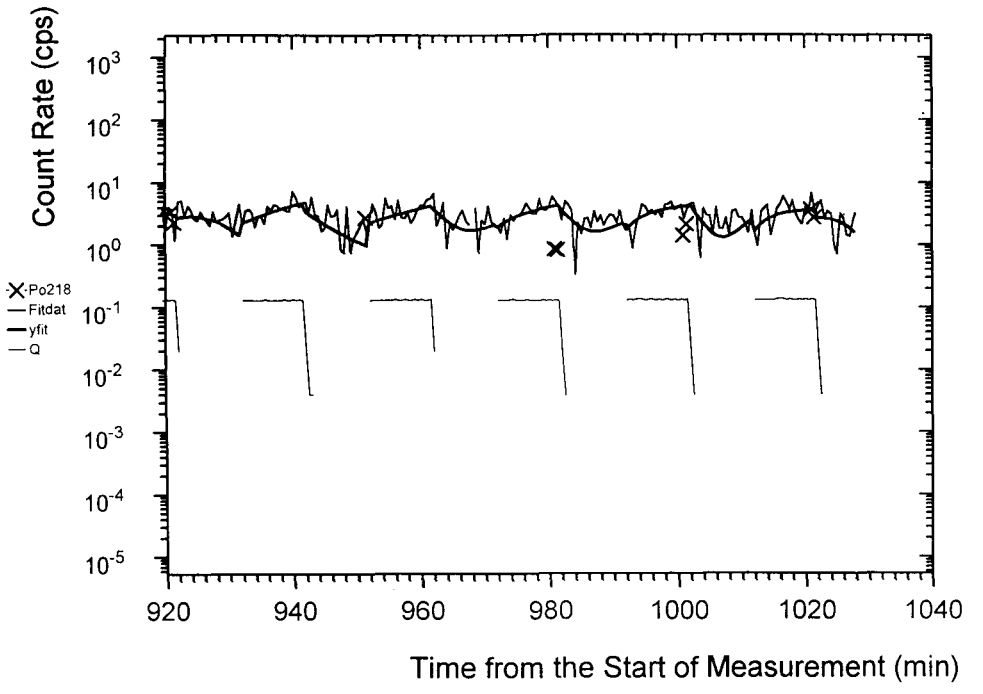

Figure 2: Results of the first on-line measurements with the extended ABPD-Monitor
The Po 214-compensated count-rate is fitted to get the equilibrium count-rate due to Po 218
The measured flow rate through the monitor is given as Q and is about 42 m³/h

With that system, working in intervals of 10 min for accumulation and stopping, the problem of wrong compensation is solved, but a contamination burst in the stopping time cannot be seen. It is planned to upgrade the system, so that it only stops the accumulation if a malcompensation or significant airborne contamination is obvious. In this case the system can decide by doing the Po 218-decay fit.

ABSTRACT (See instructions overleaf)

RADIATION PROTECTION AT WORKPLACES. THE FRENCH INSTITUT CURIE EXPERIENCE ; 1958 - 1994 - JM COSSET, B PERDEREAU, B. DUBRAY, F. CAMPANA, H. JAMMET
Institut Curie, 26 rue d'Ulm, 75005 PARIS
TEL 44 32 40 00 - FAX 44 32 46 16

From 1958 to 1994, 434 persons were referred to the radiopathology Unit of the Institut Curie - Paris, France -, for a suspicious or proven accidental irradiation.
In 250 cases (58 %), the accident occurred in **industrial facilities**, 32 patients being referred from foreign countries lacking specific radiopathology units.
In 138 cases (32 %), various **research laboratories** were involved. 11 cases were referred from abroad.
In 46 cases (10 %), the accident occurred in **medical facilities.** Therapeutic accidents or complications in cancer patients were excluded. No such cases were referred from other countries.

Detailed follow up is available for 420 cases (97 % of the total number).
In a majority of cases (309 ; 74 %) a complete survey, as well as operational and/or biological dosimetry actually demonstrated that the putative victim did **not** receive any significant irradiation.
In 26 cases (6 %) a very low-dose localized or whole body irradiation did not warrant any treatment, and the patients were only assigned to regular follow-up.
85 patients (20 %) presented with some type of complications or sequelae (including two lethal cases).
Details about the type and severity of the sequelae will be presented.

STRATEGY FOR THE ASSESSMENT OF THE RADIATION EXPOSURE AT WORKPLACES DUE TO RADON AND RADON DECAY PRODUCTS

R. Czarwinski, R. Lehmann
Federal Office for Radiation Protection, Berlin, Germany

INTRODUCTION

According to the future EU basic standards the exposures to radon decay products have to be taken into consideration. Therefore it is necessary to investigate

* which working operation could be connected with an increased exposure to radon decay products,
* which workplaces have to be considered,
* how many employees could be afflicted,
* which methods should be applied for the investigation and - as for as necessary - for supervision.

On the basis of the current radiation protection legislation in the new Federal Lands working operations which are connected with radon exposures have already been monitored. For instance, in 1994 3095 persons were supervised, 2422 of them were engaged in clean-up operations at Wismut facilities (including underground work) and 673 at non-uranium mines and facilities (conventional mining), water treatment plants, show caves and spas /1/. The extension of the monitoring to similar workplaces in the old Federal Lands is going to discussed in implementation of the EU standards.
Beyond it further workplaces affected by radon and radon decay products exist. Therefore it is helpful to get an overview about the kinds of workplaces and the number of afflicted employees.

DIMENSION OF THE PROBLEM

In regions with increased radon potential especially in the mining regions of East German Federal Lands measurements of the indoor radon concentration with an exposure time of 24 hours were conducted from 1991 to 1993. 2447 institutions participated in these investigations and more than 8000 measurements were made there. The measurements were conducted in 716 producing firms (especially small and middle-class institutions which are typically for the investigation regions), 237 education and research departments, 525 social institutions, 651 public utilities and 318 shops, banks etc..
The investigations included a broad spectrum of working rooms in different institutions like conventional bureaus, lecture rooms, production rooms etc..
Although the information by the voluntary participants about the realistic exposure conditions were often insufficient, the results are useful for an overview assessment. Table 1 shows the evaluation of measured results related to typical workplaces. It should be taken into account that these results represent an overestimation of the long-term situation because short-term measurements are made under stringent conditions (closed windows and doors). It has been shown that factors between 4 and 10 (ratio of short-term against long-term measurents in the range of higher radon concentrations) observed at dwelling measurements. They will be used for the further analysis /2/.

Because the aim of the screening measurements was the area-wide analysis of the situation in regions with a high radon potential, only a rough characterization of the investigated rooms was necessary, particularly there were no influence on their selection by the institutions.

Therefore the number of "other" is high, a majority of these rooms has occupancy times below 3 - 5 hours per day.
Against the expectation the results show that production rooms can not be neglected in the investigations.

Table 1: Results of short-term measurements of the radon concentration in radon potential regions at typical workplaces independent of the institution /3/

Using of rooms	Number of investigations	Average	Maximum	Median	Share of workplaces with short-term radon concentration above	
					4000 Bq/m³	10000 Bq/m³
		Bq/m³	Bq/m³	Bq/m³	%	%
office	1246	390	79000	110	1,4	0,5
production	696	430	13000	120	1,6	0,7
store	719	460	26000	130	1,9	0,1
other*	4002	700	170000	140	2,5	0,7

* class rooms, waiting-rooms, shops, workshops, engineering rooms etc.

To estimate the number of afflicted employees, it was assumed that
1. the percentage of investigated workplaces (rooms) with higher radon concentrations can be transferred on the number of employees who are working in these rooms and
2. only about 10% of the German area have a higher radon potential and the distribution of employees is uniformly.

Outgoing from these assumptions and measured results, the information of the Statistisches Bundesamt Wiesbaden on the total number of employees in Germany (36 mill.) and on the distribution of occupation, it can be estimated that nearly 20000 up to 60000 employees are working at places of different categories with long-term radon concentrations higher than 1000 Bq/m³, recommended by the IAEA Basic Safety Standards for a chronic exposure at workplaces. This rough estimation justifies and requires a detailed investigation of the relevance of radon exposure at these types of workplaces.

APPLICATION OF AN ACTION LEVEL

The ICRP in the publication 65 as well as the IAEA in its Basic Safety Standards recommend to establish an action level for workplaces. If the long-term radon concentration exceeds the action level, remedial measures should be initiated to reduce the radon exposure.
In the international literature there was a consent to a complex evaluation of radon concentrations in institutions (schools, stores, hospitals hotels, kindergarten etc.). However, in recent British and Finnish publications the individual workplaces or kind of workplaces in an institution, respectively, are considered /3/. This objective of the analysis of radon exposures at workplaces seems to be supported by our measurements at different kinds of workplaces and determines further investigations.
According to the current standard of measuring techniques, measurements of the annual average of radon concentration at all workplaces could be done effectively only by means of

integrating methods. However, these methods imply an overestimation of the real exposure, because the measurements result in a mean radon concentration for 24 hours but the time, in which the worker is exposed, is lower - normally 8 hours. That means an unjustified high expense of remediation or number of employees to be included into a supervision.

A first investigation shows that the parameters working time, daytime and using behaviour connected with ventilation rate are the main parameters requiring the detailed study of typical workplaces. The results of radon concentration measurements at some different kinds of workplaces (schools, police stations etc.) show deviations of mean working time exposure and integrated 24 hour exposure hitherto by factors of two to five. One example is a teacher room in a primary school:

daily average (24 hours):	290 Bq/m^3
working time average (7 a.m. to 4 p.m.):	120 Bq/m^3
night time average (4 p.m. to 7 a.m.):	315 Bq/m^3

Taking into account the variation of the above mentioned parameters, it can be assumed that even factors >10 are possible caused by the individual behaviour at the workplace. Because at present only long-term integrating radon measurements are feasible for broad investigation the methods should be adopted to ensure a realistic assessment of the radon exposure at workplaces.

A classification of workplaces into groups of similar features may be useful to estimate the ratio between working time average and daily average of radon concentration. The integral measured exposure can then be adjusted to a real exposure by correction factors which are typical for these groups. Existing regulations related to dusts, vapours, chemical noxious substances and air-conditioning will be taken into account, too, and their relevance to the radiation exposure due to radon and radon decay products is investigated.

If the approach to estimate the real working time exposure due to radon by correction factors on the basis of long-term measurements for classified workplaces is unsuitably then specific measuring methods have to be developed to monitor the radon concentration during the working time for a multitude of working places.

RADIATION ENVIROMENTAL INSPECTION IN RUSSIA

Ja.Rastsvetalov , T.Eremeeva , V.Fominych , G.Krupny , A.Kuznetsov , S.Sukhych

Institute for High Energy Physics, Protvino, Russia,Serpukhov's Sanitary-Epidemiological Inspection,Serpukhov,Russia, Mtndeleev's Metrological Institute,St.Petersburg,Russia,Protontunnelstroj, Protvino, Russia

The Serpukhov region is situated to the south of Moscow. The local extraction and production of building materials in the Serpukhov region are produced in considerable amounts.Besides that some quantity of building materials and construction units are imported to Serpukhov from other regions. According to the geological data the mean radon gas concentrations in soil are estimated as 20-40 kBq/m , but the maximum radon concentration reaches 1000 kBq/m .Developed building industry and geological peculiarities of the region make it necessary to carry out radiation control during all stages of building production. Durin years 1993-1994 in Serpukhov we controled region factors at the following objects: 19 schools, 37 kindergartens, 3 technical colleges. 11 many-storey houses, 6 sand-pits, 3 hlants of building materials. The main gavva- and radon gas control measurements were done to nation regulation [1], but in the special cases we took into account the methodical data [2] and recomendations of Institute of Radiation Hygiene (St.Petersburg). The additional radiation factors of alfa-beta contamination were measured for some rooms at schools and in the kindergartens.

The following devices have been used:

- DRG-01T, SRP-68 - for the internal gammas;
- RGA-01T, RGG-01T - for the radon gas;
- NC-302B, BDZA - for alfa contamination
- MKS-01R, NC-302B - for beta contamination;
- AMA-03F analyzer and DGDK-80B semiconductive detector for gamma spectrometry.

The summary results of our inspections are following:

1. The natural radionuclides in raw materials and building constractions. The specific concentration of Ra, Th and K-40 were measured by gamma-spectrometry method. The values of effective radioactivities Aeff were calculated according to [1] and presented in Table 1.
2. Equivalent equlibrium specific radioactivity of radon gas in indoor air A .During radiation inspections the momentary and dayly integrated values of A were meas,,ured by filtration (paper filters) and sorbtion (carbon co lumns)methods. The summar results are presented in Table 2.
3. Gamma dose rate (P).The gamma dose rates were measured inside each room of all buildings. The value of gamma dose rate lay in interval 7...33 R/h for all cases. Summary results of radiation measurements are given in Table 3 (the gamma and cosmic background not subtracted).

Table 1. Comparison Charecteristic of Building Materials

Site of sample-taking	Staff	Aeff,Bq/kg
Sand-pit "Syanovo",Serpukhov	sand	15

Table 2.Distribution of Number of Objects due to A Range of A , Bq/m

Floor	0...40	40...100	100-150	150-200
3-d floor	86%	14%	-	-
2-d floor	94%	6%	-	-
1-st floor	67%	28%	4%	1%
basement	49%	30%	18%	3%

Table 3. Distribution of number of objects due to p .

Object	No rooms with p >20 R/h	Rooms with p : 20<p <30 R/h	p > 30 R/h
Schools,colleges	79%	21%	-
Kindergartens	74%	22%	4%
Many-storeyed houses	80%	20%	-

On the basis of obtained data we conclude:

1. The products of local building industry correspond to 1-st class of radiation quality [1] (Aeff < 370 Bq/kg), this is confirmed by our annual sertification measurements. The imported raw building materials correspond to 2nd or even 3rd class of radiation quality, what depends on location of sand-pits.
2. On the factor of external gamma radiation all investigated objects correspond to "radiation free" objects. Nevertheless all new buildings must be subjected to radiation inspection because local building industry uses the imported raw materials and building products.
3. n the factor of radon gas in indoor air the radiation situation is more or less normal for all investigated objects. But some rooms in the kindergartens show the radon gas consentrations in indoor air close to thereshold levels. In these cases we recomended to take measures directed to decreasing the radon gas concentrations in indoor air

ABSTRACT (See instructions overleaf)

This paper describes the occupational exposure assessment in China, including nuclear industry, medical dignosis staff and undergroun mineers in coal and nonferrous metal industry. The collective effectiv dose are 1.0E+2 man·Sv·a^{-1}from nuclear industry which is 0.17 percent of total collective effective dose, 2.2E+2 man·Sv·a^{-1}from application of nuclear and radio-technology--0.37 percent of total collective effective dose, 5.0E+4 man·Sv·a^{-1}from underground coal-mines--85.15 percent of total collective effective dose, and 8.4E+3 man·Sv·a^{-1}from underground nonferrous-mines--14.3 percent of total collective effective dose. The total collective effective dose is 5.872E+4 man·Sv·a^{-1}. The collective effective dose from non-nuclear activities reaches 99.45% of total collective effective dose, i.e., non-nuclear activities is the largest contributor of total collective effective dose.

ABSTRACT (See instructions overleaf)

The IAEA Regulations for the Safe Transport of Radioactive Material, Safety Series No. 6, serve as the basis for worldwide safety requirements and are adopted by Member States as well as international transport organizations. In order to ensure that the regulations remain up to date with the latest technological developments and radiation protection principles, they undergo a comprehensive review and revision approximately every ten years. The 1996 revision of the Transport Regulations is nearing completion and several significant radiation protection issues were addressed during the revision. These issues, such as the incorporation of principles of the IAEA Basic Safety Standards, will be examined in detail in the full paper.

Effect of U.V. and Gamma radiation on Rn222 permeation through polyvinyl chloride (PVC). Application to the packaging of radium sources for the purpose of storage.

ABSTRACT

Mining of uranium and thorium, as well as the use of radioactive sources in radiotherapy, especially during the first half of the 20th century, have yielded waste with a various concentrations in long-lived radionucleides (particularly radium). This waste cannot be stored in traditional storage sites which will return to the public domain after 300 years, due to, on the one hand, the radium period (1,620 years) and, on the other hand, the build-up of radon, its gaseous daughter.

One solution, in order to optimise the packaging and storage of such products, could be to use successive barriers, made of polymer membranes, intended to limit radon emission. Laboratory tests have shown that polyvinyl chloride (PVC) greatly reduces radon emission from a radium source. However one should take into account the damage of the polymer with the time, due to the radioactive waste storage itself over long periods of time. Therefore, in order to check the durability of such barriers, PVC samples have been subjected to different accelerated ageing processes by exposure to ultra-violet (UV) radiations or gamma rays.

We have determined the effect of such radiations on the samples. It seems that the UV irradiation causes structural changes in the PVC as a function of the duration of irradiation . This leads first to an increase in the efficiency of the polymer as a "radon barrier", by a factor of 10 then to a long-term weakness. The gamma irradiation (dose rate : 1.05 $kGy.h^{-1}$, dose : 0.71 MGy) has the same effect, but increases the efficiency of PVC as a radon barrier only by a factor 2.7. We have observed the same behaviour for samples of PVC irradiated with a dose rate 4000 time smaller (dose rate 27×10^{-2} $Gy.h^{-1}$; dose 4.6×10^{3} Gy).

1. INTRODUCTION

Today, radon is considered as the major source of radiological exposure of man to natural radiation (1).
In order to limit the radon emission from radium-waste packaging, and comply with the different regulations in the storage facility, specific packagings should include intermediary enclosures, such as polymer membranes used as radon barriers.
This work consists of studying a polyvinyl chloride membrane (a polymer often used in the nuclear industry), and in evaluating the effect of different radiations (UV and gamma) on the ageing of this polymer.

2. EXPERIMENTAL STUDY OF THE EFFECT OF UV AND GAMMA RADIATION ON THE TRANSFER OF Rn222 THROUGH PVC

2.1 UV radiation

2.1.1. Principle

We are studying radon transport in PVC membranes which have been exposed to UV radiation over different periods. After irradiation, these membranes are arranged in a stainless steel chamber (2) included in an experimental system.
We follow continuously the evolution of radon concentration in the downstream part of the system (if we refer to the membrane) due to the transfer through the membrane of gas present in the upstream part of the system at constant concentration. All the experiments are carried out at 20°C, at atmospheric pressure, with a zero differential pressure between the downstream and the upper stream of the membrane.

2.1.2 Results

In order to qualify the radon transport phenomenon inside the polymer, we have calculated the permeation factor by modelling the experimental evolution of radon activity concentration dowstream of the membrane (2). Figure 1 shows evolution of the permeation coefficient of radon in PVC versus UV dose. The permeation factor falls when the exposure period increases. In other words, the more irradiated is the membrane, the more Rn222-proof it is.

2.2 Gamma irradiation

2.2.1 Principle

We have developed two experimental device to study the effects of gamma irradiation on radon transfert through PVC.

- In the first configuration, we are following continuously radon transfer through PVC while irradiating the membrane with cobalt-60 gamma sources (dose rate 1.05 $kGy.h^{-1}$). The temperature of the experiment is contained between 20 and 25°C.
- In the second configuration, PVC membranes are first irradiated with cobalt-60 sources (3). The membranes are submitted to a gamma dose rate of 2,7 10^{-3} $Gy.h^{-1}$(4000 times smaller than in the first configuration) After irradiation, the radon transport through the gamma irradiated membranes is studied with the same experimental device that is presented in the chapter 2.1.1.

2.2.2. Results

In the first configuration, radon activity concentration downstream of the membrane evolves up to a maximum value, then decreases in successive steps to reach a minimum value.

In the second configuration, we observe an increased of the radon concentration until a steady state wich level is function of the dose taken by the membrane.

We have had more difficulties to make a model to describe the transport of radon for gamma irradiated membranes. However, we used the model proposed by Giridhar (4) to determined the radon permeation factor in PVC in these conditions. The permeation factors estimated by Giridhar law, in the two configurations, falls when the total gamma dose increase (figure 2).

3. INTERPRETATIONS

For the UV and gamma irradiations, we observed an increase of the PVC efficiency as a radon barrier, especially for UV-irradiated PVC in our experimental conditions.

Numerous studies on radiation effects in linear polymers have shown that the chemical changes which occurs are either crosslinking or degradations (5-6). It is well known that PVC crosslinked under irradiations. In order to explain our results (the decrease of the radon transport process in PVC in the UV or gamma irradiated PVC), we have to remember that the diffusion process of gas inside the polymer occurs by small displacements of side groups or segments of chains of the polymer. As a polymer crosslinks, the coordinated segment motion available for permeation is reduced, with a significant reduction in the diffusion coefficient. It is also likely that the extend of crosslinking zones inside the polymer structure, due to the effects of radiation on PVC, increases the effectiveness of the polymer as a radon barrier

4. CONCLUSION

The objectives of this preliminary study were to investigate the effect of UV and gamma radiation on the Rn222 transfer through PVC, with the purpose of knowing more about this polymer as a radon barrier, and its potential use for containment of radium-containing waste destined for storage in sites for long-lived radioactive waste. To observe the effect of UV radiations, we have exposed samples during different periods, then studied the radon transfer into the irradiated samples. We have been able to determine a permeation factor in each instance, with good repeatability, using a theoretical model. We have found a decrease by a factor of 10 in the permeation factor between an unexposed membrane and a membrane exposed in excess of 368 hours. To study the effect of gamma radiation, we have had two approaches:

-observed the radon transfer while irradiating the polymer at high gamma dose-rates,

-irradiated the membranes at weak gamma dose rate and study the radon transfer in irradiated polymers after irradiation

As for UV irradiation, we have found a decrease of the permeation factor, but by a factor of 2,7 only between a non irradiated membrane and a membrane having received a gamma dose of 0.71 MGy (dose rate: $1.05.kGy.h^{-1}$)

When the membrane is irradiated with a dose rate of 2.7 10^{-3} $Gy.h^{-1}$ (dose : 4600 Gy) the permeation factor decreases of a factor 1.8.

Future experiments should allow us to determine a limit in using the polymer as an effective radon barrier.

ABSTRACT

The extensive use of radium sources in radiotherapy and in industry during the first half of the 20th century has yielded waste of different types (needles, tubes, luminescent paints etc.) with various concentrations of radium. These waste products have the characteristic to produce radon, a radioactive gas and its progeny radionuclides. These are of natural origin, but they still require precaution to be taken in order not to increase significantly the radiological risk to workers and to present and future populations.The management of these waste products implies the use of specific packaging that reduces as much as possible the radon transfer from the radium source to the storage facility, in order to comply with the different regulations.

So, the efficiency of the packaging as a radon barrier must be controlled. We have developed a test method to estimate the radon leakage of different containers by the measurement of radon degassing from the packaging. With this methodology, we can measure radon leakage rates as low as 10^{-5} Bq.s^{-1} .

INTRODUCTION

Some industries produce radium rich waste (treatment of ores to extract uranium, phosphates, rare earths). One of the special features of these products is that they give off a rare radioactive gas, radon, with variable emission rates depending on the intrinsic properties of the material (humidity, grain size, radium content etc.). The health risk from the radon is, in fact, due to its short life progeny which, once inhaled, can be fixed in the lungs and be harmful. That is why there are Annual Intake Limits (L.A.I.) for potentially exposed workers.
Radium containing waste can be packaged in container of different types before being stored on suitable sites. It is very difficult to design a long term, absolutely radon-tight package.
Therefore, a certain rate of leakage is tolerated, a function of the final storage conditions at site (particularly the presence or absence of ventilation).
That is why it is important to be able to quantify as precisely as possible the rate of radon leaking from the packaging of the radium waste, and why a strict methodology for testing the packaging has been developed.

1 - PRINCIPLE

To find the radon leakage rate of different type of packages, it is necessary to have what is called a "reference" radium source and to know its radon emission rate. This is put into the packaging to be tested. Everything is then put into a confinement chamber. The leakage rate of the packaging depends on the measurement of the radon collected in the chamber.

2 - DESCRIPTION OF THE TEST APPARATUS

The test apparatus comprises (figure 1):

- a stainless steel, perfectly sealed confinement chamber,
- a radon 222 measuring instruments (silicon detector, scintillation flask),
- a circuit sweeping the confinement chamber which ensures ventilation rate of 1 per hour.

3 - CHARACTERIZING THE LEAKAGE FROM RADIUM SOURCE PACKAGING

3.1 - Studying the "reference" source

In order to determine this radon emission rate of the "reference" radium source, it is put into the confinement chamber. The change in radon activity $A_{(t)}$ in it is measured. Under these conditions, the radon concentration follows a law of the following type:

$$A(t) = A_{\infty}(1 - e^{-\lambda t})$$

in which: $A(t)$: radon activity in time t ($Bq.m^{-3}$)
A_{∞} : radon activity reached at $t \rightarrow \infty$ ($Bq.m^{-3}$)
λ : radioactive constant of Rn 222 ($2.1\ 10^{-6}\ s^{-1}$)

Now,
$$A_{\infty} = \frac{E}{\lambda V}$$

in which E is the radon emission rate of the source ($Bq.s^{-1}$), and V is the volume of the confinement chamber. The "reference" radium source is preferably one of high activity ($\sim 10^7$ Bq) with a radon emission rate around 10 $Bq.s^{-1}$.

3.2 - Testing the packaging

The radium source, qualified in this away, is put into the packaging to be tested. This is then put into the confinement chamber which is closed and the circulation starts. As previously, the change in activity of the radon inside the chamber is continuously followed.

In general, the radon concentration in the confinement chamber changes as shown in Figure 2.

Let: A_v : volumetric activity of radon 222 ($Bq.m^{-3}$) in the chamber
V : confinement volume (m^3); V = [(volume of the chamber) - (volume of the packaging to be tested)]
λ : constant for decrease in radon 222 ($\lambda = 2.1\ 10^{-6}\ s^{-1}$)
t : time (s)
P_F : radon produced in the confinement chamber by leakage from the packaging ($Bq.s^{-1}$).

This can be written as follows:

$$\frac{dA_V(t)}{dt} = \frac{P_F}{V} - \lambda A_V$$

with $A_V = 0$ for $t = 0$. So that P_F can be estimated using the formule :

$$P_F = \frac{A_v(t)\lambda V}{1 - e^{-\lambda t}}$$

Thus, for a radon activity in the chamber of 100 $Bq.m^{-3}$, P_F is in the region of $2.5\ 10^{-5}$ $Bq.s^{-1}$.

4 - CONCLUSION

A methodology has been developed in order to quantify as precisely as possible the radon-tightness of containers intended for storing sources of radium 226. With this technique, it is possible to measure radon leakages as low as 10^{-5} $Bq.s^{-1}$. We can also estimate the reduction of the radon emission rate of the "reference" radium source due to the packaging.

Effect of the New Neutron Quality Factor (ICRP 60) on the Transport of Radioactive Material

J.-Y. RECULEAU [1], P. MALESYS [2]

Tel : (33.1) 40.69.77.00. Fax : (33.1) 40.69.77.01.

The aim of this paper is to assess the effect of the new neutron quality factor, given by the publication ICRP 60, on the transport of radioactive material in France.

Neutron sources, mainly transuranians, are transported in containers with walls of a thickness allowing to meet the regulatory limits of equivalent dose rate on the package surface and at different distances. These limits will be more stringent when the new definition of the neutron quality factor defined by the publication ICRP 60 is implemented.

Faced with this regulatory evolution, packaging designers and carriers of radioactive material may resort to different solutions such as increase cask shielding and qualification of the new package model, limit the payload, or fit additionnal shielding on the vehicle.

Because the new regulatory limits can lead to a modification of package models, of the equipment used for the transport, and to more numerous transports of radioactive material, this paper proposes some examples of technical solutions, and gives indications about expected changes in the design and possible increase in the number of transports in France.

THE APPLICATION OF EXEMPTION VALUES TO THE TRANSPORT OF RADIOACTIVE MATERIALS

INTRODUCTION

The principles and methods for establishing exemption values have been published by the European Commission DG XI (Radiation Protection 65) (1) and endorsed by the International Atomic Energy Agency (Basic Safety Standards) (2). These documents contain activitiy and activity concentration below which reporting is not required. The main objective of this study is to examine the relevance of the BSS exemption values to the international transport regulation.

The basic dose criteria in all feasible situations for exemption used by the BSS are 10 μSv/y for an individual effective dose in normal conditions (1 man-Sv/y for a collective effective dose), 1 mSv for an individual effective dose in accident conditions and 50 mSv for an individual dose to skin for both conditions. To derive the BSS exemption values, various exposure conditions were identified for normal and accident conditions leading to radionuclide specific exemption values expressed in term of activity and activity concentration.

Currently the transport regulation (3) includes a definition of radioactive material such that material with a specific activity below 70 kBq/kg is outside of the scope of the regulation. At the IAEA, the transport community has discussed the application of the BSS exemption values to transport and supported the dose criteria used, but was not convinced that all transport scenarios had been adequately addressed.

This paper[1] presents the calculations of exemption values for transport scenarios for a selection of twenty representative radionuclides. Those scenarios are derived from transport scenarios extracted from the BSS and from added specific transport scenarios. These results are compared to the corresponding BSS exemption values and to the 70 kBq/kg existing definition of the radioactive material of the transport regulation.

SCENARIOS AND METHODS

Several scenarios used in the BSS have been considered to be relevant for transport. In addition four basic scenarios were considered to be relevant for normal conditions of transport.

- A postman or courier delivers a package containing radioactive material to a laboratory or a hospital after having carried it during their delivery round.
- A driver, either an employee or member of the public, transports bulk material or packages in a truck or van.
- An employee or member of the public loads bulk material or packages into a truck or van.
- A member of the public travelling in an aircraft is exposed to radioactive materials being transported in the hold of the aircraft.

[1] This study has been supported by the European Commission DG XI.

Within the four basics scenarios, there are several sub-scenarios. They are described in the report « The Application of Exemption Values to the Transport of Radioactive Materials » (4).

A scenario based on the Q system (IAEA Safety Series n°7) (5), revised with the dose criterion of 10 μSv/y, was used. This scenario considered the main exposure pathways associated with accident situations of transport.

The methodology used to calculate exemption values was consistent with that used in the determination of the BSS values and is detailed in the report « The Application of Exemption Values to the Transport of Radioactive Materials » (4).

RESULTS AND DISCUSSION

The results for the transport specific scenarios were compared with the relevant ones used for the BSS exemption values to provide limiting values. One of the restrictive scenarios concerns the external exposure of a truck driver transporting 20 m^3 of bulk material for a duration of 400 hours per year. The restrictive activity values come from several scenarios but many of the results are similar. The values obtained from application of the Q-system are not limiting.

A comparison of the basic dose criteria of 10 μSv and the doses associated with the 70 kBq/kg is illustrated in Figure 1. The figure 1 reveals that a dose of up to 2.2 mSv could be expected with 70 kBq/kg of Co-60 and doses greater than 1 mSv could be expected with 70 kBq/kg of Ra-226, Th-232 and U-238. On the other hand, the 70 kBq/kg is too stringent for radionuclides such as C-14 or S-35. A single value of 70 kBq/kg for all radionuclides is not compatible with the results from the agreed transport scenarios. For the radionuclides listed in the BSS, more than two thirds of them have an exemption value less than 70kBq/kg or result in a dose greater than 10 μSv for an activity concentration of 70 kBq/kg.

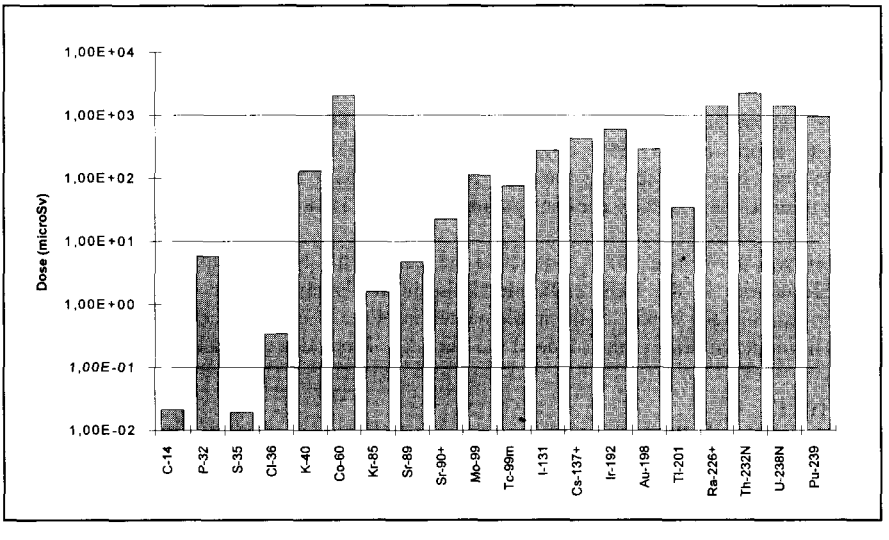

Figure 1 : Radiological impact of the 70 kBq/kg exemption level.

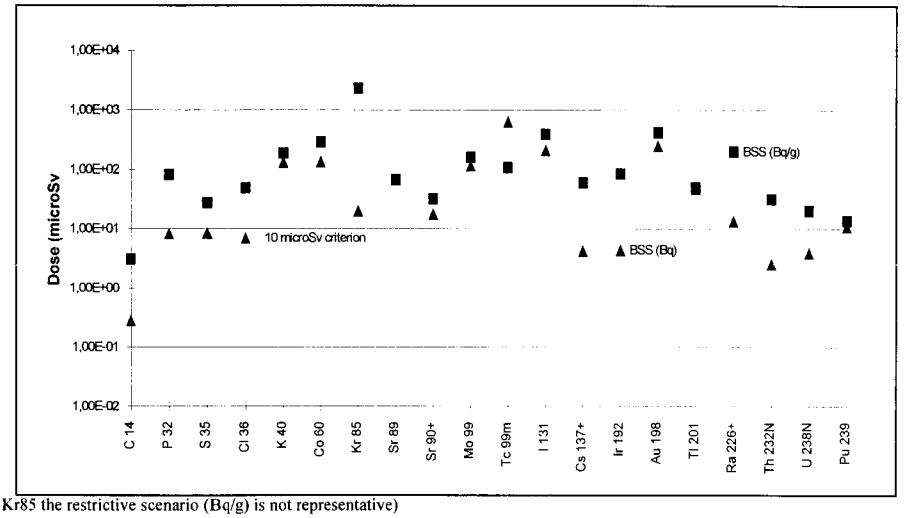
Figure 2 presents the radiological impact of the BSS exemption levels and shows that most are within one order of magnitude. Only Kr-85 is two orders of magnitude different. It can be argued that krypton is not transported as 20 m^3 of bulk material. For activity values the greatest difference is for Tc-99m, where a factor of 47 lower is observed.



(for Kr85 the restrictive scenario (Bq/g) is not representative)

Figure 2 : Radiological impact of the BSS exemption levels.

The transport specific exemption values are generally rather more restrictive than the BSS exemption values. However, these two sets of values are much closer to each other than the transport values are to the single value of 70 kBq/kg.

CONCLUSION

The activity concentrations and activities for the agreed twenty radionuclides in the transport scenarios are within two orders of magnitude of the BSS values. Such a range is insufficient to establish transport values different from those of the BSS. The generic BSS figures are therefore representative for transport.

A single exemption value is not consistent with the adopted dose criteria. Then, it seems reasonable to adopt, in the 1996 Edition of the international Transport Regulations, the BSS exemption values below which the transport regulation would not apply. In practice, it could be appropriate to restrict the activity per consignment because it is more operationally convenient.

This work was performed under contract to the EC and has been discussed by the international transport community at the IAEA. On the basis of this study, further developments could be envisaged to examine the impact of the implementation of the BSS exemption values to the transport practices. This could be done in the scope of the Radiation Protection Program.

ABSTRACT (See instructions overleaf)

The terms exclusion, exemption and clearance are defined and used in the International Basic Safety Standards for Protection Against Ionizing Radiation and for the Safety of Radiation Sources (BRSS). All of the terms are concerned with specifying the types of radiation sources which do not need to be regulated. However, the reasons that regulatory control is not needed are different in each case. Exclusion refers to sources which are not amenable to control, for example, cosmic radiation at ground level and most natural sources in the environment. Exemption and clearance apply to sources which would normally be expected to be under control but which present such a low risk that it would be a waste of resources to exercise control by regulatory means. Exemption applies to sources which never enter the regulatory control regime, while clearance applies to sources which are released from regulatory control. While the broad concepts are clear, it has become evident that some clarification and elaboration of their application is necessary.

EXPOSURE TO RADON IN CAVES AND ABANDONED MINES

D W Dixon
National Radiological Protection Board, Oxfordshire, United Kingdom

Abstract

The significance for health of exposure to radon daughters during leisure excursions in disused mines or caves is considered for visitors with interests in speleology, mineral collecting, mining history and youth training. General members of the public might also enter tunnels. Potential annual exposures based on radon measurements in various mines and caves are estimated and it is concluded that the annual exposure of individuals who undertake frequent and prolonged trips to underground systems might exceed 10^6 Bq h m^{-3}. Exposures to general members of the public are likely to be much lower.

The National Radiological Protection Board has developed proposals for a coherent and comprehensive scheme to promote dose limitation in a wide range of circumstances. These are described, with current initiatives on consultation with National Associations, local Government and many special interest groups.

1 Introduction

Most studies of radon daughter exposures are concerned with the exposures received in homes or at work in buildings or mines[1,2]. Significant potential also exists, however, for people who undertake leisure excursions into caves or disused mines[3], including, for example, people with interests in speleology, mineral collecting, mining history or youth training. Some of these activities can involve prolonged exposures in remote regions of caves, called wild caves, or in abandoned mine tunnels, where there is a potential for radon to reach very high concentrations. The potential for exposure has been investigated amongst UK groups, and a scheme has been developed to promote voluntary dose limitations during such activities.

2 Potential for exposure

The radon level in a cave or mine depends largely on the rate and direction in which air is flowing through the system. Broad trends in concentration can be assessed from a knowledge of how changes in temperature affect natural ventilation, and some systematic variations in radon concentrations can be explained, at least qualitatively[4]. Considerable uncertainty arises, however, in trying to predict radon levels under particular conditions, and the potential for exposure is most reliably estimated from measurements of radon levels and duration of exposure.

Radon levels have been investigated in various studies of UK mines and caves. The potential for exposure in showcaves of varying complexity has been evaluated both in the outer regions, where members of the public have access, and in the more remote locations which are often used for adventure caving by youth groups and others. Average radon levels in cave systems were up to 22 500 Bq m^{-3} , with a maximum concentration of 30 000 Bq m^{-3}. Extensive measurements have also been conducted by various caving groups during extensive and prolonged trips in several wild cave systems[5]. The measurements showed that average levels in systems could reach 35 000 Bq m^{-3} with a maximum concentration of 300 000 Bq m^{-3} at one location. The arithmetic mean values of all measurements in these two studies were 7 000 and 10 000 Bq m^{-3} respectively. A limited programme of measurements was conducted by NRPB in several abandoned mines that were known to be visited by casual visitors and those pursuing various hobbies. Concentrations were measured in the outermost 50 m of the tunnel and were found to be similar to the levels measured in natural systems. Although access to these tunnels is unrestricted, there is generally less scope for exploration of inner regions, since tunnels are often blocked or endangered by unprotected vertical shafts and broken rock. An exceptionally high concentration of 800 000 Bq m^{-3} was measured at one location about 20 m inside a tunnel entrance, but access was very difficult, through deep water, and it is probably very rarely visited. The results of the measurements are summarised in Table 1.

The duration of a trip underground is likely to vary considerably with the purpose of the visit. The groups who might enter systems are listed in Table 2. Members of the public who enter cave or mine tunnels out of curiosity are likely to spend only short and infrequent periods underground, perhaps an hour or so in a year, although

this might in some cases reach ten hours. The exposures accumulated by regular cavers and mineral collectors on the other hand might be substantial as a result of prolonged excursions underground or frequent entry into areas with high concentrations. Some of the highest exposures are likely to be received in wild caves or abandoned mines and might easily reach or exceed 100 hours annually for particularly enthusiastic individuals.

Radon levels in some mines or caves clearly reach a value at which a significant exposure could be accumulated during a single trip of several hours underground, and those who enter mines or caves regularly could accumulate excessive exposures. On the assumption that visitors are exposed to an average level of 10 000 Bq m^{-3} during trips underground, the annual exposure received by a regular and frequent visitor could reach 10^6 Bq h m^{-3} or more if trips are predominantly to systems with high levels. In the worst case, an exposure of this magnitude could be received during a trip of only a few hours. Exposures received by those who enter systems less often would be unlikely to exceed one-tenth of this value, although the ease of access to areas with high levels should be recognised.

3 Voluntary dose limitation

It is a general principle of radiological protection that radiation exposures should be as low as reasonably practicable and it is clearly desirable to apply this principle irrespective of the source of exposure. The first requirement, therefore, is to inform visitors about the potential for exposure so that the need for surveillance can be considered. Unfortunately, there are considerable practical difficulties in measuring radon levels in remote parts of underground systems, and information about the potential for exposure will often not be available or easy to obtain. In such circumstances, personal dosimetry can provide a suitable and convenient means of obtaining accurate estimates of dose[7]. Experience has been gained in the UK with the use of personal dosemeters for people who enter caves for leisure purposes.

Recognition of the significance of exposures that might be received in caves and mines prompted NRPB to propose a voluntary scheme for dose limitation. Essential elements of the scheme include advice that individual exposures should not exceed 10^6 Bq h m^3, that data on radon levels should be reviewed where available and that personal monitoring should be employed to assist people to remain within the annual guideline. It is also expected that information about radon levels and exposure limitation will be developed and made widely available, particularly amongst caving groups.

The scheme has been developed in consultation with the National Associations that represent and co-ordinate activities in caves and mines and it is expected that the various organisations involved will monitor and review exposure limitation practices and encourage improved procedures. Exposures received by members of the public who enter the outer parts of tunnel systems are likely to be very small; nevertheless, it is recognised that access into areas with high radon levels might be quite common in some localities. Local Authorities have certain responsibilities for health and safety in places with public access and are developing exposure limitation programmes for specific sites in their areas.

Abstract for IRPA 9 (1996)

INTERNATIONAL REPORTING SYSTEM OF UNUSUAL EVENTS (RADEV)

Authors: P. Ortiz, Robert Jarrett

A questioning and learning attitude by managers and operators of radiation sources and devices used in medicine, industry, research and teaching, combined with information on accidents, their initiating events and contributing factors is an efficient way to drastically reduce the probability of further accidents. The list of contributing factors can be readily used to test the vulnerability of a given facility.

The number of reported events in a single country is in most cases insufficient to provide significant body of lessons in a reasonable time. Therefore, an compilation of accidents at international level, would allow all countries to benefit from the lessons from each one of them. Moreover, unusual events which did not culminate in an accident can build up a body of knowledge to avoid real accidents. Therefore, it should be possible to obtain information on cases (near misses) that otherwise are not published in any scientific journal and would never reach the interested community.

For this reason, an International Reporting System of Unusual Events has been set up by the IAEA. The reporting system will consist of a database with protected fields for those confidential data which should not be included in the reports. The goals of this project is to compile the information, to revise it periodically, to extract lessons, to disseminate them so that they this knowledge can fed into the training programmes of different professionals such as: regulatory authorities on radiation safety, health authorities, managers of facilities where radiation sources are used, manufacturers and maintenance personnel and operators of these facilities.

The sources of information are expected to be national authorities on radiation protection and ministries of health, along with professional associations such as radiotherapy, medical physics radiation protection, industrial gammagraphy (non destructive testing) and industrial irradiators among others.

THE NATIONAL CENTRAL REGISTRIES OF OCCUPATIONAL AND MEDICAL EXPOSURES IN THE CZECH REPUBLIC

Ing.Karla Petrová [1], Ing.Zdenek Prouza,CSc.[2]

[1] National Institute of Radiation Protection, Šrobárova 48, 100 00 Prague 10, Czech Republic
[2] State Office of Nuclear Safety, Slezská 9, 120 29 Prague 2, Czech Republic

ABSTRACT - This paper describes recent situation in the Czech Republic concerning the registration and evaluation of occupational and medical radiation exposures. Since 1993 the creation of the Central (national) Registries of Occupational (CROE) and Medical Exposure (CRME) has been started. One of the main functions of these registries will be to provide statistics to guide policy making on a national basis. Authors give more detailed information on the structure of creating programs and discuss some actual arising problems.

INTRODUCTION

The actions leading to the creation of CROE and CRME were opened in 1993 by Radiation Hygiene Centre of National Institute of Public Health under the financial participation of the Ministry of Industry and Trade and Ministry of Health. In accordance with the changes in the structure of radiation protection in our republic this year, registries are now created in new National Institute of Radiation Protection which is supervised by State Office of Nuclear Safety (Fig.1).

Creating central registries, the Czech Republic (CZ) follows an international recommendation and world-wide trends in this field. CROE enable us to follow and control not only the individual doses of workers, but also to follow a radiation history of workers, estimate collective doses and time trends in different occupational categories, evaluate the efficiency of ALARA methods applied into the practice, help to find groups of workers significant from the point of view of radiation protection and collect data for epidemiological studies.

The survey and evaluation of medical radiation exposure (MRE) exists as a part of all reports of UNSCEAR from 1958. The aim of these world-wide studies is an estimation of world-wide dose, analyse of frequencies and dose distributions also in relation to age and sex of patients and determination of time trends in this area. Results of these studies help to find reasons for regional differences in doses for the same procedures, search the way for decreasing patient's exposure and to evaluate their effectiveness.

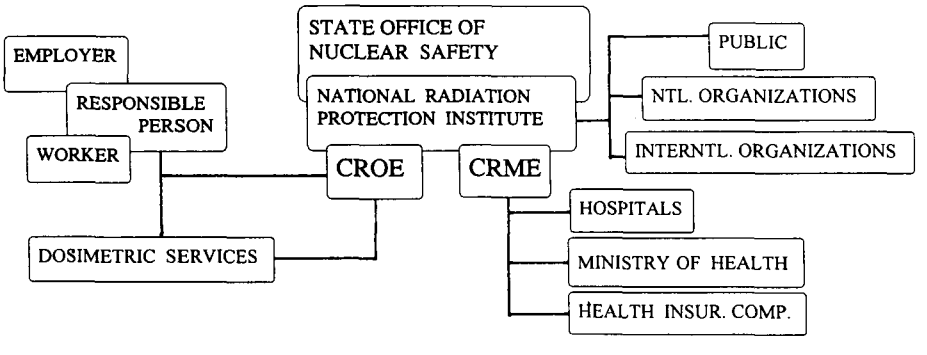

Fig.1: Organizational scheme of CROE and CRME in the Czech Republic

THE CENTRAL REGISTER OF OCCUPATIONAL RADIATION EXPOSURE IN CZ

The base of a registration and evaluation of OE is an individual monitoring of classified workers. The employer's duty, covered by the Regulation No.59 / 1972 in CZ, is to secure individual monitoring of radiation workers and record results of this monitoring. There is also legal duty of licensee to provide CROE with data in new prepared law on Peaceful Use of Nuclear Energy and Ionizing Radiation (e.g. " Atomic Act "). Dosimetric provision and evaluation of OE in CZ is the subject of a separate report to be presented at IRPA 9 Congress by Prouza , Petrová .

Databases of CROE contain detailed identification of employers including their activity categories (Tab.1) and the dose records for all monitored workers with details of their age , sex, occupational category (Tab.2), type of handling radiation source. The data will be reorganized annually and individual dose assessment will be maintain for the current year and previous five years. Earlier data will be archived. The system use special identification number for workers (birth number) and employer (random number) and all data are treated as confidential. Recently the registration cards serving for a contact between CROE and dosimetric services and employers are distributed. The cards will provide for CROE entrance data of all radiation workers in CZ and any changes in their registration. The database system is using ORACLE and operating in HP computers.

The contact with the International System on Occupational Exposure (ISOE/OECD) was opened up in 1994 and the created national system of ORE registration is built in the harmony with the recommendations and demands of this international system. This is a reason for instance for such detailed structure of occupational categories in NPP.

Tab.1: Employer's activity categories in CROE

1.0. health service (3)	6.0. defence
2.0. education, research	7.0. agriculture, food
3.0. energetics (3)	8.0. transport
4.0. general industry (4)	9.0. specialized facility (2)
5.0. uranium industry	

The start of operation of CROE is planned for 1996 . CROE will provide the new employer with summarized information of an individual's dose history, to guarantee a right annual dose calculation for workers with two or more employers, to provide statistics to national regulatory authorities and also another subjects interested in, according to CROE statute.

Tab.2: Occupational categories in CROE (the number of items for each category in parentheses)

1.0. Defectoscopy (2)	5.0.0. NPP (6)	6.0.0. Medicine (4)
2.0.Well logging (2)	5.1.0. Inspection, control (3)	6.1.0. Radiodiagnostics (4)
3.0.Radioisotopes (7)	5.2.0. Radiation protection (3)	6.2.0. Nuclear medicine (3)
4.0.Uranium industry (5)	5.3.0. Operation, maintenance (8)	6.3.0. Radiotherapy (5)
	5.4.0. Chemistry (3)	6.4.0. Veterinary medicine (1)
	5.5.0. Fuel handling (1)	7.0. The others specialized
	5.6.0. Waste disposal (1)	workers (4)

THE CENTRAL REGISTRY OF MEDICAL RADIATION EXPOSURE IN CZ

In CZ (10 mil.inhabitants) there are recently 350 radiodiagnostic, 52 nuclear medicine and 40 radiotherapy workplaces. There was performed about 9.5 mil radiodiagnostic, 250 ths

nuclear medicine and 22 ths radiotherapy procedures per year (numbers from Institute of Health Information Systems of Ministry of Health of CZ, in1993). This is big amount of data and it is impossible to sort all of them according to all demanded parameters . There are three main sources of data :

- the regular annual statistic survey of Ministry of Health which is managed by Institute of Health Information Systems (IHIS), but there is no possibility to sort patients according to their age and sex ,and there is also problem with clear definition of individual examinations,
- the organization of a national survey and use of information systems of individual health utilities - there is problem with co-operation and organization of this survey,
- the co-operation with health insurance companies - there are twenty companies in CZ now, but one of them - General Health Insurance Comp. (GHIC) is the biggest one which cover recently about 80 % of our population.

Database GHIC obtains birth number of each patient from that it is possible to determine age and sex of patient and there is unified list of all examination. CRME is operating only with a part of birth number of patient, the system will not operate with confidential personal data. In principle we would like to collect data by both way in co-operation with GHIC and with selected representatives health utilities.The data from IHIS will serve for better approximation of collected data to a national level.

GHIC provided CRME with first data which are related to the region with 1,2 mil. inhabitants for 1994. The first results for nuclear medicine procedures are showed in Tab.3 .

Tab.3: Sex and age distribution of the patients undergoing a nuclear medicine procedures in 1994 in the Czech Republic - first results of CRME

ABSTRACT (See instructions overleaf)

The peruvian regulatory control is based in the system that includes registers, licences, inspection and enforcement. Its programm was designed in two stages, taking into account risk and economic matters.

First stage was addressed to the priority for locating all of the sources - inventory -, and to carry out inspections for knowing the current protection of individuals. This stage, marked by a persuasive than a coercitive control, allowed to meet an important reduction of occupational doses (from 9 mSv/year to an average of 6 mSv/year in only four years) and solving basic aspects in the safety of sources and installations. However, results in the formal aspects were poor because only a few installations and sources were formal licenced.

In this sense, the second stage has started three years ago, with priorities on registration and licencing of sources and installations. The process, that is acomplished by coercitive actions of users, has been succesful and the results show an increase of four times in the registers and licences issued, in just three years. Besides, the inspection activities has been enfaced by trained inspectors, not belonging to authority body, increasing the quantity of sources inspected in almost two times. Results in occupational doses show a reduction to an average of 3 mSv/year. Additionally, the regulatory expenses has been reduced. This results and methodology will allow to enface others aspects as enhacing the patient protection in the short time.

DEPARTURE FROM ICRP-60 IN CANADIAN RADIATION PROTECTION REGULATIONS

R.M. Chatterjee, and M.P. Measures

Atomic Energy Control Board, Ottawa, Ontario Canada K1P 5S9

INTRODUCTION

The Atomic Energy Control Board (AECB), Canada's nuclear regulatory authority, is preparing new regulations based on ICRP-60. The proposed regulations have some features which are different from ICRP-60, e.g., the limit for pregnant workers was set at a higher level than that proposed in ICRP-60. The AECB, through its consultative process, received many responses from female staff in nuclear medicine. The concern was that it would be very difficult to prove compliance with such low doses, particularly for internal doses. There was an additional concern that hospital administrators would respond to the reduction of the current pregnant worker limit from 10 mSv to the ICRP-60 recommended value of 2 mSv by discriminating against hiring women. A new proposal for the dose limit for pregnant workers has been made which will limit the dose to the mother by means of a combining formula that will take both external and internal doses into account.

DISCUSSION

The original proposal of the AECB was identical to the ICRP 60 recommendation, i.e., 2 mSv to the surface of the abdomen and an intake of 0.05 ALI. This was criticized in the comments from the public as being unnecessarily low. In addition, it was difficult to demonstrate compliance in view of the difficulty of measurement of doses at such a low value. Therefore, a series of public meetings was held to obtain more direct comments from the female radiation workers themselves. They were asked to advise the AECB on what they thought the limit should be. Considerable effort was made to present the technical information on risk in a form that could be readily understood by the participants. Representatives of professional associations, employers and trade unions were given the opportunity to make presentations.

The response from the public meetings was to set the limit at 4 or 5 mSv for the pregnancy period, i.e., between the current limit of 10 mSv and the ICRP recommendation. The technical presentation at the public meetings had indicated the risk to the foetus from 2 mSv, and compared this to the risks to the foetus from natural causes such as spontaneous abortions, congenital anomalies, etc. The radiation risks were taken from a consultant's report to the AECB(1). This report was prepared by Dr. D. Myers, who also gave the technical presentations at the public meetings.

According to his report, a dose of 2 mSv to the foetus, which would be the approximate dose if a pregnant woman received the ICRP 60 recommended limit, would carry a risk of 4:10,000 total health detriment including fatal and non-fatal cancers. For childhood cancer alone, 2 mSv would carry a risk of 1:10,000. These risks were compared, at the meetings, to

the risks which the foetus faces from natural causes, as mentioned above, which are much higher. The participants at the meetings were of the general opinion that slightly higher risks, i.e., about double that from 2 mSv, would be acceptable when compared to the risks to the foetus from natural causes.

The meeting participants were presented with data from the Canadian National Dose Registry (NDR) for doses received by pregnant workers. Since 1986, 300 to 400 pregnant workers have been monitored for external radiation doses each year. During those years, the maximum dose to any individual, recorded for the duration of the pregnancy, varied from 1.3 to 2 mSv. These doses are in relation to the current limit of 10 mSv during the pregnancy. The NDR data for the category of nuclear medicine technologist (not those that are pregnant) indicates that 70% of these workers receive less than 2 mSv per year, and only 5% receive more than 5 mSv per year, in relation to the current limit of 50 mSv per year. Therefore, the current doses to nuclear medicine technologists would not be a major source of concern, even for those who do not choose to declare pregnancy. It should be pointed out that these doses do not include any contribution from internal contamination. What information which is available at present suggests, is that this is not likely to be a major contribution to total dose and a study on the subject, sponsored by the AECB, is nearing completion, and should give more definite information.

CONCLUSION

The limit of 4 mSv was chosen because:

a) this was the consensus of the meetings, based on acceptable risk considerations;
b) the risks from a dose at this limit are small compared to the risks to the foetus from natural causes;
c) with a current limit of 10 mSv per pregnancy, dose levels for pregnant workers are generally below 2 mSv, which indicates that ALARA is being practiced by most licensees. A limit of 4 mSv would make those that are not, review their operations;
d) we also took into account advice received from the Canadian Human Rights Law Section of the Canadian Department of Justice about the Charter of Rights implications of treating pregnant workers differently from other workers.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 8.3 (see page 7)

ABSTRACT (See instructions overleaf)

The concept of dose constraint was put forward by the International Commission on Radiological Protection (ICRP) 5 years ago. Consensus has been reached on most of its characteristics, but it is not yet applied in the European Union regulations. Under the auspices of DG XI, a study has been carried out in order to look at the practical difficulties that may be encountered in doing so. It aimed at identifying the practices which involve "restrictions" on doses, below the regulatory limits.

Both in the field of occupational and public exposures it has been found that many restrictions apply in the national regulations, or in the less formal exchange between the authorities and the industry.

Most of those restrictions have many common points with actual constraints but few of them possess all the characteristics of a dose constraint as defined by ICRP. For example, limits for gaseous or liquid discharges do aim at doses below the limit for the public and they do take into account other sources, but they have the statute of a regulatory limit. Some authorities add "objectives", below the authorized levels, which are almost real constraints, but the practice of optimisation does follow very seldom. As regards occupational exposures, the analysis of the safety cases showed that the management often proposes dose objectives to the authorities.

The paper will present the results of this investigation and propose solutions for an introduction of the dose contraint concept that would make profit of existing practices.

A POSSIBLE APPROACH TO ASSESS COMPLIANCE WITH A LIMIT BY MEASUREMENTS*)

Abstract

A proposal is made to how to prove or not compliance with a limit by radioactivity measurements, taking into account the statistical nature of radioactivy. The proposal has also some influence to the requirements for the quality of the measurement.

1. PROBLEM

Usually figures are set in standards /IAEA 1994/ or by authorities with the objective to control doses. These figures are established for different exposure conditions as emergency or chronic exposure. Such figures might be called guidelines, reference levels, action levels, limits etc., and have to be conceptually in terms of dose. For practical reasons and therefore more frequently, however, derived quantities are used as activity concentration for a given radionuclide i in a given material, e.g. in foodstuffs or in air. In the following, the activity concentration $A_{c,i}$ is denoted as A.
In any case, an apparently very precise figure is established, and the compliance with this number is achieved by checking whether the assessed activity concentration is below or above this figure. In the most frequent case, the assessment of the activity concentration by measurement, a statistical quantity results. In this case, two different kind of figures have to be compared: a deterministic and a statistical quantity.

The figures are:

a) a preset limit, indicated by a singular figure, usually expressed with one or two significant digits, e.g. 0,2 kBq/kg
b) a statistical quantity, to be expressed by a mean and a variance.

When samples are subject of measurements, a question as
" can you assure (or even guarantee) that the sample complies with..... "
is raised by authorities, by media and by the public. From a scientific point of view, striktly spoken, a positive answer can not be given at all. This is because radioactive decay does not behave to fulfil the properties of a deterministic quantity. However, the question is still asked

frequently, although being an unscientific one by definition. Although a foolish question usually deserves a foolish answer, a realistic approach which might satisfy nonscientific formalists and being acceptable from scientists is presented below.

2. BASIC CONSIDERATIONS

The fulfilment of the condition, say

$$A < L \qquad (1)$$

where: A... activity, L.. limit

can be stated only with an additional information, namely the confidence interval of the assessment. Therefore, the correct statement is

$$A < L \text{ , with a given probability} \qquad (2)$$

linking three values:

a) mean A (estimated from the measurements)
b) uncertainty σ (estimated from the measurements)
c) limit L (constant)

Taking into account the well known properties of statistical distributions, a statement:

$$A < L \text{ , with 100 \% probability}$$

can not be achieved by definition, although being required by some groups who think that the setting of limits solves all problems.

3. PROPOSAL

In the following, a possible solution of the question raised above is presented. In order to obtain a resonable answer, the question on the purpose of the assay of radioactivity has to be formulated in a more precise form.

3.1 Formulation of the questions

There are three possible questions, which have to be clearly expressed in advance:
a) what is the activity concentration?
b) is the activity concentration of the sample lower than a given value and hence in compliance with an upper limit (e.g. a possibly contaminated food sample)?
c) is the activity concentration of the sample higher than a given value and hence in compliance with a lower limit? (not considered in detail here)

3.2 Answers

ad a) The first question is answered by measurements, the answer being an activity (concentration) A and a standard deviation σ expressing the statistical uncertainty:

$$A \pm \sigma$$

This formulation of the question is not associated with compliance with limits, but rather with the assessment of the activity as such.

ad b) This is the most frequent case, namely to check whether an activity in a sample is less than or equal to a preselected figure.

It is proposed to consider a sample in compliance with the limit when the following condition is fulfilled:

$$A + n.\sigma \leq L \qquad (3)$$

The choice of the number of standard deviations n is subject of discussion and by definition somewhat arbitrary. When n is chosen too small, the measurement is uncertain. When n is large, a lowering of the limit is associated with. To obtain a compromise, it seems therefore reasonable to adopt n = 1.

4. DISCUSSION

This concept presented above has the following properties:

i) the activity of the sample is by definition less than the limit. Hence, a possible blame of a hidden increase of the limit is unfounded.

ii) The definition has an inherent property which might be even more important than the condition i) above: The acceptable uncertainty of the measurement in a given case depends on the activity level and the quality of the measurement, i.e. on the variance and the detection limit. This implies that an inexpensive measurement with a large variance is sufficient to prove compliance with the limit for samples well below the limit. On the other hand, when the activity approaches the limit, an accurate measurement permits the confirmation of the compliance of samples with the limits with almost arbitrary accuracy. Details can be found in /ÖN 94, Ts 95/

ABSTRACT (See instructions overleaf)

Monitoring of nuclear power plants (NPP) discharges into atmosphere and hydrosphere based on particulate-iodine-gase (PIG) measurements and gross beta or gamma plus tritium measurements respectively is being improved by nuclide specific measurements employing semiconductor gamma and alfa spectrometry and radiochemical methods. In connection with this progress new concept of authorized effluent limits and the related regulations implemented in Czech Republic is presented. Activity of all principally contributing to the effective dose radionuclides discharged during a year multiplied by a Sv/Bq conversion coefficient based on a standard model are summed up and the effective dose is compared with the new limit. These limits should be for discharges into atmosphere authorized as per caput collective committed effective dose in the NPP surrounding and into the hydrosphere as committed effective dose to the critical group member.

MAJOR SCIENTIFIC TOPIC NUMBER 8.3 (see page 7)

The Basic Standards for Radiological Safety enforced in Argentina in 1994, include the ICRP Publication 60 recommendations and are consistent with the International Basic Safety Standards of the IAEA. Studies performed show that no relevant difficulties should appear in accomplishing with the new occupational dose limits in the nuclear and radioactive facilities in the country, except for the Atucha I Nuclear Power Plant. It was said in previous studies that in this plant it would be necessary a significative effort for the optimization of radiological safety procedures in order to diminish the occupational doses, and to change the fuel channels by new ones free of cobalt. At the moment it have been changed 59 channels, almost 25% of all.

The Argentine Basic Standards consider special circumstances as those where radiation protection in a practice has been optimized and occupational exposures still remain above the new dose limits, and it can be predicted that reasonable efforts can, in due course, bring the occupational exposures under the limits. In this case the Regulatory Authority may exceptionally aprove a temporary change in a dose limitation requirement of the Standards -only if formally requested by the registrant or licensee-, with the constraint of 50 mSv in a year and for no more than 5 years.

It have been identified individual and collective doses due to the change of fuel channels, and the workers for whom a temporary change in the dose limits could be asked for.

RATIONAL SYSTEM OF RADIATION DOSIMETRY

Kazuaki KATOH[1], JunIchiro TADA[2]

[1] Ibaraki Prefectural University of Health Sciences, Ami, Ibaraki 300-03 Japan

INTRODUCTION

Radiation doses are the most important subject to the sciences relating to the effects of ionizing radiation on matter. Since any science at all must stand on the quantitative description of causality, uses of physical quantities as the measures are indispensable.

The current system of radiation dosimetry is built on the fundamental dose of the absorbed dose, which is defined as the "energy imparted" density, and for practical convenience, various weighted absorbed doses are introduced as subsidiary. However, it has been pointed out that these quantities lack adequacy inherently as a measure of causes, in addition to the insufficiency of the specification of the concept(1-3).

Firstly, separation of the quantities of radiation field and of the dose is not possible, since both quantities are deeply related to the same microscopic constituents, i.e., electrons(4,5).

Secondly, the value of the absorbed dose cannot be fixed at the moment of irradiation. Since the absorbed dose is a quantity of interaction product of radiation and matter, the values of the dose cannot be fixed instantaneously.

Thirdly, it is not easy to envision the physical entity of the quantity from the definition. The form of existence of the "imparted" energy is not clear in the current definition (1).

These defects can not be removed as long as an interaction product is adopted as the dose quantity. In this paper, the authors present a prescription to solve these problems.

PROPOSAL OF A RATIONAL DOSE CONCEPT

Being the system of radiation dosimetry rational, the quantity adopted as the dose should meet the following requirements.

First of all, the quantity of measure (radiation dose) is to be chosen as point specific not only in space (coordinates) but also in time (coordinate). Secondly, the value of dose should be fixed at the moment of incidence. Thirdly, the dose is to be of local field quantity.

In order to guarantee the measurability, one must define the quantity point specific in space-time coordinates. Though the problem with the space has been discussed (4), the temporal structure of energy transfer contributing to the dose has not been mentioned so far. The value of the dose defined with interaction products is not definitely settled for a given moment, since the events of energy transfer do not in general occur simultaneously.

Since the dose is to be used for the purpose of predicting future phenomena of radiation effects, its value should be clearly determined at the instance of irradiation. As far as an interaction product is used as a dose, its value for the future can only be estimated as a mathematical expectation, though its value for the past is definitely established. Thus, the dose should not vary temporally thereafter.

With the current system of dosimetry, values of the dose as well as the field are influenced simultaneously by the change in configuration of materials surrounding the point of interest. The difficulty arises in separating the field and the dose of radiation (4).

In order to meet above stated requirements, we believe that THE SOLUTION is to define the dose with a radiometric quantity, the particle fluence, not with a dosimetric quantity. Because radiometric quantities are point specific both spatially and temporally, their values are defenitely settled at the moment of incidence of radiation, and their physical entities are clearer in general. However, there is room for discussion whether particle fluence is superior to energy fluence or not.

RELATION BETWEEN THE CURRENT AND PROPOSED SYSTEMS AND PROBLEMS

Usually, very drastic changes to a prime system are not favorable. Because its influence to the society must be tremendous. However, even today, practical dosimetry is not always made in a way faithfully which follows the definition of the current system of dosimetry, e.g., neutron dosimetry, high energy particle dosimetry. In these cases, doses are evaluated through the measurement of the particle fluence using corresponding conversion coefficients. So, one has only to use these conversion coefficients as the weighting factors to the particle fluence when one wants to use the current doses subsequently in the new system.

Moreover, any dosimetric quantity, in principle, can be expressed as weighted particle fluence. No undesirable consequences are found for the moment.

For an illustration of the situation, relations of the effective doses of photons and of neutrons, an important dose in the field of radiation protection, and their particle fluences are shown in the Figs. 1 and 2 . As seen in the figures, the impact of the particle is an increasing function of its kinetic energy, which seems desirable at least from a pedagogical view point.

Dosemeters for practical uses can be so designated with the intention of adjusting their responses to these curves. In case of photon dosimetry, such a procedure can provide a more direct method than the traditional one via a third quantity such as exposure, kerma or absorbed dose.

The unit of the new dose is one of particle fluence, $[m^{-2}]$, in the sense of metrology, but the familiar names of gray or sievert may be succeedingly used as SI special units, if so desired.

CONCLUSION

It has been shown the current system of dosimetry has inevitable defects, as far as the physical quantity of the dose is not changed. Our proposal of adopting particle fluence instead might be rather drastic but it is shown that the currently used practices can be transferred to the new system without any serious difficulty.

To use particle fluence as the basic dose, the stability of the quantity is guaranteed.

MAJOR SCIENTIFIC TOPIC NUMBER 8.10 (see page 7) 2nd choice (8.6)

ABSTRA(The presence of long-lived radionuclides, such as Pu-239, in radioactive wastes has been perceived to pose a hazard of unprecedented severity and duration. This perception has caused serious difficulties in developing acceptable waste management programs. However, technical assessment indicates that concerns related to long-lived radionuclides are largely unwarranted.

Since specific activity is inversely proportional to half-life, it is clear that the longer the half-life of a radionuclide, the less radioactive it is. Fears directed toward the hazard of long-lived radionuclides might more appropriately be directed toward the stable toxic elements, such as Pb and Hg, which persist forever. Recent evidence on proton decay indicates that the distinction between stable and radioactive could be somewhat vague. It is suggested that certain misconceptions might be avoided if nuclides were classified as either radioactive ($T_{1/2}$=<10^6 yr), radiopassive ($T_{1/2}$= >10^6<10^{12} yr), or radioquiescent ($T_{1/2}$ = >10^{12}yr).

Special problems related to dealing with the long-lived radionuclides are discussed and evaluated. These include: (1) specification of ALI's for certain radionuclides, which considering their low specific activity, would be impossible to attain, (2) concerns directed toward certain nuclides, such as I-129, which could cause no significant doses, and (3) implementation of controls which would likely result in greater risks than those due to the long-lived radionuclides being controlled.

ABSTRACT (See instructions overleaf)

NEW RELATIONSHIPS IN BASIC DOSIMETRY

F. Rebigan, Institute of Atomic Physics, Bucharest, Romania

In this paper four new relations are derived, for the first time, based on the definitions of the fundamental dosimetric quantities given in the last ICRU Reports. These relations have the general form $A.\dot{B} = \dot{A}.B$, where A and $\dot{A}$, B and $\dot{B}$ are the dosimetric quantities and their rates, respectively.

Thus, the author found $\Psi.\dot{\Phi} = \varphi.\dot{\Psi}$, for a monoenergetic beam of photons, in any point of this beam and at any time. Here Ψ is the energy fluence rate, φ particle fluence rate, Ψ energy fluence, and Φ the particle fluence. The second relation is $K.\dot{\Psi} = \dot{K}.\Psi$, where K and $\dot{K}$ are kerma and kerma rate. The third relation, for absorbed dose D, and its rate $\dot{D}$, is $D.\dot{\Psi} = \dot{D}.\Psi$. Finally, for electron fluence Φ_e, and electron fluence rate φ_e, the corresponding relation is $D.\dot{\varphi}_e = \dot{D}.\Phi_e$.

At the end of paper the author states interesting remarks regarding an exhaustive description of an ionizing radiation beam or radiation field closely related to their interaction with matter.

HOT-CELL OPTIMIZATION USED IN PRODUCTION AND DISTRIBUTION OF ^{153}Sm

Sahyun, Adelia; Sordi, G.M.A.A.;Rodrigues, Demerval L.; Sanches, Matias P.; Romero Filho, Christovam R.

Instituto de Pesquisas Energéticas e Nucleares - IPEN-CNEN/SP, São Paulo - SP, BRASIL

ABSTRACT

The purpose of this paper is to optimize the shielding lead thickness necessary to the hot-cell used in the production and distribution used in the ^{153}Sm - label compound, ethilenediaminetetramethilene phosphoric acid (EDTMP) that will be constructed in radioisotope production plant. of Instituto de Pesquisas Energéticas e Nucleares", of "Comissão Nacional de Energia Nuclear" (IPEN-CNEN/SP). For this study, we considered the following attributes: number of people exposed, the magnitude of individual doses due to normal exposures, collective dose and activity handled. For the optimization we will utilize the analytical quantitative decision-aiding techniques such as cost-benefit analysis and differential cost-benefit analysis, for taking account of all protection and safety attributes in a systematic way.

INTRODUCTION

The ^{153}Sm-EDTMP is a label compound that is absorbed in the bone and has been applied to patients as a relief for pain. The IPEN-CNEN/SP is assembling a hot cell for production and distribution of this label compound to support weekly quantities of 1.85 GBq (5Ci).

We have considered as basic case for the hot cell shielding thickness, the option of protection one (01), that attends the dose limit established by CNEN[1] , and the actions taken led to the introduction of shielding in the hot cell frame, in a way to keep the annual dose lower than 40 mSv. This value was calculated considering a 25% error in the measurements.

Starting with the basic case, we have identified other options, trying to reduce the dose to satisfy the 20 mSv annual medium for five (05) years established by ICRP[2], the 15 mSv per year to cease the individual monitoring, the 4 mSv to cease the routine area monitoring and 1 mSv to not exceed the dose limits for public exposure.

The major radioprotection problems in optimization studies are related to the main attributes: the observed dose and the costs associated to reduce this doses. The adoption of other option different from that elected as optimum case, should consider the availability of financial resources.

RESULTS

The optimization study in ^{153}Sm-EDTMP production hot cell is shown in Table I where has been built with the aid of cost-benefit analysis decision-aiding techniques.

From the Table I results, we can see:

1) If we take the international standard alpha value, adopted in Brazil, of US$10000/person-Sv, the optimum option is the number eigth (08).We can also observe in column six (06), that the individual dose for this option is 0.55 mSv per year, which is about half of annual dose allowed for the general public.

2) Considering that IPEN-CNEN/SP has a hot cell with a shielding thickness considered in the option thirteen(13), we could verify the activity capacity of this hot cell for the ^{153}Sm, in a way to give the same dose observed in the optimized cell, option eight (8), column six (6). In option thirteen (13), column four (4), Table I, we can verify that the hot cell capacity is 18.5 TBq (500 Ci), what means 100 times bigger than the today's prevision.

We find interesting to reproduce the calculations that generated the Table II, using the aiding technique for decision making named cost-benefit differential analysis, because their results practically show as the study sensibility of alpha value.

From the Table II, we can see:

3) The optimum option is still number 8, as it should be, because the results are independent of the technique used.

4) If we had used the real alpha value for our country, which is US$3000.00/person-Sv, the optimum option the number 05 (five) with an annual dose of 1.9 mSv, bigger than the annual limit dose for the public but lower than the value necessary for the workplace monitoring with routine function and the saving in the radiological protection expenses should be US$36.20 per year.

5) If we use the european alpha value, US$20000.00/person-Sv, the option 11 (eleven) should be the optimum and the annual dose would be 28.8 μSv. This value is very close to 10 μSv/year, the exemption value, but the annual cost , X, should be US$16.1 per year, greater than that of the option 08 (eight).

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 8.4... (see page 7)

ABSTRACT (See instructions overleaf)

In order to implement protective actions to reduce radiological exposure "as low as reasonably achievable", the use of cost-benefit analysis has been progressively promoted among the practitioners, especially for the management of occupational exposures in nuclear power plants. Applying this procedure to the selection of radiological protection options, a monetary valuation of the avoided exposure has to be adopted (the so-called monetary value of the man-sievert), allowing for the expression of the benefit of protection in the same unit as the protection costs. The value of the man-sievert has to reflect the detriment associated with radiological exposures. As stressed by the International Commission on Radiological Protection (ICRP) in its Publication 37, it is necessary to evaluate not only the "objective" aspect of health detriment, but also the "subjective" one like the perception of risk by individuals. Moreover, in its Publication 60, the ICRP has recommended to take into consideration the dispersion of individual exposures. The integration of the equity aspects in the value of the man-sievert means that one accepts to pay more in order to avoid a unit of exposure when the individual level of exposure increases, and, moreover, that this increment of the monetary value of the man-sievert is more and more important.

This paper aims at presenting a model for the determination of the monetary values of the man-sievert dealing with the three following objectives: reduction of the collective exposure, reduction of the dispersion of individual exposures and reduction of dispersion in priority in the highest individual levels of exposure.

THE STANDARD FOR JUSTIFICATION OF RADIATION PRACTICE

Susumu Osaki

Radioisotope Center,Kyushu University 16, Hakozaki, Higashi-ku, Fukuoka, 812-81 Japan

INTRODUCTION

Justification is the first principle for the system of radiological protection proposed by ICRP. Other principles, the optimization of protection and individual dose limits, have been well studied quantitatively. The justification of a practice, however, has been scarcely discussed. The reason is obviously that the justification is related to the evaluation on both the risk and the benefit of a practice. There are social scientific problems in the discussion on the benefit and especially on the comparison between the benefit and the risk. Without the basis of the justification, the purposes of the optimization of protection and individual dose limits become ambiguous.

JUSTIFICATION OF ACTUAL RADIATION PRACTICES

Any existing practices must be justified consciously or unconsciously by some ways. The actual radiation practices, the mass screening tests for tuberculosis and stomach cancer, the use of a smoke detector with ^{241}Am, the use of an artificial tooth containing uranium and a lens of eyeglass containing thorium, and occupational radiation work are observed how they have been justified, mainly in Japan.

MASS SCREENING FOR TUBERCULOSIS: Tuberculosis had been a national disease in Japan more than 40 years ago. Many young people were infected and died, and the mass screening was wanted nationally. The buses for the X-ray inspection went around offices, schools and communities. Gradually the infection rate has fallen and tuberculosis became a geriatric disease. Then the justification of the mass screening has been controverted. In 1975, WHO recommended the stop of the X-ray mass screening for tuberculosis. The benefit has been decreasing with years, and that for the people younger than 20 years old becomes below the risk(1). Even for adult people the cost for one life saving becomes very high. The X-ray mass screening for pupils and students has been decreased in stages.

MASS SCREENING FOR STOMACH CANCER: The mass screening for stomach cancer systematically began at 1960 in Japan. The benefit of the mass screening has been compared with the risk of the X-ray exposure, and further compared with the endoscopic mass screening and with no mass screening(2). Methods for medical decision making have been applied(3), and the economical balance of the mass screening has been discussed in the scales of the mutual society of a company or a local government. The benefit of the mass screening on health and economics increases with the incidence rate which increases with ages. Furthermore in order to neglect practically the genetic effect of the exposure, the X-ray mass screening for stomach cancer is recommended for people above 40 years old.

SMOKE DETECTOR WITH ^{241}Am: The benefit of a smoke detector is the saving of life, house, and others from a fire. The exposure from the ^{241}Am source and the pubic exposure for its waste has estimated and justified from the comparison of the dead from a fire(4). The developments of electron techniques made an electron smoke detectors which is comparable in the efficiencies on fire prevention for that with ^{241}Am. The ^{241}Am smoke detectors in use have drastically decreased.

AN ARTIFICIAL TOOTH CONTAINING URANIUM AND A LENS OF EYEGLASS CONTAINING THORIUM: The justification of these goods is very difficult, because their

benefit is adornment and cannot be compared directly with the risk of the exposure. In practice, the uranium or thorium content is restricted by the government or the guild of manufacturing companies and their goods are on the market. A leaflet from UNEP(5) wrote that the use of these goods was not justified because the benefit is only adornment which is obviously worse than the health risk from the exposure. In such cases that the benefit of a practice is not concerned with health, the comparison of the benefit with the risk is difficult and needs for the social scientific considerations.

OCCUPATIONAL RADIATION WORK: Many people work under radiation environments and are exposed some amounts of dose. The benefit of the practice is the wages of working, the pay of the practice, the joy of working, and/or others. The occupational exposure is accepted naturally under the individual dose limits without the discussion on justification. The benefit changes depending on each individual, but the limit of the risk is same for all workers. If the individual dose limits were the maximum permissible doses, the occupational radiation work would be justified in respect of radiological protection.

THE DEFINITION OF THE JUSTIFICATION

The justification of a radiation practice is not only the comparison of the benefit with the risk, but also the comparison of the justification with the justification of other practices having the same purpose, as shown in above discussion. The benefit and the risk are concerned with health, economics, and others. In some cases, health and economics are trade-off. On the basis of the above observation, the justification of a radiation practice is defined as " The practice is the best in the options which are designed for the same purpose (including the option which does not execute the practice)".The capability approach developed by Amartya Sen(6) is adopted as the standard for what is the best . The capability approach can be discussed on many categories relating to a practice as the capabilities of a person to function.

THE CAPABILITY APPROACH

Sen proposed that the capabilities of functionings can be used for the standard of living(7), instead of opulence or utility. The relationship among capability, function, opulence and utility are schematically shown in Fig. 1. Opulence(goods) has been used for the standard for the evaluation of benefit and risk. Obtaining the goods gives the person command over the corresponding characteristics of the goods and the monetary cost for risk decreases the ability to buy the goods. Opulence, however, is not always proposed to the well-being of a person, because opulence can be used depending on physical and social environment. Utility is widely used in social sciences, especially in economics, and utilitialism is the most available ethical principle. The utility for a person, however, is affected for the person's subjective point of view and surrounding environment.

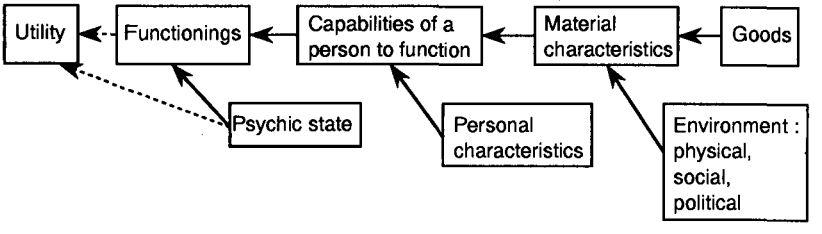

Fig.1. Utility, functionings, capabilities and other sources(7)

FUNCTIONING

The functionings of a person are included in many categories, for example, health, safety, community life etc. on the quality of life. In order to arrange many functionings, "the social indicator" or "the list of social concerns" can be used. For example the social indicators edited by Committee of Quality of Life, Council of Living Life in Japan are divided into ten main areas, 1.health, 2.education, study, culture, 3.quality of employment and working life, 4.leisure, 5.income, consumption, 6.physical environment, 7.crime and execution of the law, 8.family, 9.quality of community life, 10.social strata and movement. Under the main areas, they are further divided into 27, 79, and 160 concerns. With the reference of these indicators, the functionings relating to a radiation practice can be listed.

RANKING OF OPTIONS

If the capabilities of functionings concerned with the options can be ranked, the best option can be evaluated. But overall ranking is obviously impossible, because the comparison between functionings in different areas is very difficult. In practice, the partial ranking can contribute the evaluation of the options.

For the justification of X-ray mass screening for stomach cancer, three options, 1.no mass screening, 2. X-ray mass screening, 3. endoscopic mass screening are ranked in reference to the possibilities on mortality, economical effects, facilities of the screenings and the request from inspected people. The ranking on health has been mainly discussed and the second option is justified for the people above 40 years old.

For the justification of an artificial tooth containing uranium and a lens of eyeglass containing thorium, two options, 1. use of the goods containing uranium or thorium, 2.use of the goods not containing uranium and thorium, are ranked. The related functionings are personal adornment and health risk with radioactive materials(the public exposure with the waste is possible to be neglected). The ranking is not obvious. In this case, the author thinks that the use of an artificial goods containing uranium or thorium is justified, because low risk practices of the user only must be acceptable in society in considering with the importance of passive freedom.

From the viewpoint of the justification, the limits of occupational exposure dose should be changed with a type of occupation and should be made an agreement of the limits with the employee and the employer. The risk(an increase in the possibility of carcinogenesis) itself must be indemnified and furthermore the suffering of a cancer must be also indemnified. A new system for occupational radiation work is necessary, although difficult problems on the evaluation of the risk of low level exposures and the natural occurrence of cancer are existed.

CONCLUSION

The justification of a radiation practice are normatively defined as "The practice is the best in the options which are designed for the same purpose (including the option which does not execute the practice)". The options are ranked by the capabilities of a person to function.

ABSTRACT (See instructions overleaf)

One of the key requirements in UK radiation protection legislation is that exposures should be kept as low as reasonably practicable. New, across the board, regulations came into force in 1986. From that date, the UK's Central Index of Dose Information (CIDI), run by the National Radiological Protection Board under contract to the Health and Safety Executive (HSE), has received from Approved Dosimetry Services annual summaries of the doses reported for 'classified workers' (category A workers in the Euratom basic safety standards Directive). HSE set up CIDI especially to handle the data, particularly with a view to receiving information on trends in worker exposure as an aid to developing policy and targeting inspection and enforcement priorities.

CIDI can analyse the data by dose and age range, sex, occupational grouping and, to some extent, by type of radiation; it also, of course, produces collective and mean dose. Dose data is published annually and the first 'trends' report, analysing occupational exposure 1986-1991, was published in 1993. It clearly demonstrated that whole body doses to workers, particularly in the nuclear industry, had fallen dramatically since 1986; by the end of the period they were in most cases well below 20 mSv yr^{-1}, the average annual dose limit recommended in ICRP 60. However, it also showed that there were two categories of worker, industrial radiographers and non-coal miners, whose doses had not followed the downward trend and remained unreasonably high.

The trends data, updated to 1994, and HSE's actions in response to the information, will be described.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 8.4... (see page 7)

ABSTRACT (See instructions overleaf)

The monetary valuation of the man-sievert used for the optimisation of radiological protection is based on the loss of life expectancy associated with one unit of collective exposure and is estimated using the ICRP risk coefficients of radiation-induced cancer and genetic effects, and thus refers to the monetary value of statistical life. The review of the literature on the value of life derived from the willingness to pay approach clearly demonstrates a large range of values according to the various risk situations that can be considered in the society.

In order to apply the willingness to pay approach for the valuation of the man-sievert, a specific questionnaire has been established. Preliminary results have been obtained concerning occupational exposures in nuclear power plants. According to the framework developed for the determination of the monetary values of the man-sievert, including risk aversion considerations, a baseline value for the risk of cancer can be considered and compared to the human capital approach as well as the risk aversion coefficient driving the increasing function of the value of the man-sievert associated with the individual level of exposure.

IS THIS REMEDIATION NECESSARY? COMPARING COST VERSUS RISK ABATEMENT WITH OTHER RISK REDUCTION MEASURES

P. Andrew Karam, Ohio State University, Columbus, OH, 43210

INTRODUCTION

Radiologically-contaminated sites abound and include a wide variety of sites and sources. The responsible party is not always known . No estimate is available for potential remediation cost or volume. Area residents are concerned about the potential risk posed by these sites. This concern is transferred to their governments via their state and federal elected representatives, and to regulatory bodies. A large fraction of sites require site remediation, either at private or public expense. An assessment of the risk reduction to be accomplished is often lacking. Risks posed by site remediation may exceed those of the "no-action option."

CASE STUDIES

I assumed that all exposure takes place over 50 years, during which the workers spent 40% of their time on-site. Residents were assumed to live in the area for fifty years, spending 100% of their time in their residences. I assumed that the average person lost 35 years of life if they contracted a fatal cancer as a result of their radiation exposure. The risk associated with chronic radiation exposure is assumed to be 2.6×10^{-2} per person-Sv (1).

Hypothetical Facility (Facility X)

Facility X processed ^{238}Pu ($t_{½}$=87.7 a) for radioisotope thermal generators. As a result of normal work practices, some of the grounds have become contaminated with ^{238}Pu. The owners of Facility X now wish to convert their facility to the production of three-hole punches. The facility is an industrial area in a medium-sized city, several miles from the shores of a large lake. They are attempting to develop a decommissioning plan which will provide the maximum safety to their workers and the public while permitting them to successfully convert their facility. If they cannot do so, they may be forced to close the facility.

The plutonium contamination is greatest directly beneath the facility's main building. At this point it is 37 Bq/gm in a hemispherical volume that is 1 meter in radius. Concentration drops off linearly with distance. Options currently under consideration are remediation to a level of 0.2 Bq/gm and to 20 Bq/gm with clean backfill. If the company cannot reach an agreement with the regulatory bodies then it may file for bankruptcy.

Southerly Waste Water Treatment Plant (SWWTP)

The SWWTP was identified as being contaminated with ^{60}Co ($t_{½}$=5.27 a) in early 1991. The cobalt was apparently disposed of into the sanitary sewer system by a licensee of the Nuclear Regulatory Commission (NRC) during the mid- to late-1970s. It is not known if this material was disposed of illegally or as a part of licensed activities. The radioactive material is relatively immobile and is heterogeneously deposited around the site at the SWWTP.

Site characterization showed the highest levels of contamination to be on the order of tens of Becquerels per gram of soil (4). The estimated maximum possible exposure to a worker on-site was determined to be 0.14 Sv with a maximum credible worker dose of less than 0.01 Sv (5). The calculated dose to the public was less than 0.01 mSv over 50 years. The risk associated with the maximum credible exposure is 2.6×10^{-4}. The risk to the public is approximately 2.6×10^{-7} per person.

Chemetron Bert Avenue Dump Site

The Chemetron Corporation manufactured chemicals utilizing a depleted uranium catalyst during the 1960s, contaminating a portion of the facility. Much of this material was disposed of into an industrial dump owned by Chemetron. Approximately 1.5 million cubic feet of contaminated soil is contaminated in excess of the NRC-allowed limit of 1.3 Bq/gm. Contamination levels varied from background to over 330 Bq/gm of uranium, in addition to metals and chemicals (7).

The owner-preferred remediation option is to construct an on-site clay closure cell which would be covered with 5 meters of clean fill. The state and citizens prefer that all soil which is contaminated in excess of 31.3 Bq/gm be removed.

LEVEL OF REMEDIATION, RISK, AND COST

Facility X

Scenarios investigated for this facility included no action, excavation to a level of 20 Bq/gm with one meter of clean fill, excavation to a level of 0.2 Bq/gm with eight meters of clean fill, and placing 10 cm of asphalt cover over the contaminated areas. An "all pathways" analysis was performed for each of these options, assuming industrial use. In all cases except for the

"no action" scenario, the primary exposure source was that of direct gamma radiation exposure. This is chiefly due to plutonium's geochemical immobility. Under the "no action" scenario, the major source of exposure was dust inhalation. The "no action" option resulted in an exposure of approximately 0.13 Sv over 50 years to the individual for a risk of $3.3x10^{-3}$. Assuming a worker population of 1000, this will give a total of 3.3 lives and 114 years of life lost over 50 years.

The most cost-effective method of site remediation is to cover the site with 10 cm of asphalt. This would reduce dose to a maximum of 0.70 mSv/yr, giving a dose of 0.03 Sv over a fifty-year time span for a risk of $7.8x10^{-4}$. A worker population of 1000 will have an overall risk of approximately 0.78. The cost of this option would be approximately $1000 for materials and one afternoon of laborer time, giving a total cost of $303 per life saved, or $9 per year of life saved.

Remediation to levels of 20 Bq/gm and to 0.02 Bq/gm, result in doses of $1.5x10^{-5}$ mSv/yr and $1.6x10^{75}$ mSv/yr respectively. These maximum doses occur at a time of approximately 1000 years after deposition. If the cover layer is maintained so that erosion does not occur, then the doses are zero.

The cost associated with these options is difficult to estimate due to the difficulty of remediating a plutonium-contaminated site. The volume of material to be removed to remediate to 20 Bq/gm is that of a hemisphere one meter in radius, or 2.1 cubic meters (74 cu. ft.). Assuming a cost of approximately $1500/cu. ft. for remediation and disposal yields a total cost of $110,000 for this remediation and $960 per year of life saved. A remedial level of 0.02 Bq/gm requires excavating 1072 cubic meters (38,000 cu. ft.) at a cost of $57 million or $500,000 per year of life saved.

Southerly WWTP

Under the "no-action' remediation option the risk presented to the workers is approximately $2.6x10^{-4}$ per person. The projected dose to the public from this contamination is negligible due to the relative immobility of cobalt in the environment. The risk to workers at the SWWTP is approximately 0.26 excess deaths, assuming a population of 1,000 workers at this site.

The likely remediation option at the SWWTP will be excavation and disposal of the most highly-contaminated material. Due to the short half-life of ^{60}Co, nearly 90% of the original radioactivity has decayed away since the deposition of the material sixteen years (three half-lives) ago. Remediation at this time will reduce overall radiation exposure and its associated risk by only 10%. At the estimated remediation cost of $40 million (6), the cost per year of life saved is approximately of $44 million.

Chemetron

Modelling (for this paper) indicates that, under the "no action" remediation option, the lifetime dose to an occupant of this site would be 4.0 REM with a risk of $1.5x10^{-2}$ at zero cost. Burial in an on-site closure cell would give a dose of less than 0.01 mSv with a risk of $<2.6x10^{-7}$ per person. The projected cost of this option was $7 million (9). Remediation and off-site disposal of all material with a contamination level of greater than 1.3 Bq/gm of uranium also gives a dose of less than 0.01 mSv. The projected cost of this option was in excess of $20 million (9). The dose resulting from the removal activity may exceed that of on-site disposal due to construction activities contaminated soil, dust generation, and transportation accidents.

The cost per year of life saved at this site would be $19 million for the construction of an on-site closure cell and $55 million if the material is removed if the site is not used for residential or industrial/business purposes after remediation.

Facility and Remediation Option		Cost	Years of Life Saved	Cost per Year of Life Saved	Years of Life Saved for Same Investment (10)		
					Medical (Ave = $5000)	Fatal Injury Reduction (Ave = $48,000)	Toxin Control (Ave = $2,782,000)
Facility X	asphalt cover	$1000	113	$8.70	0.2	0.021	$3.6x10^{-4}$
	20 Bq/gm	$11,000	114	$96	2.2	0.23	$4.0x10^{-3}$
	0.02 Bq/gm	$5.7 million	114	$50,000	1140	119	2
SWWTP	current plans	$40 million	0.35	$4.4 million	8000	833	14
Chemetron	closure cell	$7 million	0.35	$20 million	1400	146	2.5
	material removal	$20 million	0.35	$57 million	4000	417	7.2

Table 1: Summary of Costs and Years of Life Saved for Remedial Options

DISCUSSION

If the level of contamination decreases linearly with distance from the source, reducing the level of contamination by a factor of two increases the volume of soil to be removed increases by a factor of eight (2^3). If risk varies directly with contamination level, in order to reduce the risk by a factor of two it is necessary to increase the volume of soil to be removed and disposed of by a factor of eight. *Any agency or organization deciding to spend money to reduce a very low risk has also decided to remove that money from other, possibly more effective risk reduction measures. If the risk being mitigated is very low in comparison to those risks to which we are exposed on a routine basis, then this money may have been wasted.*

Table 1 compares the cost of the remediation options mentioned above and general intervention categories mentioned by Tengs, et al (10). Tables 2 and 3 show the median cost per year of life saved for several US regulatory agencies and interventions.

CONCLUSIONS

Remediation of contaminated sites is expensive. The level of risk reduction achieved is not always commensurate with the investment of time, money, and materials that must be made.

In addition to fiscal considerations, there is risk inherent in any remedial activity. While a remediation will result in a lower level of risk to plant workers or area residents, all of the activities necessary for this remedial action involve some degree of risk. *If the unavoidable risks inherent in a remediation effort equal or exceed those that the site poses "as is" then this remedial action is not reducing risk, it is exporting risk to another group of people or to another locality.*

Risk is not the only consideration in an environmental restoration project. Risk reduction per dollar spent should not be used to justify either pollution or abandoning a heavily contaminated site. Rather, using risk reduction as the sole argument for site remediation is fallacious. We must consider not only risk reduction contaminated site, but the reduction of risk to the population as a whole. We cannot indiscriminately pollute the environment, but neither can we indiscriminately remediate our past mistakes. We require a balanced approach whereby we invest our money wisely by remediating those sites which pose a clear threat to either human safety, the environment, or both while devoting more attention (and money) to those activities which are more cost-effective but less glamorous, such as vaccination programs, home smoke detectors, traffic safety, and so forth.

Regulatory Agency	Number of Examples	Median Cost per Year of Life Saved
FAA	4	$23,000
Consumer Product Safety Commission	11	$68,000
National Highway Traffic Safety Administration	31	$78,000
OSHA	16	$88,000
EPA	89	$7,629,000

Table 2: Median Cost per Year of Life Saved for Federal Regulatory Agencies' Interventions

Intervention	Median Cost per Year of Life Saved	Intervention	Median Cost per Year of Life Saved
Smoke detectors	$5000	Airplane Safety	$23,000
Emerg. Vehicles	$2000	Speed Limit	$45,000
Smoking Cessation Advice	$6000	Flammability Standards	$68,000
Health Services	$14,000	Asbestos Control	$1,865,000
Traffic Safety Edu.	$20,000	Radiation Control	$27,386,000

THE RECORDING LEVEL IN THE 1990s

P J Gilvin, D T Bartlett and R J Tanner

National Radiological Protection Board
Chilton, Didcot, Oxon OX11 0RQ, UK

ABSTRACT

This paper addresses the subject of what is the lowest occupational dose one should try to measure in personal dosimetry for external radiation. This question is raised because modern personal dosemeters have improved measurement capabilities, allowing very small doses to be detected and measured. These are similar in size to natural background doses. It is not intended to provide definitive advice here, but to show what the considerations might be; the discussion is limited to measurements of photon and beta doses, and does not deal with specific systematic sources of uncertainty, such as energy dependence of response.

THE RECORDING LEVEL

The recording level is defined by ICRP (1,2) as "a formally defined value for dose equivalent or intake above which a result from a monitoring program is of sufficient interest to be worth keeping". The Commission recommends (1) that the recording level be based on one-tenth of the dose limit, pro rata for the monitoring period concerned; for personal dosemeters, this effectively sets a minimum standard. However, the Commission also recognises that lower recording levels may be justified for purposes such as analysis of collective dose. In revising the earlier recommendations of Publication 35 (1), ICRP may consider changing the fraction of the dose limit upon which the recording level is based; however, for the present purposes, the value of one-tenth will be assumed. It is to be noted that a "result from a monitoring programme" will necessarily refer to a single component, for example the beta/photon component, of effective dose or effective dose equivalent.

During the last decade, personal monitoring for photon and beta doses was achieved almost entirely by the use of film badges and thermoluminescent dosemeters (TLDs), which, in the main, could detect doses as low as 50-100 μSv. The annual effective dose equivalent limit was 50 mSv, which implied a maximum recording level of about 400 μSv for a typical four-week or one-month monitoring period. For analysis of collective dose, there was a desire to measure doses rather lower than the dosemeters could allow, with a result that the "decision limit" (see below) for the personal dosemeter was usually taken as a recording level.

However, as the 1990 recommendations of ICRP are adopted, there is naturally a pressure to reduce recording levels. Taking an average annual dose limit of 20 mSv (2), the maximum recording level for a four-week period will be reduced to about 150 μSv. This would be achievable by most older systems for photon and beta doses; however recent technological developments now allow still lower doses to be measured comfortably, as discussed below. For demonstrating that average doses are normally well below the maximum recording level, even the improved performance of modern dosemeters might be inadequate.

FIGURES OF MERIT

In describing the limiting behaviour of dosimetric methods at low doses, clear terms must be used. Here, the terminology of Christensen and Griffith (3) is used; their choice essentially followed the work of Currie (4) and of others (5,6). There are three figures of merit for any system, which are as follows. The basic figure, and the one most often quoted, is the *decision limit.* This is also known as the "critical level" or the "detection threshold", and is defined as the level of signal, expressed in terms of dose, at which there is a given confidence (normally 97.5%) that the signal is not due to variations in intrinsic background. Results below this level are not normally reported, or included in dose summations. However, this practice of artificial truncation can be criticised on the grounds that it gives a negative bias to cumulative dose assessments.

The second figure is the level of dose which will, with a certain level of confidence (often 95%), give rise to the correct detection of a dose. This is known as the *detection limit*, and its definition entails not only confidence that the "true" dose has a value at the detection limit, but also that the signal is not due to intrinsic background. See reference (6) for a full discussion. The third figure of merit is the level of dose at which the precision of measurement reaches a certain value, and is known as the *determination limit*. Its use requires the input of the required precision: Christensen and Griffith (3) suggest the use of a relative standard deviation of 45%, derived from consideration of the recommended recording level. In published performance data on dosimetry systems, however, the latter two figures of merit are not often quoted, although it is really one of these which should be compared with the recording level. Which of the detection and determination limits should be used for this comparison is a question which needs resolving.

NEW TECHNOLOGY

Recent developments in personal dosimetry have seen both an improvement in decision limits for passive dosemeters, and the advent of electronic dosemeters. Typical standard TLD systems now have decision limits of less than 25 μSv (see for example references 7 and 8), whilst better performance is claimed to be possible when laser heating methods are used (9). The availability of systems based on LiF: Mg,Cu,P (10) is expected to reinforce this capability, giving routine decision limits of 10 μSv and lower. Most recently, a system has been described which uses a special plastic matrix in a technique known as cooled optical luminescence dosimetry (11), and which may have a decision limit much lower than 1 μSv.

Active personal dosemeters have been widely used for some years, but recent advances have allowed doses to be measured over a wide range of photon and beta energies, to the extent that electronic dosemeters can now form the basis of "legal" dosimetry services. NRPB has been running a legal dosimetry service based on the Siemens/NRPB Electronic Personal Dosemeter (EPD) (12) for over a year; the dosemeter uses PIN diodes and possesses a decision limit of 1 μSv. In a separate development, the Direct Ion Storage (DIS) dosemeter, using a modified EEPROM chip, has been shown to have a similar capability (13). One of the ways in which the mode of use of active dosemeters differs from that of passive dosemeters is in the monitoring period. Users of electronic dosemeters are likely to be nuclear site operators, where dose information may be stored on a daily basis. In this case the monitoring period can be said to be one day, and the recording level may need to be viewed accordingly.

Using the ICRP recommended average annual effective dose limit of 20 mSv, the recording level for a four week or one month monitoring period can be derived as about 150 μSv. For one day, the figure will be about 5 μSv. As suggested above, this figure ought to be compared with either the detection or the determination limit for the dosemeter concerned; however the foregoing paragraphs have quoted values of the decision limit. The relationship between the decision limit and the higher figures of merit will vary according to the specific dosemeter type, and it is therefore impossible to infer the values for the latter in a general way. For the present purposes, however, it may be appropriate to compare the recording level with a value equal to twice the decision limit. Using this simplistic approach, it can be seen that most passive systems will comfortably meet the requirement to measure doses as low as the recording level for four weekly or monthly wearing; whilst active devices can similarly meet the recording level for daily monitoring. However, for analysis of collective dose, the limitations of the dosimetry systems still need to be borne in mind.

NATURAL BACKGROUND

There remains one further factor to be considered when dealing with recording levels: the magnitude and variability of natural radiation background dose. The components of natural background which are detected by beta/photon dosemeters are solely those of cosmic rays and terrestrial gamma radiations. In the UK, for example, these amount to an annual average effective dose of 600 μSv, with a range of about 300 - 1000 μSv (14) determined by geological and geographical factors.

Whilst mean occupational doses have been higher in the past, these are now being reduced to levels where natural background doses are significant by comparison. The operators of single sites can take reasonable account of local natural background by measurement, provided that the distinction between natural and occupational dose is clear. Here the uncertainty in natural background will depend chiefly upon the measurement method. By contrast, commercial personal monitoring services who supply many sites may adopt one of two approaches: a global average figure can be used, or extra dosemeters can be supplied, as controls. Both approaches have drawbacks. In the first case, local variations in background are not taken into account, whilst in the second, extra cost is involved and several dosemeters must be used to obtain a useful value.

CONCLUSION

At very low dose levels, such as are measurable by modern dosemeters, it may be the case that natural background represents a large fraction of the total dose received by an individual. It may at least be true that it is no longer the technical capability of the dosemeter which limits the smallest dose to be recorded (the local recording level), but rather the complexity and cost of eliminating natural background doses from measurements of personal dose. At present it appears that passive dosemeters with decision limits of 10 - 20 μSv, and electronic dosemeters with decision limits of 1 μSv, are sufficient to meet all low dose measurement requirements. It is probably not worth investing resources in improving decision limits further, when dosimetric performance is no longer a limiting factor in determining practical recording levels.

The views expressed herein are those of the authors and not necessarily those of NRPB.

THE MANAGEMENT OF CHANGE IN BNFL'S UK GROUP WITH PARTICULAR REFERENCE TO THE RESTRUCTURING OF THE HEALTH AND SAFETY FUNCTIONS

A R BRANDWOOD
Head of Safety, Magnox Reprocessing
BNFL, Sellafield

INTRODUCTION

BNFL's UK Group business involves reprocessing of uranium metal (Magnox) fuel, storage and dismantling of Advanced Gas Reactor (Ceramic UO_2) fuel, waste treatment and storage, decommissioning and electricity generation. These activities are carried out at three sites in the North West corner of England and Southern Scotland:-

Sellafield	-	all activities
Chapelcross	-	electricity generation
Drigg	-	waste storage

THE NEED FOR CHANGE

The privatisation of the UK Electricity Supply Market in the early 1990's created a very competitive marketplace. The nuclear component of the supply market was specifically excluded from the privatisation due to economic factors. By 1993 the threat to the UK Nuclear Industry was severe. Some of the key issues were:-

- Over-capacity in the electricity market of 25%.
- Planned gas stations would increase over-capacity to about 45% by the mid 1990's
- A review of the Nuclear Industry was pending which would critically review the economics of the industry.
- Nuclear generation was not competitive with gas generation.
- Nuclear Electric and Scottish Nuclear, the companies owning the UK Nuclear Power Stations, had made significant advances in reducing their costs and were looking to BNFL, a major supply, to reduce its fuel cycle charges which accounted for two thirds of their generating costs.
- The Magnox stations were nearing the end of their original design lifetimes.
- Three Magnox stations had closed on economic grounds.
- BNFL had evolved, over the years, from a public sector environment bringing with it the attributes of such an organisation eg, overmanning, bureaucracy, hierarchical management structures and a need to improve employees business awareness.

Against this background the UK Group Board concluded that fundamental changes were necessary.

PROCESS OF CHANGE

The UK Group Board, in discussions with its main customers, concluded that savings of the order of £100M in the operating cost base had to be achieved within five years if Nuclear Generation was to stand any chance of being competitive in the electricity supply market. It was estimated that the £100M saving would come from a manpower saving of 2,100 posts (from a starting point of 7,000 posts) and £40M from other variable costs. To achieve this saving the Board identified two main areas for change:-

- The attitudes, behaviours and beliefs of its employees (culture).
- The alignment of the business activities with the key business drivers to clearly identify the groups core activities and to sharpen business awareness and customer focus.

An absolutely critical success factor during the change process was to at least maintain, if not improve, the safety performance of the Group.

In addition these changes had to be conducted under the critical eye of the UK's regulator, the Nuclear Installations Inspectorate.

The starting point of the change process was for the Board to achieve a clear focus and ownership of the changes required. This involved the Board working on and agreeing its role, ensuring the right individuals were on the Board, forming itself into an effective team and, most importantly, agreeing a set of "values" which would underpin the whole approach of the group.

These values included such key behaviours and beliefs as (i) leading by example, (ii) safety will not be compromised, (iii) we will trust people, (iv) we will allow individuals to work to their full potential, (v) customers are important.

In line with these underpinning values the UK Group Directors, together with a team of facilitators, reviewed the "Divisional" structure of the group and re-organised it around the "key drivers" of the business into "business" units. The old structure of six divisions transformed into the new structure of seven Business Units.

Key points of the restructuring were:-

- Each 'operational' business unit had its own Head of Safety and associated staff reporting directly to the Director.
- Management layers were removed.
- Management 'spans of control' were increased.
- Each business unit had a clear purpose linked to a key business driver.

Under the old divisional structure many functions and services were centralised, including Health and Safety. The new structure devolved those services essential to the hour to hour operation of the plant to the business units whilst centralising the other services into a Services Business Unit. Hence Health and Safety advice and monitoring rest in each operating area whilst services such as dosimetry and occupational health rest in the Services Business Unit.

The need to provide focus and co-ordination across all the Business Units on such items as policy and strategy was identified and a separate Business Unit was set up for this purpose. In this unit is a small team of Health and Safety specialists lead by the Head of Safety for the Group who reports directly to the Group Director. In addition to the co-ordination role this team has a responsibility to advise the Group Director on the group performance and to provide a monitoring role.

Such a structure can only work if every individual believes in and works to the 'values'. To this end a great deal of team building, at all levels, has been undertaken, both vertically and horizontally through the organisation. In addition individual managers were selected for their management style ie, those who sought consensus, empowered individuals, were people orientated and were good communicators.

At the time of writing UK Group is 20 months into its five year programme. The next stages of the change programme are (i) to develop its business processes to world-class standard via business process re-engineering and/or continuous improvement methods, as appropriate, (ii) to continue to develop the management style and achieve the reality of the 'values'.

RESULTS TO DATE

- 7000 employees down to 6,200.
- £30M saved on operating costs per annum.
- All production targets met
- Senior Manager posts reduced by 25%.
- No deterioration in safety performance.

To demonstrate the results achieved in a typical H&S Department a comparison of the Magnox Reprocessing H&S Dept is given: 7 management layers down to 4, spans of management control of up to 12, 138 employees down to 115, 10% saving on operating costs.

LESSONS LEARNT

The key lessons are listed below:-

- You must have a vision of the future and keep working towards it.
- Leadership and commitment from the top are essential. Senior Managers must be seen to lead the process.
- You are dealing with people and they will need support (eg stress counseling, redeployment support).
- Identify all the stakeholders and involve them (INCLUDING THE REGULATOR).
- Effective communication is all important.
- Keep your plans live and react to feedback.
- Use your best people in the change process.
- Keep checks and balances in place during the change process to ensure the business does not 'fall over'.
- Involve those people affected by the change in the process.
- Be radical, no turning back.
- Reassure and look after the people you need to keep in the organisation.
- Identify the 'barriers to change' and plan to overcome them.
- Keep your nerve.

SUMMARY

Achieving fundamental change in a well established nuclear business which is highly regulated is possible and can bring large benefits.

The keys to success are leadership and commitment from all Senior Managers, involvement of all stakeholders and communication. It is essential to involve the regulator as a stakeholder.

ENVIRONMENTAL RADIOACTIVE ANALYSIS INVOLVING PUBLIC IN THE NEIGHBORHOOD OF A ^{131} I PRODUCTION FACILITY

Ana Maria Pinho L. Gordon and Gian Maria A. Sordi

Instituto de Pesquisas Energéticas e Nucleares
Comissão Nacional de Energia Nuclear
Caixa Postal 11049 -São Paulo, Brazil

ABSTRACT

The IPEN has a production plant,where elemental tellurium is processed to obtain iodine.The gaseous effluents produced in the three hot cells are filtered in a batch system before being discharged to the environment through a stack.This paper is mainly concerned with the definition of the critical group,the evaluation of the annual individual and collective effective dose due to the iodine release to the environment.This result obtained are discussed taking into account new concepts (Safety Series Standards 979 : "International Basic Safety Standard for Protection Ionization Radiation and Safety of Radiation Source ", 1995 such as exemption levels and the levels where is necessary to apply the quantitative decision aiding techniques to optimize the environmental delivery or the introduction of a new filter batch system.

INTRODUCTION

The IPEN has a swimming pool research reactor operating at a nominal power of 2 MW where elemental tellurium is irradiated. Radioactive tellurium and iodine radioisotopes are produced and ^{131} I is chemically separeted in a production plant. This chemical processing involves three hot cells and gaseous effluents are produced and filtered in a batch system before being discharged to the environment through a 25 m stack.

This paper is mainly concerned with the definition of the critical group,the evaluation of the annual individual and collective effective dose due to the iodine release to the environment in the last year (1994).

METHODOLOGY

The gaseous effluents are continuously monitored by using a air sampler coupled to a flux meter. This system is conected off line in the stack. The effluents are collected through a filter system arranged after the pump. The filters are routinely measured by using a hyperpure germanium detector with 15% efficiency coupled to a 4096 multi-channel analyser. The results are corrected for the air flux in the stack. The spectrum obtained is analised using the Omnigam software version 3.4 (EG&E ORTEC) .In order to evaluate the impact due to this effluents release the average meteorological data collected in a meteorological tower far 200m from the radioisotope processing plant have been used as input to one generic models for assessing the environmental transfer of radionuclides [1,2] .These data were collected during ten years. These were the more advantageous metereological data we have until the present moment to perform our calculation. Although we have installed since August 1995 some metereological instruments, we have not enough data. The average wind speed and frequency distribution were determined sharing the compass card in 8 sectors. The most time the wind blows in the southeast direction having an average frequency of 39 % and an average speed of 3.6 m/s.The major exposure pathway considered in the external radiation exposure were:beta and gamma submersion dose from the plume,gamma dose over contamined ground .In the internal radiation exposure we considered the intake by inhalation.There are not farming activities around 60 km of the IPEN site so doses due to the food ingestion pathway are assumed negligible.the annual effective dose have been carried out by using the AIEA transfer model [2] and by applying the proper dosimetric factors [3] . The critical group was obtained and is formed by the people living 3000m away from the discharged point in the southeast diffusion section and was obtained from the "Instituto Brasileiro de Geografia e Estatística" data and was determined the fraction of the number of persons living in the area delimited by a circular section with one kilometer of radius and the 8 compass card sectors. This Institute is encharged by the Federal Brazilian Government of the National Census. The data is a population estimation for 1991 from 1980 because we have not calculated the population distribution around IPEN from 1991 census. The main exposure pathway is the gamma external irradiation due to the deposition of radionuclides on the ground

INDIVIDUAL AND COLLECTIVE DOSE CALCULATION

The individual dose was calculated using the methodology above described. As was pointed, the critical group was formed by the people living 3000 meters away from the discharge point in the southeast diffusion section and received an effective dose of 1.9×10^{-6} Sv per year and so is below the exemption level to be considered radioactive[4] and the collective dose calculation is not necessary. In this case we can increase the plant production five times, maintaining the present environmental discharge system and we continue in the exemption level. During the last four years [5] no considerable change was observed in the operation condition of the IPEN discharge. Nevertheless the IEA-R1 reactor is being upgraded to operate at higher power (5MW) on a full-time (24 h per day) in order to attend the demand for radioisotopes in Brazil and other countries of South America. In this case, even the production increase until fifty times the present production is not necessary to record the source term because the individual dose in the critical group remains below 1/10 of the pertinent annual limit (100 μSv/year). If we consider the estimation for the future demand approximately year 2000, we can suppose an increasing of production of 150 times the present production and we need record the source term but we do not need to accomplish the environment monitoring around the IPEN facilities. Above 50 times the present production becomes necessary to evaluate the collective dose because if the value exceeds 1 person-Sv than we need to apply the ALARA principle. The collective efffective dose was calculated multiplying the population in each area by the dose calculated in the middle point of the same area. We obtained a value of 61.1 person-Sv. This value suppose that one increase of the production above the exemption level probably we need to introduce the ALARA principle and determine the different radiation protection options to reduce the collective dose. This result reflect the great number of person that live near IPEN facilities.

MAJOR SCIENTIFIC TOPIC NUMBER 8.5 ..... (see page 7)

ABSTRACT (See instructions overleaf)

Whilst the basic principles for protection of the public in a radiological emergency are well discussed and widely accepted, application of these principles in real intervention practice meets serious problems. Radiological information is the most complicated one to understand and interpret for decision makers. The paper deals with some of those points in establishing intervention levels, which need careful attention to avoid misunderstanding in decision making process: formulation and wording of criteria for implementation of radiation protection and social protection measures, interrelation between primary (in terms of dose) and derived (operational) intervention levels, and balancing realistic and conservative approaches for estimating projected, averted and residual doses. The points listed are considered on the basis of analysis of international recommendations (ICRP, IAEA, OECD/NEA et al) and experience gained in post-Chernobyl intervention policy in Russia. The findings of this consideration may be useful in updating the interpretation of general intervention principles for both pre-planning of emergency response and justification of intervention criteria at various stages after an accident.

OPTIMIZATION GUIDANCE TO POST-ACCIDENT INTERVENTION: A SPECIFIC CASE.

J. Enrique García-Ramírez, M. Arturo Reyes-Sánchez
Comisión Nacional de Seguridad Nuclear y Salvaguardias
Dr. Barragán 779, Col. Narvarte
03020, México D.F.

INTRODUCTION

ICRP recommends the application of the system of protection to intervention situations [1], i.e. those in which exposure pathways are already present; e.g. the public exposure following an accident. This implies that intervention must be justified and optimized, being the optimization the process of deciding the nature of protective action in order to obtain the maximum net benefit. This paper provides an example of one optimization model to guide a decision making process in a specific case of post-accident intervention. The involved scenario postulates the contamination of big quantities of reinforcing steel bars used in construction industry, and a lot of them present in the structure of several dwellings.

Inhabitants of these dwellings must be protected and the proposed action is to demolish those homes exceeding some intervention criterion. The objective of this study is to reach such intervention level trough an optimization process economically focused.

THE OPTIMIZATION MODEL

It is assumed that a gaussian distribution takes place in the radioactivity present among the contaminated reinforcing bars. The intervention level must be given in terms of some measurable quantity. In this study, we use the equivalent-dose rate, measured at the moment of the decision making, in some representative place inside the dwelling (i.e. relative to their inhabitants exposure).

Also in this paper, we use the cost-benefit analysis technique described elsewhere [2,3] to reach the optimization. The normalized cost (i.e. per contaminated home) of the protection is given by:

$$X = V \cdot F_d \tag{1}$$

Where:

- V is the cost of protection, which includes demolition, re-building and disposal of contaminated material per dwelling
- F_d is the fraction of demolished dwellings

On the other hand, the corresponding radiological detriment cost is given by:

$$Y = \frac{1}{\lambda} \cdot (1 - e^{-\lambda \cdot t}) \cdot \dot{H}_0 \cdot F_s \cdot T \cdot N \cdot \alpha \tag{2}$$

Where:

- λ is the involved isotope decay constant
- t is the considered period of time
- $\dot{H}_0$ is the sought intervention level
- F_s is the fraction of dwellings remaining stand after intervention
- N is the average number of people per home
- T is the average ocupancy factor per person
- α is the collective dose cost

The objective function U (to be minimized) is given by the sum of (1) and (2):

$$U = V \cdot F_d + \frac{1}{\lambda} \cdot (1 - e^{-\lambda \cdot t}) \cdot \dot{H}_0 \cdot F_s \cdot T \cdot N \cdot \alpha \tag{3}$$

$\dot{H}_0$ will be proportional to radioactivity present at the reinforcing bars, hence it will follow a gaussian distribution too, as depicted in fig. 1:

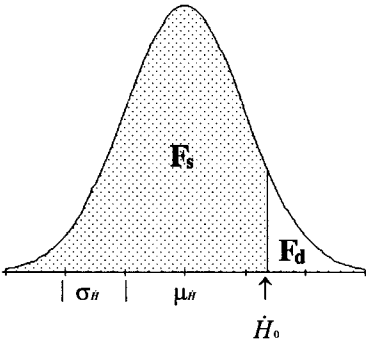

Figure 1. $\dot{H}$ distribution, and (F_d , F_s)-meaning.

In Fig. 1 $\mu_{\dot{H}}$ is the observed equivalent-dose rate averaged over the contaminated homes, and $\sigma_{\dot{H}}$ is the corresponding standard deviation. Fig. 1 illustrates the correlation existing between the chosen value of $\dot{H}_0$ and the fraction F_s (or F_d) of remaining (or demolished) dwellings through the selected distribution function. The strict shape would be the corresponding cumulative function. Table 1 shows values taken from real case ocurred in México's 1984 accident [4,5].

Table 1.- Values of parameters used as data of calculations

λ	1.50×10^{-5} h^{-1} (Co-60)
V	50,000 USD
$\mu_{\dot{H}}$	5×10^{-7} Sv h^{-1}
$\sigma_{\dot{H}}$	1×10^{-7} Sv h^{-1}
t	4.38×10^{5}
T	0.5
N	5 people per dwelling
α	100,000 USD

In Table 1, the value of V corresponds to the moment of the accident. The values of $\mu_{\dot{H}}$ and $\sigma_{\dot{H}}$ are estimated from the data of the same accident, however in a hypothetical case, they could be determined from a rapid and enough sampling. The value of t (50 years) is chosen consistently with a long term situation, whenever T, N and α values are country-specific values, being α the proper value for intervention situations.

Substituting table 1 parameter values, and giving values in ec. (3) to $\dot{H}_0$ (finding the corresponding values to F_s), we obtain the correlation between function U and $\dot{H}_0$, as depicted in Fig. 2.

Table 2, gives the results for the around-minimum values, showing that the sought value is about 7.1×10^{-7} Sv h^{-1} which would implicate that only 1.8 % of the contaminated dwellings would have to be demolished.

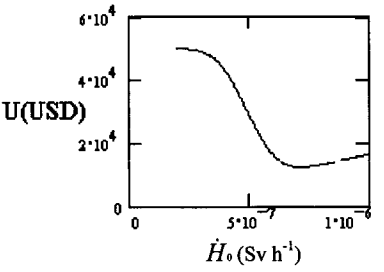

Figure 2. U function vs. $\dot{H}_0$, obtained through ecuation (3) and values of table 1.

Table 2. Some calculated values through ecuation (3) and values of table 1.

$\dot{H}_0$ (Sv h^{-1})	F_s	U (USD)
6 x 10^{-7}	0.841	16,326
6.5 x 10^{-7}	0.933	13,426
7 x 10^{-7}	0.977	12,511
7.1 x 10^{-7}	0.982	12,487
7.2 x 10^{-7}	0.986	12,500
8 x 10^{-7}	0.999	13,351

CONCLUSIONS

The assumption of considering a gaussian distribution of the radioactivity among contaminated reinforcing bars seems to be qualitatively and quantitatively right for a scenario like the contemplated in this study, and it permits that an optimization model could be applied to get a proper intervention level in order to guide a decision making process. In addition, average parameters, such as T and N in ec. (3) were introduced consistently with the fact that the overall vision must be statistically approached. Although the data from the Mexican accident were used only as an example, a retrospective view shows that, refering to adopted intervention levels, decisions took at that time can be considered right even with the fact that they were taken without an optimization analysis.

THE METHODS, MODELS AND INFORMATION SUPPORT ON ADMINISTRATIVE DECISIONS ON MEDICOSANITARY MAINTENANACE OF POPULATION OF UKRAINE IN THE AFTER CHERNOBYL ACCIDENT PERIOD

Vladislav Torbin[1] A. Babich;[2] Ju. Onopchuk[1]

1. Ministry of Ukraine for affairs of population protection from concequences of Chernobyl accident, Kiev, Ukraine
2. Institute of cybernetic n. acad. V. M. Glushkov, National Academy of Sciences, Kiev, Ukraine

The liquidation of serious consequences of Chernobyl accident, taking into consideration their character and scale, requires the huge material and human resources. The complexity and plural of factors, affecting on planning and management of measures on medical-sanitarian maintenance of damaged population, requires the processing during acceptance of decisions, large files of informations, containing parameters of healths condition of damaged population, information about the level of complex medical-sanitarian maintenance, dynamics of investments and compensation and etc.

The instability of economic situation in Ukraine, connected with transition to new forms of managing and formation of political system, does not permit to increase the resources on decisions the problems of liquidation of Chernobyl accident, requires the increasing the effectiveness, efficiency and qualities of accepted decisions on control and management of forming situation.

The operative and qualitative decision of all problems of medicalsanitarian maintenance appears possible in conditions of introduction of new methods of tax, processing and analysis of information on the basis of modern information technologies, methods and algorithms of mathematical theory of acceptance of decisions.

With this purpose are developed the principles and structures of information-analytical system of profile purpose, intended for programme realization of following technologies of organizational management are developed: 1. technology of automated planning,

including tasks:

- planning and distribution of medical equipment, medicines, reagents, instruments and other medical, sanitary- epidemiological and other health-improvement establishments;
- planning and distribution of pases on making healthier to persons, victim of a Chernobyl failure;

2. technology of automated account, analysis and acceptance of administrative decisions, including tasks:
   - account and analysis of condition the complex medical - sanitarian maintenance;
   - account and analysis of condition of health-improvement system of population;
   - account and analysis of system of preventive maintenance of mass disseases of victims;
   - account and analysis the system of maintenance of population by medical-preventive products;
   - account and analysis the parameters of condition of health of victims;
   - account and analysis of condition (including the personnel and technical maintenance) of medical establishments;
   - account and analysis given about preventive maintenance and treatment thyroid gland lossed ones;
   - formation, management and analysis the register of persons, lossed owing to Chernobyl failure.
3. technology of automating formation of expert-analytical valuations, including decisions of tasks:
   - formation of expert-analytical valuations of condition of health damaged population and sanitary-epidemiological environment of his residing,
   - formation of integrated valuations and radiation situations in administrative territories and forecast its development;
   - formation of expert-statistical valuations for definitions of priorities in investment policy on liquidation of failure and protection of population.

The decision of listed tasks is based and on the traditional methods of theory of acceptance of decision, on using of effective expert systems, on developed methods of mathematical simulation and

forecasting of development of formed situation with using the methods of mathematical (linear, dynamic) programming, theory of distributions of resources and theory of games.

The optimization of created data bases, perfection of algorithms of acceptance of decisions permits not only operatively to execute the investments medical-sanitarian maintenance of regions, but also to execute the necessary check by their effective employment.

PRESENTING AUTHOR (IF DIFFERENT)

MAJOR SCIENTIFIC TOPIC NUMBER 8.4 (see page 7); 8.5; 4.5

In estimation of the effectiveness of countermeasures (CMs) and choices of justified intervention levels use is made of the cost-effectiveness analysis (CEA), cost-benefit analysis (CBA), as well as corresponding economical, radiological parameters and different variants of the multi-attribute utility analysis. The authors works give the evidence that CM implementation under conditions of non-uniform contamination of lands and distinguishing of agricultural production obtained as "pure" (with contamination levels below the DILs) and "dirty" (accordingly, those above the DILs) can result in increase of (internal) collective doses for the population. The CEA is not applicable under these conditions, and standard algorithms of CBA require a generalization for the correct use in investigation of the scenarios stated. The CBA generalizations obtained give the possibility to estimate effectiveness of CMs (including the cases with consideration of various uses of "pure" and "dirty" production), and to define "optimum" DILs for various strategies of using the production. Estimations of countermeasures are considered with concrete examples based on a system of averted collective dose, costs of CM implementation, costs of aversion of unit collective doses (CEA), total detriment and complete CBA. Different criteria are shown to render preference to different CMs. In this connection, when it is decided to initiate the most efficient ("optimum") CMs,- along with consideration of the problem of decision making with uncertainty, also problems of multiple criteria (comparison/preference of different criteria) should be taken into account.

THE PROTECTION FROM POTENTIAL EXPOSURE IN THE BRAZILIAN LEGISLATION

Gian Maria A. A. Sordi

Instituto de Pesquisas Energéticas e Nucleares, São Paulo, Brazil

ABSTRACT

The Brazilian Legislation contemplates the work in potential danger places for practices involving originally inflammable materials, including explosive materials, and finally electricity. After the Goiânia accident, ionizing radiation was also included in the Brazilian Legislation, except for federal civil servants that were excluded because they work under special legislation. Immediately after the ICRP Publication-64 : "Protection from Potential Exposure: A Conceptual Framework" had become available , the potential exposure danger for federal civil servants was also acknowledged, and the federal government issued a new legislation based on three levels of danger, that favored them. Thus, we could include in the new legislation the main concepts of the framework suggested by the ICRP publication-64. This paper intends to discuss the manner in which the ICRP publication-64 was introduced in the Brazilian Legislation.

I INTRODUCTION

The Brazilian legislation contemplates those who work in potentially dangerous places, in practices involving inflammable material (Law nº 2573 of August 15, 1955) explosive material (Law nº 5880 of May 26, 1973) and electricity (Law nº 7369 of September, 1985) because of the possibility of electrocution.

This legislation is based on an old fashioned policy, according to which the employer must pay an extra amount in the salary if the practice does not present the same normal safety conditions.

After the Goiânia accident, the ionizing radiation was included in the Brazilian Legislation through Decree nº 97458 of January 01, 1989, and was included in the regulation norm nº 16 of the Ministry of Labor, except for the federal civil servants, who were excluded because they have on special legislation.

In December 17, 1991, Law nº 8270, concerning federal civil servants salary, as well as it's readjustments and restructuring and other provisions , came into effect, and article nº 12 states:.

Article 12 - Federal civil servants will receive additional salary concerning insalubrity and potential risk, in terms of the legal norms and regulations pertaining to workers in general and based on the following porcenteges:
I - five, ten, and twenty percent, concerning insalubrity in the minimum, medium and maximum degree respectively.
II - ten percent, in the case of potential risk,
§1 The additional amount for ionizing radiation will be received in five, ten and twenty percent, according to what is determined by the regulations.
§2 The gratuity for work involving X-rays or radioactive substances will be based on ten percent.

The author of this paper was invited by the Brazilian Nuclear Energy Commission to present scientific bases to support the federal decree mentioned in §1 above.

Next, the author was invited to participate in the study group responsible for the drafting of the decree that was submitted to the workers' associations, which eventually resulted in federal decree nº 877 of July 20, 1983. The decree contemplated the scientific bases established in the draft, which are the main objective of this paper.

II SCIENTIFIC BASES USED IN THE DECREE Nº 877 OF JULY 20, 1993

First we must mention that any individual has the right to receive the additional amount if he is working in a place where there is the possibility to receive the expected radiation doses that exceed the annual dose limits for workers, in case the potential risks become real.

The ICRP publicationS (1) were used to set the scientific bases. In these publications (1) we referred mainly to the following items:

(29) At levels of effective dose below about 0.1 Sv, only stochastic effects are expected to occur and the probability of their recurrence is assumed to be directly proportional to the effective dose. The relationship of probability of harm to dose is therefore linear without threshold in this range. A nominal proportionality coefficient of 5×10^{-2} Sv^{-1} for the probability of fatal cancer in the general population, given a dose and dose rate effectiveness factor (DDREF) of two for low dose or dose rate, is used by the Commission in ICRP Publication 60.

(30) For absorbed doses higher than approximately 0.5 Gy, delivered over a short period, some deterministic effects begin to occur in addition to stochastic effects. The dose response relationship for attributable death approximates a sigmoid curve, although the exact shape depends on a number of factors, such as the dose rate and the distribution of the exposure over time. For a dose to the whole body of approximately 3 Gy, the probability of death is about 0.5 in the absence of medical attention. For acute doses higher than about 6 Gy, delivered over a short period, practically all irradiated individuals sill suffer an acute syndrome and are likely to eventually die as a consequence of the irradiation.

(61) Limits are used in radiation safety to control the risk to individuals from all stipulated sources of exposure. However, in order to establish requirements to constrain exposure to individuals from a particular source, the Commission has recommended the use of constraints in the process of optimization, which are source related and should be established in a manner such that the sum of the risks from all relevant sources does not exceed the individual limit. For the treatment of potential exposure, the Commission recommends that the limits of risk be of the same order of magnitude as the health risk implied by the dose limits for normal exposures. However, the dose limits themselves are not applicable to potential exposure situations.

(62) Constraint for individual risks from potential exposure situations can be obtained by constraining the probability from specific potential exposure scenarios or event sequences leading to exposure, or by constraining the magnitude of the exposure or both, i. e., by limiting the probabilities of doses being incurred and/or the doses themselves. This may be achieved through measures... . .

From items 29 and 30, we see that the dose response relationship is linear up to 0.1 Sv, quadratic up to 0.5 Gy and a sigmoid curve over up to 3 Gy, where the probability of death is about 0.5 in the absence of medical attention.

In this case, we can associate approximately the three reference levels of §1 Law n° 8270 mentioned above, with these three different dose ranges using what was stated in item 61 of the ICRP publication (1), i. e., the limit of risk must be of the same order of magnitude as the health risk implied by the dose limits for normal exposure.

Following this reasoning, if the individual has an attributed dose for the potential risk above 1/10 up to 1 of the worker's annual limit dose for normal situations, he will receive the maximum additional value. If he receives an attributed dose for potential risks between the annual dose limit for the public and 1/10 of the worker's annual dose limit, he will receive the intermediate additional value. For smaller attributed doses for the potential risks, he will receive the minimum additional value.

There is still one more factor to be considered: the area occupancy time. This factor offers the probability to meet the person in the area at the moment of the accident. In this case, the area occupancy factor, T, used by the National Council on Radiation Protection (2) of the United States of America.

If the individual has an attributed potential dose based on potential risk above 1/10 of the annual dose limit for workers and remains in the workplace for more than 1/16 of the normal weekly working time (40 hours /week), he has a right to the maximum additional value. If the individual remains in the workplace for less than 1/16, but more than 1/80 of the weekly working time, he has a right to the intermediate additional value. If the fellow remains less than 1/80 of the weekly working time, he has a right to the minimum additional value.

The same reasoning is applied for the person that, according to the attributed potential dose has a right to receive the intermediate additional.

HOW TO DEMONSTRATE ADEQUACY OF PROTECTION AGAINST A CORE MELT

Robert Hock
Siemens AG, Power Generation (KWU)

INTRODUCTION

After the Chernobyl accident the public - and consequently the politicians - in western countries requested improvements in safety for future reactors even in those designs where the type of accident which had destroyed the Chernobyl plant is excluded by fundamental physics.

When the major German and French suppliers of nuclear power stations, Siemens and Framatome, decided to develop jointly a next generation reactor type, this political "request" had to be taken into account.

It was decided to include safety features to mitigate the consequences of a core melt - the severest type of accident in a western light water reactor - should it occur despite the many other safety features which are included in this design in order to reduce the probability of occurrence of this type of event to extremely low values.

The question arose: How to demonstrate the adequacy of this additional protection? It was evident that the methodology proposed by ICRP namely to demonstrate that the risk of individual members of the public caused by "probabilistic events" is sufficiently low, could not be used: Due to the low probability of occurrence the contribution of this kind of accident to the risk of any average member of a critical group would already be sufficiently low even if there were no additional countermeasures. In addition, this approach would not cover severe societal effects potentially caused by such an accident.

We therefore introduced a different methodology in order to demonstrate the adequacy of additional design features which are only required "just in case": The consequences of such an unlikely but nevertheless very severe event shall be restricted to the plant itself. Severe consequences outside the immediate vicinity of the plant shall be excluded by the design.

METHODOLOGY

In order to cover individual as well as societal consequences we used the following methodology: Despite its low probability a severe accident - a core melt - was postulated to occur. In such a "postulated de facto situation" countermeasures outside the plant may become necessary depending upon the release of radioactive substances to the environment. We intended to show that these releases are so low that there is "no need for stringent countermeasures " outside the immediate vicinity of the plant .

The need for stringent countermeasures could then be evaluated using the advice given by ICRP for "de facto situations" /1/. Countermeasures which could have a severe impact on society were considered "stringent": This includes the evacuation of the inhabitants of whole communities (i.e. the next town) in order to restrict radiation exposure during the emission of radionuclides and the necessity to relocate populations because of radioactive substances deposited on the ground.

Considering the fact, that these provisions are additional to those which shall in the practice exclude this type of accidents, temporary restrictions in the commercialization of foodstuff were not considered to be "a stringent countermeasure": This would mainly be an economic issue (small compared to the value of the plant which is also at stake in this postulated event). In addition, this economic loss would only arise should the accident occur in the growing season. In order to quantify the term "temporary", an unrestricted commercialization of foodstuff shall be possible for a "second harvest" (in Europe generally the one in the following year). In analogy to the use of the values given in ICRP publication 63 for evacuation and relocation, we proposed to use the criteria given by the European Community for the commercialization of foodstuff in a de facto situation for a postulated situation also /2/.

ADDITIONAL ASSUMPTIONS

In order to evaluate consequences in the environment in such a postulated case it is not sufficient to postulate the event itself (a core melt). The environmental conditions have to be defined also. If one would use extreme assumptions (with a corresponding low conditional probability of occurrence) this would further reduce the overall probability of having this result in reality. We concluded that "reasonable" assumptions would be those which can be used in German regulation in the evaluation of the adequacy of design features controlling design basis accidents. The main ones are:

1. The event is postulated to occur in the growing season.

2. For each countermeasure (e.g. evacuation, relocation, commercialization of foodstuff produced in a second harvest) we evaluated a corresponding pathway potentially leading to the exposure of members of the public.

3. We concluded that the safety features are adequate if the considered countermeasure was not required at any location outside a defined exclusion area in 95 % of potential atmospheric conditions (given the postulated release).

4. In order to be independent from the characteristics of a specific location (e.g. distribution of the population) it was assumed that persons could be at any location for a unlimited time and that they would be unprotected (no sheltering).

5. Relevant biological and ecological factors were taken identical to those prescribed in German regulation for the evaluation of design basis accidents.

SOURCE TERM

Two different approaches have been used:

1. A "design release limit" was defined and shown that the safety goals stated above are met in the environment if there should be a release at or below this value. As "design release limit" we specified the following values for the total release and (given in parenthesis) maximum values for any 24 hours:

Xe-133 : 1 million TBq (0.1 million TBq); I-31: 2000 TBq (300 TBq); Cs-137: 100 TBq.

Each of these three nuclides represents the behavior of a specific group. The release of other nuclides was then calculated from these values by the use of characteristic data (e.g. the ratio of the core inventory of the various radionuclides after 1 year of full power operation).

This approach allows the safety analysis to performed in two independent steps:

a. Demonstration that safety goals in the environment are met given a release at the design release limit..

b. Demonstration that the safety features of the plant keep the release below the release limit.

Because atmospheric conditions will quite likely change during the release and because consequences in the environment also depend upon the release height additional assumptions concerning these factors were necessary. With respect to a release at the "design release limit" we evaluated consequences for the two extremes: release only at ground level and release only via a 150 m stack.

2. The method described before automatically introduces unnecessary conservatism: consequences in the environment are only evaluated for the "design release limit" and not for the (much lower) "potential release". Because the contribution of different radionuclides to exposure is different, the ratio between design release and potential release is not a direct measure for the reduction in dose.
In an alternative method we therefore calculated release rates as a function of time and the location of the releases for all radionuclides taking into account the major safety features of the new design. For this evaluation a core melt was postulated releasing 100% of the core inventory of noble gases, iodine and cesium into the containment atmosphere. A conservative function describing the consecutive deposition of aerosols was used. A conservative value was also selected for the leak rate from the primary containment to the secondary containment (a so called annulus) taking into account the intended specification for the containment. The evaluation also takes into account the fact that the secondary containment will only be ventilated via filters and the stack. A sub-atmospheric pressure will be provided in this secondary containment for a sufficient period of time in case the operation of the ventilation system would be delayed (e.g. in case of lack of power). This would provide decay time for the radionuclides and would thus reduce the release. It is therefore conservative to assume that the ventilation system operates during and after the postulated event.

TRANSPORT OF RELEASED RADIONUCLIDES IN THE ATMOSPHERE

The potential exposures resulting from given release functions for all relevant radionuclides as described before were calculated for specific immission points. These points were selected in such a way that each could be considered representative for a given area. They were defined by a grid of 72 sector lines and 20 distances. The distances were optimized in order to guarantee that the actual maximum value would be less than 10 % higher than the highest value found in the grid. Because limited countermeasures i.e. the evacuation of a few persons living very close to the plant is considered acceptable under these extreme circumstances an exclusion radius was also defined. We then calculated the potential exposure at each immission point outside the exclusion distance assuming a specific weather sequence during the release. The highest

of these values was then identified. If this highest value is below the corresponding intervention value, no intervention is required at any location. The assumed weather sequence was taken from real data. This calculation could in principle be repeated for a sufficient number of weather sequences all taken from reality. If the considered countermeasure is not required anywhere in more than 95 % of the cases the safety goal is met.

The simple yes/no evaluation with respect to countermeasures, however, does not identify existing safety margins. We therefore evaluated the detailed statistical distribution by answering the question: what is the probability that value x is not exceeded anywhere outside the exclusion area ? From this probability distribution function we interpolated the 95% value. The accuracy of this interpolation could then be improved: In a second run the probability distribution function was evaluated using a more detailed structure in the neighborhood of the approximate 95% value obtained in the preceding evaluation.

Another issue is the number of weather sequences to be evaluated. Computer programs which have been generated in order to evaluate "probabilistic events" tried to overcome this problem by selecting a limited number of weather sequences (in the order of 100) and giving weighting factors to each of them. However, consequences are influenced by a variety of factors: different wind speeds, different wind directions, different precipitation rates and (for long releases) different dispersion conditions. All these factors are more or less likely to change during the release. Their impact on exposure is quite different for the different exposure pathways (e. g. radiation from the cloud or ground contamination) and is also different at different distances from the plant. This becomes even more complicated if simultaneous releases at ground level and at an elevated level occur. The determination of one weather sequence to be a sufficiently good representative with respect to all these aspects for many more situations is therefore certainly a source of inaccuracy and possibly even bias. In order to avoid any discussion on that issue we therefore calculated the consequences of all weather sequences within a given period of time. We found that a period of one year (vegetation period only, i.e. some 4000 weather sequences with hourly weather data) results in a reliable statistical evaluation.

EXCLUSION AREAS

Countermeasures could easily be performed on small areas. Such an area could therefore be excluded from the requirement. The identification of such an area, however, may be different for different types of countermeasures. Evacuation of a few persons could be performed in order to limit exposure by the cloud and by inhalation. Therefore it should be performed before or at the beginning of the release. Because variations in wind direction are difficult to predict with certainty in a de facto situation, it would be necessary to evacuate all persons within a circle around the plant. In order to find the necessary size of such an exclusion radius we performed the calculations for a large number of different exclusion radii..

In contrast to evacuation, relocation would be performed after the release and would be based on measured dose levels. Persons living on an area on which a specified dose would be exceeded would then be relocated independent from the distance to the plant. If this area is sufficiently small it could then also be excluded from the requirement. We therefore evaluated the correlation between doses caused by deposited radioactive substances and the corresponding areas independent from its location and determined the statistical distribution in order to identify the values which are not exceeded with a probability of 95 %.

CONCLUSIONS

Criteria which were developed for intervention situations may also be used for demonstrating the adequacy of a design with respect to probabilistic events. In this case an extreme event i.e. a core melt is postulated to occur irrespective of its probability of occurrence. We were able to demonstrate that the European Pressurized Water Reactor jointly designed by Electricité de France, Framatome and Siemens would not require stringent countermeasures outside an exclusion area in this postulated case. Furthermore, if all safety features of the design are taken into account, no area outside the plant fence has to be excluded from the requirement.

PROGRESS TOWARDS A CONVENTION ON THE SAFE MANAGEMENT OF RADIOACTIVE WASTE

Geoffrey A.M. Webb and Odette Jankowitsch

IAEA, A-1400, Vienna, Austria

INTRODUCTION

The Convention on Nuclear Safety (1) was prepared during the period 1992 to 1994 and after consideration by a Diplomatic Conference in June 1994 was opened for signature at the General Conference of the IAEA in September 1994. The matter of the safety of radioactive waste was discussed many times during the development of the convention but it was eventually decided to restrict the coverage to matters concerned with nuclear safety of land-based civil nuclear power plants and those aspects of radioactive waste management directly connected with and carried out on the same site as the power plant. In the preamble to the convention, however, item (ix) affirms "the need to begin promptly the development of an international convention on the safety of radioactive waste management as soon as the ongoing process to develop waste management safety fundamentals has resulted in broad international agreement".

In September 1994, the General Conference of the IAEA also passed a resolution inviting the Board of Governors and the Director General to commence preparations for a convention on the safety of radioactive waste management. The Director General therefore organized a preparatory meeting of experts from member states to discuss the basic concepts and the possible scope of such a convention and to examine working methods and the procedures for its preparation. This meeting which took place in February 1995 prepared a paper entitled "Inventory of Issues Raised" and proposed that the appropriate mechanism would be the setting up of an open-ended group of legal and technical experts to prepare the convention.

The Safety Series document at the fundamentals level on the principles of radioactive waste management was approved by the Board of Governors in March 1995 (2) and all the initial preconditions for starting work on the convention were then fulfilled.

MEETINGS OF THE GROUP OF EXPERTS

First Meeting

The first meeting of the group of legal and technical experts was held in July 1995. There were 128 participants from 53 countries and observers from 4 international organizations. The meeting elected Professor Alec Jean Baer from Switzerland as its Chairman.

In an introductory general discussion, experts agreed that the Convention on Nuclear Safety was to be considered as a model. The intention was to develop a "sister" convention on radioactive waste safety: notably it should also be an "incentive" convention and should follow a similar structure; it should contain a reporting requirement to a meeting of Contracting Parties and rely for its implementation on a peer review process thus acknowledging the sole national responsibility for radioactive waste management activities. It should so far as possible take over where the Convention on Nuclear Safety ceases to apply so as to avoid any gaps in coverage. It was also noted that consideration should be given to including the substance of the Code of Practice on the International Transboundary Movement of Radioactive Waste (3).

In the preliminary discussions there was agreement that the convention should apply to the full range of radioactive wastes as described in the Waste Management Fundamentals, namely "liquid", "gaseous" and "solid form" wastes but it was recognized that the scope would need careful definition, especially in determining what materials would be excluded or otherwise be deemed to not be covered by the convention. Materials presenting difficulties in this respect included those wastes containing low activity concentrations of radioactive materials, especially if these were only naturally occurring radioactive materials. Another difficulty of a different kind was whether the convention would apply to the storage of spent fuel not intended for disposal as waste or for which the intention was not yet firm. Although it was clear that such spent fuel did not fall under the definition of "waste" i.e. material for which no further use is foreseen, it was also clear that the safety provisions during interim storage should be the same whatever the destination of the spent fuel when retrieved from storage. A further item needing resolution was the point at which materials originating from military applications and becoming wastes would come under the convention coverage.

During the discussions the technical articles of the Convention on Nuclear Safety were reviewed in some detail. A number of provisions were found that could readily be transferred to the new convention by appropriate adjustments and changes of wording. For some, however this was not the case and there were some aspects of waste safety that had no counterpart in the Convention on Nuclear Safety.

The meeting also considered the suitability for incorporation in the convention of each of the principles in the Safety Fundamentals document (2) and the Safety Standard on the establishment of National Systems (3). There was no substantial dissention from the general message embodied in the major statements of principle but it was clear that care would be needed over the wording to be used to express them in a convention.

The meeting concluded by requesting the Chairman to produce a first draft for consideration at the next meeting.

Second Meeting

The second meeting of the open-ended group of technical and legal experts on the Convention on the Safety of Radioactive Waste Management took place from 4 to 8 December 1995. The meeting was attended by participants from 52 countries and observers from 3 intergovernmental organizations.

The meeting carried out a detailed review of a first draft of the convention, which had been prepared by the Chairman taking into account comments from "Friends of the Chair"- a small group based on geographical distribution. General agreement was obtained that this draft provided a very good basis for discussion, and the meeting proceeded to review the document on an article-by-article basis. The group agreed that the title of the draft convention should be identical to that used in the Preamble to the Convention on Nuclear Safety, namely "Convention on the Safety of Radioactive Waste Management". It was also agreed that the title should not specifically refer to spent fuel.

During the course of the meeting, various delegations submitted general position papers in addition to preparing detailed drafting comments for improvement to particular articles. These were considered to be very constructive in tone, and the meeting was characterized by a willingness to appreciate differing points of view and to suggest compromise wording where necessary to overcome particular areas of concern. A good example was the proposal to simplify and combine various definitions.

The meeting agreed that the Chairman should prepare a revised second draft , based on the numerous proposals and comments made during the course of the meeting, for distribution to Member States by mid February 1996. This would then form the basis for the deliberations of the next meeting of the open-ended expert group, which has been scheduled for 25-29 March 1996 in Vienna. Once the Group has an agreed text this will be considered by a Diplomatic Conference before being endorsed by the IAEA Board of Governors and opened for signature.

CONCLUSIONS

Based on the adoption of the Convention on Nuclear Safety as a model, the general style, format, content and procedures of the Convention of the Safety of Radioactive Waste Management have been agreed by the Group of legal and technical experts responsible for preparing a draft. There remain many specific questions to be resolved but the meetings so far have been characterized by a willingness to seek solutions and expedite progress so the prospects remain encouraging.

RADIATION MONITORING SYSTEM FOR ASTRONAUTS

Ian Thomson[1], Gary MacKay[1], Alfred Ng[2] and Leena Tomi[2]

[1] Thomson & Nielsen Electronics Ltd., Ottawa, Ontario, Canada K2C 3P1
[2] Canadian Space Agency, St. Hubert, Québec, Canada J3Y 8Y9

ABSTRACT

Astronauts in space are constantly under the bombardment of radiation particles from trapped electrons, and trapped proton. In addition, cosmic rays, while penetrating the spacecraft shell, generate secondary radiation of neutrons. As astronauts' stay in space is getting longer, the need for a real-time radiation monitoring device has become critical. ThermoLuminescent Dosimeter (TLD), used onboard both the MIR and the Space Transportation System (STS), cannot provide real-time dose reading. This paper describes a real-time direct read-out device, currently under development, which can measure skin, eye, and Blood Forming Organ (BFO) doses separately.

INTRODUCTION

The radiation environment found in space, particularly Low Earth Orbit (LEO), can be hazardous to the well being of the mission crew. Figure 1 shows the simplified space environment both external and internal to a manned spacecraft. There is a complex mixed radiation field both inside and outside the spacecraft. The types of radiation inside a spacecraft ranges from primary particles, e.g. trapped high energy electrons and protons, cosmic rays (light and heavy ions) to secondary particles, e.g. X-rays, gamma rays, neutrons. The majority of the radiation dose arises from high energy electrons and protons, with protons dominating for shields of greater than 1g/cm^2 (i.e. 4 mm Al). A study of relative doses for different missions has been presented in detail in ESA's *PARIS* study (1). Measured doses with TLDs are

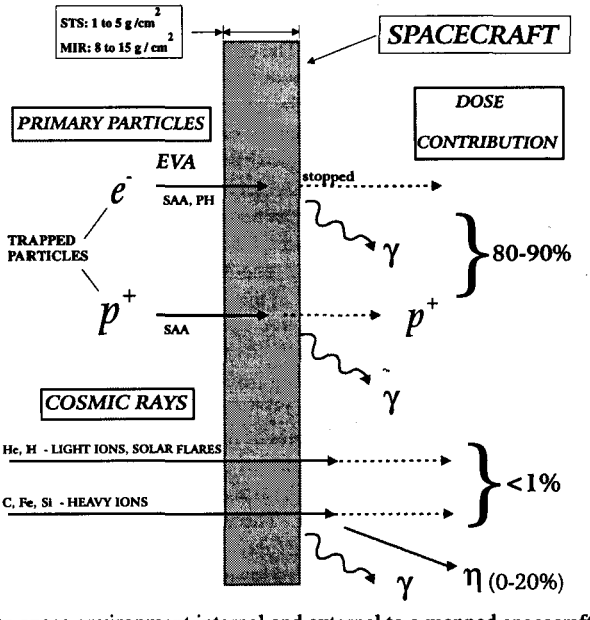

Figure 1 The space environment internal and external to a manned spacecraft

in the region of 1 mSv/day for STS, 0.3 mSv/day for MIR and 0.2 mSv/hour for Extra Vehicular Activity (EVA). These number show that the lifetime limit can be achieved much sooner for those astronauts who undertake EVA. Fry has found that (2), depending on the length and time of the mission as well as the orbit inclination and altitude, it is quite possible that an astronaut lifetime dose can be achieved in as little as 6 missions each lasting 6 months. During EVA the limiting dose could well be that absorbed by the astronaut's skin. It is imperative, especially with the construction of Space Station Alpha within the next decade, where astronauts are expected to work many hours in EVA, that the dose not only to the BFO be monitored but also that experienced by the skin and to the eye.

In 1992 a series of space radiation experiments were conducted using Thomson & Nielsen (TN) MOSFET dosimeters. Three TN MOSFET dosimeters were placed on the MIR space station to measure the absorbed dose within the interior of the spacecraft. The orbit apogee/perigee was 419/399.8 km at an inclination of 51.64°. The units were returned to earth after 96 days, 268 days and 430 days measuring 0.025 Sv, 0.075 Sv and 0.135 Sv respectively. The MOSFET's agreed with Russian TLD measurements to within 10% (3).

SPACE RADIATION ENVIRONMENT

The most important characteristic of the environment encountered by spacecraft in LEO is that several times each day it must pass through the particles trapped in the Van Allen belts. These particles are primarily electrons and protons which are trapped in the Earth's magnetosphere. For LEO there are three areas where particle fluence is of concern: the two polar regions and the South Atlantic Anomaly (SAA) The SAA occurs in a region over the South Atlantic and is due to the tilt of the Earth's magnetic axis which causes the inner edge of the trapped belts to be encountered at relatively low altitudes. Trapped electrons range in energy from a few keV to 5 MeV while trapped protons range in energy from 30 MeV to several hundred MeV.

The level of trapped particle flux varies greatly with orbit inclination and altitude. The amount of protection the geomagnetic field provides a spacecraft from cosmic rays and solar flares is also dependent on the inclination and to a smaller degree the altitude of orbit. As the altitude increases, the exposure to cosmic rays and solar protons gradually increases. The effect of orbit inclination is much more dramatic. As the inclination increases the spacecraft spends more time in regions accessible to these particles. In a polar orbit the spacecraft is no longer protected by the geomagnetic field lines and is fully exposed to cosmic ray and solar flare particles in addition to trapped electrons and protons.

Space Station Alpha's proposed orbit is approximately 400 km at an inclination of 51°. The average shielding afforded by an U.S. astronaut EVA suit is (1): arms, 0.2 g/cm^2, body 0.5 g/cm^2 and head 0.9 g/cm^2. By definition the shielding from the human body to the skin, eye, and BFO is 7 mg/cm^2, 0.3 g/cm^2 and 3.0 g/cm^2, respectively. Using these figures, the total shielding for arms, skin, eye, and BFO are approximately 0.207 g/cm^2, 0.507 g/cm^2, 1.2 g/cm^2, and 3.5 g/cm^2 , respectively. Figure 2 shows the resultant dose as simulated for an astronaut in EVA at the Space Station orbit.

ASTRONAUT RADIATION MONITOR

Thomson & Nielsen Electronics, with funding from the Canadian Space Agency, is developing a prototype Astronaut Radiation monitor. The TN MOSFET dosimeter technology has already found applications in nuclear and medical fields. Uniqueness of the sensor is its thin active region (< 0.001 mm) and its sensitivity. By using shields of various thicknesses over the sensor, the dosimeter can be simulated to measure the dosage to the skin, eye, and BFO. The size of the monitor is expected to be less than 15 cm × 10 cm × 5 cm with a mass of not more than 800 g. The monitor is designed to run on a 10 V power source (battery) and can operate continuously over 21 days. The monitor consists of three MOSFET dosimeters to measure BFO, eye, and skin dose with a lower limit of detection of 0.4 mSv. The monitor also has a charged particle detector to monitor dose rates as low as 0.01 mSv/h.

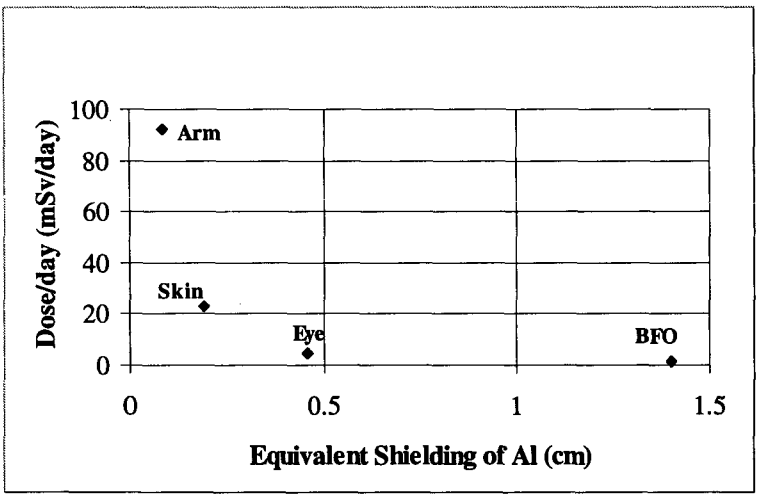

Figure 2 Simulated dose level for an Astronaut in EVA for the proposed Alpha Space Station orbit.

The monitor takes dosimeter readings once per hour, storing the measurement in memory along with the time and temperature. The dose rate detector integrates over 1 minute interval storing data in memory along with the time of measurement. In this manner the radiation environment encountered by the astronaut will be monitored and mapped. Data is obtained by interfacing the monitor to a personal computer and downloading into a computer program. It is expected that the first flight unit will be built, tested and be ready to fly in the STS in 1997.

ACKNOWLEDGEMENT

The authors wish to thank the input to the project by Dr. Steve MacLean and Dr. Alan Mortimer of Canadian Space Agency, and Dr. Ken Shortt of National Research Council. POSSIBLE IMPACT OF ICRP 60 RECOMMENDATIONS ON MEDICAL PRACTICE

L. Denis Brown Ph.D.
BB Health Physics Services, 55 Leopold Crescent, Regina SK, S4T 6N5, Canada

Introduction

Three changes recommended by the I.C.R.P. are likely to have a significant impact on medical procedures, the revised occupational dose limits, which include a new five year cumulative effective dose limit of 100 mSv and also a lower limit for exposure of the skin, the lower annual dose limit of 1 mSv recommended for members of the public and the recommendation that the dose to the foetus during pregnancy should be limited to 1 mSv. The proposed new 100 mSv in 5 years occupational dose limit has been generally presented as the most important proposal which was made by I.C.R.P. Many hospital administrators have reviewed the implications of such a dose limit for their own organization, found from past dose records that very few staff appear to be at risk of exceeding the proposed five year limit, and filed the report, or passed it on to the hospital Radiation Safety Officer, assuming that they can safely ignore it. In practice however the other major changes summarised above may have more impact on the operation of hospitals than the proposed new occupational dose limit. Some changes in working practices which hospitals may need to make to meet ICRP recommendations are reviewed below.

The Proposed New Occupational Dose Limits

Most occupationally exposed radiation workers in a hospital would regard it as very exceptional if they received a radiation dose greater than 20 mSv per year. Such exceptions may occur after there has been a major change in the workload which has not been reflected in corresponding improvements in staffing and facilities, procedures for reducing doses to normal levels are then self evident. However a few categories of workers receive consistently higher doses on an ongoing basis in some large hospitals. In diagnostic radiology these categories include staff extensively involved in cardiac catheterisation procedures and nurses in paediatric hospitals who frequently hold children during X-ray procedures. In nuclear medicine radiopharmacists producing large quantities of labelled drugs will need to handle very large activities and will receive significant whole body doses if the radiopharmacy has not been adequately designed to minimise their exposures. Nuclear medicine technicians in busy departments also sometimes accumulate relatively large doses when dispensing is carried out in house and a properly equipped dispensary is not available. Both these groups are also liable to receive significant finger doses, and meeting the proposed new limit for skin dose averaged over 1 cm^2 (ICRP 60 paragraph 173) is likely to require some changes in working procedures. In radiotherapy departments staff involved in brachytherapy also frequently receive both effective doses, and finger doses, which are not inconsiderable.

Hospital procedures with respect to the classification of staff as radiation workers vary widely; but in my experience nurses and orderlies have not generally been classified as radiation workers and they are therefore, with a few exceptions, subject to the same dose limits as members of the public. Nevertheless nurses caring for iodine therapy patients may receive significant whole body doses, and attention may also need to be paid to the dose received by orderlies responsible for transporting patients who have just received radioactive injections. In some children's hospitals which are not equipped with adequate child restrainers, or where clinicians oppose the use of restraining devices, nurses are frequently called upon to hold children during radiological examinations and this may lead to significant radiation doses being incurred. Doses to nurses are also possible when working in wards where there is a considerable use of mobile X-ray equipment, or where patients with implanted radioactive sources have been placed. In all these cases the new I.C.R.P. recommendations may necessitate such members of staff being formally designated as radiation workers subject to the new occupational dose limits rather than the existing limit for members of the public, or at least being provided with monitoring devices to demonstrate that this is not necessary.

Radiation Exposure of Members of the Public

Radiation facilities in hospitals have generally been designed so that the maximum dose which might be received in an area accessible to the public does not exceed the present public dose limit of 5 mSv/y. In principle, if this limit is reduced by a factor of five the relevant areas in every hospital should be provided with additional shielding. Equally there are likely to be other areas of the hospital occupied by general staff members where there is a possibility of exposing the workers concerned to annual doses in the range 1-5 mSv/y and these will therefore also need additional shielding. Such areas can include canteens, physicians rest rooms, teaching rooms and office space. Paragraph 168 of ICRP 60 indicates clearly that the Commission expects such modifications to be completed as early as possible. Shielding requirements for diagnostic radiology suites are calculated using a formula which includes relevant data on all the x-ray sources present, the work loads for each, the occupancy factors for adjacent areas and the existing structural shielding. Although many rooms with low work loads have been more than adequately shielded to allow for increasing future work loads, this has not been a universal practice and, when the recognised formula has been rigidly applied, existing shielding may be quite inadequate to meet the recommended new limits. This is not a technical problem as additional thin sheets of lead can quickly cure any deficiencies, but the economic impact of introducing such requirements for a significant proportion of the existing radiology departments would be enormous. Some calculations made by Health Canada suggest that this problem may be most severe for dental operatories currently shielded only by gypsum plasterboard, but that standard radiographic facilities with workloads of around 200 mA-min/week may require more than an additional 0.5 mm of lead shielding.

Similar concerns apply to most existing nuclear medicine and radiotherapy departments, but with two important differences. The number of departments affected is very much smaller, but the problem of adding additional shielding within the constraints of the existing building may be very much greater because of the higher energy of the radiation of concern. For example there are relatively few 20 MeV linacs, but retrofitting the shielding of the bunkers in which these are installed to increase the beam attenuation by a factor of five would often be almost impossible. Radiotherapy departments may also be faced with a need for the installation of additional shielding where their brachytherapy sources are stored, and around the beds of patients with implanted sources.

Additional problems will affect nuclear medicine departments. These have all developed rules for allowing the discharge of patients after the administration of significant quantities of radioactivity. Such rules are generally based on limiting the dose which could be received by any member of the public outside the hospital to less than 5 mSv. These rules will have to be rewritten to reflect the new I.C.R.P. limit once this has been introduced. The Commission has introduced one concession which may help in this regard, the greatest problems will arise in the patient's home where it is likely that the patient will spend the longest periods of time in the vicinity of other people. In paragraph 139 of ICRP 60, it is stated that any exposure knowingly and willingly received in the course of supporting and comforting patients, may be classified as a medical exposure that is not subject to the normal dose limits. Other rules that limit the activities that can be discharged from busy departments, or from the homes of outpatients may also have to be modified. An indirect effect of the new public dose limit in ICRP 60 is likely to be a reduction in the permissible concentration of radionuclides in effluent, and this would have very important consequences for the operation of nuclear medicine departments. Calculations made by one Canadian hospital suggest that such changes would necessitate delaying the discharge of all iodine therapy patients, at a cost to the hospital of several million dollars per year.

Radiation Doses Received by Pregnant Workers in Hospitals

The I.C.R.P. recommendations have raised considerable concerns among female nuclear medicine technologists in hospitals who fear that it may not be possible for them to continue normal work during a pregnancy if these new recommendations are implemented. They believe that should this prove to be the case it would lead to the preferential employment and promotion of male staff, and would therefore have a very adverse effect on their career prospects. Similar concerns are felt by some X-ray technologists who are routinely involved with high dose procedures such as cardiac catheterisation. Other pregnant workers, such as nurses, orderlies or even cleaning staff, have become aware that a large reduction in the permitted dose during pregnancy is being

recommended, and this has led to concerns that the doses which they are currently experiencing may be too high and may be harmful to their expected child. Explaining to all these workers that such fears are generally unwarranted has placed a considerable additional burden on many hospital Radiation Safety Officers.

Optimisation in Hospitals

One of the most important points stressed in this I.C.R.P. report is the need to improve optimisation procedures in hospitals (ICRP 60 paragraph 180). Any attempt by a hospital to comply with the various recommendations necessitates a complete review of its ALARA program, with particular attention being paid to the available dose data and to ways in which existing dose levels for both staff and members of the public could be reduced. This could not be restricted to consideration of occupational exposures only as the I.C.R.P. report places great emphasis on the need to reduce the dose delivered to the patient during commonly used diagnostic procedures. Some of the principal areas in which it appears possible to improve the optimisation of the uses of ionizing radiations in hospitals as recommended in this ICRP report, are reviewed below:

(a) Radiotherapy

External beam treatment bunkers have all been designed to ensure that the dose which could be received by members of the public (including ancillary hospital staff) does not exceed 5 mSv/y. A requirement to reduce this by a factor of five would involve additional shielding of the bunkers that may be felt to be impracticable. An alternative in some circumstances may be to address specific concerns individually, for example where rooms immediately adjacent to a treatment bunker are continually occupied by ancillary hospital staff, problems could be alleviated by relocating accommodation so that these rooms are restricted to uses involving low occupancy factors such as storage. Although no major problems should be encountered in controlling the doses received by occupationally exposed staff associated with external beam treatment procedures, this does not apply to brachytherapy where there is often a long history of relatively high radiation doses to the staff involved. Optimisation may require more hospitals to adopt remote afterloading techniques to reduce these doses.
The doses received by other staff; such as porters, orderlies, nurses and nursing auxillaries who are not classified as radiation workers but who may be exposed to radiation from brachytherapy sources; will also have to be reviewed very carefully. In most instances additional shielding would probably help to meet optimisation requirements, but it may also be important to review whether some of these workers should be reclassified as occupationally exposed radiation workers. If this becomes necessary additional problems arise as soon as one of the staff concerned became pregnant and has to comply with the ten times lower dose limit to the foetus which the I.C.R.P. are now recommending. Serious problems would result if these considerations lead hospital administrators to preferentially appoint male staff to some of these positions.

(b) Diagnostic Radiology

The most important aspect of optimisation in diagnostic radiology is the reduction of patient doses associated with different procedures by improved quality assurance procedures. This is too large a subject to discuss further here, but there is increasing recognition that patients have the right to be given dose measurement data relating to any procedures that they undergo, and in many instances this should also include comparative data generated in other centres. In the case of staff, optimisation generally involves a careful review of the maintenance procedures for equipment and of the use of personal shielding such as aprons, gloves and lead spectacles.

(c) Nuclear Medicine

As with diagnostic radiology, optimisation will involve attention both to doses delivered to patients and those received by staff. An effective quality assurance program for imaging equipment is clearly essential. It is also necessary to assess whether the availability of imaging equipment is adequate. In an expanding department it may become necessary to reduce scanning times by increasing the activity administered. It is easy for such temporary expedients to become permanent practice. Attention also need to be paid to the optimisation of doses outside the hospital which result from the discharge of treated patients; at the minimum such patients must be given adequate instructions on elementary radiation hygiene and on the precautions that they should follow to protect family members. In the case of doses to staff members the most promising (and expensive!) approach to optimisation is usually a careful review of both equipment and working practices in the radiopharmacy and the dispensing area.

CRITERIA FOR THE RELEASE OF PATIENTS ADMINISTERED RADIOACTIVE MATERIAL

Stephen A. McGuire, Stewart Schneider, and John E. Glenn

U. S. Nuclear Regulatory Commission, Washington, DC 20555, USA

INTRODUCTION

In June, 1994, the U. S. Nuclear Regulatory Commission proposed amendments to its regulations concerning criteria for the release of medical patients administered radioactive material. The existing criteria are that the release of patients from hospitalization may be authorized if the activity in the patient is less than 1,110 megabecquerels (30 millicuries) or if the dose rate at a distance of 1 meter from the patient is less than 0.05 millisievert (5 millirems) per hour. The proposed new criteria for patient release would be based on the potential dose to individuals exposed to the patient. Under the proposed new criteria, the release of a patient could be authorized if the total effective dose equivalent to any other individual from exposure to the patient is not likely to exceed 5 millisieverts.

RECOMMENDATIONS OF ADVISORY BODIES

The 5-millisievert value is consistent with the recommendations of national and international advisory bodies. In the U. S., the National Council or Radiation Protection and Measurements (NCRP) recommends public dose limits of 1 millisievert for continuous or frequent exposure and 5 millisieverts for infrequent exposure. The International Commission on Radiological Protection (ICRP) recommends that the limit for public exposure should be expressed as an effective dose of 1 millisievert in a year, except that, in special circumstances, the dose could be higher in a single year provided the average over 5 years does not exceed 1 millisievert per year. The NRC's radiation protection regulations incorporated the 1-millisievert long-term objective as a dose limit and included a provision to allow for a 5-millisievert limit on an occasional basis. Section 20.1301(c) provides that an annual dose of up to 5 millisieverts is acceptable if there is a need for it and if steps are taken to reduce the dose to as low as is reasonably achievable. In the case of released patients, it would be unlikely for a single individual exposed to a patient to receive a significant dose from more than one therapeutic administration because large therapeutic doses are rarely administered more than once within several years.

METHODOLOGY FOR CALCULATING EXTERNAL GAMMA DOSE

The dose to total decay $D(\infty)$, is calculated using the following equations. For radionuclides with a half-life greater than 1 day

$$D(\infty) = \frac{34.6\Gamma Q_o T_p (0.25)}{(100\ cm)^2}, \quad (1)$$

and for radionuclides with a half-life less than 1 day

$$D(\infty) = \frac{34.6\Gamma Q_o T_p}{(100\ cm)^2}, \quad (2)$$

where Γ = exposure rate constant for a point source, R/mCi-h at 1 cm,

Q_o = initial activity of the point source in millicuries, at the time of release,

T_p = physical half-life in days.

Equation 1 assumes, for radionuclides with half-lives greater than 1 day, that the individual likely to receive the highest dose from exposure to the patient would receive a dose of 25 percent of the dose to total decay (0.25 in Equation 1) at a distance of 100 centimeters (1 meter). For radionuclides with half-lives less than 1 day, the factor 1.0 is used in Equation 2 because the assumption that the time that individuals will spend near the patient will be limited is not valid when most of the dose is delivered in a relatively short time.

Doses among individuals who may come in contact with a released patient are highly variable and reflect the crucial, but difficult to define, parameters of time, distance, and shielding. Based on time and distance considerations, it is reasonable to conclude that for the overwhelming majority of released patients, the maximally exposed individual is likely to be the primary care-provider, a family member, or any other individual who spends significant time close to the patient.

Based on time, distance, and shielding factors, which describe normal lifestyles of the U.S. population, it is highly unlikely that doses equal to spending 100 percent of time at a distance of 1 meter from a patient would result to any individual including a patient's spouse. As a standard medical practice, patients undergoing therapeutic treatments with radiopharmaceuticals are given firm instructions, both verbally and in writing, regarding basic principles on how to minimize doses to other individuals.

Given all considerations, a reasonable estimate of the maximal likely dose to an individual exposed to a patient is 25 percent of the dose to total decay at a distance of 1 meter. The selection of an occupancy factor of 25 percent at 1 meter for estimating maximal likely exposure is based on judgment of time-distance combinations that are believed likely to occur when instructions to minimize time spent close to the patient are given.

The occupancy factor of 0.25 at 1 meter is also supported by empirical data. Harbert and Wells (1) monitored the external dose of 8 family members of 3 patients treated for thyroid carcinoma using iodine-131. The actual doses were far below the calculated doses for an occupancy factor of 25 percent, indicating that the model generally provides a conservative estimate of the dose.

Harbert and Wells (1) also measured the external doses to 11 family members of seven hyperthyroid patients. In each case, the measured doses were at least a factor of 10 below the doses predictedd by Equation 1 using an occupancy factor of 0.25 at 1 meter.

Jacobson et al. (2) measured the external doses to 10 family members of 7 iodine therapy patients. In each case except one, the external dose to the family member was below that predicted by Equation 1 using an occupancy factor of 0.25 at 1 meter and well below 5 millisieverts. In the case of the exception, the family went on a extended vacation spending much of the time together in an automobile. This demonstrates that if reasonable efforts to maintain distance are not made doses can be higher than predicted by Equation 1.

Buchan and Brindle (3) monitored the doses of 54 family members of patients who underwent iodine therapy for hyperthyroidism. This study is interesting because no instructions on minimizing dose were given. Thus, the results can be taken to represent the doses that would be received if no instructions were given or if instructions were totally disregarded. The effective occupancy factor at 1 meter was less than or equal to 0.25 in 45 of the 54 cases (83 percent). Thus, even in the complete absence of instructions, the occupancy factor at 1 meter was usually less than 0.25.

In conclusion, both empirical measurements and professional judgement support an occupancy factor of 0.25 at 1 meter as a generally conservative value. Using this value in Equation 1 should generally overpredict the dose even if instructions are not given or are not strictly followed.

PERIOD FOR INTERRUPTION OF BREAST-FEEDING

The proposed new criteria would apply to breast-feeding infants. The regulation would require that breast-feeding women receive instructions on the interruption of breast feeding if the dose to a nursing infant could exceed 1 millisievert if there were no interruption of breast feeding. The doses were calculated for newborn infants; doses to one-year-old infants would be less than half the doses to newborns. The external dose, typically small relative to the internal dose, is considered separately.

External doses were calculated using an occupancy factor of 0.16 and an effective distance from source to receptor tissue of 0.2 meter.

The decision on whether instructions would be required is based on the sum of the maximum value of the internal dose range for the newborn infant plus the external dose assuming no interruption of breast-feeding. The duration of interruption is selected to reduce the maximum dose to a newborn infant to less than 1 millisievert. The actual doses that would be received by most infants would be much less. The physician may use discretion in the recommendation, increasing or decreasing the duration of interruption somewhat depending on the mother's concerns about radioactivity or interruption of breast feeding.

INTRODUCTION

In almost 100 years since the discovery of radioactivity, the properties of radioactive materials have been exploited in products such as clocks and watches incorporating luminous paint which are freely available to members of the public. Over time, regulatory authorities have felt it necessary to apply some degree of control to the supply and use of such products in order to protect public health. In many areas of radiation protection, national authorities take note of international recommendations when developing national standards, but the existing detailed guidance of the International Atomic Energy Agency (IAEA) for consumer products is incomplete and out of date [1]. Recently, a thorough revision of the International Basic Safety Standards (BSS) has occurred [2], which has prompted a review and revision of the related guidance published by the IAEA. A draft Guide on Regulatory Requirements for the Use of Consumer Products Containing Radioactive Substances has now been completed and is currently under review within the IAEA's system for development of documents in its Safety Series of publications.

OBJECTIVE AND SCOPE OF THE DRAFT GUIDE

The major objective of the draft Guide is to provide guidance on interpretation of the BSS in developing national regulatory requirements for the control of consumer products containing radioactive materials. In this context, a consumer product is taken to be anything supplied freely to members of the public and which, once acquired by the consumer, is essentially beyond further regulatory control. An additional aim is to provide guidance which promotes harmonization of policy between countries so that difficulties in international trade are avoided. The Guide applies to the distribution, sale, use and disposal of all consumer products in which radioactive materials have been deliberately incorporated, but not to their manufacture, which is covered by other Safety Series guidance.

PRINCIPLES OF PROTECTION

The Guide follows the fundamental radiation protection philosophy of the BSS and is based on the principles of justification of practices, optimization of protection and limitation of individual dose. It treats the supply of consumer products as a practice. If the incorporation of radioactive materials into a consumer product can be justified, the Guide requires a system of regulatory control to be applied to the practice. The system described includes the possibilities of exclusion, exemption and authorization of the practice, where authorization may take the form of licensing or registration, and is intended to provide an appropriate balance between measures that are necessary to protect the public and over-regulation.

Exposures to radiation from consumer products may be excluded from regulatory control if they arise from natural radioactivity in raw materials, for example, and public use of the product does not lead to pathways of exposure which are undesirable and amenable to control. The practice of supplying consumer products may be exempted from regulatory control if the consequent exposures are sufficiently small and if the product supplied is inherently safe. Specifically, if individual effective doses are expected to be less than 10mSv in a year and the collective dose is expected to be less than 1 man-Sv, the practice may be exempted without further consideration. It is anticipated that the majority of consumer products would fall into this category. If these conditions are not met, the practice might still be exempted if exemption can be shown to be the optimum regulatory option.

When supply of consumer products cannot be exempted from regulatory control, the supplier is required to meet specified conditions. The practice would normally be registered, as licensing is unlikely to be necessary for products made freely available to members of the public.

REQUIREMENTS FOR REGULATORY CONTROL

The Guide specifies requirements for the regulatory authority in establishing the regulatory status of the practice. In summary, the regulatory authority should require an initial notification from all suppliers of consumer products containing radioactive materials, make an assessment of the practice based on the decision tree illustrated in Figure 1, and then exclude, exempt or register accordingly. To avoid unnecessary notifications, the regulatory authority may issue a statement freeing suppliers from further notification relating to products similar to those already covered by exclusion or exemption. Different strategies need to be adopted for novel products, new models of existing products, products already on the market before regulations are established and those already in the public domain but no longer marketed.

The Guide specifies requirements for manufacturers and importers of consumer products and for quality testing and labelling of products and packaging. It also covers responsibility for surveillance, when necessary, of the supply and use of consumer products which have been exempted or authorized. The Guide recommends that, given the levels of activity usually encountered in consumer products, no restrictions should normally be placed on their disposal.

CONCLUSION

The draft Guide sets out what is regarded as being required for the regulation of consumer products in a manner consistent with the BSS. It also includes annexes providing information on some existing consumer products, on prototype tests for one of the most ubiquitous products - the smoke detector, and on the types of analysis employed in assessment of radiation risk arising from the use of consumer products. It is hoped that the Guide will be published before the end of 1996.

1 - INTRODUCTION

On the initiative of the chairmen of the three Radiation Protection Societies (Italian, French and Spanish), it has been decided to extend the study carried out at TAORMINA (Sicily, Italy) joint conference on the harmonization of radiation protection practices.

In order to formulate proposals on this topic, a Working Group was created at the end of 1993 made up of representatives of each Society, with the objective of harmonizing the individual radiological monitoring documents and methods of recording and managing dosimetric information in data banks.

2 - THE PRESENT SITUATION

The present situation of the three Countries, in relation to data banks and individual radiological monitoring documents, is as follows:

•ITALY

•a lot of dosimetric services (80),
•dosimetric data validated by a qualified expert,
•some examples of individual radiological documents (i.e. INFN, ENEA),
•an example of national dosimetric data bank.

•SPAIN

•individual radiological document edited by the Regulatory Body for all the exposed workers,
•shared responsability between the contractors and the utilities,
•regulatory dosimetric data bank.

•FRANCE

•individual radiological document limited to "EDF" nuclear power stations,
•medical monitoring card (regulatory),
•re"operational" data bank (DOSINAT-DOSIMO),
•regulatory data bank.

3 - FOCUSING ON THE PROBLEMS

The analysis of the existing situations has showed the evidence of some problems:

3.1 - Individual radiological document

•some residual differences in rules,
•difficulty of changing documents in use,
•assigned responsabilities,
•lack of operational dosimetry at some plants.

3.2 - Data bank

- lack of guidance on data banks in the Directive,
- different software and hardware,
- problems in worker identification,
- different codification in use,
- different radiation protection quantities in use.

4 - WORKING GROUP PROPOSALS

The proposals of the Working Group, on the basis of the criteria established in the European Directive 90/641 "On the operational protection of outside workers exposed to the risk of ionizing radiation during their activity in controlled areas", have been the following:

4.1 - Individual radiological document

- Each country shall have an its own national individual radiological document: the existing ones will be recognized by other countries,
- the definition of the needed information for a communitary worker to be accepted (see the document "Recommendations of the AIRP-SEPR-SFRP Working Group").

4.2 - Data Bank

- The definition of the needed information for a communitary worker to be accepted in a communitary installation has been proposed (see the document "Recommendations of the AIRP-SEPR-SFRP Working Group),
- a common data codification on the basis of communitary criteria will be established,
- a standard data transmission methodology will be defined: periodicity, exchange format, type of transmission, information retrieval and access, ecc.

5 - CONCLUSIONS

The authors of this presentation have presented the document on the proposals to the DG-X1 of the European Commission and to some Commununitary Countries. Moreover they whish for the participation of other radiaction protection Societies in order to continue on working on the harmonization in the context of the European Union.

ABSTRACT (See instructions overleaf)

The new scientific evidences on dose effect relationship and experiences and conclusions gained after Chernobyl accident have caused international scientific organizations to reconsider existing standards and codes and if necessary prepare the new ones. The Main Commission of ICRP finalised new recommendations at the and of 1990. Recommendations have appeared in the Annals of the ICRP in 1991 as Publication 60. Besides that, IAEA together with other sponsoring organizations have been working on preparation of new Basic Safety Standards for protection against ionizing radiation. Our expert teams actively have participated on reviewing and drafting the standards.

At the end of 1994. an expert group started a preparation of new radiation protection act in FR Yugoslavia. Working on this task, it was decided to prepare the whole legal system in radiation protection according to international recommendations.

Characteristics and experiences in implementing international standards in national specific legal system are presented in this paper. Subjects that should be regulated more precisely are suggested as well in this paper.

MAJOR SCIENTIFIC TOPIC NUMBER 8.7. (see page 7)

ABSTRACT (See instructions overleaf)

Many years ago the countries of Latin America has started differents programs of nuclear development according to their own realities, but at same time they have made great efforts to strenghten the radiological protection in order to regulate properly the different applications of ionizing radiation sources.

In Latin America it notices that there is an increasing interest to work in this field which is assumed with responsability by different competent authorities. The control of ionizing radiation fall mainly on entities of nuclear energy but the State Health Offices, in the most of cases, has the responsability of controlling the X rays equipment of medical use.

The regulatory authorities are recognized by law in spite that the legal rules are not enough to achieve an adequate control in many countries. However, the most of them rely on a implemented system of register and installations license.

This paper shows the more important aspects concerning to the regulatory activities in Latin America.

PRINCIPLES FOR THE REGULATION OF RADIOACTIVE WASTE DISPOSAL FACILITIES IN THE UNITED KINGDOM

J O McHugh,[1] R E Smith,[1] S M Stearn,[1] and A Martin[2]
[1]Her Majesty's Inspectorate of Pollution, London, UK
[2]Alan Martin Associates, Surrey, UK

INTRODUCTION

In the United Kingdom, the Radioactive Substances Act 1993 (RSA 93) provides the framework for controlling the creation and disposal of radioactive wastes so as to protect the public from hazards which may arise from their disposal to the environment. The Act imposes requirements for registration of the use of radioactive materials and for authorisation of accumulation or disposal of radioactive wastes. The responsibilities for determining applications for authorisation are different in each of the four countries of the United Kingdom.

Her Majesty's Inspectorate of Pollution (HMIP) has responsibilities in respect of England and Wales and has in preparation, a document setting out the principles and requirements against which any application for a specialised land disposal facility for radioactive waste will be assessed. This paper sets out the background to the document (referred to here as 'the principles document') and its main features and requirements.

On 1 April 1996, HMIP will become part of a new Environment Agency.

BACKGROUND AND SCOPE

The principles document was first issued for public consultation in 1994, in parallel with a consultation document issued by the UK Department of the Environment, setting out the preliminary conclusions of a review of radioactive waste management policy. The policy review has been completed and a White Paper (Cm 2919) was published in 1995 as a firm statement of Government policy (1). The policy is based on the same basic principles as apply more generally to environment policy in the UK and, in particular, on that of sustainable development. The White Paper gives a widely quoted definition of this concept as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs". This requires that:

- decisions should be based on the best possible scientific information and analysis of risks;
- where there is uncertainty and potentially serious risks exist, precautionary action may be necessary;
- ecological impacts must be considered, particularly where resources are non-renewable or effects may be irreversible; and
- cost implications should be brought home directly to the people responsible - the polluter pays principle.

More specifically, and consistent with the above, the Government states in Cm 2919 that radioactive wastes should be managed and disposed of in ways which protect the public, workforce and the environment.

Following publication of the White Paper, the principles document was revised and issued in late 1995 for further consultation. The radiation protection principles and criteria are designed to ensure that there is no unacceptable risk associated with radioactive waste management. In defining these principles and criteria and in their application by the regulators, it is recognised that a point is reached where additional costs of further reductions in risk exceed the benefits arising from the improvements in safety achieved, and that the level of safety and the resources required to achieve it should be consistent with those accepted in other spheres of human activity.

The revised principles document describes the regulatory framework in the UK and the procedures for authorisation of radioactive waste disposal. There is a key chapter setting out four fundamental principles and two chapters containing more detailed requirements that will be taken into account by the regulators when assessing compliance with the fundamental principles. Another issue considered by the regulators to be central to their ability to determine an application for authorisation of a disposal facility is the timely supply of information by the developer. A chapter of the document provides guidance on the scope of the information HMIP considers it will need. The document emphasises the need for a range of technical assessments, that would include but not be confined to a risk assessment, to inform the judgements that the regulators will need to make.

PRINCIPLES AND REQUIREMENTS

Within the approach outlined above, HMIP has the duty to ensure that all disposals of radioactive waste to facilities on land are undertaken so as to safeguard the interests of present and future generations and the wider environment, in a manner that commands public confidence and takes due account of costs. For this purpose, four fundamental principles are defined, taking account of the principles of radioactive waste management set out in the IAEA Safety Fundamentals document issued under the RADWASS programme (2). A prospective developer will need to show that the proposals conform with the four fundamental principles.

Principle No. 1 - Independence of safety from controls

Following the disposal of radioactive waste, the closure of the disposal facility and the withdrawal of controls, the continued isolation of the waste from the accessible environment shall not depend on actions by future generations to maintain the integrity of the disposal system.

The objective of disposal of radioactive waste is to provide sufficient isolation of the waste from the accessible environment so as to ensure the long-term radiological protection of humans and of the environment. However, HMIP recognises that there are mechanisms and events that, at some future time or at some low probability, can result in some release of radionuclides into the environment. The practical implication of this principle is that authorisations for disposal will not be given until it is shown that the overall degree of containment provided by the disposal system after closure is such that the continued safety of future generations does not depend on monitoring, surveillance, preventative or remedial actions after control over the facility is withdrawn.

Principle No. 2 - Effects in the future

Radioactive wastes shall be managed in such a way that predicted impacts on the health of future generations will not be greater than relevant levels of impact that are acceptable today.

Underground disposal facilities can provide a period of isolation which may be some thousands of years for near-surface disposal or some tens of thousands of years or even longer for deep disposal. The degree of isolation required, and therefore the type of facility chosen, depends on the concentrations and radioactive half-lives of the radionuclides present in the wastes, among other factors.. Eventually, some release of radioactivity to the accessible environment may occur, leading to a radiological risk to any human communities in the vicinity of the site. In specifying radiological requirements, the time over which assessments are to be undertaken is not defined since the view is taken that this is a matter for the developer to justify.

Principle No. 3 - Optimisation

The radiological detriment to members of the public that may result from the disposal of radioactive waste shall be as low as reasonably achievable, economic and social factors being taken into account.

In UK terms, this will involve demonstration that the best practicable means are being employed to restrict the radiological detriment to members of the public both before and after withdrawal of control over the facility. It will need to be shown that, among other things, the safety case has a sound scientific and technical basis and that good engineering principles are being applied in facility design, construction, operation and closure.

Principle No. 4 - Radiological protection standards

The assessed radiological impact of the disposal facility before withdrawal of control over the facility shall be consistent with source-related and site-related dose constraints and, after withdrawal of control, with a risk target.

The radiological protection standard for members of the public for the period up to withdrawal of control over the facility is expressed in terms of source-related and site-related dose constraints. During this period, the releases will be monitored and control measures applied to ensure that protection standards are achieved. The Government has accepted that the value of the source-related constraint should not exceed 0.3 mSv/y.

For the period after withdrawal of control, the safety case depends entirely on current assessments of the future performance of the disposal system. Because of the uncertainties inherent in such assessments, they are usually based on probabilistic techniques and the protection standard is more appropriately expressed in terms of radiological risk rather than dose. However, in this case, the standard is expressed as a target on risk to the individual, rather than a limit or constraint, in recognition of the more limited level of assurance of conformity that can be achieved. The risk target is set at 10^{-6} per year.

The release of radioactivity and its impact are dictated by the contents of the facility, its engineering design, the characteristics of the waste and the nature of the site. A number of technical requirements are included which are intended to provide guidance on the aspects that the regulators consider important to the safety case.

SUPPLY OF INFORMATION

Under UK legislation, the developer of a disposal facility is under no obligation to supply information to the regulators until an application for authorisation is made. However, it is envisaged that for a major disposal facility, a developer may choose to make early application and this will allow a programme and structure for the supply of information to be agreed. This aspect is considered to be fundamental to the process of authorisation of a specialised disposal facility for radioactive waste and a chapter of the document sets out the regulators' requirements. This covers a wide range of information related to the site, the facility and the waste, as well as results and supporting information from modelling studies and safety assessments.

The treatment of uncertainty is central to the establishment of the post-closure safety case for a radioactive waste disposal system and a requirement is placed on the developer to demonstrate that the safety case takes adequate account of all relevant uncertainties. This will entail:

- definition of the scope of the assessment;
- systematic identification of all relevant sources of uncertainty;
- quantification of significant uncertainties, where practicable;
- implementation of measures to reduce uncertainty; and
- maintenance of a detailed audit trail.

ADDITIONAL FACTORS

The UK takes the view that consideration of risk analysis alone cannot determine whether a disposal facility is safe. Whilst such calculations can inform a judgement about the safety of a facility, other technical factors, including some of a more qualitative nature, will also need to be considered in arriving at the decision. Sufficient assurance of safety over the very long timescales that need to be considered is likely to be achieved only through multiple and complementary lines of reasoning. Examples of performance indicators other than risk that might be used in technical assessments are given in the report of an IAEA Working Group(3) and include radiation dose, radionuclide flux, time, environmental concentration and radiotoxicity.

Each technical assessment such as a risk assessment is to be seen as a one of the inputs informing the judgements that the regulators must make. To support the judgements, the regulators may need to undertake their own performance assessments, based on information supplied by the developer. HMIP has developed a capability for such assessments, to ensure that it understands fully the issues to be addressed in any such assessment, and to ensure that it can perform such an analysis should the need arise.

CONCLUSIONS

A document is in preparation setting out guidance on the principles and requirements against which the environmental regulators will assess any application for authorisation of a specialised disposal facility on land for low- and/or intermediate-level solid radioactive waste. A draft of the document has been issued for public consultation and formal publication is expected in the near future.

ABSTRACT (See instructions overleaf)

ICRP recommendations form the basis for statutory radiological protection provisions worldwide, but the processes by which they acquire a statutory form can be both complex and various. For a Member State of the European Union, adoption of revised ICRP recommendations should first await their incorporation in a revised 'basic safety standards' Directive adopted under the Euratom Treaty. Once that Directive has been adopted, then the varied procedures within Member States will come into play as the Directive provisions are transposed into national legislation.

Adoption of a Directive is not of itself a quick or simple procedure and must take account of national customs and practice in the various Member States, which can vary quite widely. Even at national level, the opinions and wishes of employers, worker representatives, competent authorities and professional bodies seldom coincide exactly, even within their own category (for example, what is acceptable to a large employer may be seen as totally unreasonable by a small one). In the UK, the Health and Safety Commission and, on their behalf, the Health and Safety Executive consult widely before making worker protection regulations or publishing guidance. This slows down the process but does result in provisions that are generally accepted as workable by those affected. UK provisions include an approval system for dosimetry services, with agreed criteria to ensure consistency of standards and procedures.

THE IAEA RADIOACTIVE WASTE SAFETY STANDARDS

E. Warnecke, G. Webb
International Atomic Energy Agency (IAEA)
Wagramerstrasse 5, P.O. Box 100, A-1400 Vienna, Austria

INTRODUCTION

Radioactive waste is generated from the production of nuclear energy and the wide ranging application of radionuclides, for example in industry, research and medicine. The safe management of these wastes is important for the protection of human health and the environment.

The Radioactive Waste Safety Standards (RADWASS) programme is a contribution by the IAEA to the safe management of radioactive waste. Within the programme a set of internationally agreed documents is being developed to assist Member States in complementing or establishing a national framework for the safe management of radioactive waste.

INITIATION OF THE RADWASS PROGRAMME

More than thirty publications in the IAEA Safety Series had been issued on various aspects of radioactive waste management by the mid 1980's but the coverage of the subject areas was not consistent or comprehensive. Accordingly it was decided to establish an ordered structure to ensure a systematic approach to the subject. This was carried out through a review and reorganization of the IAEA publications in the waste management area and at the end led to the creation of the Radioactive Waste Safety Standards (RADWASS) programme.

The initial concept of the RADWASS programme was developed in 1988. The structure, content and scope of the programme was elaborated by international experts in 1990 and work on the programme started in 1991. The development of the programme included submissions to the IAEA Board of Governors at various stages, endorsement by the International Radioactive Waste Management Advisory Committee (INWAC) and in-house approval by the Director General.

The programme included a total of twenty four documents consisting of one Safety Fundamentals document, six Safety Standards (one in each of the six subject areas: Planning, Predisposal, Near Surface Disposal, Geological Disposal, U/Th Mining and Milling Waste, and Decommissioning) and seventeen Safety Guides. The programme was planned to be carried out in two phases, a Phase I from 1991 - 1994 and a Phase II in the post 1994 period.

PROGRESS OF THE RADWASS PROGRAMME

When the RADWASS programme was initiated it was already envisaged that a formal review of the programme would be undertaken in 1993 to define publication production rates and resources needed for the post 1994 period. INWAC carried out this planned review in March 1993 which resulted in a expansion of the programme from twenty four to fifty five documents. This expansion included the addition of eleven Safety Guides, e.g. on licensing, quality assurance, discharge limits, safety assessments and definitions, and twenty Safety Practices to the programme. Furthermore, "Environmental restoration" was added to the subject area "Decommissioning". The status of the programme at that time and the key results were presented at the SPECTRUM '94 in Atlanta [1].

Recently, the two highest ranking documents, the Safety Fundamentals "The Principles of Radioactive Waste Management" [2] and the Safety Standard on "Establishing a National System for Radioactive Waste Management System" [3], have been published in the IAEA Safety Series. That means that six out of twelve Phase I documents are now available. Three Safety Guides are finished and on their way to publication and fourteen documents are under preparation.

NEW DEVELOPMENTS

At the March 1995 session of the Board of Governors, the Director General of the IAEA announced a major reorganization of the Department for Nuclear Energy and Safety. He announced that the existing Department would be split into two new Departments for Nuclear and Radiation Safety and for Nuclear Energy in order to separate safety related and promotional activities of the IAEA. This reorganization became effective from 1st January 1996.

The new Safety Department will cover all radiation and nuclear safety activities performed by the IAEA including activities on the safety of radioactive waste management. At the same time new procedures for the preparation of all safety related documents are being established with the aim of further harmonization of their content, structure and format. For this purpose new advisory bodies are being established to assist the IAEA in the review of all safety related programmes and the preparation and review of the respective documents.

All these activities coincided with a review of the RADWASS programme that had already been planned for 1995. As a consequence, the 1995 review of the RADWASS programme is proving to be more intense and deeper than expected in 1993. This paper will focus on the results of the ongoing discussion, the decisions to be expected in the first half of 1996 and the effects of these activities on the course of the RADWASS programme. At present it seems to be most likely that the programme will be further expanded in the subject areas "Environmental Restoration" and "Discharge" and that the scope of the other subject areas will remain the same but the number of documents will be decreased.

NEW ADVISORY COMMITTEES

In the past, different processes have been applied for the preparation and review of IAEA's Safety Series publications. In order to achieve a better compatibility between the Safety Series publications a new, more uniform, preparation and review process is being introduced. The following set of advisory bodies with harmonized terms of reference is being created:

- the Advisory Commission for Safety Standards (ACSS),
- an Advisory Committee in each of the areas of Nuclear Safety (NUSSAC), Radiation Safety (RASSAC), Transport Safety (TRANSSAC) and Waste Safety (WASSAC).

The ACSS is a standing body of senior government officials holding national responsibilities for establishing standards and other regulatory documents relevant to nuclear, radiation, waste and transport safety. It provides advice to the Director General on the overall safety-standards-related programme and will, for example, resolve outstanding issues referred to it by any of the above mentioned advisory committees.

The advisory committees are standing bodies of recognized senior experts in the respective subject area. They provide advice to the Secretariat on the overall safety programme in the respective subject area.

The new Waste Safety Standards Advisory Committee (WASSAC) provides advice to the Secretariat on the overall radioactive waste safety programme and has the primary role in the development and revision of the Agency's radioactive waste safety standards. It will provide advice and guidance on the RADWASS programme which, in the past, has been the task of INWAC or extended INWAC (INWAC was extended by a regulator if the national representative was an operator). WASSAC, for example, will have to agree on the texts of Standards, Guides and Practices and will make recommendations to the ACSS in accordance with the IAEA's safety standards preparation and review process.

REVISED RADWASS PROGRAMME

The RADWASS programme, Safety Practices excluded, has been reviewed within the IAEA. In particular, this review was done in close co-operation with establishing the RASS (Radiation Safety Standards) programme in order to avoid any unnecessary overlaps or duplications between the two programmes. The resulting draft of the revised programme will be subject to the review by WASSAC in its February 1996 meeting. The following major changes of the RADWASS Programme will be proposed to WASSAC for approval:

1. The programme is organized below the Safety Fundamentals in the three areas "Infrastructure and General Aspects", "Waste Management (Practices)" and "Restoration (Interventions)".

2. "Infrastructure and General Aspects" is replacing the previous subject area "Planning" with only a few modifications.

3. "Waste Management (Practices)" will be subdivided into the three subject areas "Predisposal", "Discharges into the Environment" and "Disposal". The relevant parts of "Decommissioning" and "U/Th mining and milling waste" will be included into these subject areas.

4. "Discharges" are now organized as a new subject area, whereas it was covered previously by a Safety Guide only. Those aspects that are closely related to radiation protection have been moved from RASS into RADWASS.

5. "Restoration (Intervention)" is expanded in the programme because it is organized as a new area whereas it was previously in a common subject area with "Decommissioning". It is covering the subject areas "Environmental Restoration" and "Facility Restoration".

6. Numerous documents on the level of Safety Standards and Safety Guides were combined. For example, the Safety Standard on "Disposal" will include near surface disposal, geological disposal and disposal of U/Th mining and milling waste.

The proposals for a revised RADWASS programme may be changed during the review by WASSAC in February 1995.

CONCLUSIONS

The overall goal of the RADWASS programme still stands, however the in-depth review being carried out with the framework of a more unified approach to Safety Standards is likely to result in a substantial "mid-course" correction.

UPDATING RADIATION PROTECTION REGULATIONS IN EGYPT

Mohammad A. Gomaa, and Anas M. El-Naggar

Atomic Energy Authority Cairo - Egypt

INTRODUCTION

The Aim of this treatise is to present the rational steps taken in the process of updating the Radiation Protecution Regulations in Egypt. The contents of the review will include a historical synopsis, and the current state of art regarding competent authorities. Furthermore, the various committees formed with responsibilities for specific issues are indicated, including the role of the Ministry of Health (MOH), and that of the Atomic Energy Authority (AEA). Finally, the efforts made towards updating the radiation Protection Regulations in Egypt are highlighted.

HISTORICAL

The Radiation Protection Activities in Egypt were and still remain among the duties and responsibilities of the Atomic Energy Authority according to Act 288, (1). The regulations controlling the use of Ionizing Radiation and Protection Against their Hazards were specified in Governmental Decree No. 59, (2); which mandated that both Ministry of Health (MOH), and the Atomic Energy Authority (AEA) were the competent authorities, with specific jurisdiction for each. All Radation Protection matters related to Sealed Sources, X-Ray Machines, and Accelerators, are the responsibility of the ministry of Public Health; and matters related to Open Sources, and Nuclear and Radiological Accidents, are the responsibility of the Atomic Energy Authority.

During the mid seventies, and the early eighties, the need for updating the Radiation Protection Regulations in Egypt appeared an urgent issue to both competent authorities. The reasons behind this urgency were the exparding application of radiation sources in medicine, industry, and other fields; the increase in number of occupational radiation workers; and the drafting of a new Act in 1983 pertaining to the Nuclear Control and Safety of Nuclear Installations (3).

The period following that witnessed increased activity and efforts on the part of scientists from the Atomic Energy Authority, and responsible persons from the Ministry of Public Health. These efforts were mainly directed towards the formulation of a scientific and administrative structural hierarchy to promote Radiation Protection Activities in Egypt.

A concise presentation to this effect was reviewed at the IRPA-7 meeting (4). In 1988, both competent authorities the MOH and AEA sanctioned the recognition and adoption of IAEA, S.S, 90, 1989 "Basic Safety Standards" as the fundamental conceptual criteria for Radiation Protection Regulation in Egypt. This document was also used to help in the redrafting and updating of the Egyptian Radiation Protection Regulation.

THE MINISTRY OF HEALTH [MOH]

The general layout of the current organizational structrure of the Radiation Protection Activities of MOH is shown in the follwing blook diagram.

Ministery of Health	Chairs	Central Committee Radiation Protection (CCRP)
Vice Minister for Medical Practice		Technical Committee for Ionizing Radation (TCIR)
General Director for Radiological Practice and (EBRP)		Executive Bureau for Radiation Protection (EBRP)
Comptent Authority	For	X-Ray Machines, Accelerators, Sealed Sources

The MOH issued the Ministerial order No.265 (5) which stipulated the "Radiation Protection Procedures for Industrial Radiography". This was published in the Egyptian Gazzette in 1991. This ordinance was essentially based on ICRP publication 26, 1977(6), and IAEA, SS,9,1982(7); applying the System of Dose Limitation.

THE ATOMIC ENERGY AUTHORITY [AEA]

The new hierarchical organization of the AEA in Egypt was instituted (8) according to the following

AEA chairman		Board of Directors

- Nuclear Research Center (NRC)
- Radiation Research and Technology Center (NCRRT)
- Hot Laboratories and Waste Mangement Center (HLWMC)
- Nuclear Safety and Radiation Control Center (NCNSRC)

Comptent Authority	for	Reactors, Unsealed Sources

Several Committees were formed at the AEA in order to formulate and stipulate Radiological Protection and Nuclear safety regulation, and authorize their implementation. The following are the name of these Committees:

- The Nuclear Regulatory and Safety Central Committee as the competent Authority for Nuclear Installations . (1995)
- The Committee for studying the Safety Analysis Report for the Second Egyptian Research Reactor .
- The Consultative Committee for detection of Radioactivity in Foodstuff.
- The Lisensing Committee for Unsealed Sources.
- The Committee for Transport of Radioactive Materials.
- The Committee for Medical Response in Nuclear and Radiological Accident, 1993.
- The Radioactive Waste Disposal Regulations - Adopted by the Board of Directors of AEA, (9).

ACTIVITIES OF RADIATION PROTECTION GROUP.

The Radiation Protection Group of the [Egyptian Society of Nuclear Sciences and Applications (ESNSA), is the Affiliate society of IRPA in Egypt. This group although small in number of its members, is very active in promoting Radiation Protection concepts in most places where scientific activities exist. This activity comes under Radiation Protection Culture. Besides that, satellite meetings and discussions are always held with other concerned groups from the Ministry of Health, the Nuclear Materials Authority, the Nuclear power plants Authority, and other scientists from Universities; to consider issues related to updating Radiation Protection Regulations in Egypt. Other activities of this group include the participation in lecturing at training programmes in Radiation Protection. Also authorship of a Radiation Protection Manuscript for teaching purposes.

This Radiation Procection Group is intimately related with the National Network of Radiation Physics, and the activities of both are either incorporate or run in parallel. The most recent of such corporate performance was the two day seminar (11-12 Nov. 1995) organized under the title "Radiation Protection Regulations in Egypt - the need for updating"(10). This seminar was attended by about hundred scientists involved in Radiation Protection and Nuclear Safety, and also experts on the Law, legislative, and judicial matters.

Several important recommendations and issues related to updating of Radiation Protection Regulations in Egypt; were considered. The adoption of ICRP New Recomendations, publication - 60, (1991); and the IAEA S.S. 115-1 International Basic Safety standards for Protection Againts Ionzing Radiation, and the Safety of Radiation sources, 1994 (11); as the basis for Radiation Protection Practices in Egypt, and for the reformulation and updating Radiation Protection Regulations.

THE IAEA RADIATION SAFETY STANDARDS

Geoffrey A.M. Webb

Head, Radiation Safety Section, Division of Radiation and Waste Safety,
IAEA, Vienna, A-1400, Austria

INTRODUCTION

The objective of producing documents on radiation safety in the IAEA Safety Series known as RASS (Radiation Safety Standards) is to develop an internally consistent set of documents that reflects an international consensus on the principles of radiation protection and safety and their application in practice. During the final stages of preparation and approval of the International Basic Safety Standards (BSS) in 1994 (1), a comprehensive review of all the publications in the Safety Series related to radiation safety was initiated. The review was carried out mainly by staff of the Radiation Safety Section with input from Advisory Groups, Technical Committees and Consultants on particular topic areas. The results of the review include, for each existing document, an appraisal of its status, i.e. whether it is still valid or should be revised and updated to comply with the BSS or whether it should be declared obsolete and withdrawn. The most important output from the review is an overall structural plan for the RASS documents which clearly indicates their relationship to the BSS and identifies those areas in which documents do not exist and should, in due course, be developed.

During 1995 the Director General established five advisory bodies to assist the Agency in developing safety standards. The principal body is the Advisory Commission for Safety Standards (ACSS) which has an overview role in providing advice to the Director General on the safety standards programme and in reviewing the work of the four advisory committees. The Radiation Safety Standards Advisory Committee (RASSAC) provides advice to the Secretariat on the radiation safety programme and on the development and revision of the Agency's radiation safety standards, including publication of documents on radiation safety in the Safety Series. The other advisory committees have similar roles in the areas of nuclear safety (NUSSAC), waste safety (WASSAC) and transport safety (TRANSSAC).

The structure plan and proposals for documents described in this paper will be presented to the first meeting of RASSAC in 1996, any modifications can be found in the poster display.

THE STRUCTURE PLAN

All Safety Series documents should fit into an hierarchical structure with Fundamentals explaining the underlying rationale and the basic principles for protection and safety, Standards setting out in a more regulatory style the mandatory provisions, Guides that elaborate for general areas the manner in which the mandatory provisions are to be implemented and giving further explanations, and Practices developing the application of the Standards and Guides in particular areas or concerned with specific techniques.

The procedure that was adopted in structuring the radiation safety documents was to recognize the importance and broad scope of the BSS and to carry through the structure of the BSS, especially the appendices. The resulting structure is shown in Figure 1.

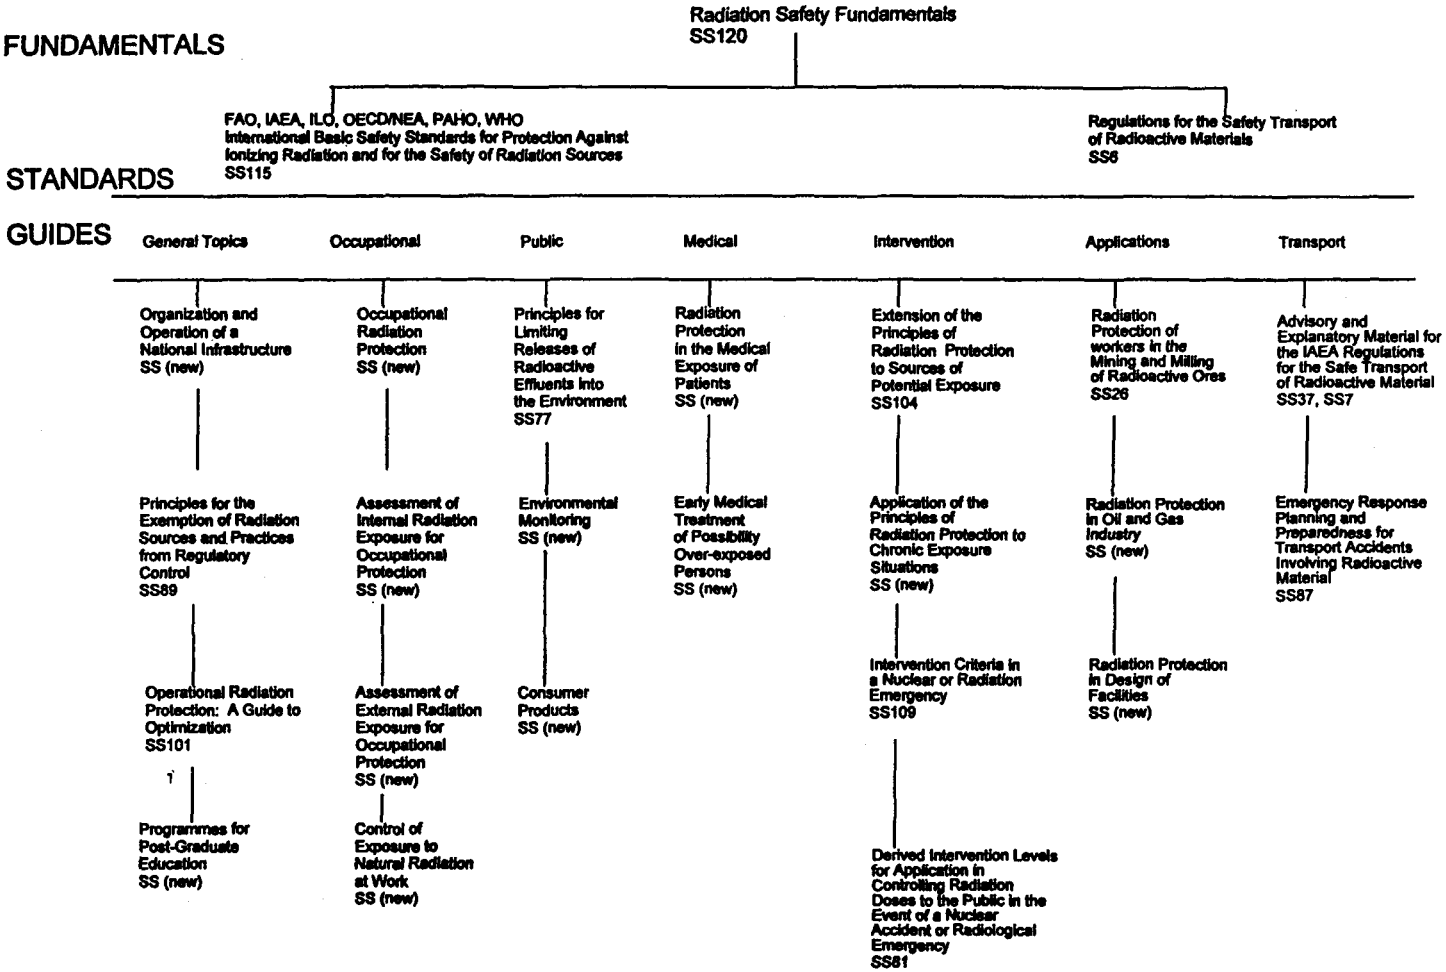

Figure 1. Safety Series Document Structure on Radiation Safety, Showing the Major Safety Guides

FUNDAMENTALS AND STANDARDS

The document at the Safety Fundamentals level concerned with radiation protection and the safety of sources is intended to complete the set of three Fundamentals documents; the other two, which have been published as SS110 and SS111-F, deal with Nuclear Safety and Radioactive Waste Management. The Safety Fundamentals explains the approaches to radiation protection and safety for persons in senior political or regulatory positions and persons who, although not safety specialists, make decisions relating to the uses of radiation in medicine, industry, agriculture and other areas.

The BSS were approved by the Board of Governors in September 1994 following a major effort over several years to achieve a consensus embracing all the Sponsoring Organizations. The BSS have been issued in English as an interim publication; the final publication (in Arabic, Chinese, English, French, Russian and Spanish) will be issued as soon as possible, now that all five other Sponsoring Organizations have given their formal approval and the final tables of dose per unit intake have been received from ICRP. The BSS establish basic requirements for radiation protection and safety, specify obligations and responsibilities and set out the requirements for application to practices and in intervention situations. The transport regulations are reaching the end of the review and revision process and should be published in revised form in 1996.

GUIDES AND PRACTICES

The major Guides are shown in Figure 1 for each of the areas. The Guides on general topics deal with the interpretation or implementation of the BSS and related general matters. A set of three Guides relating to the control of occupational exposures is being developed in a co-ordinated fashion. One Guide will deal with overall implementation of the requirements in the BSS, explaining and advising on how they are to be converted into practical control measures. It will be supplemented by two Guides, one on the assessment of internal and one on external occupational exposures. A Guide dealing with the application of the BSS requirements in limiting releases of radioactive effluents will be developed and supplemented by a revised Safety Practice on generic models and parameters and by a new Safety Practice on default release limits to be used when the situation does not warrant an in-depth analysis. The safety of consumer products containing radioactive materials will be the subject of a Guide which has been in production for some time and can now be finalized in compliance with the BSS. Although controlling the exposure of patients to radiation used for medical purposes is a very important aspect of radiation protection, it has only recently been fully dealt with in the BSS. There is now a need for a new Guide to supplement and expand on the requirements of the BSS. The systematization and extension of the approach to intervention to cover both emergency and chronic circumstances has been one of the major recent developments reflected in the BSS. A new Guide is under development dealing with the difficult practical matter of applying the principles to chronic exposure situations.

In order that users of the Safety Series may have accessible in one place the important aspects of major applications, guidance has been given in such a form. The most important area relates to the mining and milling of radioactive ores, and the relevant Guides and Safety Practices are being revised and updated. A Guide dealing with the problems of the oil and gas industry is planned. An important practical problem relates to the use of minerals containing thorium in industrial operations for which a new Guide is proposed.

TRANSITION EFFECTS IN THE IMPLEMENTATION OF THE NEW RECOMMENDATIONS- BSS

Petrica Sandru
Romanian Society for Radiological Protection, Bucharest- Romania

ABSTRACT

According to the Constitution, the Romanian nuclear national legislation, which is in a growing process of developing, is tightly connected to the actual international legislative framework.
The provisions and the recommendations lay down by the International Community in the ICRP-60 document and in the International Basic Safety Standards, led to specific approaches that take into account the different levels of development in the nuclear field as well as countries social and economic peculiarities. Thereby, a process of harmonization of the international provisions with the local features is a logic and necessary step toward a rational enforcement of these standards.
Both the principles and the quantitative values (limits and levels) acquired in the ICRP-60 document and in the International Basic Safety Standards after a mutual general consent have a specific impact on practices and interventions related to the existed sources as well as on the new sources, for instance the process of implementation of a multi-purpose irradiator in Romania.

GENERALITIES

The unprecedented international effort that has been started in 1992, oriented on providing standards for protection against the ionizing radiation and the safety of the sources, according to the spirit inspired by the International Commission for Radiological Protection in [1], has been fulfilled in 1994 through an interim IAEA' Safety series report, hereinafter BSS, [2].

Although, these are the first global international standards, with a comprehensive content of the domain, on which the all relevant international organizations have had a mutual consent, the harmonization of the Member State's different positions left the standards' provisions with some weaker points which could create confusion in the process of adoption and enforcement at a national level.

Besides, the efforts of tacking over the new terms are not always a smooth process and finally the funds for the measure implementation are not wholly available. Legislative and practical problems should consider the transition effects in the implementation of the new recommendations in Romania.

LEGISLATIVE FEATURES

Current Status:

The present legislative status is still dominated, unfortunately not for longer time, by:
the old Board of the Ministers' Decision, 1961, followed by regulations in which both nuclear practices have been classified in four distinctive categories and control as well as supervised areas are defined; the nuclear law, 1974, and the law for the quality assurance, 1982. All legislative approaches are obsolete and do not answer properly and internationally accepted at most of the problems. For instance these are not structured distinctly in requirements for the practices and requirements for the interventions, the organizational and institutional changes imply the redefinition of the competent authorities, medical exposure is not among its subjects. Also, our regulations for practices,[3], 1976, have outdated notions, quantities and values. Many basic concepts are no longer valid and even the internal structure of these regulations could no longer stand against BSS's provisions. The old custom of separate and distinct treatment of the radiation protection and safety of the sources missed most of the provisions on potential, emergency and chronic exposure.

For the intervention activities, we have distinct regulations, intensively used in the emergency preparedness plans, which could be considered as being bread- new, 1993, but the intervention levels and the action levels are different; also some terms have to be revised.

In absence of specific regulations, the IAEA's guidelines have been used.

Changes:

A general process of revising of the national legislative framework started several years ago with new proposed nuclear laws concerning the promotion of research and applications as well as the organization and the responsibilities of the Regulatory Authority. These laws are presently under the debates of the Parliament. Their content had to be changed quickly because at the time the BSS document was in work, drafts of the laws were ready. After it was accepted that the new international standards will have a strong impact on these laws, divergent opinions argued to what extend the BSS should be followed.

One opinion stressed out the necessity of inclusion as many as practicable provisions in a harshly translative manner so that the requirements contended do not be already outdated at the very day of the law's enforcement. The other opinion pointed out that only the BSS' structure should be retained and a carefully process of adoption should be focused on the basic and necessary provisions as well as on the definitions, leaving for the regulations the most delicate aspects together with the values. Anyway it is sure that these new laws will treat separately practices and interventions, will include medical exposure and will give an understandable meaning to radiation safety culture.

The new regulations that are expected to be drawn from the national nuclear laws but no effective initiative have been started so far. So, an anachronism situation is going to occur because we are expecting to have law s in compliance to BSS but older regulations in which terms and notions like: source, nuclear installations, irradiating installations, the distinctive meanings of dose and exposure, clearance and exception and the various guidance levels, dose constrains, kerma, radiation weighting factors and tissue weighting factors, risk, safety culture, controlled and surveillance areas, working levels, etc., are not met or have different sense.

Besides, there are others important issues that could not be easily eluded:

- the problem of fitting the BSS's concepts to the Romanian language; based on the experience gained trough our specialists involved in the drafting of BSS, we tried to avoid such aspects by organizing conferences, seminars and debates on the BSS in which we worked on the adoption of the new raised terms to Romanian language. Thus, we found real difficulties in deriving Romanian corespondents for clearance, exceptions- to obtain a different meaning vis a vis exclusions- projected and adverted doses or risks.
- the shortcomings of some data; because of divergent opinions, BSS looses aspects that affect the initial goal of comprehensively, we mention here: guidance levels for chronic exposure situations, others except the radon, values for the operational intervention levels for each radionuclide like the committed effective doses per unit of intake which BSS offers for the practices, values of the risk limits and constrains for the potential exposure.
- ambiguities in the definition of ionizing radiation- an energy threshold is asked by the regulations- and the lack of definitions for the source term, raw nuclear material and environmental restoration; all these could lead the considering of the other documents.

Here, we appreciate that a positive movement is that the Romanian Society for Radiological Protection, [4], is accepted as a counterpart of the civil society for legislative proposals analyzing.

On the other hand BSS should be followed by the guides and practices that have to develop in depth the generally provisions.

An internationally agreed content for license and registration should be recommended to gain a harmonization among various kinds of authorization.

PRACTICAL FEATURES

Current Status:

There are sources that are operated for years according to the older requirements, limits and levels; the decision to change should be carefully weighted, and without doubts, accompanied by cost -benefit analysis. Also there are installations under construction, on- going projects, sources near to be commissioned or decommissioned. Comprehensive assessments should be performed on what are we going to change, how will we change it and who will finally pay for that changes; anyway cost- benefit analysis should be carried out.

Specifically, the new limits for occupational exposure translated into the operational quantities, dose rate, together with quantitative values for risk of potential exposure, [5], are going to lead to re-assessing of the controlled and the supervised areas next to radiation sources.

There is a widely spreader restrained in switching to new terms and quantities. All the existent literature displays an old and slightly different approach of radiation safety. A similar situation has been met at the time of transition from a rontgenological way of approaching the field to an energetical one, particularly the movement from exposure to absorbed dose through intermediate status of rontgen echivalent physically. Even after years the old units are used in practice; for example, even whether ICRP and BSS recognize absorbed dose as the basic idea for radiation protection the calibration is still largely performed in terms of exposure. So, just for tacking over this particular situation it is necessary for training and funds.

Comparative it could be image that lectures, laboratory work as well as handbooks are conditions for a wholly offensive.

5 Changes:

To met BSS requirements for areas zoning a methodology was developed. Although some older sources comply even to the new limits, being considered at its time under more restrictive conditions, there are many of them that need revising of the normal and potential exposure's boundaries. Often the implementation of practicable measures is out of the question because of the lack of the funds at this stage. However, the methodology will be helpfully for the new sources, for example for the commission of a large scale irradiation installation, at the design phase at the time of BSS endorsement. This is an example of possible change with minimal social and financial cost.

By using the values of the new committed effective dose per unit of activity via inhalation or ingestion, instead of the older ALI values, a few source-related assessments and individual-related assessments were carried out for assessing both the impact and the new source constrains. Also through the same data new planning zones for intervention have been obtained, thereof it is a need to revise the emergency plans.

CONCLUSIONS

1. At this stage we are in a "legislative phase" in which we are expecting to have soon recent national nuclear laws in compliance with BSS provisions, limits and levels, and a "practical phase" of assessing the possible changes- new controlled and supervised areas, new environmental impact studies, new planning zones for interventions; for all these facts cost- benefit analyses are imperatively asked.

2. The presence of older regulations, which could not be discharged in the very next years, and de facto status of the sources, related to practices or interventions, are realities in the actual Romanian nuclear framework.

3. The transition will be a continuous process without thresholds; this aspect is conditioned even by the transition of the BSS itself.

4. Training courses and workshops are imperatively to be organized in this period of transition.

5. BSS should be followed by guidance and practices for the basic requirements supporting.

6. A free process of information and data exchange have to be supported through the Member States.

7. The overall social, economic, politic and institutional effect as well as the psychological impact ought to be assessed; generally people do not like changes, furthermore they have an aversion to them.

8. For some aspects BSS misses the declared comprehensively and even symmetry, the lack of: guidance levels for chronic exposure for radionuclides others than Rn, operational quantities for interventions, zoning of the nuclear areas, transport of the radioactive materials.

9. It is necessary to evaluate the degree of correlation between BSS and other international documents and agreements, a specific case is the liability in case of nuclear accident; IRPA could take the initiative on bringing all the internationally distinct actions at a common factor.

10. The long- time projects, decommissioning, waste management, repository for radioactive waste, should be treated carefully considering the actual requirements of the BSS as well the future expected changes that could be promoted by ICRP.

BECQUEREL CENTURY: GOOD AND BAD IN RADIATION FIELD

Petrica Sandru
Romanian Society for Radiological Protection, Bucharest, Romania

ABSTRACT

The purpose of this poster is to offer a synthetic as well as comprehensive image on this century of radioactivity with its beneficial and non-beneficial aspects. It is both a historical and an allegorical graphical presentation of the man's habitat, which have had in all the times a strong radioactive component. In order to paraphrase, but in a different way, another optimist message of this century perhaps we have to say that the cradle of man is radioactive and all the steps outside it should be very carefully considered. During this last century man started to challenge the nature in its intimate features, i.e. those associated to radioactivity phenomenon.

In the first phase the world was fully confident on the radiation peaceful applications, then in the second phase all these beneficial aspects have been detonated toward military applications which astonished all the people by the harmful effects of radiation, finally we have been passing in a new era dominated, all over the world by a spirit of harmonization and consent by which we are going to reach a globalization of radiation protection and safety principles and measures. Even if it is the latest source of energy which man has stolen from the nature, nuclear energy is now -from a technical point of view- a strong option for the human future and is going to gain more and more in the public acceptance branch. If this poster should have been confined in a phrase then the motto can be: with too much radiation we cannot be and live, but without radiation we cannot survive.

GENERALITIES

Human Being has been obstinately searching to understand what is good and what is bad around him. Along the centuries he has the intuition that the answer is probable the key that can unlock the universe for him. He has been groping for a clue in soil, water, air and fire, and far beyond these, sometimes he got a bit of true for which the dulls were happy and the sagas gloomy.

Man looked for an aid at his fellows being them priests or political rulers, monarchs or celebrities, scientists or prophets, and thought that they can help him to choose right. However, always just a moment separated him from the land where milk and honey are flowing, [1]. Invariantly, that hardly expected moment does not want to show up as it was promised and after that a terrified world raises instead and the man hidden his soul in myths, fairy stores or dreams. However, he learnt that at least he was at the very border between god and bad but missed something that nobody told him.

This old and new story is also the tale of radioactivity. She was a fairy living far from the people's eyes but making all the good that his father has learnt. Without any exceptions she modulated smoothly - with 2.4 mSv yearly- all the things she met on the Terra so that all the things lived peacefully. More than that she gave them a chance to grow. A fine balance ruled on the earth marking that without radiation we cannot live but with too much radiation we cannot survive.

It was the year 1896 when an inquisitive person, namely Henry Becquerel, rise a portion from the invisible veil, that covered the earth from the time when no person stepped on it, and said what he saw. Even that what he said was by far limited, humanity opens again the box in a harshly manner and rummaged till its bottom.

The early pioneers of this new field, among them: Herman Rontgen, M. Sklodowska Curie, Piere and Joliot Curie, were exuberance in announcing that a pure good thing finally shows up, and even they believe that. But later other reliable scientists, among them: L. Szilard, T.R. Oppenhaimer, E. Teller, I. V. Kurchatov, W. Heisenberg, A. Saharov, adulterate the initial aim and find something that is "good" only for the war time, i.e., nuclear bomb,[2]. From that moment man alienate and besmirched the mild face of the fairy of radioactivity.

WITHOUT RADIATION WE CANNOT BE AND LIVE

Man's cradle is without doubts radioactive. In the manner as any thing is neither good nor bad only the quantity can give a sentence, the habitual radioactive environment preserves life and helps the evolution at the same time. Man's features are tightly connected to the natural exposure, compiled by specialists around 2.4 mSv, [2]. This value is suspected to be among other natural constants that have been favoring the life on earth. Although there are both spatial differences- for example man's natural exposure varies with altitude and other local conditions- as well as temporary disrupters -for example at the times of pole inversion earth should had been devastated by deadly cosmic exposure- the value remained million of years roughly invariant.

Of course, the value itself does not tell us the true comprehensively, this depends by our degree of

knowledge and hypotheses made. It is obvious that the value has to be changed by considering other ionizing radiation that are now neglected. We mention here only the recognized ionizing effect of the electro-magnetic radiation, e.g. that part of visible and mainly ultraviolet bands. The intrinsic limitation of our knowledge should not restrict us at a border of a self- imposed frontier; other exotic ionizing radiation with biological effects will be assumed.

The life is strong conditioned by the influence of visible and UV photons in the processes of photosynthesis and vitamin production into our bodies. Human Being supplemented the influence of natural background with man- made exposure, also with beneficial effects: medical radiodiagnosis and radiotherapy, applications of the radioisotopes in industry, agriculture, hydrology and mainly to nuclear power production. Many of our commodities are indebted to man- made exposure.

However, human being in his inquisitive searching toward more safety radiation sources is exceeded by far by the nature. This "designed" a marvelous fusion reactor that is equipped, for the users' sake, with ingenious radiation protection in depth measures: distance, time, shields, magnetic traps, differentiable absorption layers, ozone filter.

WITH TOO MUCH RADIATION WE CANNOT SURVIVE

The loosing of one of the radiation protective means with which the sun- earth system is designed, for instance Terra's magnetic field, could lead to the extinction of the life on our planet. If we believe that the human being is among the most vulnerable creatures, his lethal dose is among 1 and 3 Gy, then we can see how easy the life can lose its witnesses.

Also the rarefaction of ozone layer could have acute biological effects on all the life forms.

Although at this stage, man cannot influence significantly the effectiveness of the natural safety barriers of the sun - earth system and because there are still doubts on an artificial depreciation of the ozone layer, man can significantly contribute brutally by nuclear bombing to the enhancement of the radiation exposure. Thousands of nuclear missiles installed on the ground, or submarines, or ships, or planes are frightening the natural fine balance. The nuclear testing in atmosphere from the 50s, 60s produced a total man-made collective effective dose of 30,000,000 man x Sv, [3].

We pay annually for our social comfort from nuclear power production with 400,000 man x Sv. In addition accidents involving nuclear power plants are sources of harmful effects. Chernobyl is equivalent to 600,000 man x Sv.

Radioisotopes' production and use contribute annually with 80,000 man x Sv, [3].

Moreover there are other significantly sources of exposure: for instance: fertilizer industry, 300,000 man x Sv on each year, nuclear weapons fabrication, 60,000 man x Sv, satellites re- entries in atmosphere, underground nuclear testing 200 man x Sv, [3].

However, finally it is up to us whether or not to preserve the earth and the life it has been developed for million of years.

CONCLUSIONS

1. God said " Do not eat from the Tree of the Good and Bad' Knowledge".
2. The Nature is just as it is.
3. Terra is a little and finite starship.
4. Demography, destruction, comfort, power, restoration. ecological development
5. Will finally win the human's reasoning faculty ?; Dubito ergo cogito....
6. The author propose a subjective separation of good and bad, however these could be reversed.

MAJOR SCIENTIFIC TOPIC NUMBER 1 (1.1) (see page 7)

ABSTRACT (See instructions overleaf)

The UK Ionising Radiations Regulations 1985, made specifically to implement most of the requirements of the 1980 Euratom BSS Directive, include provisions relating to occupational exposure to sources of natural radiation. The definition of "radioactive substance" includes any substance which contains radionuclides whose activity cannot be disregarded for radiation protection purposes . This means that some low specific activity ores and sands fall within this definition and are therefore subject to relevant requirements of the Regulations.

Radon is covered more explicitly by applying many of the controls where the work involves exposure to radon daughters at a level greater than 6.24×10^{-7} Jm^{-3} (0.03 Working Levels). For above ground workplaces, if a defined measurement protocol is followed, this level approximately equates to 400 Bq m^{-3} and is generally recognised as the workplace action level. The regulatory approach has been to seek remedial building measures so that the workplace is removed from control. Otherwise the full regulatory provisions, such as classification of people and areas, dose monitoring, medical surveillance etc., may well need to be applied.

The UK Health and Safety Executive, through commissioning research and use of existing information on workplaces and homes, has been able to target employers likely to have a radon problem and to raise their awareness of it. HSE is able to offer simple advice about getting workplaces tested and about remedial measures, if this proves necessary.

REGULATORY FUNCTIONS AND MEDICAL EXPOSURE

César F. Arias
Ente Nacional Regulador Nuclear, Buenos Aires, Argentina

INTRODUCTION

Must the patients subject to medical radiation practices be protected ?
What does the protection of patients means ?
Who must protect the patients ?
Is it not a sole responsibility of physicians ?
These are some of the questions this paper attempt to discuss.

MEDICAL EXPOSURE

Last international recommendations on radiation protection assign new emphasis to *medical exposure*, the expression used by the International Commission on Radiation Protection to name the exposure of patients to radiation for diagnostic or therapeutic purposes (1). The International Atomic Energy Agency, the World Health Organization, the Pan American Health Organization and other international organizations (2) have shown similar concern for medical exposure as for ocupational and public exposures. These are signs of a remarkable evolution toward a better protection of the patients.

Medical exposures have some particular characteristics:

a) Patients are *intentionally* exposed to radiation. Benefit from medical practices can not be obtained unless patients receive some dose of radiation (*necessary dose*).

b) Dose limits are not applicable because benefits and risks of radiation has to be evaluated on the same individuals and therefore there is not room for inequity..

c) Optimization has a lower constrain (necessary dose) while optimization of ocupational and public exposures has upper constrains (dose limit or another constrains)

d) Justification and optimization principles apply to medical exposure. They are more closely interrelated than in any other aplication of radiations. To be justified a medical exposure must produce some *benefit* to the patient health. Bennefit depends on the *right prescription* of the practice and the *good quality* of its performance it is to say optimized performance. A medical practice that has not been optimized may have poor quality and provide no benefit to the patient and therefore should not considered to be justified. Prescriptions rely exclusively on *human factors* (the knowledge and experience of physicians). Performance rely on human factors (mainly physicians and physicists) and on *physical factors* (proper equipment, its maintenance and calibration, rigth treatment planning, etc.)

e) Diagnostic practices involve relative small individual doses and very large collective dose. (3) Significant part of collective dose attributable to diagnostic practices in most countries could significantly be reduced without loss of benefit (4) through a better justification and optimization of procedures. Diagnosis is the field of radiation applications where the most substantial reduction of collective dose may be achieved at very low cost.

f) Therapy procedures involve large individual doses and the efficacy of treatments depends on the accuracy and distribution of doses in a very sensitive way. Significant part of therapy procedures may be inefficient due to a poor accuracy in delivering doses to the tumor or failures in protecting normal tissues.

g) Potential exposures asociated to medical sources have to be considered (5). Accidents caused by medical sources are a significant proportion of radiological accidents. Along last fifty years 38 % of deaths in radiological accidents were produced by medical sources (6) and most of them were patiens.undergoing radiation treatments. These only are the recognized accidents. Most of them were caused by significant deviations from prescribed doses. However it is well known that even a small deviation from the prescribed dose (10% for instance depending on the type of tumor) may cause a significant reduction on the cure probability. Unles good quality control procedures are implemented it is quite feasible that nobody realize that a significan fraction of treatments are carried out whith smaller probability of cure than what correspond to a good technique. Where is the boundary between an accident and a bad practice ? Is it a matter of

perception ? Many patients may not have positive reactions to radiation therapy (what may signify death) due to lack of good quality treatments. Should those situations be considered accidents or bad practices ? Radiation therapy is probably the field of radiation applications where more lifes can be saved through a human and physical resources of good quality.

h) There is not public perception of risk from medical sources . Since they are associated with preservation or recovery of health they seem to be inherently good. Medical practice with radiation sources may be carried out with great impunity.

REGULATORY AUTHORITY

Since dose limits are not applicable to medical exposure physicians have unlimited freedom to irradiate patients Regulatory authorities have to decide how deep their regulation on medical exposure should go. Whatever the decision be it will imply some sort of interference with medical practice. .

Regulatory Authorities, when are not the same as Health Authorities may find some conceptual dificulties to aplly regulations on medical exposure.. That means a sort of self constrain to impose requirements because they may collide with medical practice freedom

There can no be restrictions on medical procedures prescriptions Regulations on medical exposure can be oriented to enforce quality improvement through three main tools: by promoting good expertice of the human resources involved, by promoting the use of adequate equipment and techniques and by promoting quality control procedures.

ARGENTINE EXPERIENCE

Argentina started their regularory activities on Radiation Protection in 1958 when the National Atomic Energy Commission (CNEA) iniciated the promotions of radioactive material applications. The first regulations stablished the basic principles of the license process "to attend public utility reasons and to prevent the possible harm of nuclear trasmutation and reactions" (7).

Since that time individual and institutional authorizations were granted by the Regulatory Authority (CNEA) when specific requirements were fulfilled. There are evidences of concern about the protection of patients in that regulation. Physicians had to have specialized education and proper training to be authorized. "Medical facilities had to have adecuate means for a clinic attention of patients." .

Further regulations preceisely defined.the requirements to obtain authorization to utilize radioactive materials or accelerators in medical practices (8). These include specialized courses and training periods of about three years. Those requierements are still in practice and were important steps toward good quality medical exposures. Unquestionably these requierement interfere severily with the profesional freedom of physicians to use ionizing material in medicine. However as this process was accompanied by a true leadership in research and education from the same institution that applied the regulations there was a good degree of acceptation. Another important factor was the fact that every authorization request has been analyzed by an advisory committee integrated by experts in the use of ionizing radiation; most of them physicians or physicists specialized in medical application of radiations. So petitioners have been judged by their peers.

Ap to 1980 institutional authorizations were granted after verification of generic radiation protection and safety measures mainly considering the protection of workers and public There was not special regulation on physical aspects to assure good quality medical exposure.

In 1980 an additional regulation was adopted jointly by the CNEA and the Public Health Secretariat (SSP) exclusively to promote the improvement of medical exposure quality in radiotherapy and nuclear medicine.(9). This regulation was previously discussed with the most representative physicians and physicists in the fields of radiotherapy and nucler medicine.. Their main requirements are:

a) specifications of some characteristics of equipment to avoid excessive obsolescense.
b) specifications on maintenance and quality control of equipment
c) use of complementary equipment for simulation and calibration
d) specifications of minimun set of units to integrate radiation therapy faccilities to cover the most frequently techniques in teletherapy and braquitherapy.
e) minimun set of units to integrate nuclear medicine faccilities to cover the most common diagnostic techniques.
f) composition of minimun staff of physicians, physicists and technicians..
g) need for authorizations renewal every five years.

This regulation was thought as an evolutionary process since periods of time were allowed to fulfill the requirements..

Had the Regulatory Authority of Argentina (CNEA) enough power to enforce such a regulation ? The fundamental regulation (7) gives it sufficient faculties to regulate the conditions for granting individual and institutional authorizations. However, since the 1980 regulations on radiotherapy and nuclear medicine advanced significantly in the field of medical exposure it was though that the support of the Public Health Authorities (SSP) would help to achieve acceptation among physicians. As a consequence of an agreement signed between the Public Health and Regulatory Authorities the regulation was jointly enforced by these two institutions mainly through the regulatory faculties of the Regulatory Authority. As stated in the text the SSP "requires the concurence of CNEA to enforce the regulation." It must be noticed that Regulatory and Public Health Authoriies have kept an excelent level of cooperation in Argentina.

In 1994 Argentina updated its basic standards and the concept of medical exposure was incorporated as well as the optimization of medical exposure through the proper utilization of equipment and techniques (10). In 1995 the Regulatory Authority was separated form CNEA. The new institution is the National Nuclear Regulatory Entity (ENREN) and all the regulatory faculties were transfered to it. However there has been different interpretations on whether the ENREN has the same faculties as CNEA had to enforce the existing regulations on medical exposure. At present this is a matter of analysis. This an example of institutional caution to act in the field of medical exposure even when there has bee a generalized acceptation of requierements imposed by the 1980 regulations.

However a good degree of cooperatrion between the new Regulatority Authority and the Public Health Authority will most probably warranty the continuation of a policy unquestionably positive for the protection of the patients, avoiding an involution on the achieved goals.

CONCLUSION

Medical exposure is the field of radiation protection with the largest possibilities for reducing unnecesary doses and consequently negative effects of radiation without associated benefits. It also has the greatest posibilities of increasing benefitial consecuences of medical radiation sources by improving diagnostic and therapeutic techniques quality. Therefore Regulatory Authorities should not be absent in this field.

But they should not act alone. Regulations on this matter should not be prepared without the intervention of physicians and physicists with recognized expertise on medical aplications of radiations Cooperation of Public Health Authorities is most desirable. Even when the Public Health Authorities may not have operative capacity to enforce regulations in some countries Public Health Organizations have the faculty of judjing what is benefitial or not in the medical practice.. Agreement between Public Health and Regulatory Authorities may result in a sinergistic combination of resources. International Organizations have provide good example of cooperation between this two areas.

The Russian State System for Quality Assurence of Radiation Measurements

Prof. Yu.V.Tarbeyev, Dr. V.I.Fominykh, Dr. I.A.Kharitonov
The D.I.Mendeleyev Institute for Metrology, St.Petersburg, Russia

The State system for ensuring quality of radiation measurements (hereinafter referred to as "System") has been establishing in Russia throughout a long period of time. When arranging the System, any measurements of physical quantities and parameters, which characterize sources and fields of ionizing radiations, were considered as the radiation measurements (RM).

The System has some distinguishing features caused by the factors which are basically characteristic for this field of measurements made in Russia.

The first factor resides in the fact that in Russia, the RM are currently central problems because of a great number of installations where the ionizing radiations exhibit activity. Among them there are radiochemical enterprises, atomic power plants, research reactors, Navy and Civil fleet with atomic engines, radionuclide diagnosis, radiation therapy etc.

The second factor is a great variety of the RM types, stemming from a large number of physical quantities and parameters: specific activity - with numerous radionuclides being measured, the flux and flux density of the charged particles and neutrons - within a wide range of energy, power of the absorbed and equivalent doses - within a wide power range for different types of radiations etc., as well as from a number of problems, the solution of which require such measurements as: technological (at the enterprises and plants), diagnostic (in medicine and manufacture), radioecological (at monitoring laboratories) and so on.

The third factor consists in the necessity to conduct quite often the RM for economic subjects such as atomic power plants or ecology organizations which have the same interests and should come to some responsible conclusions related to the fate both of manufacture and of population.

To satisfy the above requirements, the System should be arranged in such a manner that it could be used as an objective basis for solution of any problems including the disputable ones which refer to the RM.

Thus, from the very beginning, the System has been created with the aim to provide the metrological assurance of all economy branches of Russia in the field of the RM, using as a basis the centralized principle which means:

- reproduction of measurement units which are the main ones for a given field of measurements with the help of state standards;
- the legalized hierarchy chart for calibration of measuring means with an approved list of secondary and working standards and definite intercalibration intervals;
- availability of specifications regulating methods and accuracy limits of measurements for the whole park of the working measuring means being in usage.

At present the System is based on 11 state primary and special standards which provide to reproduce the main measurement units for the activity of radionuclides in sources, gases, aerosols, flux and flux density of the charged particles and neutrons, power of the absorbed dose of photon, neutron and beta-radiation as well as some other measurement units.

The size of the units reproduced by the standards is transferred to the working

measuring means according to the hierarchy calibration charts including more than 50 working standards operating in the form of suitably designed dosimetry and radiometry set-ups installed at the leading enterprises or at the main metrological laboratories. As the certified radiation sources, they use radionuclide sources, x-ray apparatus, reactor channels, output accelerator beams. All measuring means including working standards, are tested every 3-5 years, the same interval being used for metrological certification of the measurement methods.

The System described, which to some extent appears to be bulky, has demonstrated its efficacy in carrying out the works on liquidation of consequences of the accident at the Chernobyl Atomic Power Plant.

First of all, it was found to be very important that all radiometers and dosimeters being used at the accident site, had been calibrated in the established units and that the measurements were performed according to the specified procedures. This enabled to assess the accident scale correctly, to bring out the major seats of origin of the damage and to forecast the development of radiation conditions. Thus, it was possible to organize and monitor the radiation dose of individuals promptly and on a large scale.

Coincidentally with the liquidation of the direct accident consequences, a demand arose for a radiation inspection of population, food, soil, water. This problem was promptly solved at a high level of reliability with the help of the standard solutions of radionuclides (SSR), which were used for manufacturing the standard specified measures of activity (SSMA) serving as full-scale models (simulators) of the test samples taken at the contaminated locality. Certification of the SSR was carried out with the help of the standard set-ups being a part of the state standard for the radionuclide activity. The SSMA were used to calibrate scales of the radiometers and spectrometers, as well as whole body counters at the laboratories of sanitary-epidemiology services including those situated in the regions of the radiation contamination. At the same time, to certify the radiometer set-ups and to measure the radionuclide activity in the samples, some methods and corresponding procedures were developed. Thanks to the System, they were brought up to their direct executors.

Thus, owing to the existence of the System, it was possible to solve the problem of carrying out reliable radiation measurements under the conditions of liquidation of the large-scale accident consequences. This in itself is a good evidence that the choice of a centralized system for metrological assurance within this field of measurements in Russia has been chosen correctly.

Once the System has been created, it is being continuously developed and improved. One of the most urgent problems which it faces now, is the creation of a network of laboratories for monitoring the radiation. These laboratories will be accredited for the right to carry out the radiation measurements according to the rules regulated by the ISO/IEC standards for the testing laboratories included in the system of radionuclide product certification. This will permit to harmonize the structure, rates and rules accepted for the System functioning in Russia with due regard to the corresponding elements of the testing laboratories of the other countries where the international standards are being used.

FROM REGULATIONS TOWARDS RADIATION PROTECTION CULTURE

M.C. Boehler
Electricité de France, General Management/Radiation Protection Department, Paris, France

INTRODUCTION

Compliance with the technical standards and specifications is a necessary but not sufficient condition for quality in radiation protection. Reaching this quality objective is not a matter of forcing improvements by a regulatory policy of reducing dose limits, but of promoting a real radiation protection culture. The spread of such a radiological protection culture encourages the deliberate adoption in everyday practice of behaviour likely to reduce exposure to ionising radiation as low as reasonably achievable.

The aim of this paper is to demonstrate that the need to diffuse a radiological protection culture is inspired by the philosophy behind the system recommended by ICPR Publication 60 (1) on the management of residual radiological risk and, in particular by the behavioural and incentive approach implied by the optimisation principle. Special attention will be given to the fundamentals likely to contribute in a definition of radiation protection culture.

THE PHILOSOPHY BEHIND THE RESIDUAL RADIOLOGICAL RISK MANAGEMENT SYSTEM RECOMMENDED BY ICPR PUBLICATION 60

The changes to the place and functions of the concepts of dose limits and optimisation of radiological protection as set out in ICPR Publication 60 are contributing to the promotion of a dynamic action based on a behavioural approach, and this should no longer be based simply on the strict regulatory application of individual dose limits.

The system of prevention based on the threshold concept has given way to a system of radiological risk management system based on the "prudent avoidance" principle associated with the recognition in the 1950s of stochastic effects and the later adoption of the hypothesis of a linear relationship with no "safe" threshold in terms of low doses.

The adoption of this hypothesis, which is not the result of a scientific knowledge but of an intellectual approach aimed at encouraging action in radiological protection, has had the following consequences: limits are now considered to be the lowest boundaries of unacceptable doses. Values above this limit should be very strictly controlled, and doses under the limit should only considered to be acceptable in so far as residual exposure levels are optimised.

According to this approach, we should implement a management approach to radiological protection in terms of individual and collective doses, based on the establishment of optimised dosimetry objectives, in addition to controlled radiological protection based on compliance with individual dose limits. The implementation of the principle of optimisation in no way does away with the need for conventional radiological protection monitoring, which it should complement.

Quite simply, compliance with dose limits no longer ensures high quality protection. As ICPR Publication 60 recalls, dose limits can no longer be seen as the boundary between that which is safe and that which is dangerous nor as the simplest and most effective way of maintaining exposure at sufficiently low levels and of encouraging improvements.

It is the principle of optimisation which initiates action in the area of residual radiological risk management and which motivates operators to try to reduce doses within an optimal allocation of resources. The approach recommended by the principle of optimisation is to encourage initiative and innovation rather than "imposing" a limit to be complied with. Thanks to the specific nature of the principle of optimisation, we are able to go further than a merely legal perception of standards represented by given quantitative data. The principle of optimisation can be compared to a behavioural requirement which encourages operators to on-going efforts in achieving a given result. The operator may therefore be held responsible not for not having achieved a specific result which corresponds to an optimised dose, but rather for not having implemented reasonable actions to reduce doses (2).

In so far as optimisation is inciting and qualitative, regulations may only involve optimisation as a general requirement, since flexibility is required in its application within the regulatory framework together with the use of guidelines. This is the type of approach which the European Commission recommended in its Communication

of 31 December 1985 (3) and which was adopted for example when drawing up the French regulations concerning the principle of optimisation.
Radiological protection regulations should therefore have two qualities. They should not only be restrictive in terms of compliance with dose limits within the framework of a posteriori radiological protection monitoring but above all, they should encourage the promotion of the optimisation and improvement of behaviour in terms of a real management of radiological protection. Compliance with this principle is as essential as compliance with individual doses, in accordance with the logical sequence which French regulations represent in transposing the basic principles of radiological protection: "Equipment, procedures and the organisation of work should be designed so that occupational individual and collective exposure is kept as low as reasonably achievable below the limits which have been laid down (4)."

TRIAL CONTRIBUTION TO THE DEFINITION OF RADIOLOGICAL PROTECTION CULTURE

This quest for the "best" in the on-going effort to improve the quality of action required by the principle of optimisation is behind the "culture of radiological protection". If we use the definition of safety culture given in INSAG Document 4 published by the IAEA, we could define the culture of radiological protection as follows: "the radiological protection culture represents a state of mind in terms of radiological protection, that is, the view of radiological protection held by individuals and organisations, the value given to it and the interest shown in it. This state of mind influences occupational attitudes and practices" (5).
In practice, the dissemination of this radiological protection culture should involve a dynamic review when necessary of methods of thinking and working, so that radiological protection is given the place it deserves.
The key factors for the dissemination of this culture, which is based on individuals' awareness of the importance of radiological protection based on the assumption of prudence in the management of residual risk, are as follows:
- the commitment of the management to a policy of radiological protection and the adoption of the concept of optimisation within the management structure of the company (6-7);
- the definition of responsibilities, particularly through the clear allocation of tasks to those concerned;
- the motivation of the personnel, which takes the form of the establishment of objectives, personal responsibility and self-discipline in terms of radiological protection, knowledge and skills in the field of radiological protection as provided by theoretical and practical training, through good distribution of information and by extensive experience feedback at both international and national level.

Commitment of the management and adoption of the concept of optimisation within the management structure

Such a commitment may only exist and last if the management has the desire to encourage a culture of radiological protection because it considers it to be in the interests of the company and two main reasons for this can be put forward.
On the one hand, the cost of achieving the level of performance required in the field of radiological protection should not affect the attainment of the main objectives of the company. Since the principle of optimisation is a reference point for the company in that it underlines the necessity of improving the allocation of protection resources, thus avoiding waste, it is integrated in the management culture of the company.
On the other hand, the dissemination of such a culture, based on a policy of dose reduction can contribute to improving the image of the company in the eyes of the public and of its own personnel.
The expression of the will to encourage such a culture must be sufficiently clear as to convince the personnel that its performance in the field of radiological protection will be as important an assessment criterion as its performance in the area of production.
It is essential that the management confirms this movement by making a general policy statement and then goes on to demonstrate to the personnel, through its attitude, its total commitment to promoting the culture within the company. In practice, it should adopt a clear and effective approach by which the processes affecting radiological protection are reviewed on a regular basis and by taking a direct interest in the more important matters concerning radiological protection, whilst bearing in mind the basic message which is that exemplary dose management requires the implementation of the principle of optimisation.

Definition of responsibilities

The competent authority for radiological protection at national level should be able to oblige the company to promote a radiological protection culture by, in particular, holding the management responsible for allocating the necessary resources to comply with the principle of optimisation. In France, the regulations make the operator responsible for the organisation of work and, in addition he alone in practice can control dose rates, the operator bears the main responsability for the optimisation within nuclear installations.

This review of the legal responsibilities of the management of the company should be combined with the practical delegation of responsibilities together with a clear definition of tasks and the corresponding resources. Such a definition is essential to avoid any ambiguity and problems of shared responsibility, which could lead to overlaps, omissions or the watering down of responsibilities. The necessity for a rigorous definition of the tasks of all and the corresponding delegation of responsibility should be seen, first and foremost, as a policy for prevention aimed at identifying the errors made in order to avoid any repetition and not as a means of punishing the shortcoming which led to such errors.

Attitude of personnel

Motivating the personnel both during the preparatory phase and during operation, increasing their awareness of personal and collective responsibility in the field of radiological protection is one of the essential conditions for the success of any dose management system. The aim should be to ensure that all accept the principle of optimisation as a "state of mind" rather than an additional workload imposed by the management.

Their cooperation should go beyond a specific commitment for a given operation and justifies an on-going effort, since experience feed-back shows that nothing can ever be taken for granted in the field of radiological protection. Those involved should systematically adopt a disciplined and prudent approach based on professionalism, communications and "time for thought" giving pride of place to a questioning approach.

The development of professionalism implies the implementation of an ALARA training programme and the integration of the ALARA approach within the personnel training structure, followed by regular retraining. The mobilisation of the personnel during operations requires on-going information as to objectives and results and a policy of motivation, which consists, for example, in taking into consideration commitment to the ALARA approach in the annual personal assessment. The stimulation provided by a questioning attitude can be seen in the ALARA check lists used during project reviews, before and after completion, which correspond rather to encouraging thought rather than the drawing up of restrictions.

CONCLUSION

The introduction of a culture of radiological protection based on the principle of optimisation within the management structure of the company, will modify both the philosophy of action and behaviour. In speaking of the ethics of radiological protection, experts are not referring to a phenomenon of fashion but rather to awareness, in that the analysis of radiological risk includes both behavioural and technological aspects. The development of a radiological protection culture, based on the principle of optimisation, responds to these ethical concerns through reasonable behaviour based on social, economic and health protection value judgements and through the responsibility for the actions this requires. The success of the optimised management of exposure levels, through the motivation of all those concerned, relies on a policy of information and transparency in so far as the residual risk of ionising radiation and the resources used to reduce such risks to levels as low as reasonably achievable are concerned. The dissemination of this culture of radiological protection will probably be a determining factor in the dynamic improvement of information concerning nuclear risk and the public's acceptance of it.

ABSTRACT

The brazilian labour legislation establishes, since 1950, some privileges for people working in activities which imply exposure to ionizing radiations. Comparing the present legal framework with technical radioprotection knowledge, one can detect several incoherences covering : classification of such activities ; additional payments ; reduced labour journey ; more vacations ; medical surveillance ; early retirements ; special norms for women .An analysis of these incoherences lead us to propose a new frame of labour rigts and radioprotection norms , coupling brazilian juridical principles and modern radioprotection knowledge .

INTRODUCTION

The brazilian labour legislation have established, since 1950,several privileges for workers exposed to ionizing radiations but, time evolution of the juridical scenery raised some incoherences, mainly when faced to time evolution of radioprotection knowledge. Topics covered by this study were : 1-classification of activities where exposure to ionizing radiations occurs;2-additionals of salary; 3-special work conditions : reduced labour journey,increased vacations, specific medical surveillance, and restricted norms for women ; 4-early retirements.The following text is divided in three topics : the present scenery,incoherences detected and suggestions for a new legal scheme.

THE PRESENT SCENERY

A- Classification of activities

Decree 3214 of the Ministry of Labour, in 1978, edited that an activity is considered **insalutary** when it is done over a ``tolerance limit'':concentration or intensity of a agent, bellow which a worker will not suffer any health damage during his professional life . Decree 83080, in 1978, recognized ionizing radiations as patogenic agents, harmful to health .The Labour Laws Consolidation - CLT , establishes that an activity is considered **dangerous** when, due to its nature or methods, it implies permanent contact with a dangerous agent , under considerable risk conditions.Regulation 3393 of the Ministry of Labour, in 1987, considering that ``any exposure to ionizing radiations is potentialy harmful to health'',classified such

activities as dangerous (where and when a potential risk is always present).

B- Additionals of salary

Law 1234, in 1950, established an additional of 40% for federal sector workers,when direct and permanently exposed to R-X or radioactive substances. Law 8270, in 1991, reduced this percentual to 5,10 or 20% , according to duration of exposures and potential doses of each worker.All other workers could also receive an additional of 40%, calculated not over their salaries but over the official national minimum salary, situation changed by regulation 3393, above mentioned, which estipulates an additional of 30% over each worker's salary.As a particular category , technicians in radiology, through Decree 92790, since 1980, receive 40% over their salaries, as ``life risk and insalubrity.

C- Work conditions

Brazil adopts convention 115 of the International Labour Organization, concernig protection of workers against ionizing radiations. Law 6189, among others, establishes that the National Nuclear Energy Commission - CNEN , is the authority encharged of editing norms concerning the safety of activities which implies exposure to ionizing radiations. Present general and basic norm is the NE-3.01 Diretrizes Basicas de Radioproteção (Basic Radioprotection Rules) [1], that defines as ``nuclear worker''somebody that, due to his professional activity, is exposed to doses over the level established for the public (1 mSv/year).

REDUCED WORK JOURNEY - federal sector workes and technicians in radiology have the legal right to work only 24 hours/week (normal journeys are between 40 and 44 hours/week).

VACATIONS - Once again, only federal sector workers and technicians in radiology have the legal right to vacations of 20 days/semester (normal vacations are 30 days / year). Since 1991, law 8112 prohibited the federal sector workers of ``selling''one third of their vacations period, in exchange of an additional payment.

MEDICAL SURVEILLANCE - CNEN [1] establishes a periodical examination ``according to the nature of the activity and dose absorbed''. Workers of the federal sector must be submited to this examination each semester , no matter the nature or dose of their activities. Examinations are also requested before job engagement , at resignation or retirement and when dose limits are surpassed.

NORMS FOR WOMEN - CNEN [1] establishes that pregnants cannot work in areas classified as ``controlled''(doses above 3/10 of the worker's limit),and also lower limits of accumulated dose to foetus (1 mSv) and to the abdomen of

women with reproductive capacity (10 mSv/three successive months).Law 8112, since 1991, establishes that women working for federal organims, must be excluded of activities and areas where they could be exposed to ionizing radiations ``during pregnancy and lactation periods''.

D- Early retirements

Federal Constitution establishes the right to retire after 35 years of work, for man, and 30, for woman,or after a reduced time(special retirement) for activities under special conditions, defined by law,considered harmful to the health or physical integrity of a worker.In consequence, 25 years in activities with exposure to ionizing radiations are sufficient for a special retirement, but federal sector workers are still waiting for a specific law to receive this constitutional benefice.

INCOHERENCES DETECTED

Analysing the present frame of the brazilian legislation [2], one can detect the following incoherences:

1- ionizing radiations are either considered as insalutary and dangerous agents, but since CNEN doesn't specify clearly a tolerance limit, at least two levels could be considered :
a- 1 mSv/year, which characterizes a ``nuclear worker'';or
b- 50 mSv/year, maximum recommended for nuclear workers;
but , for stochastic effects , this is a mere speculation, since the increasing of dose levels only increases their probability of occurrence.There is not a threshold dose isolating a safe from a harmful zone, as is the case for deterministic effects, where it is clear that the tolerance limit should be the deterministic levels for occurrence of each effect;

2- CLT specifies that, to be considered as dangerous, an activity should imply permanent contact with a dangerous agent, in a high risk situation. conditions not demanded by regulation 3393 that, in 1987, classified as dangerous,``any'' activity with exposure to ionizing radiations;

3- since 1950, workers of federal and others sectors are treated in different ways,even when doing similar activities, despite Decree 97458 that, since 1989, edits that ``characterization and classification of insalutary and dangerous activities done by workers of a federal organism, will be the same prescribed for others workers;

4- limitation of exposure time to a maximum of 24 hours/week conflicts with modern concepts of dose limits, admited as the best criterion for a safe activity; semestral vacations and early retirements present the same kind of incoherence (people with these privileges usually work in two or even more institutions, in similar jobs).In 1995, law 9032, prohibited

REVISION OF NATO STANDARDIZATION AGREEMENT (STANAG) 2345 "EVALUATION AND CONTROL OF PERSONNEL EXPOSURE TO RADIO FREQUENCY FIELDS"

B. Jon Klauenberg[1], James H. Merritt[1], and Robert Gardner[2]

[1]Armstrong Laboratory, Occupational and Environmental Health Directorate, Radiofrequency Division, Brooks Air Force Base, Texas 78235-5324
[2]Directorate of Defence Health and Safety, Ministry of Defence, Bromley BR1 2JB, England.

North Atlantic Treaty Organization (NATO) joint operations, which reach across borders of countries that have different standards, could present a logistical nightmare were it not for Standardization Agreements, called STANAGs. STANAGs are established to provide uniform policies and procedures to insure international cooperation and to maintain the most effective levels of commonality, compatibility, inter-change-ability and inter-operability in military operations.

Since signals produced by radar and communications equipment are not contained by national boundaries, a STANAG for Radiofrequency Radiation (RFR) is essential. The STANAG-2345 *"Control and Evaluation of Personnel Exposure to Radio Frequency Radiation"* establishes criteria for the evaluation and control of personnel exposure to radio-frequency radiation within NATO forces. It defines hazard assessment, allows for control measures, indicates actions in case of accidental overexposures and establishes permissible exposure limits.

The promulgation of this STANAG in 1979 was the culmination of deliberations among scientists and health professionals within the NATO community that began in May 1973. At the time of adoption it contained guidance based on the then state-of-knowledge. The standard has not been updated since it was issued, despite great advances in the knowledge-base defining health and safety aspects of RFR. Several standards setting groups recently updated their standards, including the American National Standards Institute revised safety guidance for RFR. This has left a large technology gap between the newer standards and STANAG-2345.

It is critical that a revision of the STANAG be developed that is in consonance with current scientific understanding and with modern national safety standards. In 1992, a program to update STANAG-2345 was initiated. Obtaining wide scientific consensus was deemed to be critical and many NATO countries participated in the effort. The Armstrong Laboratory co-directed, with the Italian National Institute of Health and the Italian Air Force, a NATO Advanced Research Workshop *Developing a New Standardization Agreement (STANAG) for Radio-Frequency Radiation* held in 1993 at Pratica di Mare Italian Air Force Base near Rome. The workshop served as a springboard for revision of the STANAG. This workshop brought together over 40 world class scientists from nine NATO countries to review the state-of-the-science on the biological effects of electromagnetic energy, with particular attention to radiofrequency radiation. Most of the participants either are currently heading or have had senior leadership positions in major research and standards setting organizations. Over forty presentations were made and papers have been published as a NATO Proceedings *"Radiofrequency Radiation Standards: Biological Effects, Dosimetry, Epidemiology, and Public Health Policy"*. The volume provides updated review by leading research and policy experts of the knowledge-base as it is transitioned to the standards setting process.

The process of rewriting the standard involved many hours of meetings in both the United States and in Europe and many very animated discussions. In October 1994, the United Kingdom Ministry of Defence and the Armstrong Laboratory co-directed a second workshop in London where general agreement on language was reached.

In February 1995, the United States Technical Representative briefed the 44th NATO General Medical Working Party on the progress made toward updating the STANAG. Custodianship of STANAG-2345 was transferred to the United States and the RFR Division of Armstrong Laboratory was appointed United States Technical Representative. Technical representatives from NATO countries met at Brooks Air Force Base, San Antonio, Texas, in May 1995. They made minor modifications in accordance with their rational concerns and then signed a consensus statement supporting the final draft STANAG, marking a further step in the process of transitioning knowledge-base to international policy.

The United States, United Kingdom and French Technical Representatives briefed the NATO Radio and Radar Hazards Working Party in September, 1995 in Brussels, Belgium. Involving the member nations in the entire process has paid off. It is anticipated that the technical consensus that has been formed will transition into ratification by all NATO members.

Highlights of the revised STANAG 2345 (Edition 2) are the following:
(1) The proposed STANAG 2345 (Edition 2) is a single tiered standard. It is based on the "controlled" level concept which is similar to the occupational level concept. Although both levels are safe, the military operational situation suggested that the controlled value was the most appropriate.
(2) The STANAG (Edition 2) is frequency dependent and covers the range from 3kHz to 300GHz. International safety standards have long recognized the frequency dependence factor and the revised STANAG has incorporated this essential concept.
(3) Most important, the STANAG 2345 (Edition 2) provides minimal safety guidance thereby insuring safe operations. National standards which are more restrictive or conservative are not superseded.

ABSTRACT (See instructions overleaf)

Everyone attending the IRPA meeting will give a simple answer: YES

All of us know that natural ionising radiation arises in outer space, where cosmic rays are formed, and in earth, where radionuclides normally present in soil, air, water, food and even our bodies undergo radioactive decay.

How many among the "general public" know that radioactivity is the natural phenomenon of disintegration accompanied by the emission of ionising radiation? How much has been done to teach the population that penetrating radiation (gamma rays, alpha and beta particles, neutrons and muons) and radioactive material pervade the natural environment. And that exposure occurs by irradiation from sources outside the body and upon the decay of radionuclides taken into the body through ingestion and inhalation. Very little.

Even today, a hundred years after humankind learned about ionising radiation and radioactivity, the subject is not addressed at any stage in either primary and secondary schools world wide. One can not forget that an effort has been done, may be biased to gain public acceptance, by the nuclear industry to produce leaflets, brochures, teaching aids, even comics aimed to child and adolescent understanding but because there is not national curriculum requirement their impact is small.

If we agree that ionising radiation is a fact of life, it has to be thought as such in primary and secondary schooling. Then it is time to start some action to encourage the education authorities to introduce radiation and radiation protection in primary and secondary schools curricula in our own countries.

THE ETHICAL DILEMMA POSED BY OVERLY CONSERVATIVE ENVIRONMENTAL STANDARDS

A. John Ahlquist and Thomas M. Gerusky
Office of Environmental Restoration; EM-46
U.S. Department of Energy
19901 Germantown Road
Germantown, MD 20879-1290
USA

The searing introduction of the public to the human health effects from large doses of ionizing radiation came from the nuclear weapon explosions at Hiroshima and Nagasaki, Japan at the end of World War II. The horrors of a war using such weapons are part of the human consciousness. This introduction created fear and concern over ionizing radiation from man-made radionuclides or natural radionuclides enhanced by man's activities. This leads to a public over-emphasis on reducing exposure to man-made ionizing radiation whatever the expense might be. A study that evaluated costs of 500 life saving interventions found that radiation control activities had a median cost of $27 million (US) per life per year and were four of the top ten most expensive [up to $34 billion (US) per life per year]. [Tengs, 1994]

We were personally involved in a cleanup in northwestern Alaska where 1.1E8 Bq (3 mCi) of ^{137}Cs, buried over one meter deep in a mound 51 km from the nearest village, were removed because of fear and mistrust even though there was no physical hazard to anyone from the buried material. In the late 1950's an experiment, called Project Chariot, was proposed under the United States Plowshare Program (peaceful uses of nuclear explosives) to create a harbor along the northwestern coast of Alaska using nuclear explosives to move earth. The nuclear experiment was never conducted. However, as part of the extensive ecological and environmental studies in preparation for the experiment, the United States Geological Survey did tracer experiments in 1962 to determine how fallout radionuclides [total of 9.6E8 Bq (26 mCi) at the time of the experiment] might move through the tundra. At the end of the five day experiment, and in violation of the license authorizing use of the material, the material (contaminated soil, vegetation, wood and plastic) was buried on site in a mound about two meters high. (The material was to have been removed from the site.)

A combination of factors lead to the decision to remove the mound. The mound was re-discovered in September 1992, 30 years after burial. It reminded people of a difficult political battle against Project Chariot that was waged at that time by the local populace as well as a number of other residents in the Alaska. The concern felt in those days was rekindled by this rediscovery. The mound's location in a pristine hunting area, where people are dependent upon hunting, caused significant local concern about contamination of the food supply. The facts that the burial was in violation of the license and that the license permitted 1.85E11 Bq (5 Ci) to be used [although all evidence indicated only 9.6E8 Bq (26 mCi) was used] fueled the public outrage because some felt that the remaining 1.84E11 Bq (4.974 Ci) were used on site and were now missing. Also, the re-discovery occurred two months before a major election. The outrage created pressure on the politicians to act quickly and decisively. The Department of Energy (DOE) accepted the responsibility for subsequent activities. The isolated location meant that investigation, and removal,

if necessary, could not proceed along normal investigative lines where surveys and sampling and analysis are followed by a risk assessment and presentations to affected stakeholders before a decision on the appropriate remedial action. The cost of setting up the infrastructure to do the assessment work was so high that the extra cost of doing actual mound removal (which was the only acceptable alternative to the local populace) did not add that much more to the cost. Surveys were done, the mound was removed, and the contaminated soil was shipped to Nevada for burial in five weeks during the summer of 1993. Total costs were around $7 million (US). Fortunately, this work in a harsh environment where the only form of transportation to and from the location was by small aircraft landing on short dirt airfields, was accomplished without any injury to the workers although worker risk was always a prime concern.

This removal is a classic example of what Dr. Peter Sandman, a specialist in risk communication, talks about when he says that risk is the hazard (known to most technical people as the technical risk of probability times consequences), plus the public concern or outrage, i.e.,

RISK = HAZARD + OUTRAGE

Thus, hazard, or technical risk, can be zero and the "risk" can still be high because of public outrage. [Sandman, 1993] In ethical debates this concept might be framed with the understanding that one cannot divorce ethics from community and the values of that community. Often, the community value on man-made radiological contamination of the environment is not equal to biological likelihood of damage from that contamination. Therein lies the ethical dilemma that confronts many in the radiological protection community. How much effort, time, money and worker risk should be expended to mitigate a non-hazard as understood by the professional? How much better would society be if the money were not spent or were spent on higher priority activities? Most radiation protection professionals have probably confronted this dilemma sometime in their careers.

Another place where this dilemma occurs is in the setting of environmental standards for the cleanup of radionuclide contamination of soil. The United States Environmental Protection Agency is being pressed to set a single risk level for contaminates in soil and is giving consideration to a lifetime cancer risk of 1E-6. When the pathway analysis is done, cleanup is not feasible for a number of radionuclides (such as ^{137}Cs, ^{90}Sr, ^{232}Th) because the calculated concentrations are a fraction of background concentrations or are below detection levels of laboratory instruments. Besides, a risk level of 1E-6 is well below the natural background lifetime risk which ranges from 1E-3 to 1E-2.

It is interesting that for radon, the outrage factor is generally low to non-existent. In areas where the radiation protection professional might urge radon mitigation, the public is often apathetic. Is this because radon is a natural substance and ubiquitous? Or is it because the action falls to the individual and his/her pocketbook and is not something that can be blamed on others? Or, might it be a combination of these factors?

What might be done? As a matter of ethics, radiation protection professionals should speak out wherever the opportunity presents itself. Seek out ways to communicate beyond the typical dry, technical approach always hedging for uncertainty however small.

The United States Congress is currently considering legislation that would make funding for environmental cleanup based on risk. This would mandate that technical considerations be given primacy in funding priorities. This would significantly reduce the dilemma of the radiation protection professional.

The DOE is working diligently on interactions with community and regulatory stakeholders at DOE sites. This has led to some interesting results. At one facility, activists were given play money equal to the budget for environmental restoration and the costs for desired remedial activities and then asked to prioritize activities based on the money available. Various taxes and infrastructure charges were taken away before actual prioritization could begin. Several activists completely changed their positions on their individual items of concern when faced with the decision of how to prioritize across the whole site. At another site, when the activists were given access to areas that were formally off limits, their fears subsided and consequently their opposition to the DOE priorities also subsided. Across the complex, community groups are involved in future land use planning. Their recommendations have often been in favor of recreational and industrial uses for land lightly contaminated with radioactive materials. This mitigates the need to clean up to the more conservative residential-farmer scenario at much larger costs.

Another communication method is to bring in unbiased professors, who are skilled teachers, to teach risk assessment to stakeholders. Courses, given free of charge, have been taught by Dr. Genevieve Roessler (radiation risk) and Dr. Margit von Braun (chemical risk). Attendees have included national laboratory scientists, regulators, DOE staff, and representatives of women's groups, Native American tribes, homeowners associations, Congressional staff, etc. There is an interesting synergism that occurs when this mix of people learns together. Mistrust is replaced by understanding and comraderie. This enables all stakeholders to talk from a common basic technical understanding.

The communication efforts must be strong, deliberate and unending to overcome what we call the information half-life factor. Over time, knowledge of events decays away (similar to radioactive decay) among those who did know and a new generation appears that has no political awareness of past events. Any event that triggers a new wave of concern among those who have forgotten or were unaware of a past event creates a political firestorm which overcomes reasoned debate, as happened in Project Chariot. In new situations, it is better that the public learn of a possible concern by our proactive approach to informing them rather than learning from newspaper headlines or television soundbites.

HUMAN RADIATION EXPERIMENTATION: A HEALTH PHYSICS PERSPECTIVE

Ronald L. Kathren
Washington State University, 100 Sprout Road, Richland, WA 99352 USA

ABSTRACT: This paper observes ethical human experimentation can be considered in terms of two basic principles or tests: informed, willing and knowledgeable subjects; and expectation of benefits. A number of human experiments are evaluated in terms of these principles, including a sixteenth century toxicology experiment, the deliberate exposure by an x-ray pioneer, and the plutonium injection cases of the 1940's. The following rational ethic is proposed for the practice of health physics with respect to human radiation experimentation: ***At all levels, the health physicist has a professional as well as personal obligation to ensure that proper humanitarian requirements, including proper informed consent and willing subjects, are carried out with respect to human radiation experimentation, and must be convinced that the real or potential benefits to be derived from the experiment clearly exceed the potential detriment and risk.***

INTRODUCTION

Since the primary mission of the health physicist is protection of people and the environment from the harmful effects of radiation while at the same time permitting (and indeed promoting) its beneficial applications, human radiation experimentation is a topic of particular interest to the health physicist. However, the leading professional societies involved with radiation protection, including the International Radiation Protection Association and most national associations, provide little, if anything in the way of guidance. The Code of Ethics of both the oldest and by far the largest national organization, the American Health Physics Society, is published annually on the inside back cover of the Society Handbook, and provides nothing specific with respect to human radiation experimentation or public benefit. Indeed, this Code is, in a general way, patterned after the Code of Practice for professional engineers, minus the business aspects. Similarly the current Code of Ethics of the American Academy of Health Physics and its professional certification arm is vague and general, and refers only to obligations and responsibilities of the health physicist to the profession.

In developing a health physics perspective regarding human radiation experimentation, it is important to bear in mind what might be called the fundamental guiding principle of health physics. As elucidated in numerous publications, and in particular by the International Commission on Radiological Protection, this principle can be paraphrased thusly: *No person should be subjected to any additional radiation exposure unless the benefit to be derived clearly exceeds the risk to be incurred.* This is the fundamental underpinning of the concept of ALARA and the day to day practice of health physics. But, whose benefit and whose risk? Is it the individual, or the society, or somebody else who derives the benefit? And, is it the individual, or the society, or somebody else who incurs the risk? These are important questions that need to be considered by the health physicist in the overall context of human radiation experimentation.

TYPES OF HUMAN RADIATION EXPERIMENTATION

Human radiation experimentation can take many forms, and can be divided into two categories. Category I exposures are those in which the purpose is to direct administration of radioactivity or external radiation in order to study the radiation in relation to the individual. Perhaps the most common or obvious Category I exposures involve new and unproven radiological therapies or diagnostic procedures with significant exposure to radiation. A corollary, perhaps, to the preceding, are radiation effects studies in which a person or persons may be exposed to radiation to determine the effects on the healthy body. Category I exposures would also include biokinetics studies in which radioactive substances, albeit in small quantities, are administered for studies of uptake, distribution and excretion, and determination of various biokinetic parameters such as biological half-life for medical or health physics applications.

Category II exposures are those in which the radiation exposure is incidental to the primary purpose of the investigation or treatment. These include tracer studies of various kinds; additional diagnostic or evaluation procedures involving radiation exposure required by a nonradiological experimental treatment; and major exposure ancillary but essential to a particular treatment. Category II exposures might even be extended to include the exposures incurred by personnel involved in the preparation, handling, and administration of the radioactivity or external irradiation procedures. The radiation experimentation in the United States over the past half century has encompassed all types of Category I and Category II exposures.

POTENTIAL LEVELS OF INVOLVEMENT OF THE HEALTH PHYSICIST

The health physicist can become identified with human radiation experiments on many levels. He or she can be a member or even the leader of the experimental team carrying out the research. A somewhat lesser level of involvement would be to provide direct health physics support to the experimental team. More indirect but still at a higher level of involvement would be review and possible approval of the experimental protocols as a member of an Institutional Review Board, Human Subjects Committee or similar body, or review and approval of the experimental protocols from a professional health physics standpoint only. At a lower level is incidental involvement, which may arise out of and in the course of employment, such as when the colleagues of the health physicist seek advice or consultation on a specific aspect of the research, or when the health physicist is aware that the research is planned or being carried out by the institution. The lowest levels of potential involvement are incidental and not related to the employment or professional practice of health physics. For example, the health physicist may be aware that a human radiation experiment is planned or being carried out at another institution, or that waste shipped to his or her institution has been generated as a byproduct of a human radiation experiment.

ELEMENTS OF APPROPRIATE HUMAN EXPERIMENTATION

Although there are many points of view ranging from impermissibility of any type of human experimentation to the permissibility of extensive types experimentation on certain classes of people, it is the generally accepted viewpoint that human experimentation is permissible and even desirable under certain circumstances, and with certain assurances and controls. Much has been written with regard to ethics of human experimentation, and specific cases and scenarios present conundrums and paradoxes with ample basis for discussion and serious consideration, but in sum and substances, the basic principles are twofold. First, the subject(s) must be fully informed, knowledgable and understanding of the procedure and its attendant risks and discomforts and detriments, and must be unreservedly willing to participate. The second principle is that there must be some reasonable expectation of benefit.

The above principles are generic, much like the Biblical injunction "Thou shall not kill". And, like the injunction, detailed examination of each of the basic principles poses a host of further questions -- e.g. What is 'reasonable'? What constitutes 'knowledgeable'? Or 'understanding'? Whose benefit? Is it acceptable to experiment on a comatose patient if there is reasonable hope of achieving an otherwise impossible cure? -- are might best be left to detailed discussion and consideration by ethicists, scientists, semantisicists, clergy and laity and as such outside of the scope of this paper. More instructive would be an examination of past practices in the light of these two principles or tests, with an eye towards developing a rational ethic for health physicists with respect to human radiation experimentation.

PAST EXPERIMENTS IN THE LIGHT OF THE TWO GUIDING PRINCIPLES

In his diary *Journals Into Diverse Places*, the great French barber surgeon, Ambrose Paré (1510-1590) describes a visit to another country in which a test was made of the efficacy of the bezoar stone at preventing poisoning. It had long been believed that the bezoar stone, the hairball of a calf, would prevent the action of certain poisons. A cook, condemned to death the next day for stealing, was offered the opportunity to test the bezoar stone, with the understanding that if it worked, he would be set free. If, of course, it did not work, the cook would still die, although much less pleasantly and humanely. The cook cheerfully and willingly chose to participate in the experiment. He was administered a caustic poison, but the bezoar stone had no effect. Despite the ministrations of Paré and the attempts to

ease his suffering, the cook died an agonizing and horrible death.

Did this experiment, carried out nearly five centuries ago, meet the two tests? The answer is clearly affirmative. The cook was willing and informed, and understood the potential consequences of his participation. Thus the first test was met. There was also expectation of direct benefit to the subject, who would be set free and not executed if the experiment worked, as well as to the greater community from the knowledge gained vis-a-vis the effectiveness of this potential treatment.

The second experiment involved a group of men in the U.S. suffering from syphilis in the 1930's who were denied treatment so that physicians could observe the end stages of that disease. This experiment met neither of the tests; the subjects were completely and deliberately uninformed and presumably would have unwilling to forgo treatment. There was no expectation of benefit either to the subjects or to anyone else, for the end stages of tertiary syphilis were already well known, and had been for many years.

The third example is that of the first known human radiation experiment. On November 18, 1896, less than a year after the discovery of x-rays, American physicist Professor Elihu Thompson reported the results of deliberately exposing the little finger of his hand to x-rays, describing the physical damage, pain and suffering that he had incurred. Thompson's classic experiment met both tests: he was both willing and knowledgeable (although he did not anticipate such serious consequences, he knew as much about potential biological effects of x-rays as virtually anyone) and there was a clear expectation of benefit in the form of better understanding of the possible biological effects of x-rays, and of protection of people from excessive exposure.

Another example of radiation experiments, this one with a more equivocal answer to whether the two tests are met, relates to the plutonium injection cases. In the 1940's, 18 individuals thought to be suffering from incurable diseases that would result in death within ten years were injected with plutonium so that the biokinetics of this new manmade element could be studied and documented. Whether this experiment met the test of willing, informed, and understanding subjects is open to question; there was no documentation, and it is impossible to reconstruct what may or may not have been told to the subjects as they and the scientists carrying out the experiments are largely deceased. that there was an expectation -- indeed almost a guarantee -- of benefit in the form of new knowledge potentially useful for establishment of safety standards is unequivocal. But whether this benefit would have overridden the potential detriment, even if the subjects had been fully informed and willing is also open to question.

One final human radiation experiment bears consideration. In the 1960's, a group of mentally impaired children at the Fernald School in the northeastern United States was administered tracer doses of iron in a nutrition study. The fact that these were children, with serious mental deficiencies, raises the ethical question of the acceptability experimentation on groups or individuals whose ability to evaluate the merits of their participation is lacking or minimal. Even though the consent of the parents (who were likely not informed that a radionuclide was to be used in the study) was obtained, the ethical question remains. Permitting such a practice would seem to open the door to justification of the grotesque medical experiments carried out by the Nazis on groups they considered inferior and hence incompetent to judge whether they should participate as individuals.

TOWARD A RATIONAL ETHIC FOR HEALTH PHYSICISTS

The above lead to a simple rational ethic for health physicists with regard to human radiation experimentation: ***At all levels, the health physicist has a professional as well as personal obligation to ensure that proper humanitarian requirements, including proper informed consent and willing subjects, are carried out with respect to human radiation experimentation, and must be convinced that the real or potential benefits to be derived from the experiment clearly exceed the potential detriment and risk.*** In practice, this means that the health physicist should not participate in or provide support to experiments that do not meet the two basic criteria for human experimentation. Moreover, the health physicist has a professional and societal obligation to attempt to prevent any such studies with human subjects that do not meet humanitarian considerations. This is a fundamental responsibility of the professional practice of health physics, which after all, is devoted to the betterment of mankind.

In conclusion, it perhaps bears mention that the term *humanitarian requirements* as used in the above proposed ethic is of necessity dynamic and not static. What is acceptable today may not be so tomorrow. Consider, for example, the bezoar experiment described by Paré, which met both of the tests or criteria for human experimentation. By the standards of today, such an experiment would be unthinkable for manyethically based reasons. But we can and must learn from the past, so that as Santayana has pointed out, we are not condemned to repear our mistakes.

PERCEPTION OF RADIATION RISK FROM A CROSS CULTURAL PERSPECTIVE

J.Brenot[1], A. Hessler[2], W. Joussen[3], L. Sjöberg[4]

[4] Center for Risk Research (CFR), Box 6501 11383 Stockholm, Sweden

INTRODUCTION

Regarding radiation risk individual coping strategies range from apathy, no worry, avoidance, information seeking, changes in life style, inter alia. How they occur and when, is a necessary information for the development of better risk communication programmes. To address these points four particular situations involving radiation were chosen, namely indoor radon exposure, X-ray diagnostic, consumption of irradiated food, and radioactive waste management. Situations correspond to very different contexts, natural exposure (with indoor radon), daily life (with medical diagnostic and food consumption) and the industrial and energy context (with waste). From a cross-cultural perspective it was deemed fruitful to compare these situations in various countries.

RESEARCH METHODS

Three groups of scientists were involved in the study which was funded by the European Commission (1). IPSN (France) and CFR (Sweden) used the conventional approach to risk communication, that is considering successively the involved parties (transmitters, receivers), their goals, the content of the exchange and the exchange process. They designed large surveys respectively in France and Sweden to study public opinions, and analysed the four radiation risk situations by looking over health risk, authorities' actions, people opinions, experts' views, and recommendations about risk communication. IFS (Germany) designed communication strategies in relation with the social representations of the four situations. They did an inventory of risk debates and risk communication strategies in Germany, Netherlands and Belgium, evaluated those strategies and stressed the importance of the local contexts. Their approach, more qualitative, was based on in-depth interviews and the work in focus groups.

INDOOR RADON EXPOSURE

Indoor radon represents an everyday exposure affecting all the individuals who normally should be concerned with. In fact public opinion surveys show, first, that the radon risk is more or less well known by a majority in the US, UK and Sweden and by a minority in France and, second, that the radon risk is underestimated. Possible explanations are: radon is a natural gas and nature is seen as benevolent and friendly; the gas cannot be sensed so the risk is forgotten; the possible effect, i.e. lung cancer, takes a long time coming; the exposure-effect relationship is uncertain particularly for low exposures; private homes are under people own control so the risk may be considered as voluntarily taken; some equity exists, indeed everybody is exposed. Moreover information is lacking about radon, its possible effects, how to test and mitigate.

To increase people awareness, communication campaigns were launched (2,3). In all countries actions were under the responsibility of public authorities which consider radon as a public health problem. Actions in the US and Sweden were extensive and all the channels available were used (booklets, newspapers, TV, meetings, etc.). In the UK, communication was rather information (guides and brochures). In France actions were very few. In general people show apathy and a very low motivation to have their homes monitored and to reduce the radon concentration indoor without any monetary incentive from authorities. Indoor radon mitigation remains in most countries a home owner's decision and, up to now, authorities have not defined when and how mitigation should be compulsory. The radon risk situation is a case for which information can be successful, i.e. memorized (see the US experience), but fails to improve the situation, i.e. lower the radon levels. A possible way among others for improving the situation is the setting of new regulatory requirements on housing by public health authorities which simultaneously would have to inform the public on the reasons of such regulations.

X-RAY DIAGNOSTIC

In Sweden the general public does not see X-ray diagnostic as a possible health risk and its trust in medical personnel is high (2). Articles in the press upon the risk of cancer associated with X-ray examinations do not seem to have affected the perceived risk. Authorities have avoided to directly inform the Swedes about such a risk. Most of the governmental actions have been aimed at the medical profession with the purpose of reducing the patient dose without alarming the public. In France people who consider X-ray examinations dangerous are very few, from 11 % to 23 % depending on the survey, even if they are 40 % on the average to

think that the truth about the associated risks is not said (1). Efforts to reduce doses from X-rays are directed towards physician's practice rather than patient's behaviour.

In general there are no large differences in perception between countries. The risk is not taken into account by people and risk control is let to physicians. Communication with the public consists in giving neutral information for general education purpose. Major communication efforts are directed towards medical and dental practicians to make them aware of dosimetric data and quality insurance necessity.

FOOD IRRADIATION

Irradiation is a method for food preservation. It reduces the microbial contamination, removes bacterias and avoids germination. The process does not contaminate the food. No toxic effects have been found when the irradiation dose is delivered following an appropriate protocol. Intensive discussions about food irradiation took place in Sweden during the 1970's (2). A strongly negative public opinion led authorities to prohibit irradiation of food and importation of irradiated foodstuffs. The most common misconceptions are: the food becomes radioactive and unsafe; the food changes in terms of smell and taste; nutrients are less. In France food irradiation is permited and debates about the risks of the practice have not reached the public. The use of irradiation for food preservation is not known in general. In a 1995 French representative survey, people who feel personally endangered by the practice are 29 %, 26 % do not know precisely, and they are 41 % to think they are not (1). Food irradiation cannot be considered as a French issue.

To summarize, the technology and the sale of irradiated food are not allowed in many countries (for instance Sweden and Germany) although scientific evidence of negative effects on health is missing. This fact makes the difference between countries. People living in countries where food irradiation has been banned have a better knowledge of the practice due to the controversy which took place at the ban period. In other countries where the practice is authorized, as France, very few people know what it is.

RADIOACTIVE WASTE MANAGEMENT

The radioactive waste issue is a popular topic in Sweden because the site of a final repository for high level waste must be found (2). The waste management agency SKB has begun preliminary studies in different regions (Storuman, Malä, and Östhammar). Afterwards SKB must propose at least two locations candidate for the repository site, and to end the local population must take part in a referendum before any final decision. Regarding radioactive waste, public attitudes are affected by how people perceive nuclear power risks and if they feel that the responsible authorities can be trusted. Many public opinion surveys have been made in Sweden. Lay people do not consider themselves very well informed. For them science is incomplete and experts disagree; these opinions are clearly opposed to those of experts in radioactive waste who consider the risks as small and the technical problems of the disposal as solved. Radioactive waste are associated with the probability of large disasters, non reversible effects, as well as injuries to vegetation and animal life, and to future generations. Respondents think that waste risks stand for a large share of all nuclear power risks. In most cases they are strongly opposed to any possible siting of a repository in their community. A waste facility is considered to lead to negative health effects, to give the region a bad reputation, and not to bring large economic advantages. However the Swedes are convinced that the management of their nuclear waste is their own problem. SKB informs the public with booklets and articles. Up to now information campaigns conducted by SKB have not affected people opinions. The solution for going ahead in the siting problem is in introducing the concerned citizens in the decision making process.

In France the high level waste siting has not been solved and the waste management agency ANDRA is searching one or two underground laboratories for testing (1,4). The siting procedure was established in 1991 at the National Assembly level by the French deputees. The waste issue is perceived as an important society problem by a very large majority of people, as underlined by the results of the many surveys performed in France since 1976. Consistently lay people feel endangered by radioactive waste and express a very strong demand for safety, the logic here emphasizing social control rather than an individual control. Their trust in authorities is also very low.

Is the radioactive waste situation very different from those of chemical and industrial wastes, especially with respect to siting ? Not really. The siting issue for any type of waste is difficult to solve in all developed countries. Analysing risk communication in case-studies of the past, or discussing with experts in focus groups lead to similar views. People are always very interested and have an « intellectual civic » representation of such issues. There are no solutions based only on the technical arguments of authorities. Information given has no visible influence upon individuals' opinions and behaviours. The policy is to involve concerned communities in a global formalised negotiation process driven at a political level, which means the participation of elected bodies, interest groups and the operator which is a national agency in most countries. Health and social considerations enter in the process, but economic incentives as well. Anyway, the negotiation is completely site and social context dependent. Experience has shown that lessons gained from the analysis of success or failure at one site do hardly transpose to an other site and social context.

FROM SOCIAL REPRESENTATIONS TO COMMUNICATION POLICIES

The four radiation risk situations described above show many similarities from country to country but also some differences. There are no simple links between perceptions and the various risk coping actions which may be taken by people and authorities. A tentative to structure those links was carried out by IFS (Germany). To study the interaction between the individual and each of the four risk situations, that is how opinions are elicited about each particular risk, discussions in focus groups were conducted in Germany, Netherlands and Belgium. The concept of social representation was used to characterise the process of opinion formation. Six different representations formed the background of risk evaluation by focus group members. They correspond to specific argumentation patterns used when considering a particular risk: traditional indifferent, individual distant, rational economic, intellectual civic, environmental apprehensive, and to end progressive modern. The IFS study (1) showed first, that an individual had not only one representation for the four situations evaluated but took one or another depending on the situation, and second that the social image of a situation within a society might be derived from individual's representations. Then it was proposed for each situation a communication policy in accordance with its social representation, as illustrated in table 1. Communication policies are six : neutral information - general education; context information - local emphasis; comparing information - involving decision; feedback information - set up dialogue; contrast information - achieving discourses; no information - shift strategy.

Table 1 : Social Representations and Risk Communication Policies (IFS Study)
for indoor radon, X-rays, food irradiation and radioactive waste
in Germany(D), Belgium(B) and Netherlands (NL)

↗ = high → = medium ↘ = low ● = nothing

social representation	technology / process / product												risk communication strategy

intellectual civic	↘	→	↘	↘	↘	→	↗	→	→	↗	↘	↘	❹ contrast information achieving discourse
environmental apprehensive	●	●	●	●	●	●	↘	●	●	●	●	●	❺ [no information] shift strategy
progressive modern	●	●	●	↘	●	●	↘	●	●	●	●	●	❻ feed-back information set up dialogue
	↓↓↓↓↓↓↓↓ social image of technology in society			↓↓↓↓↓↓↓↓ social image of technology in society			↓↓↓↓↓↓↓↓ social image of technology in society			↓↓↓↓↓↓↓↓ social image of technology in society			recommended risk communication strategy related to a particular social image

CONCLUSION

For the four radiation risk situations retained more similarities between countries have been observed than differences with respect to perception and communication. In a search of rationalization, a tentative has been made to relate social representations to communication policies which proposes interesting views which must be precised in future work. Results obtained within the cross-cultural approach offer fruitful comparisons for researchers and decision makers involved in risk management, and for this reason more cross-cultural studies in these fields must be encouraged.

ABSTRACT (See instructions overleaf)

The public is constantly harangued about all sorts of risks and its perception of risks plays an important role in governmental decision making.

This paper presents results of one of preliminary studies of the attitudes to ionizing radiation compared to other risk factors.

In the area of social psychology attitude is defined as a tendency to positive or negative reaction towards certain characteristics, objects and situations. It is caused by structure and content of the whole personality, especially by its subconscious part, and defined by the past, education and social surroundings.

Primary goal of this research was to divide risk perception attitudes according to different variables such as: sex, education level, years of life, history of occupational exposure and so on.

SOME ETHICAL PROBLEMS IN RADIATION PROTECTION

Lars Persson, Swedish Radiation Protection Institute,
S-17116 Stockholm, Sweden

ABSTRACT

The paper is focussed on the work of international organisations to establish ethical principles for protection against ionizing radiation.

INTRODUCTION

The United Nations have devoted much efforts to the protection of man. Already in the Universal declaration of human rights adopted in 1948 (1), it was stated in article 3: "Everyone has the right to life, liberty and the security of person".

In the field of establishing ethical principles for radiation protection the work of the International Radiological Protection Commission (ICRP) has been of outmost importance (2).

The ethical issues in radiation protection are receiving an increased international interest (3). Several radiation protection recommendations of importance from an ethical perspective have been published since 1990 and a review is timely to summarize the present ethical issues in the radiation protection field.

INTERNATIONAL RADIATION PROTECTION STANDARDS IN AN ETHICAL PERSPECTIVE

ICRP Publication no. 60

The recommendations of ICRP have today a profound influence on radiation protection all over the world. The ICRP has in Publication no. 60 (2) elaborated a conceptual framework for radiation protection mainly of ethical nature but also based on experimental work and risk assessment. An important presumption of the ICRP conceptual framework is that even small radiation doses may produce some deleterious effects. The three main principles of ICRP for proposed or continuing practices are the following:

1. The justification of a practice,
2. The optimisation of protection (ALARA: As low as reasonable achievable radiation doses, considering economic and social factors),
3. Individual dose and risk limits.

Medical exposures are usually intended to provide a direct benefit to the exposed individual. If the practice is justified and the protection optimised, the dose in the patient will be as low as is compatible with the medical purposes. Any further application of limits might be to the patient's detriment. ICRP therefore recommends that the dose limits should not be applied to medical exposures.

The system of radiological protection recommended by ICRP for intervention is based on the following two principles:

1. The proposed intervention should do more good than harm,
2. The form, scale, and duration of intervention should be optimised (according to ALARA).

IAEA Fundamentals for radiation protection

The International Atomic Energy Agency has in 1995 adopted safety fundamentals relating to radiation protection and the safety of radiation sources (4). These fundamentals are mainly of ethical nature and they are partly based on the protection principles given in ICRP publication 60 (2).

According to IAEA the primary aim of radiation protection is to provide an appropriate standard of protection and safety for humans without unduly limiting the benefits of practices giving rise to radiation

as well (9).

ICRP in para. 16 in (2) believes that the standard of environmental control needed to protect man to the degree currently thought desirable will ensure that other species are not put at risk. The same idea is stated by IAEA in (5) in principle 2 (radioactive waste shall be managed in such a way as to provide an acceptable level of protection).

IAEA in (5) states in principle 4: Protection of future generations as follows: Radioactive waste should be managed in such a way that predicted impacts on the health of future generations will not be greater than relevant levels of impact that are acceptable today. This principle is derived from an ethical concern for the health of future generations. In the establishment of acceptable levels of protection the latest ICRP and IAEA should be taken into account.

The fact that ICRP does not happen to use the term precautionary principle does not mean that it does not use the concept, which, of course it does. In fact, the whole philosophy of ALARA and protection against stochastic effects is based on not proven assumptions on radiation harm (the hereditary harm from radiation has never been demonstrated in humans, nor has cancer at low doses), because these assumptions seem to be scientifically justified.

The substitution principle (to replace a harmful agent with a less harmful) is not used by ICRP but follows directly from ICRP's first principle for practices (justification). Inter alia ultrasound is today used for prenatal examinations instead of X-rays.

Some moral problems to be deliberated in the future are: Adaption to radiation, The existence in nature of higher doses than the established limits, and The variation of the radiation risk among individuals.

exposure or incurring disproportionate costs in the case of intervention. This primary aim is expressed by the following specific protection and safety objectives:

Protection Objective: to prevent the occurrence of deterministic effects in individuals by keeping the doses below the relevant threshold and to ensure that all reasonable steps are taken to reduce the occurrence of stochastic effects in the population at present and in the future.

Safety Objective: to protect individuals, society and the environment from harm by establishing and maintaining effective defences against radiological hazards from sources.

These objectives are achieved by the application of eleven fundamental principles.

IAEA Fundamentals for radioactive waste

Many of the hazards associated with radioactive waste are similar to those associated with other toxic waste. However, the nature of radioactive waste implies the possibility of exposure to ionizing radiation. An acceptable level of protection therefore needs to be provided against radiation hazards as the main source of harm of radioactive waste. The principles of radiation waste management have thus a bearing on protection also against radiation.

The International Atomic Energy Agency has in 1995 adopted Safety fundamentals relating to radioactive waste management (5). These fundamentals are mainly of ethical nature and they are also as the IAEA Fundamentals for radiation partly based on the protection principles given in ICRP Publication no. 60 (2).

According to IAEA the *objective of radioactive waste management* is to deal with radioactive waste in a manner that protects human health and the environment now and in the future without imposing undue burdens on future generations. This objective is achieved by the application of eleven fundamental principles.

ILO Convention 115

There exist also some ethical principles in the International Labour Convention no. 115 concerning the protection of workers against ionizing radiations (6). This convention came into force in 1962. In article 5 of the Convention the main protective objective is formulated as follows: "Every effort shall be made to restrict the the exposure of workers to ionizing to the lowest practicable level, and any unnecessary exposure shall be avoided by all parties concerned."

OTHER RECENT WORK ON ETHICAL ISSUES IN RADIATION PROTECTION

Ethical issues in radiation protection have since the latest ICRP recommendations in Publication no. 60 were adopted in 1990 (2) been dealt with by inter alia Silini (7), Prêtre in ref. (3), and Shrader-Frechette in ref. (8). Silini tries to answer the question if the present system of radiation protection was founded on sound ethical principles. His answer is yes but with some remarks. Clarifying the meaning of the principle of justification and including environment in addition to humans are improvements proposed. To protect individuals as human beings and not as workers or public is another suggestion. Prêtre attempts to connect the three ICRP protection principles with the four ethical principles: Responsibility, Respect of life, Justice, and Common good. He shows that, in general, all ethical aspects in some way or other flow into the ICRP principles of radiation protection. Shrader-Frechette studied risk and ethics in a radiation protection perspective. In her paper she argues that evaluation of radiation risk often include a spectrum of extreme and unrealistic views. Ethical analysis of risks in terms of uncetainty, equity, consent, and compensation can help to provide more just, moderate, and realistic evaluations.

DISCUSSION

The linear hypothesis of radiation protection and the ALARA principle are considered to be ethically acceptable guidelines and similar guidelines should influence our attitude toward exposures to harmful chemicals

ABSTRACT

THE "G.R.R.I.N.S." AND THE INFORMATION OF HEALTH PROFESSIONS

Professeur J.C. ARTUS, Dr BATT/SANSON, Dr G. BROGLIA, Dr H. FROSSARD, Mr R. GARCIA, Dr J.M. GELAS, Dr R. GRANIER, DR C. MAYER, Mr J. MERCIER, Mme J. RIOU, Dr J.M. VINOT.

The "Groupe Régional de Reflexion et d'Information sur le Nucléaire et la Santé " (Régional Group of Reflexion and Information about Nuclear energy and health) is a working party created after Tchernobyl disaster in order to provide the framework for a pluridisciplinary reflection about the risks induced by the development of Nuclear technology on health and to carry out informing actions towards professionnal working in health services.
(Association law 1901)

The public preoccupation on the sanitary incidence of the ionisant radiations have to induce health professions to be able to answer theirs patients interrogations.
Experience shows that practitioners are not sufficientty informed and we have to propose them correct informations outwards all the polemics. All this is done in a health worry.
This is the GRRINS goal fixed to itself.

MEMBERS :

Those taking place in the working party : Doctors from occupational medecine or Nuclear medicine, biologists, physicists, hygienists, radio toxicologists, chemists and radiologists.

AIMS :

- Training students, doctors, chemists.
- Informing medical professionnals, newspapers, decision makers.
- Contributing to the actions of local information committees close to energy plants and other publis structures (department board for hygiene).

PLACE OF SETTLEMENT :

South of France (Rhône Valley), region with a large nuclear establishment.

ACTION :

- Investigation towards 13 000 practitioners, doctors, chemists, dentists, vets from Vaucluse, Gard, Hérault, Aude, Lozère and Pyrénées Orientales.
- Spreading of educational documents (films, video films, lectures, slides, books) produced under the aegis of learned companies.
- Participation in various teaching (post graduate and ordinary degrees, dissertations, training courses).
- Publication of a report "the GRRINS'Letter" with a circulation of 10 000.
- Yearly organisation of a day's work on a particular subject entitled "the Lascours Talks" :
  * 1990 : Ionizing radiances in daily life.
  * 1991 : Medical radiation (diagnosis and therapy).
  * 1992 : Ionization of food products.
  * 1993 : Are there more cancers around Nuclear centers ?
  * 1994 : Radioactive waste : which risks for health ?
  * 1995 : The domestic radon.

RESPONSES TO RADON REMEDIATION ADVICE

E J Bradley
National Radiological Protection Board, Oxfordshire, United Kingdom

Abstract

It is estimated that around 100,000 homes in the UK exceed the Action Level of 200 Bq m^{-3}. About 20,000 of these homes have been identified and the householders have been advised to reduce the radon levels. As part of an initiative to encourage remedial action a short questionnaire was sent to around 10,500 houses with radon at or above the Action Level to obtain data on any remedial action taken and the factors which influenced the decision. The results showed that around 20% of householders who replied had taken some form of effective remedial action and that cost was the major consideration. The best estimate of the overall rate of remediation is about 10%.

1 Introduction

Doses from radon are the largest component of the average radiation exposure in the UK and are estimated to account for about half of the annual dose of 2.6 mSv received by a typical member of the population (1). The majority of the exposure to radon occurs in dwellings as most people spend most of their time at home. Levels in homes can vary, and an extensive survey of the radon levels in UK dwellings has been carried out. The UK Government Action Level for radon in dwellings is set at an annual average whole-house concentration of 200 Bq m^{-3}. Householders with measured concentrations at or above this Action Level are advised to reduce the level in their homes and given information on mitigation techniques (2).

To date, measurements have been made in over 200,000 homes in the UK as part of a programme supported by Government Departments (3). One area which has been found to have a higher proportion of homes above the Action Level is the southwest of England and in particular the counties of Cornwall and Devon where it is estimated 36,000 homes are affected. Householders who had measurements of radon at or above the Action Level in these two counties were surveyed by postal questionnaire to obtain information on the types of remediation , if any, that they had undertaken.

2 Survey

Some 10,500 householders where surveyed by questionnaire. Questions included the remedial method used, the costs incurred and also reasons why they had decided not to undertake mitigation. Multiple choice reply was possible for several types of method or reason and householders could add any points that were not covered by the questionnaire. Data were obtained from over 5,000 completed questionnaires and then analysed. Around a third gave data on remedial measures and the remainder gave reasons for not taking advice to remediate.

Information on remedial measures used by the householders indicated that around 20% of those who replied had used an effective remedial measure such as underfloor depressurisation, increased underfloor ventilation, positive pressurisation of the living space or permanent additional ventilation . Multiple methods were employed by many householders, some having used five different types of remediation. The types of effective remedial measure used are shown in Figure 1. The costs of installing each type of remedial measure ranged up to £6000, but over 75% of householders spent less than £1000. The average cost incurred was about £700.

3 Remediation

The methods of remediation usually employed in homes fell into two main categories: those which prevent the radon from entering the living area of the house, for example underfloor depressurisation (sump), increased underfloor ventilation or sealing of cracks or other entry points in the floor and walls; those which reduce the level of radon in the dwelling, for example permanently increasing ventilation by the installation of trickle vents in windows. Sealing alone is not recommended but should be combined with another effective method. Householders are encouraged to choose the most effective methods of remediation. The proportion of householders installing underfloor depressurisation and positive pressurisation is banded by original radon level in Figure 2. This illustrates that the proportion of householders using these effective methods increases with radon level.

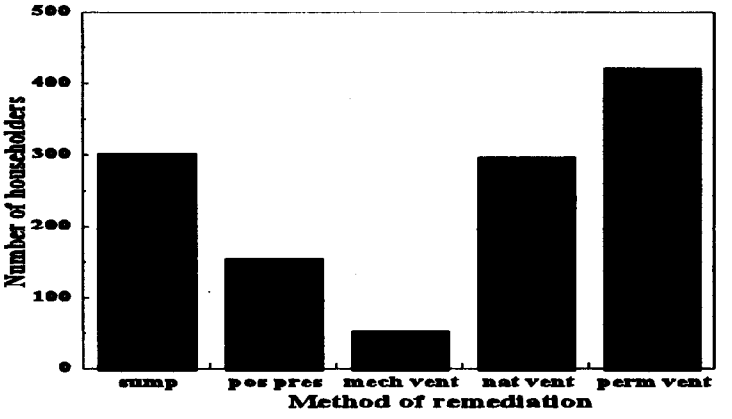

Figure 1 Types of effective remedial measure used

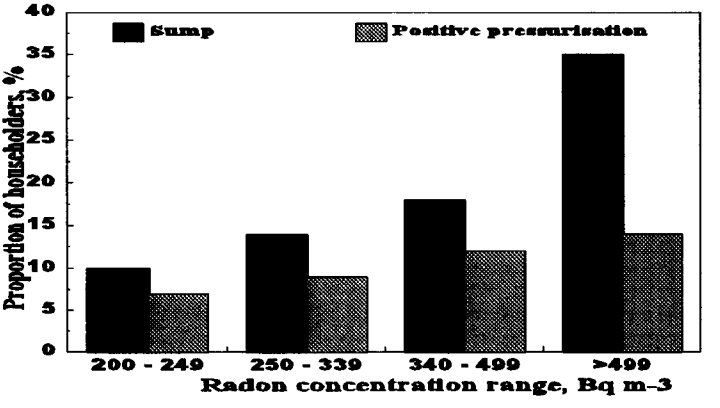

Figure 2 Comparison of the proportion of householders using the most effective remediation methods with radon level

The most effective form of remediation, installation of an underfloor depressurisation system or radon sump, was chosen by over 300 householders, with some of these using additional measures such as sealing. Underfloor depressurisation is estimated to reduce the radon level by about 90% on average (4). The use of this method should reduce the average concentration well below the Action Level, with an estimated reduction in the average level of around 700 Bq m^{-3}. The average cost to install this type of system was found to be £950, but for those householders who installed the system themselves the cost reduced to about one third or £300, making it very cost effective.

4 No action

Of the 5,000 householders who provided information, around 4,000 gave reasons why they had not carried out remediation. The main reasons can be divided into four categories: cost; no perceived risk; difficulty in implementing remediation; soon to move house. Some householders felt that the responsibility lay with the landlord or that taking the remedial measures would cause too much upheaval. The majority of householders gave more than one reason for not taking action. The distribution is shown in Figure 3.

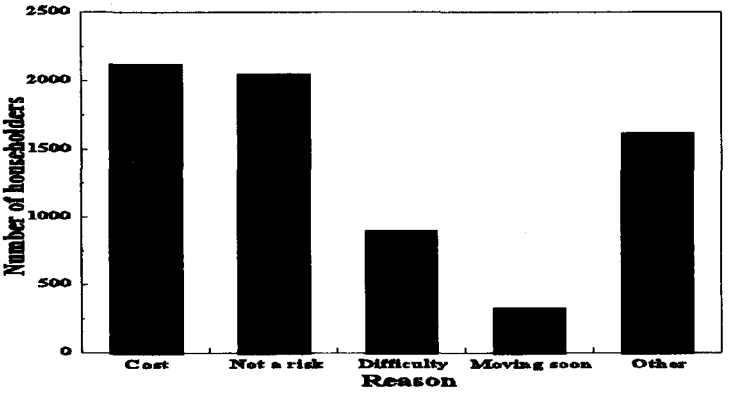

Figure 3 Reasons given for not taking remedial action

Over 50% cited cost as one of the reasons for not remediating and a similar percentage did not perceive there to be a risk. However, around 700 householders, some 17% of those who gave reasons for not remediating, did indicate that they still intended to remediate.

5 Conclusions

Of 10,500 householders with radon above the UK Action Level of 200 Bq m^{-3} who were given advice to reduce their radon levels, around 20% of the half who responded had used at least one method of remediation which would reduce levels by 50%. Thus the overall remediation rate, including householders who did not respond, is around 10%.

The methods chosen by the householders reflect the radon level in their homes, those with higher levels having used more effective methods. This suggests that the provision of clear and firm advice is an important part of any radon programme. Over 300 householders installed the most effective form of mitigation, underfloor depressurisation, with an estimated average reduction in their level of around 700 Bq m^{-3}.

The average cost of mitigation was around £700, with the most effective method of remediation, underfloor depressurisation, costing around £950 on average. Costs are tending to fall as experience is gained. Costs were reduced significantly if remediation was carried out by the householders themselves.

For householders who had not remediated, a major factor was the cost involved, but, radon was not perceived as a risk by many householders despite the clear information provided by Government and NRPB. This phenomenon of denial is well known (5) and indicates the need for more perceptive ways of providing advice and encouragement.

RADON: A CASE FOR PUBLIC PERSUASION

B M R Green and P R Lomas
National Radiological Protection Board, Chilton, Didcot, OX11 0RQ, UK

Abstract

The importance of reducing individual exposure to elevated levels of radon is well understood by radiation protection specialists, and successful methods of locating the areas most at risk have been developed. However, less attention has been paid to informing the general public about the health risks and encouraging those in radon-prone areas to take action. In the United Kingdom, techniques have been developed to persuade householders in high radon areas to take advantage of a Government scheme that provides free long-term measurements of radon in the home. Improvements in the methods of contacting householders in the target areas and in the presentation of the facts has resulted in a twofold increase in the rate of take-up of measurements since the first large-scale surveys.

Introduction

In 1990, the National Radiological Protection Board recommended to the Government a strategy to tackle the domestic radon issue [1]. The Government accepted the advice and commenced a programme to identify the majority of homes with elevated levels by the year 2000 [2,3]. The plan, based on the concepts of a radon Action Level, set at 200 Bq m^{-3}, and the designation of radon Affected Areas, is consistent with the recommendations of ICRP[4]. In addition, provision was made by the Government to fund long-term radon measurements in the homes most at risk. The standard measurement method is to install two passive integrating radon monitors in each home to be tested, one in the living area and one in a bedroom.

NRPB has designated radon Affected Areas in several parts of the UK and, on behalf of the Government, carried out large-scale surveys in those parts most at risk [5,6,7,8,9]. The initial objective of these surveys has been to encourage householders to take up the offer of free radon measurements in their homes. The outcome is the identification of dwellings above the Action Level, the first step towards the ultimate objective of persuading householders to carry out remedial measures in their homes. This reduces the high radiation doses received by the householder, his immediate family, and subsequent occupiers of the dwelling. It is estimated that there are some 100,000 dwellings above the Action Level in the UK.

Identification of households at risk

The methodology used to define radon Affected Areas in the UK is based on assessing the risk of dwellings being at or above the Action Level by 5 km grid squares of the Ordnance Survey Grid [10]. The technique results in an estimate of the percentage of dwellings in each grid square that will exceed the Action Level. The squares are ranked in descending order of probability to give a listing of the most radon-prone areas. The addresses of all dwellings in each square are obtained from the Post Office Address File (PAF) maintained by the Post Office and available on CD-ROM. These addresses are used in postal radon campaigns as discussed below. The PAF, which is regularly updated, also provides information on local council and health authority districts.

Contacting the householders

The first large-scale offers of free measurements to householders were made using a specially designed leaflet delivered direct to every dwelling by the normal mail. The leaflet gave simple facts about radon and the free measurement scheme and contained a small form to apply for the test. The householder was asked to complete the form with his name and address and return it in an envelope to NRPB at his own expense. Posters advertising the scheme were distributed to local authorities for display in council offices, libraries, and so on. Further supplies of the leaflet were also made available at these locations.

Subsequent campaigns, in different parts of the country, used similar leaflets but these were enclosed with a letter individually addressed to the householder. The individual address was already printed on the reply form.

To apply for the test, the householder needed only to complete the form with his name and return it to NRPB in a pre-paid and pre-addressed envelope.

In the final campaign reported here, in parts of the English county of Somerset, an extra leaflet was included in the package sent to householders. This leaflet, prepared by the local council and health authorities, contained a strong anti-smoking message as well as encouraging the householder to apply for a free radon measurement. The local authorities also organised a vigorous media campaign to coincide with the mailing of the first batch of letters.

The response

The difference in the response rates to these techniques is quite pronounced as illustrated in the table. The most striking point is the high response rate compared with leaflet campaigns on other topics when a response of a few percentage might be expected. Even in the early campaigns in Cornwall, Devon, Derbyshire and Northamptonshire, when the householder received only the leaflet and was required to provide an envelope and pay the return postage, the response rate was over 10%. When the leaflet was delivered in an envelope addressed to the occupier at an individual address, a return envelope provided and the return postage pre-paid, the response rate doubled to 20% or more as demonstrated by the second campaigns in Northern Ireland and Somerset. A further significant increase in the response rate appeared when the mailing was accompanied by a media campaign as was the case in the Scottish regions and in the first Somerset mailings. However, the responses from the two campaigns in both Somerset and in Northern Ireland indicate that the effect of media coverage is quite short-lived and that the response rate drops back to a lower rate once the initial media interest wanes.

Conclusions

Positive response rates of around one in four have been achieved with carefully prepared literature and the provision of return stationary with pre-paid postage. Local media coverage increases the number of positive replies to almost one in three. The same approach could be used to maintain contact with householders with elevated radon levels so as to encourage them to undertake remedial action.

Acknowledgements

Radon surveys in the UK are supported by the Department of the Environment and the territorial Departments.

Table. Response rates to large-scale offers of free radon measurements

Area	Technique	Number sent	Positive replies	
			Number	%
Cornwall & Devon (first campaign)	Leaflet alone	640000	77000	12
Derbyshire & Northamptonshire (similar approach)	Leaflet alone	350000	38500	11
Grampian & Highland Region (concurrent LA campaign)	Leaflet, letter and return envelope	2260	720	32
Northern Ireland I (within a year of designation)	Leaflet, letter and return envelope	20900	5100	24
Northern Ireland II (over a year since designation)	Leaflet, letter and return envelope	26700	5500	20
Somerset I (concurrent media campaign)	Leaflet, letter and return envelope	40000	12400	31
Somerset II (no concurrent media coverage)	Leaflet, letter and return envelope	60000	14300	24

FUZZY MEASURE ANALYSIS OF PUBLIC ATTITUDE TOWARDS THE USE OF NUCLEAR ENERGY

(1) INTRODUCTION

It is important to identify the structure of public acceptance or rejection when new technologies are developed and implemented. The structure of attitudes should have the essential attributes and their interrelation. In such a structural analysis the attitudes need to be decomposed into meaningful attributes by a suitable model. However, the data obtained in this type of study may be more or less subjective and fuzzy, and the following problems may be pointed out:

(1) A man does not always have an additive measure such as probability to evaluate fuzzy objects.
(2) The attributes of an object in his evaluation process are not always independent of each other.

In either case a linear model may not be applicable.

This paper is concerned with applying fuzzy measures and fuzzy integrals to analyze public attitude towards the use of nuclear energy.

Probability theory deals with the definition and description of models involving the probability concept. Probability judgements are concerned with repetitive events which have basic similarity. Most applications of probability theory may be interpreted as special cases of random processes. If, as in many games of chance, equal probabilities are assigned to each of the simple events of a given finite fundamental probability set, then the probability of realizing a compound event (success) defined as the union of specified simple events ('favourable' simple events) can be computed as the ratio of the number of favourable simple events to the total number of simple events. It is on the basis of these considerations that probability is deduced by resolving the various outcomes into a number of equipossible alternatives. However, when we apply the term probability to a non-repetitive event or an isolated case, for example, probability of 'Julius Caesar's visit to Great Britain', or probability of a certain country secretly producing nuclear weapons, it is impossible, at any rate in any obvious way, to generate a sequence of trials and thus measure the probability of its occurrence by means of a frequency ratio. We have, therefore, to estimate it by a more or less subjective intuitive appraisal of such evidence as we may have. Since in such cases a universally acceptable quantitative estimate of the degree of our confidence in the statement cannot be given, probability when used in this sense cannot form a part of a scientific assertion in the conventional sense.

To avoid confusion, it is, therefore, better to restrict the use of probability in a scientific sense to repetitive events only and to use the term 'possibility' when we wish to speak of our expectations of non-repetitive events, as suggested in fuzzy set theory. In addition to the probability and possibility measures, belief, credibility, certainty, necessity, plausibility measures, etc. are also introduced as special cases of fuzzy measures.

(2) FUZZY MEASURES

A fuzzy measure of Sugeno is an extended probability measure in one sense, which assumes, in general, only monotonicity without additivity.

Let X be a universal set and $\mathscr{B}$ be a Borel field. Then a set function g defined on $\mathscr{B}$ with the following properties is called a fuzzy measure.

(i) $g(\emptyset) = 0, g(X) = 1$ (boundedness)

(ii) If $A, B \in \mathscr{B}$ and $A \subset B$, then $g(A) \leqslant g(B)$ (monotonicity)

(iii) If $F_n \in \mathscr{B}$ for $1 \leqslant n < \infty$ and a sequence $\{F_n\}$ is monotone (in the sense of inclusion), then $\lim_{n\to\infty} g(F_n) = g(\lim_{n\to\infty} F_n)$ (continuity)

A triplet $(X, \mathscr{B}, g)$ is called a fuzzy measure space, and g is called a fuzzy measure of $(X, \mathscr{B})$.

For applications, it is enough to consider a finite case. Let K be a finite set $K = \{s_1, s_2, ..., s_n\}$ and P(K) be a class of all the subset of K. Then a fuzzy measure g of (K, P(K)) is characterized by the first two properties since the third one implies continuity.

In particular, $g(\{s_i\})$ for a subset with a single element s_i is called a fuzzy density like a probability density. We denote $g^i = g(\{s_i\})$. As a special form, g_λ fuzzy measures have the following characteristics:

$$A \cap B = \emptyset \Rightarrow g_\lambda(A \cup B) = g_\lambda(A) + g_\lambda(B) + \lambda g_\lambda(A) g_\lambda(B) \quad (-1 < \lambda < \infty)$$

When the fuzziness coefficient $\lambda = 0$, λ-fuzzy measures are probability measures. $\lambda > 0$, belief measures; $-1 < \lambda < 0$ plausibility measure.

(3) FUZZY INTEGRAL

Let h be a measurable function from X to [0, 1]. Then the fuzzy integral of h over A with respect to g is defined as

$$\int_A h(x) \circ g = \sup_{\alpha \in [0,1]} [\alpha \wedge g(A \cap F_\alpha)]$$

where $F_\alpha = \{x, h(x) \geqslant \alpha\}$ and $\wedge$ stands for minimum.

In the above definition , A is the domain of a fuzzy integral which is omitted if A is X.

Now let us see how to calculate a fuzzy integral. For simplicity, consider a fuzzy measure g of (K, P(K)) where K is a finite set previously defined.

Let $h : K \to [0, 1]$ and assume without loss of generality that $h(s_1) \geq h(s_2) \geq \ldots \geq h(s_n)$. Renumber the elements of K, if not in descending order. Then we have

$$\int h(s) \circ g = \bigvee_{i=1}^{n} [h(s_i) \wedge g(K_i)]$$

where $K_i \triangleq \{s_1, s_2, \ldots, s_i\}$ and $\vee$ stands for maximum.

A fuzzy integral can be used as a model of subjective evaluation of fuzzy objects where the attributes of an object are measured by a fuzzy measure and the characteristic function of an object is integrated with respect to a fuzzy measure. In the example about the nuclear power plant let h : K [0,1] be the characteristic function of the plant, i.e. the function expressing the characteristics of the plant. For example, we set h ('output'), h ('safety'), h ('price') etc. Then the overall evaluation of the plant is given by the fuzzy integral of h with respect to g, i.e. the grade of subjective importance of each attribute. As is clear from the definition of a fuzzy measure, a fuzzy measure is not only a subjective scale for guessing whether an a priori non-located element in X, a universe, belongs to a subset A of X, but also concerned with such cases as the grade of subjective importance of an attribute referred to in the foregoing from a practical point of view. The fuzzy integral model is applicable to non-linear cases, where one does not have to assume independence of one attribute from another. In the example given it is highly possible that there is a certain dependence between 'safety' and 'price'. If this is the case, we cannot use a linear model as far as we regard 'safety' and 'price' as the attributes of the plant.

We have to consider the dependence of attributes from two points of view. One is objective dependence such as between 'safety' and 'price', and the other is subjective dependence. Even if an attribute seems physically independent of another, one may consider that they are subjectively dependent in some cases.

The uncertainties involved in human judgement are usually non-additive and fuzzy, and therefore could be treated more adequately with the fuzzy theory.

(4) CONCLUSION

We applied the fuzzy measures and fuzzy integrals to analyze public attitude towards the use of nuclear energy by distributing questionnaires to about 100 students of engineering department of Kinki University, Higashi-Osaka, Osaka, Japan. Before and after the Chernobyl Accident we noticed a distinct difference in mental structure. Before the accident, the students of pro-nuclear group were whole-heartedly in favour of the use of nuclear energy, based on fringe benefits, impacts on society and economic progress, but after the accident they showed a favourable attitude towards the use of nuclear energy based on economic progress, but with some reservation because of the potential threats.

This calculation was conducted by Mr. Sen'ichi Mokuya in Master's Program of Science and Engineering, Tsukuba University, Japan.

ABSTRACT (See instructions overleaf)

The Health Physics Society first published a position statement on radon in October 1990. In mid-1995 that statement is undergoing revision by the HPS Radon Section to reflect the continuing controversy on radon health risks. In particular, a January 1995 study by the National Cancer Institute (the Missouri Study) concluded that no correlation was demonstrated between radon and lung cancer incidence. This study provided material for the news media to widely proclaim that radon was a huge, costly, government hoax.

In June 1995, another study by the National Cancer Institute demonstrated a statistically significant increased lung cancer risk at levels equivalent to a lifetime exposure at 4 pCi/L. This study also confirmed previous estimates of 15,000 lung cancer deaths a year in the United States due to radon exposures. Among these estimated deaths, 10,000 were among smokers and former smokers, while 5,000 were among never-smokers (a much greater proportion than previously estimated).

Some health physicists are saying the radon action level at 4 pCi/L should be increased to at least 8 to 10 pCi/L. Some are also saying that the linear non-threshold dose model is not applicable to radon health risks and that radiation hormesis may apply. At the same time, other health physicists point out that radon is not only the greatest source of radiation energy deposition in the human body, it is greater than all other sources combined on the average. They contend that if we are concerned with any risks from radiation, then radon has to be the major focus of that concern.

The HPS position will provide guidance that recognizes the controversy on radon health risks and recommend prudent actions in keeping with the HPS mission to assure public health and safety.

THE WHITE PAPER ON RADIATION PROTECTION AT ELECTRICITE DE FRANCE

Ph. ROLLIN
Electricité de France, Paris

The general public is increasingly interested in questions concerning the environment, and people are particularly sensitive to the consequences arising from the operation of nuclear power plants. Radiation protection standards are becoming increasingly stringent: recommendations drafted in 1990 by ICRP (ICRP 60) will soon be applied on a general scale. In this context, EDF became aware of a deterioration in the results of dosimetry monitoring in its plants[1] (an increase in the collective dose per nuclear power unit from 1989). This encouraged the Company to undertake a critical analysis of the situation, and to comprehensively rethink all the questions linked to radiation protection. This work led to the publication of the White Paper on Radiation Protection in mid-1993.

The White Paper deals with various aspects:

- medical and biological fundamentals,
- worker protection,
- protection of the public and the environment,
- information provision and training,
- emergency situations.

The major principles to note are:

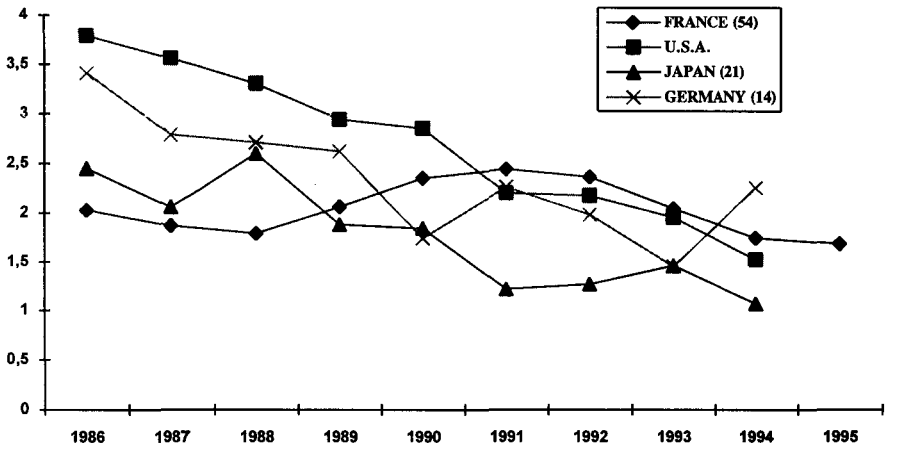
- The application of optimization techniques ("ALARA") to **work organization** is a key point in dose reduction; national and regional structures were set up to deal with this; and ambitious targets were established (35 % reduction of annual collective doses between 1992 and 1995).

Dose reduction started effectively; doses went from 2.36 man.Sv per unit in 1992 to 1.68 man.Sv in 1995.

[1] As of 01.01.1996, EDF operates 54 PWR nuclear power plant units of 900 and 1,300 MW.

Collective dose per unit

man.Sv



- Efforts have also been made **to reduce doses** by other methods:

  - design of facilities: study of new materials, better use of materials and premises to reduce exposure time during maintenance,
  - study of robotic implements,
  - study of new decontamination techniques, etc.

- Many provisions have been made to bring **radiation protection of contractors' workers** up to the same level as EDF workers. In particular this has involved:

  - developing an EDF system, called DOSINAT, to follow up dosimetry nationally using daily individual dosimetry data obtained from electronic dosimeters; this computerized system can follow up migrant workers who move from site to site, preserving dosimetry records, which were previously difficult if not impossible to obtain. An overall system for all French nuclear operators, DOSIMO, is being developed.

  - developing formal agreements with these companies, in particular to achieve a better division of work in nuclear and non-nuclear zones that takes account of dose limitations.

  - drafting training requirements both in radiation protection and on working in nuclear environments, formalized by the creation of an "access book". Training to be supplied by approved organizations (on the basis of training specifications and quality organization auditing).

- In the **environmental field**:

  - radioactive waste from nuclear power plants, already very low, will be brought to the level of the most efficient generating plants in this field. Note that going any further in this offers no advantage in health terms.

  - quantities of radioactive waste are gradually being reduced with the development of enhanced compacting, incineration and recycling techniques.

  - studies are underway on the elimination, or at least the reduction in volume, of long life waste.

- Improvement of overall radiation protection requires the general awareness of personnel ("radiation protection culture") as well as a redefinition and promotion of the "radiation protection skills".

- **Information provided to the public** is very important. EDF undertakes to supply everyone with clear and credible information, based on openness and honesty. But informing people well is difficult because of the variety of publics; which is why EDF has an information policy adapted to various public sectors which can act as select information channels, in particular:

  - health professions
  - media
  - teachers and students,
  - elected representatives.

Documentation for the various public categories is being updated.

- Finally, one of the White Paper conclusions is that, in the French context, **cooperation with Public Authorities should be developed**. The facilities to be set up are significant, and everybody should be able to make contributions while maintaining their respective roles. This concerns both the realization of a large national database, and the improvements in the company medical follow-up structures, which are currently too scattered.

  By mid-1995, 2 years from publication of the White Paper, the results obtained are very encouraging. Undoubtedly the most important thing is the awareness of the problems, and then dealing with them with the necessary energy and determination; that is what has been done and what augurs well for the future.

RISK COMPARISON AND COMMUNICATION IN RESEARCH AND POLICY

John E.T. Moen[1] and Ben J.M. Ale[1]

[1] National Institute of Public Health and the Environment, Laboratory of Radiation Research
P.O. Box 1, 3720 BA Bilthoven, The Netherlands; E-mail address: lsojem@rivm.nl

INTRODUCTION

In the field of ionizing radiation quantitative risk analysis is a commonly accepted tool in assessing the acceptability of practices and applications of radioactivity. Harmonization has been greatly promoted by the efforts of the International Commission on Radiological Protection and other international bodies. In the last few decades, risk is also becoming one of the yardsticks in many areas of environmental policy in measuring both the acceptability of an activity and the effectiveness of specific measures. Risk analysis is thus developing into a major tool and risk assessment into one of the primary procedures with which standards are being developed and policies being set [1]. The increasing pressures of economic market forces and the globalization of the economy is urging organizations and countries to be cost-effective, competitive and also to define their position in environmental matters in relation to others. The importance and the broad scope of applications of risk analysis are illustrated by many studies (for a review see, for example, reference 1). The process of environmental risk analysis often follows a similar path, as illustrated by the diagram in Figure 1.

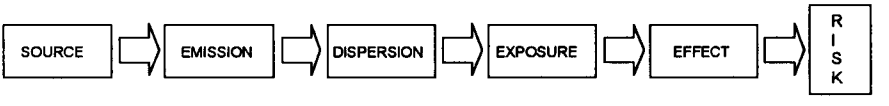


Figure 1. A diagram of environmental risk analysis processes.

Risk as an expression of the result of one's effort can be a binding quantity. However, as risk analysis and assessment have been developing in different scientific disciplines and on the borderline of science and policy, a lot of divergence in terminology and methodology has entered into the field. In practice, this leads to considerable confusion to the extent that assessment sometimes is used while meaning analysis. Such confusion weakens the possibility of defending any resulting policy decision in the political arena, defying the original purpose of the risk analysis exercise. Simply expressed, the more widely risk analysis is accepted as a tool of policy support, the less widely the results of such risk analyses may be accepted by politicians and the general public in defining their political choices.

PROBLEMS

In the development of the techniques of risk analysis many choices as to the definitions of key elements in the analysis had to be made. Consider the definition of the risk target in most studies: the human being. In some cases this target is defined as a "spinach-eating infant", in others one takes a human to be a 20-year-old well-trained marine. Sometimes emergency-response actions are considered to be immediate and effective, sometimes they are supposed to be too little too late. Comparable variations exist with regard to almost all parameters being used in risk analyses in human and ecotoxicology and in chemical safety studies. These observations are not new, and are in fact well documented in several papers and publications (e.g. 1, 2, 3). However, they have led to surprisingly few changes in day-to-day applications of risk analysis.

In various fields of environmental policy, and in some countries even within the same field of environmental policy, differing assumptions have found their way in the risk analysis process and subsequently in policy development. In the field of major chemical hazards, in the United Kingdom the individual risk is expressed as the frequency of a protected individual receiving a dangerous dose, whereas in the Netherlands it is expressed as the frequency of an unprotected individual receiving a

[1] Many definitions of risk exist. We mean by *risk* the probability, or frequency, of occurrence of a particular effect (adverse event); by *risk analysis* the process of obtaining a numerical outcome for this risk; by *risk assessment* the valuation of the calculated risk.

fatal dose. The different numerical outcomes of analyses based on such widely different presuppositions create profound difficulties in policy-making and negotiations with the parties involved, such as industries. Recently, in a report on problems associated with risk analysis and environmental risk management (4), a committee of the Health Council of the Netherlands gave a general indication of the problems that may arise from confusing terminology.

Even more complications are met in risk communication, in explaining the results of risk studies to - often non-expert - politicians and, most importantly, to the public. The public may be well aware that it functions as potential victim in risk studies, and therefore claim a position in discussions on risk outcomes in its role as the primary driving force behind the (democratic) policy process. Unclear statements and diffuse terms may influence the debate on the acceptability of risks, and act as a trigger for far-reaching action with possibly unpredictable results. The situation is even more aggravated by virtue of the fact that interested parties may want to introduce definitions to steer the outcome in a desired direction. For instance, the comparison between driving by passenger car and flying with a commercial airline will have a markedly different result if compared on the basis of numbers of casualties per calendar year, per passenger-hour or -mile.

COMPARABILITY OF RESULTS

Nevertheless, the possibility of comparing the results of analyses and the policy indications is the original idea behind the development of structured risk analysis techniques and should remain so in the future. Any difference in the results of decision-making between countries or fields of policy should be the result of a conscious weighting of risks against profits and not the accidental result of unknown or unexpressed differences in definitions, techniques or assumptions. Adequate risk comparison is related to making the criteria for risk limitation explicit, for instance "individual vs. collective risk", "fatalities vs. morbidity", "regular vs. potential emissions or explosions" etc. When this explicitation is lacking, discussions on risk analysis and assessment may lead to lengthy and fruitless sessions.

EXAMPLES

The environmental risk policy debate in the Netherlands forms a typical example for the developments described. Originally, risk policy was developed for petrochemical installations. A maximum risk exposure was defined as the chance per year of an unprotected individual being killed as a result of an accident (5). The limit was set to 10^{-6} per year per installation. Subsequently, the same limit was declared applicable for all possible confrontations with risks induced by exposure to human-induced hazards, including chemicals in the environment, accidental releases of nuclear power plants and applications of ionizing radiation in general. This creates some interesting problems.

Firstly, exposure to a chemical disaster - which was the original subject of risk policy - has immediate lethal effects stemming from intense thermal radiation, explosive effects and high dosages of toxic chemicals. Delayed effects are rare, to the extent that they are almost never considered. An exception may be the long-term effects of exposure to accidentally emitted chemicals such as dioxins (Seveso). These effects, however, are never included in "normal" risk analyses for chemical plants.

On the other hand, when assessing the environmental aspects of possible applications of radioactive substances and radiation, the main effects of ionizing radiation taken into consideration nowadays are delayed effects, with the possible exception of the planning of new nuclear power plants. Assumptions on these delayed effects involve assumptions on the duration and pathways of exposure. Often complicated processes and pathways of environmental dispersion related to inhalation and ingestion of contaminated food are critical in the risk calculations.

Furthermore, risk analyses for the collective exposure of populations to ionizing radiation are based on assumptions related to the age distribution of the population, food intake etc. The individual population risk is obtained by dividing the collective risk by the total population. This approach is hardly or not at all comparable with the assumption of the "unprotected individual" as used in the field of chemical safety. Nevertheless the resulting figures are both designated individual risk and as such are taken to be directly comparable.

The same applies when this "individual risk" is being compared with other risk sources, such as the aforementioned driving or flying. Yet, many publications do present seemingly unambiguous lists of risks, usually trying to prove the apparent innocence of some source of risk.

WHAT SHOULD BE DONE?

There is a clear and urgent need for clarification and, if possible, harmonization of terms, procedures and assumptions, driven by the continued difficulties that arise in making policies and explaining them to the public. Several efforts have been made, or are still in progress, to at least clarify the terms of reference in the various fields. The efforts of the ICRP in radiation protection have already been mentioned. A recent document of the Health and Safety Executive in the United Kingdom (6) is an example of an attempt in the field of industrial safety to clarify several important aspects. A project under the auspices of the expert group on chemical accidents of the OECD is under way. However, to our knowledge all these activities are limited to only one of the fields previously mentioned, whereas in the opinion of policy-makers and the general public clear interactions exist.

What is even more striking is that, with the exception of ICRP, all attempts at clarification and harmonization originate from the policy scene. The participation of the scientific and technical community is limited. However, scientists are the originators of information forming the basis for policy decisions. It is therefore vital for continued or reinstated trust in these analyses that scientists be unambiguous about what they mean when presenting a number as the result of an analysis. For the further development of the field of risk analysis it would be of great importance if scientists and experts came together to clarify and organize their doings in a more interdisciplinary way.

A simple academic exchange of ideas and viewpoints alone does not seem to suffice. This year a project was started at the National Institute of Public Health and the Environment (RIVM) to present different types of risks geographical and coherently. In this so-called CUMU-project geographical mapping of risks and the use of GIS technology is proving to be a way to a useful organisation of discussions between experts on risk from different disciplines. Mapping risks forces the participants to take the whole chain, from source to risk, into consideration, and to reflect on their own premisses and axioms. During the mapping process a confrontation with the more philosophical aspects of risk comparability is almost inevitable. However, such discussions take place in the positive atmosphere of working together towards a collectively produced "risk map". In this way, making the relevant positions explicit is more fruitful than in comparing risk approaches as such without a common goal. We feel that this approach may be of a wider significance than for this project only.

To facilitate further discussion, RIVM plans to organize a conference on risk-map technology and risk comparison in the spring of 1997. In our opinion, active participation in activities aimed at crossing borders between the different fields of "risk" and contributing to more broadly coherent ways of risk assessment and risk communication could be of great interest to the radiation protection community.

HEALTH PHYSICS EDUCATION AND TRAINING IN IRAN

M. Sohrabi

National Radiation Protection Department
Atomic Energy Organization of Iran
P. O. Box 14155-4494, Tehran
Islamic Republic of Iran

ABSTRACT

Health physics education and training (HPET) are close counterparts for an effective enforcement of radiation protection (RP) regulations and development of an advanced RP infrastructure in a country. The related history in Iran dates back to over 30 years ago advancing towards promotion of a "Sustainable Training Program" (STP) through programs such as academic courses, intensive courses, research, on-the-job training and media training. The STP has been effective in development of an advanced national infrastructure for effective enforcement of regulations in different applications and provision of self-sustained national services. In this paper, the elements of a long-term national STP are discussed with a hope it could act as a model in developing countries.

INTRODUCTION

The history, status (1) and infrastructure of radiation protection (RP) in Iran as well as on health physics education and training (HPET) up to 1990 have been reported before (2). As regards to HPET, this author believes that they are powerful counterparts for enforcement of regulations and they should be implemented far before promulgation of a law (3,4). This is the case especially in Iran where RP regulations have been implemented based on international regulations even far before promulgation of the AEOI Act of Iran (3) and the RP Act of Iran (4). The author also believes that although international agencies could support RP manpower training of developing countries, experiences in Iran shows that developing countries should develop a "Sustainable Training Program" (STP) through academic courses, intensive courses, research, on-the-job training and media training. The elements of STP as implemented in Iran are discussed in this paper with a hope they could also be applied as a model in developing countries.

1. ACADEMIC TRAINING PROGRAMS

The university academic degree programs can be a major part of a STP in a country for development of qualified manpower and radiation protection infrastructure. Early in 1960's, the first formal courses related to radiation protection offered in the MSc program in physics of the University of Tehran (UT) including three credit hour courses on health physics, nuclear physics, reactor physics, cosmic ray physics, radiation detection, nuclear electronics, etc. Further potential for specialization in health physics has been through MSc theses in health physics from different universities (e.g. see ref. 5 and other papers of the author at this congress). Also, a MSc degree program was organized by the Health Faculty of the UT in cooperation with the World Health Organization (WHO) twice during 1973 to 1975. In 1977, the NRPD at AEOI also organized a MSc equivalent program through which about 30 health physicists have been trained. The graduates of this program and many others trained are now serving as health physics officers at the AEOI and in many other institutions. At present, courses in health physics, nuclear physics and radiation detection are being offered at BSc level in almost all technical universities in Iran. Since 1987, MSc and PhD programs in nuclear science and technology with options in Health Physics and in Radiation Medicine Engineering have been established at the Amirkabeer Technical University in Tehran in cooperation with the AEOI. A MSc program in Nuclear

Science and Technology has also been established around 1988 at the Sherif Technical University in Tehran with options in Health Physics and in Medical Radiation Engineering. Some MSc programs in Medical Physics are also being offered in some medical universities. All these programs will assist in manpower development for a strong national infrastructure on radiation protection.

2. INTENSIVE COURSE PROGRAMS

Intensive short courses have been a major component of development of RP infrastructure in Iran for over thirty years and in particular within the last decade. A six weeks course on "Radioisotope Applications" has been offered many times since 1960 for safe peaceful applications of radioactive materials. Since then, many intensive courses related to health physics have been conducted. In 1985, to establish a strong base for implementation of regulations of RP Act of Iran to be promulgated (4), a STP by provision of intensive courses was established for workers in medicine, industry, research and education. The courses consist of 100 hours of theory and practice in four weeks. The courses are mandatory to be taken before starting any radiation work of potential health hazard such as for example in industrial radiography. Up to now, 44 intensive courses have been organized with about 2300 participants. The courses usually have one preliminary exam at the beginning, one at the end of each week and one exam two weeks after the termination of the course. About 50% of the participants usually pass the course and receive a certificate. Those failed in the final exam have the chance to take it once again; if not successful, the course should be taken again.

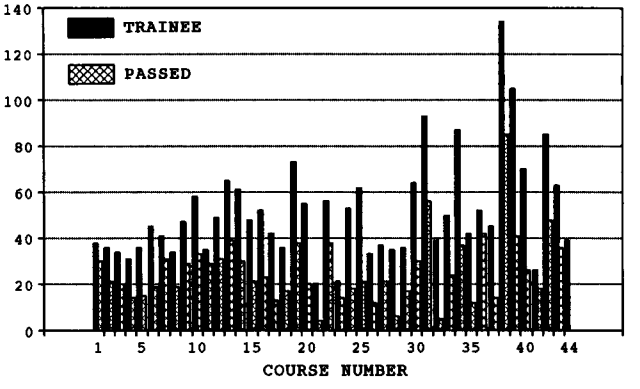

Fig. 1. Number of examinees (solid bar) and those passed the exams (dotted bar).

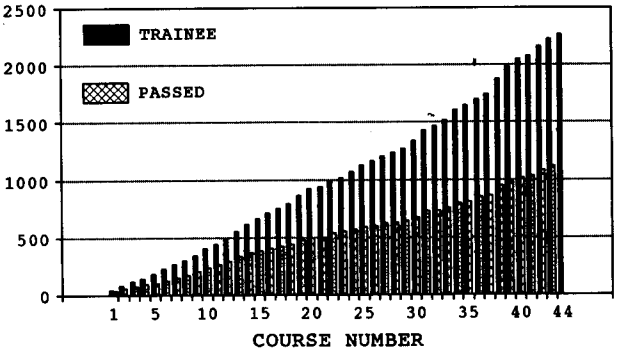

Fig. 2. Cumulative number of participants and those passed the exams.

Figure 1 shows the number of participants taking the final exam for the first or second time (solid bar) and those passed the exam and received a certificate (dotted bar). Figure 2 shows the cumulative bar chart of the number of participants (solid bars) and those passed the exam and received a certificate (dotted bars). This author believes that even those failed, just by their presence in the lectures have gained enough knowledge and experience to protect themselves and the others.
Also, regional and interregional IAEA courses have also been organized; e.g. a two-weeks interregional course on "Handling of Radiation Accidents" organized by TUNC in 1967 and a four-weeks regional training course on "Notification, Registration, Licensing and Control of Radiation Sources and Installations" again sponsored by IAEA and organized by the NRPD in August 1995.

3. RESEARCH TRAINING PROGRAMS

Research programs in health physics through MSc and PhD theses are also an important component of a STP. For example, so far as the NRPD alone is concerned, about 50 MSc and PhD theses have been conducted under the supervision of this author on topics related to radiation detection and dosimetry development and measurements using SSNTDs, TLDs, gas detectors, etc.; determination of genetically significant dose (GSD) in Iran; quality assurance in radiotherapy, diagnostic radiology, mammography, CT scan, nuclear medicine, etc.; radon dosimetry; studies in high level natural radiation areas; non-ionizing radiation, etc. Such programs are also conducted in medical and technical universities and some other research institutions. BY these programs, the country is relatively self-sufficient for development of health physics manpower bearing in mind that always international exchange of information and cooperations are vital.

4. ON-THE-JOB TRAINING PROGRAMS

In parallel to the manpower development given above, on-the-job training of staff and radiation workers have been advanced at the NRPD and other institutions such as in hospitals and through fellowship programs of the IAEA. This is also a major counterpart of development of manpower. The NRPD has also been the host country for many IAEA fellows to have special training at the NRPD.

5. MEDIA TRAINING PROGRAMS

The media training programs have been carried out by TV, radio, journal articles, brochures, posters, etc. This has been in particular very effective for control of public exposures as regards to medicine and fetus exposure control. Such topical programs are occasionally carried out for public awareness to an extent not causing radiophobia.

CONCLUSION

The above programs have been very effective for efficient implementation of radiation protection regulations in the country. Based on experiences gained, the STP is the only apporach to meet the minimum radiation protection requirements in a country and to promote an advanced program.

Remember When Science Was Fun? Encountering "Nuclear Fallout In Your Wood Stove" and Other Mysteries at the Northwestern New Mexico Regional and State Science and Engineering Fairs

James M. Hylko and Mark L. Miller
Roy F. Weston, Inc., 6501 Americas Parkway NE, Suite 800
Albuquerque, New Mexico 87110 USA

INTRODUCTION

The Rio Grande Chapter of the Health Physics Society is a proud supporter of the Northwestern New Mexico Regional and State Science and Engineering Fairs. In this role, the Chapter provides judges and furnishes monetary awards to recognize those students, between grades 6-12, and their teachers whose projects include the utilization or investigation of ionizing (e.g., gamma) or non-ionizing (e.g., UV exposure, microwaves) radiation. The Chapter promotes public information and education about health physics by sending every award winner and sponsoring teacher a copy of *Career Opportunities in Health Physics*, including information about degree programs and scholarships. Also, the Chapter provides a 1-year free subscription to the *Rio Grande Chapter Newsletter*, and publishes the names of the award winners, the titles of their projects, the names of their teachers, and the names of their schools. Furthermore, Chapter members are encouraged to assist contestants and award winners by providing mentoring opportunities, and educational resources such as textbooks. This paper reviews the Rio Grande Chapter Science and Engineering Fair Program with respect to judging categories and criteria, project titles, what the Chapter has learned from the students, and an overview of the 1995 Regional, State, and International Science and Engineering Fair Programs.

JUDGING CATEGORIES AND CRITERIA

The students may enter their projects in one of the following categories:

Behavioral and Social Sciences	Environmental Science	Botany
Mathematics	Biochemistry (Senior Division Only)	Medicine and Health
Chemistry	Microbiology	Computer Science
Physics	Earth and Space Sciences	Zoology
Engineering	Team Projects	

The judging criteria issued to the students by the International Science Fair Program provides guidance regarding the display, use of materials, and safety. Nevertheless, the primary responsibility of the judge is to evaluate the collection and interpretation of the data, and only secondarily, to scrutinize the physical display of the project. The actual judging criteria, the percentage contributing to the student's score, including questions and considerations during the evaluation process are as follows: **Scientific Thought/Engineering Goals (30%)** - A) Does the student understand the fundamental scientific principles involved with the project? B) Are the conclusions formulated clearly and follow the presentation? C) Does the student recognize sources of error or alternative interpretations? **Thoroughness (15%)** - A) Does the project show care and dedication, or was it thrown together hastily? B) Does the quality of the project show consistency with the stated objective? **Skill (15%)** - A) Does the project reflect the ability of the student? B) The student is not penalized for lack of craftsmanship or experience in working with materials, since many students may have highly developed skills in certain areas. C) Reservations about the ability of the student to complete the type of project on display can be evaluated during the interview. **Creative Ability (30%)** - A) Does the student present a fresh approach to a problem, or merely copied an experiment already documented in the peer-reviewed literature? B) Does the student make ingenious use of materials and/or equipment? C) Does the student formulate the problem to obtain meaningful answers that are within the intellectual capacity, training, and means of a middle school or high school student? **Exposition (10%)** - A) Proper exposition of the information using graphs, illustrations, and the written report will convey the main ideas and results after a few minutes of observation. **Teamwork (Team Projects Only)** - A) Does the project identify the tasks and contributions of each team member? B) Does each team member appear to be fully involved, and familiar with all aspects of the project? C) Does the final exhibit reflect the coordinated efforts of all team members?

Perhaps the most educational and rewarding aspect of the science and engineering fair, for both participants and judges, is the interview. The interview allows the judge an opportunity to discuss one-on-one with the student the source of ideas, the basic scientific principles and methods used to develop the project, and significance of the conclusions. During the interview, the judge can also suggest methods to improve collection and interpretation of scientific data. In addition, the judge can notify colleagues at nearby laboratories and universities to either donate equipment to the schools directly or make equipment and facilities available to conduct additional experiments. The access to advanced equipment provides an opportunity for the student to collect supplemental data to test their hypotheses using hands-on experimental techniques.

PROJECT TITLES

A sampling of the project titles from the Regional and State Science and Engineering Fairs are as follows:

Radiation Roundup (Natural and Man-Made Sources).
Does Radiation Affect Seed Fertility?
WIPP - How Does it Affect You?
How Radioactivity Levels in Soil Differ Across the North-Central Region of New Mexico.
Radon vs. Home Construction.
Nuclear Energy (Observing Radioactivity).
Effects of UV-B Radiation on the Biosynthesis of Amino Acids in Plants.
Nuclear Fallout in Your Wood Stove.
Does an Electromagnetic Field Affect the Germination and Growth of Plants?
Can Microwaves Kill Bacteria on a Contact Lens?
Does an Electromagnetic Field Affect the Rate of Mutation in *Drosophila melanogaster*?
Making Water Safe: UV the Culprit Becomes UV the Hero.
What are the Effects of Microwave Radiation on Bean Seeds?
Zap It - Microwaves vs. Bacteria.
What are the Effects of UV-B Radiation Upon the Biosynthesis of Amino Acids in Plants and Upon Plant Growth?
Particle Acceleration.
Light Wavelength and Fungal Growth.
Does Sunscreen Really Block Ultraviolet Light?
The Effects of UV Light on the Chlorophyll of *Isochrysis galbana*.

WHAT THE CHAPTER HAS LEARNED FROM THE STUDENTS

After interviewing teachers and students, the representatives from the Chapter have discovered that the immediate availability of equipment determines the scope of the project. Typically, the students will conduct experiments monitoring the effects of plants, etc. following exposure to ultraviolet light, microwaves, and electromagnetic fields (i.e., non-ionizing radiation). Usually, students whose parents are employed in the health physics profession (e.g., X-ray technician) will conduct their experiments using ionizing radiation.

THE 1995 REGIONAL, STATE, AND INTERNATIONAL SCIENCE AND ENGINEERING FAIR PROGRAMS

The following information provides an overview of the 1995 Regional, State, and International Science and Engineering Fair Programs.

Northwestern New Mexico (NWNM) Regional Science and Engineering Fair Program

- The NWNM Regional Science and Engineering Fair takes place every March.
- The NWNM region includes approximately 70 schools.
- 737 (162 senior and 575 junior) students participated in 1995.
- 110 students qualified to compete at the State of New Mexico Science and Engineering Fair.
- 2 students and 2 alternates qualified for the International Science and Engineering Fair held in Hamilton, Ontario, Canada.
- The Program Committee hosts a teacher workshop every August to evaluate suggestions for enhancing the science fair program. A sampling of enhancements have included, but are not limited to the following:
    - A) Informing new middle school and high school science teachers about the NWNM Science and Engineering Fair Program, and establishing a database for future correspondence.

B) Generating new ideas for future science fairs (e.g., team projects).
C) Involving corporate and organizational displays.

- The Mentorship Program provides professional contacts with experts, and produces national champions at the International Science and Engineering Fair.

The 43rd Annual State of New Mexico Science and Engineering Fair Program

- The State of New Mexico Science and Engineering Fair takes place every April.
- The State of New Mexico Science and Engineering Fair includes 6 regions.
- 325 total (136 senior and 189 junior, 12 senior and 14 junior team projects) students participated in 1995.
- Winners from the senior division proceed to the International Science and Engineering Fair.

The International Science and Engineering Fair Program

- The International Science and Engineering Fair represents the United States, U.S. Territories, and 29 International Affiliated Science Fairs throughout the world.
- 1019 students participated in 1995.
- Primary communication is with the Fair Directors of the various Regional, State, and International Affiliated Science Fairs.
- The 47th International Science and Engineering Fair will take place in Tucson, Arizona, May 5-11, 1996.

CONCLUSION

The Regional, State, and International Science and Engineering Fair Programs provide tremendous opportunities for students and teachers to meet and interact with professionals from the field of health physics. Although the professionals possess strong backgrounds in the application and control of ionizing radiation, most students conduct experiments using non-ionizing radiation because of the availability of generating sources. Based on personal interviews, students and teachers will exclude the use of ionizing radiation because of the perceived dangers, or the lack of access to specialized equipment. Nevertheless, the Rio Grande Chapter is notifying teachers and students about the availability of resources (e.g., radioactive sources, detection and measurement equipment, neutron activation analysis) at nearby laboratories and universities to perform experiments using ionizing radiation. The information contained herein furnishes valuable insight to enhance future science fair programs, and serves as a guide for those individuals wishing to increase their involvement with these and similar programs (e.g., mentoring) that are available to students wishing to explore career opportunities in health physics.

TRAINING COURSE FOR BORDER GUARDS ORGANIZED BY THE INSTITUTE OF ATOMIC ENERGY IN ŚWIERK, POLAND

N. Golnik, J. Janeczek, B. Filipiak and Z. Haratym
Institute of Atomic Energy, 05-400 Otwock, Świerk, Poland

INTRODUCTION

Danger of illegal trade in radioactive and fissile material has recently increased due to disintegration of the former Soviet Union. A substantial part of these materials is suspected to be smuggled through Poland to Western Europe. Proper countermeasures like establishing radiation detecting gates at border crossings and specific training programs for border guards have been set up by Polish authorities.
On request of Polish Border Guard Command the Institute of Atomic Energy (IAE) has prepared a series of training courses for border guard officers. The courses covered both theoretical and practical subjects concerned with radiation safety and were focused on detection and safeguarding of radioactive or fissile material at border crossings.

THE PURPOSE OF THE COURSE

The main subject areas covered by the course included: transport regulations for radioactive materials, radiation protection safety procedures, operation of radiation survey meters and physical properties of fissile materials. Since border guard officers could not spend much time off their posts, the duration of the course had to be limited to three days of intensive training. Emphasis was laid on developing practical skills in detecting and safeguarding of nuclear material. The practical part covered also hands on experience in measurement of radiation, decontamination of areas and persons, and setting up radiation safety zones.

The syllabus of the course was evaluated and approved by the Polish Atomic Energy Agency. A handbook covering the course material was edited in Radiation Protection Division of IAE and published by the Institute's Publishing Division. The handbook contained texts of all lectures and technical parameters of radiation monitors used during the course. There was also included a complete set of example documents accompanying isotopic sources in transport and their marking.

SYLLABUS OF THE COURSE

1. Elementary information on ionizing radiation

- types of radiation and their properties (alpha, beta; range, penetration power)
- natural and man-made radiation sources (exposure of the population to these sources)
- basic concepts and quantities (activity, Radioactive Decay Law, half-life)
- types of radiation sources (radioisotope sources opened and sealed, radiation generators)

Demonstration: basic properties of alpha, beta and gamma radiation.
The aim was to distinguish different types of radiation and act accordingly in protecting yourself and the general public when the source is found. To know what activity means and how it is changing with time.

2. Exposure to ionizing radiation

- biological effects of radiation (health hazard resulting from exposure to ionizing radiation)
- internal and external exposure and methods to limit these
- dose limits for occupationally exposed persons and for members of general public
- characteristics of potential exposure at border crossings

Demonstration: penetrating power of alpha, beta and gamma radiation; shielding.
The aim of this lecture was to make trainees aware of the danger of exposure to ionizing radiation. They were also practicing with the role of distance, time and shielding in limiting external exposure with numerical examples. Past incidents with radiation sources on border crossings were called on and evaluated as examples.

3. Assessment of internal and external exposure

- measurement of external exposure (dose rate and contamination measurements, personal dose)
- measurement of internal (whole body counter, thyroid activity counter, activity of excreta)
- basic rules of work in contaminated areas (radiation safety zone, decontamination procedure)

Each trainee was asked to perform decontamination of himself and of a given area. Direct and indirect (smear test) measurements of contamination were performed using alpha and beta calibration sources.

4. Operation of dosimetric equipment

- radiation monitors different types
- contamination monitors for measurement of alpha, beta and gamma contamination
- radiation detection gate (type installed at border crossings)

The trainees were operating monitors under conditions of a simulated radiation accident. They were also taught how to prepare and check the monitor before starting measurement.

5. Isotope transport regulations

- dose limits and transport regulations for radioactive materials (according to international standards)
- transport of radioactive materials (containers, marking, surface dose rate limits, documentation)
- regulations concerning vehicles for transport of radioactive materials

Demonstration: containers, packets and their marking

6. Practical training and demonstrations

- practical operation of radiation measuring devices
- detection and safeguarding of radiation source (use of manipulators, containers and shielding)
- demonstration of different radiation source packing and transport documentation
- demonstration of specialized laboratories of IAE (whole body counter, thyroid activity counter, spectrometric laboratory)
- a visit to fissile material store (uranium of different shapes, plutonium containers and fuel elemnets)

CONCLUSIONS

Two series of courses were organized and altogether 300 border guard officers were trained in 1994. Each course was concluded with a theoretical and practical examination. The practical part consisted of a simulated radiation accident arranged with low activity calibration sources. The trainee was asked to resolve the situation according to the rules. All important elements from the practical part of the syllabus were involved in the examination together with relevant regulations.
Each trainee was given a copy of the handbook for future reference.

THE ROLE OF INFORMATION, EDUCATION AND TRAINING IN REDUCING DOSES

J.J. LE COZ - J. ABRAS
Department of Safety, Radiation Protection and the Environment
EDF/DEPT, SAINT-DENIS (FRANCE)

SUMMARY

During the early years of EDF's nuclear reactor construction programme, there was intensive initial training aimed at informing new generations of workers of the work they were going to doing. This ambitious objective, aimed at putting an increasing number of units into service in total safety and at rates of up to 6 to 8 units per year, was a success.

The mass training programme which centralised and concentrated on knowledge of the process and procedures, was ideally suited to the requirements of a standard population of reactors and to the various trades concerned, which were less varied and numerous than those of today. The present situation is slightly different and training should be directed towards the experience of operations, retrofits and knowledge of new technologies.

Accordingly, we have moved towards a more individual style of management for a greater body of knowledge.

The population concerned consists of some 50 000 workers. This document sets out the policy implemented by EDF:

- mobilisation of EDF managers and contractors,
- integrating the ALARA concept into specific operations,
- reducing the amount of information.

Today, the ALARA concept represents an excellent opportunity for making progress. Man, his knowledge, his experience and initiative, represents the most important source for progress in the field of radiological protection. In order to be able to use his creative potential to the full, man must be imbibed with both a radiological protection culture and a safety culture. This must be the main priority of nuclear operators.

FOREWORD

In order to provide quality electricity generation at the lowest possible cost and under the best possible conditions of security and safety within its installations, EDF must:

- develop the professionalism of the people concerned through operation itself (EDF personnel) and maintenance operations (EDF and contractor personnel);

- improve and maintain the safety and quality culture;

- improve the quality of relationships between those involved in maintenance by enabling them to become part of a close partnership approach.

EDF's DOSIMETRY POLICY

Since 1991, EDF has committed itself to a policy of optimising collective dosimetry and this has already resulted in a reduction of approximately one third over five years. This will to succeed is being maintained to make EDF one of the best nuclear operators in the world.

In so far as personal dosimetry is concerned, the objective of not more than 20 mSv for each worker should be achieved before the year 2000.

For this, it was decided to implement systematically the concept of the optimisation of dosimetry (ALARA). The various aspects which influence dosimetry (training, operation, maintenance, experience feedback, information processing system, etc.) are described in terms of progress.

INFORMATION AND TRAINING ON THE OPTIMISATION OF DOSIMETRY

An initial analysis of the reasons for high dosimetry has shown that significant improvements can be made by basing information on an extremely simple concept, the ALARA concept: defining dosimetric targets during operational preparation, measuring performances through site monitoring, analysis of discrepancies (and, if necessary, corrective actions) and obtaining feedback of experience after completion.

It was decided to embark on a campaign of awareness for EDF managers and for contractors. The performance and durability of radiological protection depend first on the total commitment of senior management followed by the rest of the employees. Getting men to reflect carefully before taking decisions, rejecting improvisation, adopting a systematic approach to solving problems, identifying and controlling doses is not a natural process and only senior management can initiate and develop this style of management in accordance with the requirements and specific nature of the company (heat lagging, auxiliaries, valves and fittings).

The second stage could be called "communications in the field". Communications with workers is the responsibility of both the contractor and of EDF personnel (training on arrival on site, ALARA posters, displaying dosimetry targets and performance for unit shutdowns, presence of an ALARA team on the site, etc.).

The sites with the worst records were analysed according to the ALARA concept and dosimetry targets are fixed together by the contractor and EDF when orders are placed. For certain operations, models are used to train operators.

Extension towards more detailed analysis, through collective dosimetry targets, is being considered for 1996.

In so far as prototype sites are concerned, EDF operates a specialised centre, the CETIC, where it is possible to develop certain operations (actions and positions of workers, tool modifications, etc.).

CONCLUSION

EDF, together with its contractors, should return to being one of the leading nuclear operators in terms of radiological protection. The required optimisation of dosimetry will be achieved through the awareness of all those concerned (senior managers, managers and other workers), training in the ALARA concept, increased professionalism including careful preparation, monitoring of operations (dosimetry and quality), training on models, if necessary, and experience feedback from sites.

All this, of course, goes to create the radiological protection and safety culture of everybody concerned within the nuclear industry.

SYSTEM OF REGIONAL CENTRES OF FIRST AID IN CASES OF RADIATION ACCIDENTS IN GERMANY

F. Fehringer, G. Seitz

Berufsgenossenschaft der Feinmechanik und Elektrotechnik, Köln
Industrial Injuries Insurance Institute for the Electrical Industry including Precision Mechanics, Cologne

When in the seventies the number of occupational radiation exposed persons in the Federal Republic of Germany increased from about 35,000 (1974) to about 160,000 (1978) the Industrial Injuries Insurance Institutes felt prompted to reflect about special measures to prevent radiation accidents and provide health care for this special cases. They did so without any actual occasion: accidents were persons have been exposed by ionizing radiation were in the seventies just as rare as today. But that fact does not allow the Industrial Injuries Insurance Institutes to neglect the existing potential for severe accidents.

So the Industrial Injuries Insurance Institute for the Electrical Industry including Precision Mechanics and the Industrial Injuries Insurance Institute for the Chemical Industry created the Institute for Radiation Protection in 1978. The primary task of that Institute is to guarantee an effective first aid in the case of a radiation accident.

To realize that task the Institute contracted 11 wellknwon institutions like radiological departments of large hospitals or the medical departments of research centres where the knowledge on diagnostic and therapy of radiation effects is present. They are called „Regionale Strahlenschutzzentren", Regional Centres for Radiation Protection (RCRP) (Fig. 1).

In the case of radiation accidents these RCRP are the logistical centres for all arising questions of treatment. They have facilities for reconstructing exposure situations and assessing and evaluating doses, including measurements of internal contamination, as well as for medical in-patient or out-patient treating like internal or external decontamination.

Another important task of the RCRP is to advise employers in all radiation protection questions which arise with the industrial application of ionizing radiation. Of course the centres give also answer to many question from members of the public, for example the personal effects of the power plant accident at Chernobyl.

The Institute for Radiation Protection offers regularly training courses and lectures to the stuff of the RCRP. That is necessary because radiation accidents are seldom in the Federal Republic of Germany and therefore the stuff can not keep practical experiences. For that reason the offered training courses impart practical training as well as theoretical foundations. Confronting the participants with hypothetical radiation accidents is basic part of the courses.

These training courses also provide the contact between the stuff of the RCRP among each other and to a team of excellent experts on the field of radiation protection and radiation protection medicine. These experts can be contacted from the RCRP in the case of a radiation accident. Additionally the Institute invites representatives of the state authorities and of the

industrial branches where ionizing radiation is applied. In the last 13 years about 500 persons have taken part in the training courses.

Additionally to the training courses the Institute supports the RCRP by sending information about actual news in the fields of radiation protection and radiation protection medicine.

THE CONCEPT OF RADIOECOLOGY EDUCATION IN BELARUS

Alexander M. Lutsko, Valeri L. Gurachevski, Alexander A. Milutin,
Andrei I. Timoshchenko, Vladimir A. Figurin

1. INTRODUCTION

The lack of adequate radioecological education and hence, 'radiation ignorance' is almost notorious for the whole world. During the last decade the world power producing companies have issued a great number of colourful booklets and information materials designed for totally unprepared public. They undoubtedly contribute to advertising the atomic energy but do not provide useful radiation related information as mostly comprise general knowledge on e.g. the atom structure or NPP operation principles covered in a very much elementary if not primitive way.

Meanwhile the atomic energy is becoming a substantial element of the environment and calling for much more serious and adequate information. In this context the population of Belarus as the most suffered from the Chernobyl accident with the anthropogenious radioactivity continue affecting almost all the spheres of man's activity must know about radiation no less then about electricity.

Had the people of Belarus been duly informed and at least initially educated in the elementary methods of individual radiation protection and agriculture production control, had they been aware in psychological peculiarities of life in the contaminated territories along with the sufficient number of specialists with the expertise required for working out the recommendations for those who were to make decisions, the consequences of the Chernobyl disaster, including social, psychological and medical aspects, could have appeared not so heavy; the efficiency of protective measures undertaken at that time might also have been much higher then that had been observed. The necessity of general and obligative radioecological education follows from the long-term character of Chernobyl disaster consequences, geographical position of Belarus (some nuclear power plants (NPPs) of other countries are operating now near its boarders), the claim of the strict radiation control in all branches of economy including export and import.

A certain work to develop the system of radioecological education in Belarus was carried out. According to decision of the Ministry of Education and Science in 1989 the radiation safety disciplines were included in the academic plans of all secondary and higher schools. In 1992 the International Sakharov College of Radioecology (now it is the Institute, ISIR) was opened in Minsk and the training of the specialists with higher education in radioecology has been begun. In some institutes like Belarusian Agricultural Academy special radioecological chairs are opened. The training and retraining of the specialists for radiation control network and activities is targeted to mitigate the consequences of the Chernobyl accident and it is supervised by the Training Informing and Radioecological Centre of the Management Academy of the President of Belarus.

At the time being the text books on radiation protection, unique as they are as there are no analogous in the world, have already been published and in mass edition in Belarus.

Nevertheless, there has been neither a unified concept of radioecological education developed yet nor the integral educational system purposefully designed for teaching radioecological disciplines at various educational levels. The latter is of special concern and importance as the social tension is being induced by the lack of knowledge in behaviour of the radioactive materials and substances exercised by all age groups of population living in the contaminated territories. The problem is even more aggravated by the fact that before the Chernobyl accident the radiation culture, i.e. standard

knowledge on radiation protection did not exist at all. Consequently, the decisions on elimination the consequence of the Chernobyl accident made at the amateur level were inefficient and regretfully still remain so.

It has led to the following objective discrepancies arisen, developed and/or become profound between

- necessity to provide vital activity of the Belarusian population within complicated radioecological conditions and the level of the population's awareness in questions of radiation safety;
- necessity of psychological rehabilitation of Belarusian population and the absence of corresponding programmes of radioecological education and enlightenment;
- nessecity of qualified and efficient managing the mitigation of the Chernobyl accident consequences and the state of the radioecological knowledge among decision-markers of all levels;
- nessecity of wide range employment of ionising radiation in different human activities and unsatisfactory knowledge of its features among workers;

The concept proposed below is worked out in correspondence to the more general "Conception of protection measures in reconstructing period for population resided at the Belarus territory suffered by radioactive contamination because of the Chernobyl disaster" adopted by Cabinet of Ministers of Belarus. It is based at the current view of the Chernobyl problems in reconstruction period and on experience of the world science.

2. BASIC STATEMENTS OF THE CONCEPT

2.1. The radioecological education is the intermediate part of the Belarus national educational system and is targeted to form a current knowledge for adequate understanding and apprehending of wide range of problems connected with radiation impact on the environment and a human being, employment of ionising radiation in national economy and alleviation of consequences of radiation incidents, accidents and disasters.

2.2. The radioecological education should be spread over the whole adult population. It is suggested as for citizens educated at traditional educational levels (secondary, special secondary and higher levels of education, the network of training and retraining specialists) but for another part of population through their enlightenment and informing on questions of radiation safety and hygiene.

2.3. The content of the radioecological education at different levels is formed by taking into account the basics of scientific knowledge just formed among students and is the same for definite categories of students .

2.4. In secondary and special secondary schools the radioecology is introduced as the obligative subject at graduate courses.

2.5. In higher institutions the radioecology is delivered obligatevely. Its content depends on a training speciality profile. In higher institutions training specialists on radioecology the separate subject on general radioecology can be not introduced.

2.6. The content of radioecological education within the network of training and retraining specialists is defined by corresponding programmes of the Ministries, Councils and Boards supervising the organisations which deliver their workers to train or to retrain.

2.7. The enlightenment and informing of population in questions of radioecology is conducted at the base of special permanently operating studying, consulting and informing centres of radiation safety and hygiene placed in large towns and district centres of polluted areas of Belarus. The special attention should be paid to residents of

contaminated territories, resettled citizens, clean-up workers and people residing within the 30-km zones round operating NPPs.

2.8. To satisfy needs of the Republic in specialists on radioecology including training the academic staff the creation of profiled higher and special secondary institutions or opening special departments in existing institutions is required.

3. REALISATION OF THE CONCEPT

Taking into consideration the difficult economic situation in the country it is clear that the realization of the conception must start with the most effectual measures, which would lead to the best results with minimum expenditures.

3.1.At the secondary educational level the compulsory radiation protection course must be introduced in the school-leavers forms in the most suffered Gomel, Mogilev, Brest regions using the textbooks editted in 1994. It needs to found special educational rooms to consult teachers (radiometric instruments, textbooks of methodics, posters carried out in ISIR) in the regions which were mentioned already.

3.2.To develop and to introduce special radiation safety programmes according to the age of the children from the suffered regions in health-improvement and rehabilitation centres using the textbooks editted in Belarus and equipping them with educational consulting rooms.

3.3.Prolonged consequences of the disaster demand urgent planning of the gradual substitution of the expert posts in the State Authorities making decisions connected with the problems effected by Chernobyl accident, by the specialists who received a special training in ISIR and retraining at the Republic Academy of management.

CONCLUSION

In the future radioecological education must become a multilevel training embracing various strata of society. In Belarus where the fifth part of the territory is polluted by the radiowastes it is necessary to know the personal protectional rules. It provides not only successful radiation safety but it also creates normal conditions of living and managing in the radiation environment.

The concrete ideas discussed at the special seminar where the interested organisations took part were presented to the Government of Belarus.

In the face of developing nuclear technologies the radiation accidents can not be excluded completely in future, and the efficiency of eliminating their consequences will greatly depend on the knowledge and expertise available, thus the experience acquired in Belarus in providing radioecological education, the various forms of which are being currently introduced into the national system of education might be helpful for many other countries.

THE NEED OF EDUCATION OF BIOTECHNICAL SPECIALISTS IN THE FIELD OF RADIATION PROTECTION

Ranko Kljajić[1], Z. Mašić[1], R. Mitrović[2], and B. Petrović[2]

[1]Scientific Institute for Veterinary Medicine, Novi Sad, Yugoslavia
[2]Scientific Institute for Veterinary Medicine of Serbia, Belgrade, Yugoslavia

ABSTRACT

Education is the base for a successful carrying out of radiation protection measures. Starting from this fact, in the field of biotechnology protection measures should be carried out by biotechnical specialists (veterinarians, agronomists, technologists). In FR Yugoslavia, at the Faculty of Veterinary Medicine a separate course "Radiobiology and radiation hygiene" was introduced in undergraduate and postgraduate studies in 1976. However, other biotechnological specialists do not study the field of radiation protection separately at their faculties. Because of this, the Expert Group for Radiation Protection in Biotechnology formed at the Federal Ministry of Economy initiated the introducing of a course for this field in undergraduate and postgraduate studies at the faculties of agriculture and technology in FR Yugoslavia.

This paper presents the basic elements of the educational plan and program of the course "Radiobiology and radiation hygiene" for students of biotechnical faculties in FR Yugoslavia and discusses the results obtained until now.

INTRODUCTION

Radiation protection is a wide and a complex field with a range of specific problems. To solve these problems, a multidisciplinar approach and team work, with participation of specialists of different profiles (physicists, chemists, veterinarians, agronomists, doctors, food technologists, lawyers, sociologists etc.) is necessary. Taking into consideration that for an effective undertaking of radiation protection the knowledge of main characteristics and effects of ionizing radiation is necessary, as well as of the characteristics of the milieu where radioactive substances are located and which they affect, the protection can only be successfully fulfilled by reciprocal connection of these knowledge (1,2).

In addition, the basis of each protection, and so of radiation protection, is the prevention, i.e. undertaking of measures that prevent the intake of radioactive substances into human organism. Since the main way of the intake of radioactive substances is the ingestion (intake through food - it makes 70% of the total intake), the most effective way from the aspect of prevention and protection is to break the chain, i.e. to prevent the food contamination in the process of production, processing and turnover. This task can most successfully be fulfilled by biotechnical specialists (agronomists, veterinarians and technologists), whose main task is the production of "healthy" food and indirectly also the protection of human health (3-5).

THE BASIS FOR INTRODUCING OF TEACHING

Taking into consideration that the danger of radioactive contamination of greater proportions considerably increased in the last period, not only because of the possible use of nuclear weapons but also because of a real danger of accidents on nuclear power plants in peaceful times, the education of biotechnical specialists from the field of radiation protection deserves much bigger attention.

In order to include biotechnical specialists equally and competently in solving complex problems of radiation protection, it is necessary to introduce a separate course from this field in undergraduate studies and to organize postgraduate studies at all biotechnical faculties (Faculty of Veterinary Medicine, Faculty of Agriculture, Faculty of Food Technology).

SITUATION IN FR YUGOSLAVIA

In the previous period, the education from the field of radiation protection in undergraduate and postgraduate studies of biotechnical specialists had only an informative character. An exception is the Faculty of Veterinary Medicine in Belgrade, where since 1976 the field of radiation protection has been separately studied in undergraduate and postgraduate studies.

At the end of 1992 a meeting of representatives of biochemical faculties in FR Yugoslavia, of the Federal and Republic Ministries of Agriculture as well as of the permanent Expert Group for Radiation Protection in Biotechnology was held, that was devoted to measures that should be carried out in the field of biochemistry to reduce the radiation risk. On the basis of adopted conclusions, the Expert Group for Radiation Protection worked out The Bases for Elaboration of Educational Plan and Programme for teaching in the field of radiation protection in biotechnology at biotechnical faculties (Faculty of Agriculture, Faculty of Veterinary Medicine and Faculty of Food Technology) in FR Yugoslavia.

BASES OF THE EDUCATIONAL PLAN AND PROGRAMME

1. *Title of the course:* "RADIATION HYGIENE AND PROTECTION IN BIOTECHNOLOGY"

2. *Aim:* Education and training of biotechnical specialist to became able to carry out production and population protection, to reduce the radiation risk and to provide the production of healthy food and fed by complete perceiving of the production cycle and food processing as well as by applying measures of radiation-hygienic prevention, control and protection.

3. *General teaching plan:* Teaching would be carried out during one semester at the end of the third or at the beginning of the forth year of studying (semester VI or VII) with 3 + 2 classes per week, i.e. 45 + 30 classes per semester.

4. *General teaching programme:* The teaching programme is conceived and standardized for all biotechnical faculties, but in certain chapters the focus and the content of the subject are adapted to particularities of individual faculties and majors (Faculty of Agriculture - Husbandry, Cattle-Raising, Fruit and Wine Growing, Plant and Food Protection, Melioration, Food Technology of Plant Products, Food Technology of Animal Products, Agroeconomy; Faculty of Veterinary Medicine; Faculty of Food Technology).

a) *Theoretical teaching - lectures:* The lectures include the following topics:
1. Introduction with theoretical base and elements of radioecology, radiobiology and radiation hygiene and protection;
2. Sources of ionizing radiation in the biosphere;
3. Ways of spreading, migration and transfer of radionuclides;
4. Characteristics and effects of ionizing radiation;
5. Detection and dosimetry of ionizing radiation, radiation values and units;
6. Radiation load and radiation risk;
7. Endangering of biotechnical production by radioactive contamination in normal occasions as well as in case of emergency;
8. Preventive protection measures from radioactive contamination;
9. Radiation protection in biotechnology;

10. Rehabilitation measures and radiation decontamination in biotechnical production;
11. Radiation-hygienic control of biotechnical production;
12. Radiation-hygienic expert opinion on soil, plants, animals, food, water and feed;
13. Organization of the biotechnical monitoring system in normal situations and in case of emergency;
14. Carrying out of measures of radiation-hygienic control and protection from the field of biotechnology during export, import and transport on the territory of Yugoslavia;
15. International and domestic standards, conventions and legislation from the field of radiation protection.

b) *Practical teaching - practice:* The practice includes the following topics:
1. Introduction and work in radiological laboratory;
2. Measuring instruments for the detection and dosimetry of ionizing radiation - introducing with characteristics and principles of work;
3. Measuring of the radiation phon and determination of KonZ;
4. Estimation of the semilethal and the lethal radiation dose;
5. Instruments for measuring of radioactivity level - their characteristics and principles of work;
6. Ways of sampling and sample preparing for measuring of radioactivity level;
7. Measuring of the total beta activity by using the anticoincidental beta counter - LARS-5;
8. Measuring of the total beta activity by using the method of thick-layer-sample in normal conditions - LARA-86;
9. Measuring of the total beta activity by using the method of thick-layer-sample in case of emergency - LARA-10;
10. Estimation of the consuming value of food;
11. Gamma and alpha spectrometry - demonstrative;
12. Decontamination of space and equipment - estimation of the decontamination effect.

The Expert Group took care that the plan and the programme are uniform, consistent and compatible for all biotechnical faculties and that they correspond to modern scientific knowledge from this field.

c) *Literature:* For carrying out the teaching and preparing exams there is a contemporary domestic literature, which is cited as references.

CONCLUSION

Introducing of irradiation protection in education of biotechnical experts would provide reducing of radiation risk for the population, more effective protection and control during import as well as the possibility of an equal and recognized participation in the international turnover and exchange.

The proposed bases of the teaching plan and programme can be very useful during introducing the radiation hygiene in the educational system for biotechnical specialists.

INFORMATION DES PROFESSIONS DE SANTE A ELECTRICITE DE FRANCE

INFORMATION FOR HEALTH PROFESSIONALS AT ELECTRICITE DE FRANCE

C. GALLIN-MARTEL[1], J. LALLEMAND[2], C. VROUSOS[3], H KOLODIÉ[4], H. PONS[5], M. DURR[6]

L'information des professionnels de santé dans le domaine des effets médicaux et sanitaires des rayonnements ionisants et de l'utilisation industrielle de l'énergie nucléaire reste trop souvent insuffisante et limitée aux spécialistes. Or de la qualité de cette information dépend pourtant en grande partie l'acceptation par la population d'un voisinage à risque potentiel et bien entendu ses réactions en cas d'incident ou d'accident. En effet, des différentes enquêtes réalisées, il apparaît qu'en situation normale, les professionnels de santé constituent des référents essentiels pour le public et qu'ils sont des relais d'information crédibles. En situation de crise, le champ de l'information rationnelle sera altéré par les rumeurs et la désinformation dont les conséquences en terme de santé publique peuvent être caractérisées par l'émergence de comportements inadaptés à l'échelle individuelle et collective. Dans cette situation, les médecins et pharmaciens, dont l'autorité morale et la compétence technique sont reconnues, auront un rôle essentiel de conseiller en santé publique à remplir auprès de la population.

Le corps médical perçoit à la fois le rôle que la population est susceptible de lui demander de remplir dans ces circonstances et son manque souvent très important d'informations adaptées. Interrogés sur les effets médicaux des rayonnements ionisants, les professionnels de santé déclarent être non ou mal informés à près de 90 %. Le même pourcentage souhaite être informé sur la conduite à tenir face à un irradié ou un contaminé et sur les mesures sanitaires de protection. Cette information doit transiter par l'intermédiaire de documents écrits à 58 %, de séances d'Enseignement Post-Universitaire (EPU) à 55 %, ou de colloques à 46 %. Concernant la formation initiale des médecins, il faut rappeler les résultats de l'enquête réalisée par questionnaire en 1992, auprès de 508 facultés de médecine de 24 états membres de l'OCDE. Plus de la moitié de ces facultés n'offrent pas un enseignement organisé de radiopathologie et de radioécologie durant le cursus des études médicales. Sur les établissements qui déclarent enseigner ces matières, seuls 18 % exigent un contrôle de connaissances.

Face à cette attente de formation et d'information des professionnels de santé, EDF a décidé de réaliser une information objective, validée scientifiquement, crédible et adaptée aux lecteurs. C'est dans ce but que des spécialistes hospitalo-universitaires, des représentants des Ordres et des organisations syndicales respectives, des responsables de la formation continue et des grandes administrations impliquées, sont associés à la réalisation des documents publiés au plan national et aux séances d'enseignement post-universitaire organisées au niveau

Information for health professionals on the medical and health effects of ionising radiation and the industrial use of nuclear energy is all too often inadequate and restricted to specialists in this field. Yet the quality of such information depends to a great extent on its acceptance by the population living close to a potential risk and its reaction in the event of an incident or accident. Indeed, from various studies, it would appear that, under normal conditions, health professional represent a reference and credible source of information for the public. However, in crisis situations, the range of rational information will be distorted by rumours and misinformation, the consequences of which, in terms of public health are reflected by the emergence of unsuitable individual and collective behaviour. Under such circumstances, doctors and pharmacists, whose moral authority and technical competence are recognised, will play an essential role in giving public health advice to the population concerned.

The medical profession sees the role that the public is likely to require it to adopt under such circumstances in the light of its often significant lack of suitable information. When questioned on the medical effects of ionising radiation, almost 90% of health professionals admit to being badly informed or uninformed. The same percentage expressed a wish to be informed as to the action to be taken when confronted with a victim of irradiation or contamination and the corresponding health protection measures. Such information should come from written documents (58%), Post Graduate training sessions (55%) or conferences (46%). In so far as the initial training of doctors is concerned, we should bear in mind the results of a study based on a questionnaire sent to 508 universities of medicine of the 24 members states of the OECD in 1992. The medical curriculum of more than half of these faculties did not provide any formal training in the fields of radio-pathology and radio-ecology. Of the institutions which did provide training in these fields, only 18% of them tested the knowledge of their students.

Given the expectations of health professionals for training and information, EDF has decided to publish objective, scientifically validated and credible information suited to its target audience. It is with this aim in mind that university hospital specialists, representatives of the respective trades union organisations, in-service training managers and the public bodies involved have come together to produce documents to be published nationally and to provide post graduate training at local/regional level.

At national level, these activities mainly concern:

loco-régional.

Les principales actions nationales réalisées concernent :

1. Médecins

La brochure *"Médecins et Risque Nucléaire"* constitue un des éléments de l'opération **Isère Département Pilote** dans la prévention des risques majeurs initiée en 1987 par le Ministre de l'Environnement. Des informations sur la conduite à tenir face aux diverses modalités d'accidents radiologiques, les mesures sanitaires et la place du médecin de famille dans l'organisation générale des secours sont proposées. En 1992, la 4ème édition actualisée et restructurée a été publiée et sa diffusion effectuée auprès de l'ensemble des médecins généralistes et des médecins spécialistes concernés. Au total, plus de 100 000 exemplaires ont été diffusés.

La revue *"Médecins et rayonnements ionisants"* publie des articles concernant la radiopathologie, la radioécologie et l'utilisation médicale des rayonnements sous l'égide d'un comité scientifique national présidé par le Professeur M. Tubiana. Sa diffusion est de 45 000 exemplaires. Sa périodicité est de trois numéros par an. Une évaluation de la perception de cette revue par le corps médical a été réalisée début 1993. Sur 500 réponses reçues : 96 % souhaitent continuer à la recevoir et 74 % la conservent. Neuf numéros ont été publiés depuis septembre 1991.

Le Service de Radioprotection d'EDF publie de très nombreux articles dans les revues destinées aux médecins généralistes ainsi que dans les revues spécialisées sous l'égide des Docteurs M. Bertin et J. Lallemand. Ce service organise par ailleurs tous les ans des réunions d'information sur un thème en rapport avec l'actualité scientifique et publie des brochures largement diffusées auprès du corps médical (en 1995 : Radiocancérogénèse : les acquis récents, 64 p., 3 000 exemplaires).

2. Pharmaciens

Deux brochures d'information ont été éditées en février 1995 :

- *Pharmaciens et Nucléaire - Informations Pratiques* (20 pages - 70 000 exemplaires) est diffusée sous l'égide du Conseil National de l'Ordre à tous les pharmaciens exerçant en France. Elle répond aux principales questions posées par les pharmaciens et précise leur rôle en situation de crise.

- *"Pharmaciens et Nucléaire - Conduite Pratique en Cas d'Accident"* (90 pages - 10 000 exemplaires) est diffusée aux pharmaciens directement concernés. C'est un document de référence dont l'objectif est de préciser les éléments à connaître en cas d'incident ou d'accident. Il concerne le pharmacien, en particulier, dans le cadre de son rôle de conseiller

1. Medical doctors

The leaflet *"Médecins et Risque Nucléaire"* (Doctors and Nuclear Risks) is one of the components of the operation **Isère Département Pilote** in the field of the prevention of major risks, which was initiated in 1987 by the Minister for the Environment. Information on the action to be taken in the case of various forms of radiological accident, the corresponding health measures and the role of the family doctor in the general emergency organisation were promulgated. In 1992, the 4th, revised and restructured edition was published and circulated to all general practitioners and specialists concerned. In total, more than 100,000 copies were issued.

The journal *"Médecins et rayonnements ionisants"* (Doctors and ionising radiation) publishes articles on radio-pathology, radio-ecology and the medical use of radiation, under the aegis of a national, scientific committee, chaired by Professor M. Tubiana. Some 45,000 copies of the journal are printed and it is published three times a year. At the beginning of 1993, poll was taken within the medical profession as to its perception of this journal. Of the 500 replies received, 96% expressed the wish to continue to receive the journal and 74% kept past issues. Nine issues have been published since September 1991.

The department of Radiological Protection of EDF publishes a large number of articles in general medical and specialist journals, under the aegis of Doctors M. Bertin and J. Lallemand. This department also organises information sessions on subjects related to recent scientific events and publishes leaflets with a wide circulation within the medical profession (in 1995: Radiocancérogenèse: les acquis récents, 64 p, 3,000 copies).

2. Pharmacists

Two information leaflets were issued in February 1995:

* *"Pharmaciens et Nucléaire - Practical Information"* (20 pages - 70,000 copies) is published under the aegis of the "Conseil National de l'Ordre" (national organising body) and circulated to all pharmacists practising in France. It provides answers to the questions most often put by pharmacists and sets out their role under crisis situations.

* *"Pharmaciens et Nucléaire - Practical action in the event of accident"* (90 pages - 10,000 copies) is circulated directly to the pharmacists concerned. This is a reference document, the aim of which is set out the various elements to be known in the event of incidents or accidents. It concerns pharmacists particularly in so far as their role as health advisers to the public is concerned.

en santé publique.

Leur réalisation a associé des pharmaciens d'officine, des enseignants des facultés de Pharmacie et de Médecine de Grenoble et de Lyon, l'Ordre National des Pharmaciens, l'O.P.R.I., des spécialistes d'EDF et du C.E.A..

These leaflets are produced in collaboration with dispensing chemists, teachers at the universities of Pharmacy and Medicine of Grenoble and Lyon, the "Ordre National des Pharmaciens", the OPRI and experts from EDF and CEA.

3. Vétérinaires

Une série d'articles a été publiée sous forme de suppléments à la *"Dépêche Vétérinaire"* sous la responsabilité de M. Michon, membre de l'Académie Vétérinaire : *Effets des irradiations aiguës sur les animaux domestiques* (09/02/91) ; *Les pollutions radioactives : conséquences pour le cheptel* (26/10/91) ; *Pollutions radioactives de denrées alimentaires d'origine animale : prévisions quantitatives* (25/04/92) ; *Les normes de protection radiologique - l'interprétation sanitaire de la pollution radioactive des denrées alimentaires* (19/06/93) ; *Organisation de la sûreté nucléaire - maîtrise des conséquences d'un accident nucléaire* (19/03/94).

3. Veterinary Surgeons

A series of articles, published in the form of supplements to the *"Dépêche Véterinaire"*, under the responsibility of M. Michon, member of the Veterinary Academy: *"Effects of severe irradiation on domestic animals"* (09/02/91); *Radioactive pollution: consequences for livestock: qualitative forecasts* (25/04/93); *Radiological protection standards - a health related interpretation of radioactive pollution of foodstuffs* (19/06/93); *Organisation of nuclear safety - controlling the consequences of a nuclear accident* (19/03/94).

4. Infirmières

En partenariat avec la Société Française de Biophysique et Médecine Nucléaire, EDF a mis en place un stand d'information lors des *Salons Infirmiers Européens* de 1993, 1994 et 1995 qui se sont déroulés à Paris. Une très importante documentation a été distribuée et des contacts multiples se sont établis avec la profession. Le logiciel *"Radiance"* a été présenté. Une brochure spécifique d'information est prévue en 1996.

4. Nurses

EDF, in association with the "Société Française de Biophysique et Médecine Nucléaire", has set up information stands at the European Nursing Exhibitions, held in Paris in 1993, 1994 and 1995. Many documents have been circulated to and contacts established with the profession. The *"Radiance"* software was presented and a specific information leaflet is planned for 1996.

Malgré cet effort en faveur de l'information des personnels de santé, il reste encore beaucoup de tabous à dissiper. L'actualité nous confirme que des informations plus ou moins alarmistes diffusées par les médias méritent d'être reprises sous la plume de personnalités compétentes et d'être replacées dans leur juste contexte.

Cet effort d'information doit être poursuivi activement pour que le corps médical puisse remplir avec compétence et indépendance son rôle de conseiller en santé publique.

In spite of all these efforts to spread out information to health professionals, many taboos and misconception remain to be dispelled. Current experience shows us that information, which is to a greater or lesser extent of an alarmist nature, published by the media, should be handled by competent personalities and placed in its proper perspective.

These efforts should be actively pursued so that the medical profession is able to fulfil its role as public health adviser,in both a competent and independant way.

A BRIEF HISTORY OF FEDERAL SUPPORT FOR HEALTH PHYSICS EDUCATION AND TRAINING IN THE UNITED STATES

Paul L. Ziemer
School of Health Sciences, Purdue University
W. Lafayette, IN 47907

INTRODUCTION

Since the formation of health physics as a profession following the end of World War II, the federal government of the United States has played an active role in the support of education and training of health physicists. The purpose of this paper is to review the types of federal support that have been available from the federal government in the past and to examine the current status of support. Individuals trained in health physics through the nuclear navy programs have not been included in this discussion.

THE FIRST 25 YEARS (1948-1973)

In January 1947, following passage of the Atomic Energy Act of 1946 by Congress, The Atomic Energy Commission (AEC) assumed the responsibility for the nuclear energy program of the United States. The AEC recognized immediately that it could only meet its objectives if a cadre of qualified individuals were available with the needed levels of education and training to deal with the new science and technology. Consequently, the AEC began developing a number of programs to meet this anticipated need. In 1948, the National Research Council selected 20 students as the first group to receive Atomic Energy Commission fellowships in radiological physics (1). Ten were sent to the Oak Ridge National Laboratory, and ten went to the University of Rochester.

In October 1946, the organization now known as Oak Ridge Associated Universities (ORAU) was incorporated under the name Oak Ridge Institute of Nuclear Studies (ORINS). ORINS became a prime contractor to the AEC and began to develop a variety of activities involving faculty and graduate students. One of the AEC's most significant educational activities, carried out through ORINS, was the graduate fellowship program in health physics. In 1949, the AEC requested ORINS to organize and administer a program of special graduate fellowships that would provide one year of graduate study in health physics at Vanderbilt University or at the University of Rochester, followed by a three-month field experience at either the Oak Ridge or Brookhaven National Laboratory. The first group of fellows in the program were appointed for the 1950-51 academic year. The program was designated as the *AEC Radiological Physics Fellowships* for the period 1950 to 1959. Additional universities where added to the program, eventually reaching 18, and other AEC laboratories were selected for the summer rotations with 2 labs used each year (beyond Oak Ridge and Brookhaven) from a list of 7 participating labs.

The 18 universities that participated in the AEC fellowship program between 1950 and 1973 [and the numbers of fellows trained] were as follows (2): Georgia Institute of Technology [9]; Harvard Univ. [16]; New York Univ. Medical Center [4]; Purdue Univ. [8]; Rutgers Univ. [5]; Texas A & M Univ. [3]; Univ. of California at Berkeley [56]; Univ. of Illlinois [14]; Univ. of Kansas [66]; Univ. of Kentucky [5]; Univ. of Michigan [40]; Univ. of Minnesota [7]; Univ. of Pittsburgh [4]; Univ. of Puerto Rico [3]; Univ. of Rochester [208]; Univ. of Tennessee [48]; Univ. of Washington [95]; and Vanderbilt Univ. [347]. The total number of fellows participating in this AEC program between 1950 and 1973 was 940, trained at a total program cost of $6,078,000.

In 1959, the program was expanded to permit three years of support leading to the doctoral degree. It was designated as *AEC Special Fellowships in Health Physics*, a title which continued to 1970. In 1970, the name was changed to *AEC Special Fellowships in Radiation Science and Protection.*

In 1960 the AEC established a special fellowship program for individuals already working in the health physics field who had at least two years of experience. The program operated through 1967 and supported some 30 health physicists at a program cost of $597,000.

The Public Health Service (PHS) Radiological Health Training Grant Program was created in 1961 to provide a training mechanism to meet the national need for "radiological health specialists" as projected by the National Advisory Committee on Radiation in a 1959 report to the Surgeon General (3). As a result, the Department of Health, Education, and Welfare through the PHS was assigned the task of training professional and technical workers in the area of radiological health. A 1960 symposium at Princeton University on "University Curricula in Radiological Health" recommended a core curriculum for participating universities. The training was to operate at

two academic levels, Radiological Health Specialists at the graduate level and Radiological Health Technicians at the undergraduate level.

In 1961, the Division of Radiological Health of the PHS was authorized to administer the institutional training grants. By 1964 some 35 universities were participating in the specialist program and 10 in the technician program. Annual appropriations for the program reached $2.5 million per year. A total of $23,584,928 was appropriated to support this program over its 14-year lifetime. The annual reports (4, 5, 6) of the Public Health Service's Division of Radiolgical Health (later called the Bureau of Radiological Health) identify some 39 Universities that participated in the Specialist (graduate) program. The PHS Technician Training program was typically a two-year Associate of Arts or Associate of Science degree program. As many as 10 institutions participated in this training.

Ingraham (7) indicated that the PHS program goal was to train approximately 1200 individuals. It is unclear from the literature how many individuals were trained through the PHS Training Grants. The numbers should be included in the annual report on radiation protection enrollments compiled by the DOE (8), but the PHS component can not be identified. As an approximation, if the cost per trainee is assumed to be $12,000 to 15,000 as estimated by Moeller and Eliassen (9), then as many as 1800 radiological health specialists would have been trained through the PHS programs.

THE PAST TWENTY YEARS (1974 - 1994)

Following the 1975 reorganization that split the AEC into the Nuclear Regulatory Commission (NRC) and the Energy Research and Development Administration (ERDA), the former AEC Health Physics Fellowship program was continued by ERDA and,later, by the Department of Energy (DOE). During the ERDA years, the program was initially designated as "Traineeships for Graduate Students in Energy Engineering, Industrial Safety and Hygiene, and Environmental Fields", and was later identified as "Graduate Traineeships in Energy Related Fields". With the formation of the DOE in January, 1978, the program emerged as the "Nuclear Science and Engineering and Health Physics Fellowship Program". As before, the program was administered by Oak Ridge Associated Universities. There was an interruption in the program shortly after the DOE was formed when in 1978, DOE announced the suspension of graduate traineeship programs for Fiscal Year (FY) 1979 because of budgetary restraints and reassessment of priorities. In FY-1981, planning money was provided to reinitiate the graduate fellowship programs and fellowship awards resumed in FY-982. The number of fellows supported has been modest compared to the earlier AEC fellowship program. The numbers of new fellows in health physics portion of the DOE program were as follows: 8 in 1982, 5 in 1983, 7 in 1984, 4 in 1985, 1 in 1986, and 1 in 1987 . The values for 1988 -1993 remained modest at about 5 per year. In FY-1995 the program was on "maintenance funding" for the 5 fellows already in the program. No new health physics fellowships were awarded for the 1994-95 school year.

In 1990, the DOE's Office of Environment, Safety, and Health launched a new "Operational Health Physics Fellowship Program" which supplemented the existing health physics fellowship program (10). The "operational" program (now called the "Applied Health Physics Fellowship Program") is primarily a master's level program and is intended to prepare participants to move directly into mission oriented health physics work rather than pursuing the doctorate for research oriented careers. The program includes a practicum experience and DOE has designated 20 practicum sites within the DOE laboratory system.

The first fellowship period for this program began in the fall of 1990. Thirteen Universities were initially designated by the DOE as qualified participants. Four were later added and three of the original ones are no longer participants. These 17 institutions are (10, 11): Univ. of Cincinnati, Colorado State Univ., Univ. of Florida, Georgetown Univ., Georgia Institute of Technology, Massachusetts Institute of Technology, Univ. of Massachusetts at Lowell, Univ. of Michigan, Univ. of Missouri-Columbia, Univ. of N. Carolina, Ohio State Univ., Univ. of Pittsburgh, Purdue Univ., Rutgers Univ., San Diego State Univ., Univ. of Tennessee, and Texas A & M Univ.

The program is budgeted to support approximately 20 new graduate students per year. For FY 1993 there were 20 new students and 14 returning students for a total of 34 participants. The FY 1993 budget for the program was $919,000. The previous year's budget (FY 1992) had been $ 750,000.

A related fellowship program that could provide training opportunities for individuals interested in health physics has been the DOE's Environmental Restoration and Waste Management Fellowship Program which began in January, 1990. At present, the fate of this program for future health physics support is uncertain.

For more than a decade the U.S. Nuclear Regulatory Commission has had concerns about the availability of trained personnel to meet their own agency needs. In 1990, the NRC began its "Graduate Fellowship Program" which was administered by ORAU (12). The program is a 24-month M.S. curriculum designed to produce professionals in the areas of nuclear engineering, health physics or specialty engineering. Participants receive a

stipend of $ 20,400 per year, and participating universities receive an institutional allowance of $ 5000/yr. Unlike the DOE fellowships, the NRC fellowships entail a service obligation. This includes a 9-month pre-fellowship orientation during which the individual is employed at the GS-7 government level, and a post-fellowship obligation of 2 years of service for each year of graduate support as an employee at the GS-9 level. In 1991, there were 4 NRC fellowships awarded, two of which were in health physics (13) In 1992 there were 2 new awards, one of which was in health physics. In 1993, three awards were made. Clearly this program is supplying a very modest number of health physicists.

PROGRAM SUPPORT AND THE ACADEMIC INFRASTRUCTURE

The annual costs for training health physicists through the academic programs can be estimated from past budgets and numbers of students trained. Moeller and Eliassen (9) had made an estimate for the PHS trainees that were in programs during the 1960's. Training costs for the AEC/ERDA/DOE programs have likewise been estimated. Based on information received from Williamson (13, 14) the annual cost for trainees was about $5000 in 1957 and had risen to about $30,000 by 1995.

Historically, the AEC fellowship programs provided "institutional allowances" to assist the universities with costs associated with the programs. In the case of the PHS training grants, each institution was provided not only the funds for the student stipends, but also funds for faculty salaries, equipment and supplies. Over the past 20 years, with the termination of the PHS grants and the reliance on rather meager institutional allowances from the ERDA/DOE programs to support the infrastructure, the number and strength of many programs has diminished. An important step in reversing this situation was taken by the DOE in 1992 with the initiation of the "Health Physics Faculty Research Award Program". The program had a total budget in FY 1992 of $336,000 and provided awards of about $50,000 to each of 4 faculty members. In FY 1993, the program budget was $576,000 and a total of 8 awards (4 new and 4 renewal) were made. These awards include funds for student support, faculty salaries, and research supplies. The FY-1994 budget was similar.

The development of trained health physicists in the United States over the past 45 years has been closely linked to and dependent upon federal support, particularly at the graduate level. In recent years, such support is decreasing. The support for education and training that occurred in the early decades of the profession has resulted in today's strong cadre highly qualified health physicists. As federal support for advanced training erodes, we may expect some adverse impacts to appear in the future. Although private support and increases in short-course offerings may assist in meeting future needs, there will be an ongoing need for federal support of health physics training if we expect to maintain the overall quality of of our professional work force into the 21st century.

THE REGULATORY EVALUATION OF RADIATION PROTECTION TRAINING PROGRAMMES AT CANADIAN NUCLEAR POWER PLANTS

Michèle Légaré, David Tennant
Atomic Energy Control Board
P.O. Box 1046, Station B, Ottawa, Canada, K1P 5S9

ABSTRACT

The responsibility for providing the necessary assurance that the use of nuclear energy in Canada does not pose undue risk to health, safety, security and the environment is vested with the Atomic Energy Control Board (AECB). This responsibility has led the Operator Certification Division of the AECB to develop methods to obtain assurance that nuclear power plant operations personnel are well trained and adequately competent to perform their duties. The features of the AECB approach to evaluation of training programmes based on a Systematic Approach to Training is described. An overview of the Canadian nuclear power plants' radiation protection qualification levels is given. The developing evaluation process is contributing to the improvement of licensee radiation protection training programmes. This is making possible the transfer of part of the responsibility for licensed personnel radiation protection qualification assessment to the licensees, thus enabling a reduction in the Operator Certification Division formal qualification activities.

INTRODUCTION

The federal agency responsible for the regulation of the nuclear industry in Canada is the Atomic Energy Control Board (AECB). Its mission is to provide assurance that the use of nuclear energy in Canada will not cause undue risk to health, safety, security or the environment. The health and safety of the more than 10,000 workers in seven Canadian nuclear power plants (NPPs), and the general public who may be affected by the operation of these reactors, is a primary concern of the AECB. Assurance of adequate radiation protection of the general public is acquired by approval of the design, and surveillance of the operation and maintenance of the reactors. The safety of the plant workers, responsible for good operation and maintenance, is achieved by adherence to good radiation protection practices.

Regulatory evaluation of NPP staff competence is vested with the Operator Certification Division (OCD). The mandate of OCD is to obtain assurance that all NPP operations personnel are well trained and competent to perform all their duties, including adhering to the radiation protection requirements.

NEW APPROACH

The quality of the training programmes in place has been verified to some extent by the AECB since 1962, but only since 1991, have radiation protection training protection programmes received specific attention through systematic regulatory evaluations against pre-determined standards. For many years the principal focus of the regulators was the training given to the two licensed positions in the NPPs: Control Room Operator (CRO) and Shift Supervisor (SS).

Indeed a pre-requisite to being granted approval to fill a position the passing of an AECB written examination in radiation protection. For these two positions, the emphasis is being shifted from the direct AECB examination of candidates at the end of their training, to the regulatory evaluation of the radiation protection training programmes together with licensee administered testing. However, certain areas of radiation protection knowledge for these two positions, for example, emergency response and effluent discharges, which could more directly affect the public, will continue to be examined by the AECB.

The basic radiation protection principle adopted at Canadian NPPs is that all operations personnel shall be able to provide effectively for their own radiation protection. This requires that personnel be fully aware of their roles and responsibilities with respect to access rights at their NPP, and that they be able to plan and perform work in a radioactive environment, using the appropriate protection as necessary. Consequently, all operations personnel must be suitably trained to protect themselves against potential radiological hazards. The new approach undertaken by the AECB also includes the evaluation of radiation protection training programmes for all operations personnel.

RADIATION PROTECTION QUALIFICATION LEVELS

Colour is used by the utilities to indicate the qualification level of personnel and is prominently displayed on the thermoluminescent dosimeter badge. The levels are "Red", for a person with no training in radiation protection at the site, followed by "Orange", "Yellow", and "Green", the highest level of qualification. The Orange level provides sufficient training to allow a plant worker or contractor unescorted access to areas of the station where levels of radioactivity are expected to be very low. A worker with this qualification can only do radioactive work under the supervision of a fully qualified person (Green). The Yellow badge is the intermediate qualification and provides the knowledge and skills necessary for a person to work in an environment where radiation might be present (levels of 10 μSv or more). The associated training includes work planning, dosimetry, radiation detection instrumentation and use of protective clothing. The Green badge is held by experienced individuals who must ensure the radiation protection of other lesser qualified individuals performing radiation work. The Green badge qualification is the entry level requirement to the training of licensed control room personnel.

THE EVALUATION PROCESS

The AECB expects that all NPP radiation protection initial and continuing training programmes conform to a Systematic Approach to Training (SAT). This widely accepted approach is described in detail in IAEA-TECDOC-525[1]. It is an effective and efficient process to provide job competency since it requires that training be designed to meet job performance requirements. The AECB uses a three phase model to describe SAT: 1) Preparation phase, 2) Implementation phase, 3) Evaluation phase. The first phase includes an analysis of the job and tasks requiring training (assessed through the frequency, importance to safety and difficulty of the task) and the design and development of the training material. The second phase, involves the selection of instructors, delivery of training and the testing of trainees. Finally, the third phase covers the use of feedback to maintain and improve the training programme.

In order to use a consistent approach when evaluating training programmes, the AECB has ecently developed the following three-step method: 1- Identify and check the adequacy of ıtility Requirements/Guidance for training programmes, 2-Review the supporting training documentation, 3- Determine if training is implemented in accordance with the documented process. The first two steps are completed at the AECB office. The last one is performed at site and involves observation of training in the classroom (radiation protection principles and practices), laboratory and on-the-job (instrumentation, protective clothing, access control), and interviews with staff and management. The tools used to assess the quality of training are derived from the AECB Objectives and Criteria for Regulatory Evaluations of NPP Training Programmes[2] which are based on SAT. The classroom and field observations as well as interview questionnaires are derived from this document. An interim report is presented before leaving the site, and a final report is later sent to the utility indicating where actions are required in order for the programme to be more effective. To gain assurance of the adequacy of the training, the three step method is used to evaluate all levels of radiation protection qualification at all stations. Attending all training sessions would be an overwhelming task. Therefore, the approach favoured is to select a cross-section of the programme. As an example, for a typical course, a few tasks would be chosen for which the learning objectives, training material, lesson plans, course notes, facilities, delivery and practice sessions, as well as the associated areas of the written and field tests for this task would be reviewed using the guide mentioned above. To better assess the preparation phase, an evaluation team member periodically attends the meetings of a licensee's Radiation Protection Training Group whose current primary role is revising the formal job and task analysis. During interviews, questioning covers all aspects of training, which allows the evaluation team to assess all phases of the training process.

CONCLUSION

The regulatory evaluation process, by expecting that the licensee radiation protection training programmes be in accordance with the SAT process, results in a training programme focussed solely on the job requirements. From the perspective of the licensee, this increases the programme effectiveness and efficiency by eliminating the components of the training that do not contribute to worker competency, thus saving resources. From a regulatory perspective, these evaluation activities, using a three-step process and criteria based on SAT, provide further evidence that, as a result of the training programmes, the plant workers will have the necessary skills and knowledge to perform their job duties effectively and safely. This additional assurance gained by the AECB through training programme evaluation is also making possible the transfer of part of the responsibility for licensed personnel radiation protection qualification assessment to the licensees, thus allowing a reduction in the Operator Certification Division examination activities.

The CEFRI and Radiological Protection Certification of French Companies and Training Organizations

In the matter of risk prevention, the quality of training is essential. This is why the French Committee for Certifying Companies in Training and Followup of Personnel Working Under Ionizing Radiation (CEFRI) was created in 1990.

Besides the employers of Category A and B workers, represented by the GIIN (nuclear industry trade group), associated within the CEFRI are the operators of French nuclear facilities (EDF, CEA, Cogema, and the military), the French Radiological Protection Society (SFRP), the national health insurance agency, and the Office of Protection Against Ionizing Radiation (OPRI). In addition, the Committee receives support from the Ministries of Labor and Industry.

The fundamental objectives of the CEFRI are as follows:

- To contribute to the reduction and prevention of the risks to personnel working in nuclear facilities; and
- To enable French companies active in this field to objectively demonstrate the preventive actions implemented.

After performing an audit, the CEFRI issues certifications:

- To companies (including companies providing temporary workers) that perform work in nuclear facilities, concerning the quality of personnel training (whether provided by an outside organization that is itself certified or by the company itself) and concerning the organization that the company has set up to ensure the followup of exposure and medical surveillance of its personnel; and
- To specialized training organizations, concerning the contents and quality of the training provided.

The four operators of French nuclear facilities (EDF, Cogema, the CEA, and the military) have already defined a schedule of requirements for this certification, as concerns the training organizations, the companies providing temporary workers, and the companies present in certain specific fields of activity, such as cleanup, industrial logistics, etc.

INTRODUCTION

Environmental restoration (ER) is the process of removing a facility from service, the demolition of structures, the identification and disposal of all hazardous and radioactive wastes, the decontamination of equipment and materials, and the restoration of a site for unrestricted use. The number of ER projects encompassing hazardous, industrial, and radiological conditions is expected to increase in response to various program requirements or mission changes. As a result, the practicing health physicist (HP) may have to address unique health and safety (H&S) issues beyond those of performing routine radiological activities. These unique H&S issues could include, but are not limited to the razing of buildings, the removal of radioactive materials and hazardous chemicals, below-grade excavation, confined space entry, storing flammable or combustible liquids, monitoring exposure to hazardous substances, contacting energized systems (e.g., electricity, hydraulics), noise abatement, the nullification of manufacturer warranties, and the operation and movement of heavy equipment. The purpose of this paper is to educate the practicing HP about these issues by reviewing specific regulations governing all H&S activities, and to provide an example of a site-specific H&S primer (e.g., Health and Safety Plan [HASP]). This primer advises the practicing HP about sound H&S principles, furnishes basic strategies for performing a hazard assessment/job safety analysis (HA/JSA) that can be applied to any ER project, and describes various engineering and administrative controls to mitigate hazardous exposures to ER personnel. In addition, 26 inspection checklist topics are available from the primary author to evaluate the adequacy of the engineering and administrative controls, or to necessitate the use of personal protective equipment (PPE) thereby mitigating the corresponding hazard.

REGULATIONS, STATUTES, AND ORDERS

The specific regulations governing all H&S activities are found in *Title 29 of the Code of Federal Regulations, Parts 1910 - General Industry Standard* (1) and *1926 - Construction Standard* (2). Also, applicable state, tribal, and local statutes, including U.S. Department of Energy Orders will have to be considered depending on the geographical location and regulatory jurisdiction of the ER site. Essentially, the regulations, statutes, and Orders are intended to provide uniform guidance that is generic in nature, thus allowing for the evaluation of site-specific H&S conditions at all ER sites. The regulations, statutes, and Orders also address general program guidance issues such as monitoring performance, records and reporting, and requirements for training ER personnel commensurate with the hazards encountered at the ER site.

SITE-SPECIFIC HEALTH AND SAFETY PRIMER

The types of hazards and inherent risks encountered by ER personnel often exceed the scope of performing routine HP activities. Therefore, to educate the practicing HP about these hazards and inherent risks, H&S personnel have developed a site-specific H&S primer. The primary element of this primer that will influence budgets and overall operations significantly, is the HA/JSA of site activities performed by ER personnel. A typical HA/JSA involves the following:

A) The identification of the job, task, or operation.
B) The breakdown of the job, task, or operation into individual steps.
C) The identification of all hazards associated with each step.
D) The application of controls to mitigate exposures corresponding to the identified hazards.

The methods available to mitigate exposures to ER personnel are listed in order of preference:

A) Engineering controls - the most preferred option for worker protection that includes the specification, design, purchasing, and performance of specialized equipment.

B) Administrative or work practice controls - the incorporation of H&S provisions into working-level procedures, and performing in-house inspections.

C) The allocation of PPE - since the complete elimination of the hazard may not be practical, ER personnel may be required to wear applicable PPE (e.g., respirators). However, the use of PPE is always the least desirable option since it may require additional training, medical examinations, as well as the cooperation of ER personnel to wear the PPE properly.

To familiarize the practicing HP about the proper use and application of H&S engineering and administrative controls at ER sites, a list of common elements and their H&S implications are provided for information only, and are not limited to the following:

A) Berms and tarps - designed to contain leakage of chemicals.

B) Below-grade excavation - the application of trenching, shoring, and barriers to prevent the collapse of materials.

C) Confined space entry - the placement of barriers (e.g., fencing) preventing unauthorized entry to confined spaces having limited or restricted means for entry or exit, and are not designed for continuous occupancy. Other requirements may include atmospheric testing, respiratory protection, and capabilities for emergency rescue of ER personnel occupying the confined space work area.

D) Fire hazard analysis - the availability and type of fire equipment shall be posted, and commensurate with the type of combustible materials and ignition sources present at the ER site.

E) Hazard communication program/material safety data sheets (MSDS) - the complete inventory and storage of chemicals in approved cabinets, and proper labeling of containers and tanks.

F) Lockout/Tagout (LOTO) of energized systems - the deactivation of pneumatic, hydraulic, gravitational, and electrical systems prior to initiating maintenance activities.

G) Noise abatement - the selection and placement of noisy equipment in proximity to ER personnel, or the use of sound barriers.

H) Equipment warranties - modifications compromising the intended design and/or operation of equipment shall be removed from service, and may result in nullifying agreements between the manufacturer and the purchaser.

I) Operating heavy equipment - drivers operating trucks, dozers, and scrapers have limited visibility and shall be given right-of-way privileges. The application of brakes and tire chocks shall be applied when equipment is stationary for purposes of inspection, or not in use.

In addition, 26 sample checklist topics are available from the primary author to enhance inspection capabilities by ER personnel. The sample checklists are provided as guides only, and are not limited to the following:

1. Chemicals
2. Compressed Gases
3. Construction Tools
4. Dusts, Gases, and Organic Solvents
5. Dusts, Gases, and Organic Solvents (Medical)
6. Ergonomics
7. Life Safety Code - Exits, Walkways
8. Explosives and Blasting Agents
9. Fire Prevention and Fire Protection
10. Flammable and Combustible Liquids
11. Hand and Portable Tools
12. Heat
13. Machinery and Machine Guards
14. Job Planning and Job Briefing
15. Material Handling and Storage
16. Medical and First Aid
17. Noise
18. Noise Stress (Medical)
19. Personal Protective Equipment
20. Sanitation
21. Temporary Grounding
22. Traffic Barricades
23. Trenching and Shoring
24. Vehicles and Cranes
25. Walking and Working Surfaces
26. Welding, Cutting, and Brazing

Additional components of the site-specific H&S primer should include, but are not limited to the following:

A) A brief summary of the historical information, physical characteristics, and meteorology of the site.

B) A map identifying structures, areas of remediation, and traffic patterns.

C) Access control and training requirements.

D) Medical monitoring and surveillance requirements for ER personnel coming in contact with hazardous substances.
E) First aid and response to medical emergencies.
F) Decontamination of ER personnel and equipment.
G) Transportation safety.
H) A waste minimization/pollution prevention program.

CONCLUSIONS

The types of industrial and hazardous conditions encountered at ER sites will require practicing HPs to address unique H&S issues beyond the scope of performing routine radiological activities. Therefore, the implementation of a site-specific H&S primer developed by certified ER personnel (e.g., Certified Safety Professional [CSP], Certified Industrial Hygienist [CIH]), in conjunction with the application of engineering and administrative controls will offer the practicing HP an opportunity to grow professionally by gaining experience with new disciplines associated with ER projects. In addition, the cooperative effort provided by H&S and HP personnel will provide a strategic approach to affirm balance between disciplines, maintain ease of communication between applicable participants, and identify pertinent issues at multi-hazard (e.g., chemical, industrial, and radiological) ER and similar project sites.

A UNIVERSITY SAFETY PROGRAM FOR USE OF RAMS

William J. Fields, Jr.

University of Missouri-Kansas City, Kansas City, MO 64108-2792

To remain in compliance with 10 CFR Parts 19 and 20, and the conditions of our Byproduct Materials License, the Division of Radiation Safety (DRS) of the Office of Chemical, Biological and Radiation Safety (CBARS) of the University of Missouri-Kansas City (UMKC) has established a three level training program for persons using radioactive materials (RAMs) and those persons frequenting areas in which RAMs are used. Attendance at each level of training is mandatory. Training for new employees before involvement with RAMs and annual refresher training is provided to all personnel. The training is conducted by the Radiation Safety Officer and DRS Health Physicists. Applicable literature is distributed during the training programs.

Faculty and staff who apply for and received approval from the Radiation Safety Committee to use RAMs are called Authorized Users (AUs). Authorized Users, independent of the amount of training and experience they have, must attend the mandatory Level 1 training program. Introduction to the program includes a discussion of the relationship between the radiation safety program, the U.S. Nuclear Regulatory Commission Byproduct Materials License, with conditions, issued to UMKC, and applicable Federal and State regulations pertaining to the use of RAMs. Copies of the UMKC Handbook of Radiological Operations, and NRC Regulatory Guides 8.13, **Instruction Concerning Prenatal Radiation Exposure**, and 8.29, **Instruction Concerning Risks from Occupational Radiation Exposure**, are distributed and discussed. Information contained in 10 CFR Parts 19 and 20 is reviewed with emphasis on those sections that impact directly upon the AU's use of RAMs, e.g., dose limits and posting requirements. License conditions that apply, e.g., experimental animals that have been administered licensed materials shall not be used for human consumption, are described. A looseleaf version of the Handbook is given to each AU and contains the following seven sections: Section 1.0 Management of Radiation Safety, Section 2.0 Radiation Control, Section 3.0 Procedure for Laboratory Inspections, Section 4.0 Radioactive Waste Disposal Program, Section 5.0 Application for Use of Radiation Sources, Section 6.0 Forms and Section 7.0 Definitions and Acronyms. Emphasis is directed toward the sections on Radiation Control, Radioactive Waste Disposal Program and Forms. The section on Radiation Control contains information on personnel and area radiation control, emergency procedures, receipt, storage and use of RAMs and criteria of health physics coverage. The section on Radioactive Waste Disposal Program contains information on waste handling procedures and the responsibilities of the RSO and the AU with respect to the disposal of RAM wastes. The Form section contains copies of the forms used in the conduct of the radiation safety program. A sampling of the forms included in this section are the following: Application for Use of Radiation Sources, Authorization for Possession and Use of Radiation Sources, Laboratory Radiation Safety Orientation Checklist, Radioactive Materials Delivery Form, Radioactive Waste Pickup and Quarterly Inventory.

Radiation safety practices at UMKC including dose limits, ordering and receiving procedures for shipments of RAMs, laboratory survey procedures and emergency procedures to be followed in the event of a minor or major spill are discussed. The dose limits published in 10 CFR Part 20 and the As Low As Reasonably Achievable (ALARA) concept are reviewed. Investigational dose limits are also presented. A generic emergency procedure to be followed by the AUs and their associates in the event of a spill, complete with emergency telephone numbers of DRS personnel and the UMKC Police Department, is distributed. Pager numbers of DRS personnel are also made available.

Two procedures are used to order RAMs. The first follows the Purchasing Department's procedures by requiring the AU to complete a purchase requisition. This purchase requisition must then be approved by DRS to assure that the AU is authorized to use the RAM to be ordered. The processing time for orders placed in this manner may take two or three weeks. Therefore a second ordering procedure allows the AU to order RAMs via the telephone. Authorization must still

be obtained from DRS prior to telephoning the order into the company. Both procedures are discussed in detail. It is emphasized that deviations from these procedures will not be allowed because all RAMs must be accounted for as the authorization limits of the byproduct materials license cannot be exceeded.

A requirement of the radiation safety program is that all shipments of RAMs must be delivered to specific locations. UMKC consists of three separate campuses: Volker, Hospital Hill and Truman. It is explained to the AUs that shipments of RAMs must be received either at Central Receiving for those users on the Volker Campus and at the Medical School for those on the Hospital Hill Campus. RAMs are not currently in use on the Truman Campus. All shipments of RAMs are inspected and delivered to the AU's laboratory by DRS personnel. Another requirement of the radiation safety program is that each laboratory in which RAMs are used must be surveyed after each day's use. The survey must be performed with calibrated equipment and documented. In laboratories where low energy β-emitters are used the survey should consist of wipe sampling of areas in which RAMs are stored, used and the surrounding environs. In laboratories where moderate to high energy β-emitters and γ-emitters are used the survey should include radiation monitoring and wipe sampling of areas in which RAMs are stored, used and the surrounding environs. A further requirement concerns the disposal of RAM wastes. The policy at UMKC is that liquid RAM wastes are not to be disposed of into the sanitary sewerage system other than those incidental to washing laboratory glassware that has been used for low level RAM work and previously rinsed, at least once, into a liquid RAM waste container. Liquid RAM wastes are collected in one-gallon plastic bottles appropriately labeled. Solid RAM wastes are collected in specially marked and plastic-lined 12- and 28-gallon fiberboard drums. Separate waste containers are provided for different radionuclides to facilitate disposal. DRS personnel collect and dispose of all RAM wastes by decay-in-storage, by disposal into the sanitary sewerage system or by shipment to a commercial disposal facility.

The final topic for discussion for Level 1 training is the requirements for recordkeeping. It is stressed that complete records must be maintained for the receipt, use, and disposal of RAMs. Records of laboratory surveys, calibration of survey and laboratory counting equipment and other information pertinent to the description of the experimental program that would be of interest in determining the adequacy of the radiation safety program in each laboratory must be on file. Attendance records attesting to the fulfillment of the training requirements of the radiation safety program must also be maintained by the AU.

The Level 2 training program is directed toward radiation workers, associates of the AUs. Radiation workers conduct experimental protocols under the authorization granted to the AU by the RSC. This level of instruction includes some of the subject matter covered in Level 1 but emphasis is on the hands-on, day-to-day operational aspects of radiation safety in the use of RAMs. A bound pamphlet containing Sections 2 and 4 of the Handbook (important hands-on information and procedures) and NRC Regulatory Guides are distributed and discussed during this level of training. The contents of Section 2 are thoroughly discussed including: smoking, eating or drinking **shall** not be permitted; pipetting **shall** not be done by mouth; RAMs in liquid form **should** be stored and transported in double containers; flammable liquids **shall** be contained in UL approved containers, and work **should** be planned ahead. Conditions of use of protective apparel, e.g., laboratory coats, are addressed. Laboratory coats **should** be buttoned up when worn and **shall** be monitored periodically. The use of the types of personnel monitoring devices, the lapel film badge, the TLD extremity badge and self-reading pocket dosimeter, is explained. The bioassay requirements for users of ^{3}H or $^{125,131}I$ are defined. Section 4 contains information on the collection and disposal of RAM wastes.

Requirements for laboratory survey procedures, contamination levels and decontamination, and recordkeeping are examined closely. The purpose and use of survey meters and laboratory counting equipment applicable to the experimental protocols conducted in the laboratory are discussed. The Laboratory Radiation Safety Orientation Checklist which covers item such as RAMs used in the laboratory, posting, safety precautions and emergency procedures is reviewed. The Radiation Worker Checklist, a compilation of information collected during the training program, which provides DRS personnel with a measure of the individual's ability to use RAM, to understand radiation safety procedures and to use survey and laboratory counting equipment is also covered. Instructions for completing the RAM waste pickup and quarterly inventory forms and completed

examples of each are discussed.

Level 2 training is completed when the radiation worker first uses RAMs. DRS personnel oversee the first use of RAMs to verify 1) that the person can conduct the experimental protocol, 2) demonstrates radiation safe practices, and 3) performs the proper survey after use. If, in the opinion of the DRS person overseeing the first use, the radiation worker has performed satisfactorily, then that individual is free to continue to use RAMs without DRS supervision. However, if the individual has not performed satisfactorily, then subsequent oversee episodes may be required before permitting the person to work unsupervised.

Level 3 training is provided to groups of ancillary personnel frequenting areas in which RAMs may be used. These training sessions are very specialized for each group. The material covered during these training sessions is essentially the **DOs** and **DON'Ts** of frequenting areas in which RAMs are used or stored. There are four groups of ancillary personnel that receive training. They are personnel associated with the following departments: 1) Custodial, 2) Campus Facility Management, 3) Campus Police and 4) Receiving. A listing of all laboratories in which RAMs are used, examples of the warning labels in use on the campus and the Regulatory Guides are distributed to each group. Custodians are instructed not to handled any container with a 'Caution - Radioactive Material' label affixed to it. They are told not to empty any container of waste, solid or liquid, that is so labeled. The Custodians are told not to clean up posted areas in the laboratory, e.g., fume hoods or bench tops, in which RAMs are used and stored. They are not to clean up any spilled liquids unless the liquids have been identified by personnel associated with the experimental work conducted in the laboratory and are not hazardous or radioactive. Custodial personnel are also instructed to report any unusual conditions or findings to the Office of CBARS.

Campus Facility Management, the personnel responsible for maintenance of the buildings and equipment on the campus, are also required to attend a training program. It consists of similar instructions for the Custodians. CFM personnel are instructed not to work on any equipment with a 'Caution - Radioactive Material' label affixed to it until they have contacted DRS to determine if the equipment is free of any residual contamination. Types of equipment could include refrigerators, centrifuges, fume hoods and sinks. In anticipation of potential problems, the fume hood blowers, located on the roof tops of the buildings, have affixed to them 'Caution - Radioactive Material labels containing the name of the AU, the laboratory number and the DRS telephone number. Facilities must be surveyed prior to any remodeling.

The UMKC Police Department is used, by DRS, primarily for emergency response to incidents involving RAMs. The Department is given a callup list of DRS personnel who are available to respond to emergencies during off-hours. Police Department personnel are instructed in procedures to be followed in the event of an emergency involving RAMs, e.g., a spill. Instructions include containing, if possible with minimal risk and exposure, the RAM; if necessary turning off the utilities; holding all persons involved in the spill until DRS personnel can monitored them for contamination and radiation exposure; controlling any crowd that may assemble; and limiting access to the involved area to authorized personnel only. The communications section of the Police Department provides liaison with the Kansas City (KC) Fire and Police Departments if their services are required during an emergency involving RAM. KC Fire and Police Department personnel are familiar with UMKC's facilities through training provided by CBARS personnel. If medical treatment is required, the UMKC Police Department can contact local ambulance services and hospitals.

Personnel who work for Receiving accept delivery of shipments of RAMs. Their training consists of discussions of the following topics: 1) Types of packaging and labeling (NOS, White I, Yellow II and III), 2) Inspection of shipments of RAMs, for physical damage, including wetness, 3) If package is damaged, retain the driver of the delivery service and the package and call DRS, and 4) If package is not damaged, call DRS for to pick up the package, inspect and delivery it to the purchaser's laboratory.

In addition to these training programs, CBARS personnel also conduct training programs in the management of hazardous chemicals and biological agents.

THE CHANGING ROLE OF HEALTH PHYSICISTS AS REFLECTED BY CHANGES IN PROFESSIONAL HEALTH PHYSICS TRAINING COURSES

L. Denis Brown Ph.D.
BB Health Physics Services, 55 Leopold Crescent, Regina SK, S4T 6N5, Canada

Background

Health Physics is a profession with long, honourable traditions; and this paper could be subtitled "Health Physics - The First 100 Years". The discovery of X-rays by Conrad Roentgen in 1895, and of natural radioactivity by Henri Becquerel in 1896, was followed two years later by the isolation of radium by Marie and Pierre Curie; and then, during the last years of the nineteenth century, by explosive world wide growth in the utilisation of both these new discoveries for medical diagnostic and therapeutic purposes. The fact that these new medical tools carried associated risks was very quickly learned. Physicians who most enthusiastically adopted them often experienced severe skin injuries to heavily exposed digits, and there are numerous photographs of the hands of such individuals after experiencing several amputations. Regrettably many ultimately fatal radiation induced cancers also began to appear before the end of the last century, by the first world war there were 200 of these and the death toll already exceeded 50. In the face of this two edged weapon it is not surprising that many of the physicians and medical physicists working in this area turned a great deal of their attention from the exploitation of the new technologies to the protection of their colleagues. These individuals were the pioneer health physicists and, although this name was not used at the time, their background experience in both medicine and physics laid scientific foundations for the new discipline which have remained its keystone ever since.

Initially attempts to develop improved safety standards for radiology concentrated on the development of equipment and procedures which would minimise inadvertent exposure to X-ray beams. A Boston dentist, Dr. William Rollins, was particularly active in this respect, and he has been referred to as "the father of health physics". By the summer of 1915 such developments led the British Roentgen Society to pass a resolution recommending the universal adoption of stringent safety rules designed to ensure the personal safety of operators conducting roentgen-ray examinations. In November of the same year the Society followed up this resolution by publishing what appears to have been the first comprehensive set of such rules. However at this time monitoring for scattered radiation was still carried out either with fluoroscopic screens or by photographic means and any formal scientific basis for health physics awaited the development of appropriate units and instruments for the measurement of radiation exposures. This development took place at the Second International Congress of Radiology in Stockholm in 1928 where a Committee was appointed to study the introduction of an appropriate unit for dose measurements. The Committee was responsible for the introduction of the Roentgen as a unit of measurement. It subsequently developed into what became known as the "International X-Ray and Radium Protection Committee", and in 1934 under this name it recommended the universal adoption of a daily personal dose limit for radiation workers, a requirement that had been first introduced in the USA in 1929. Later it was this committee that developed into the International Commission on Radiological Protection in 1950.

The Evolution of Health Physics as a Profession

It is almost certainly true that during the inter-war years these organizational developments were of less significance in the evolution of health physics as a profession in its own right, than the dedicated work of many extremely competent physicians and medical physicists in hospitals throughout the world. Both fundamental research in radiobiology and sophisticated investigations of dose distributions within the body played a necessary part in the development of improved radiotherapy practices. They also laid a foundation for the safe control of artificial radionuclides when these became available in quantity following the development of the nuclear reactor, and equally important they ensured the availability of the core of expert scientists who were responsible for the safety of workers engaged in the development of atomic weapons during the second world war. These scientists were the first group to be formally referred to as health physicists, partly in order to conceal the exact nature of the work in which they were engaged. At this time the total quantity of radium which had been isolated for use

throughout the world would have comprised less than a one inch cube, yet they all knew that experience in the luminising industry had shown that lethal internal doses of radium could be very quickly absorbed. It has been reported that, when first recruited, they were given a realistic and frightening impression of the scientific problems they faced by a comparison of this quantity with the quantities of artificially produced long life alpha emitters which would be generated during the program to develop atomic weapons! There is no doubt that when the veils of secrecy were finally lifted fifty years ago their dedicated efforts had led to the development of a fully fledged health physics profession. During the next few years general expectations developed that nuclear power would be quickly and almost universally adopted, and consequently a significant number of additional health physicists would need to be trained. The first University M.Sc. courses in health physics were therefore established at this time. Numerous shorter courses were also introduced by a variety of training institutes, these were mostly intended for various groups of workers of very different academic capabilities who used radiation sources in their employment.

Health Physics as an Academic Discipline

Not only the ICRP itself but also national regulatory bodies in many countries have paid a great deal of attention to the need to ensure that all workers exposed to sources of ionizing radiation receive comprehensive training covering both the associated risks and the safety procedures that must be followed. Until recently the development of such training courses has tended to be emphasised at the expense of formal academic training of the senior staff responsible for designing and implementing complete radiation safety programs in large institutions. For example in 1979 the Health Physics Society devoted its Mid-year Topical Symposium to Health Physics Training, and an examination of the proceedings for this meeting shows that it was largely devoted to the training of health physics technicians, and of workers incidentally involved with the uses of ionizing radiations, relatively few papers discussed the academic training of personnel expected to be responsible for conducting health physics programs. This is perhaps not surprising as most such programs were already under the control of very experienced personnel who had learned on the job. Some of the early academic courses even found it difficult to recruit enough students and not all of them have survived. However most of these senior personnel have now retired, or are close to retirement, and the way to senior positions in the profession is no longer readily open to those who have not undergone a formal academic training. A review of the changing syllabus followed by such training courses therefore provides an easy way to assess how the issues of most importance to professional health physicists have changed over the years. The author attended a University M.Sc. course in radiation safety during the 1960's, and has subsequently been involved in both teaching and syllabus preparation for three further academic courses of the same type. It was only an incidental review of the subject matter covered in his first course which led him to full recognition of the substantial changes in the type of work undertaken by a health physicist that have occurred during the past four decades.

Syllabus Evolution in Academic Health Physics Training

The earliest academic courses covering radiation safety were designed for trainee medical physicists. They provided extensive coverage of the fundamental scientific disciplines of anatomy, physiology and biochemistry, together with training in the interaction of gamma radiation with matter, radiation dosimetry, radiobiology, dose distributions in tissue, medical imaging, etc. These courses also usually included a limited amount of information about ICRP recommendations, radiation control regulations and personal monitoring, but they were strongly directed towards students expected to make their career in a hospital. More general radiation safety courses first evolved from such medical physics courses to meet the needs of students planning to work in research centres, industry, or government. In addition to the fundamental scientific disciplines referred to above, these courses included a great deal more emphasis on instrumentation of all types, on the design of radiation shielding, on the in-house calibration of equipment, and on radiation measurements. Generally such topics as the operation of personal monitoring programs, contamination of materials, low level counting, bioassay procedures and whole body counting were covered in some detail. There was also some discussion of the role and recommendations of the ICRP, but regulatory requirements did not loom large at this time. Visits from government inspectors to research centres or industrial operations were relatively infrequent, and at this time the requirements of such inspectors were usually easily complied with.

About ten years after participating in such a course, I became involved in developing the syllabus for another course designed for a similar class of M. Sc. students. The most important changes from the type of syllabus outlined above which were felt to be necessary included increased emphasis on compliance with regulatory requirements, some coverage of the need to maintain adequate documentation of all procedures followed, an introduction to the rapidly increasing role of computers (e.g. for record keeping, calculating shielding requirements, contributing to the design of research projects, etc.), and adequate treatment of the many new developments in radiobiology - particularly at the cellular level. To make time for these topics to be fully addressed it was necessary for some of the material relating to medical imaging to be eliminated, but since many of the students would continue to be involved with work in hospitals, a comprehensive treatment of quality assurance procedures for medical imaging equipment remained.

The third such course with which I was directly involved put much more emphasis on both regulatory requirements and record keeping, since these were matters which were beginning to occupy more and more of the time of a program manager. The increasing power and availability of computers led to more attention being paid to their use in meeting such requirements. Questions of the potential legal liability of the responsible organization, and consideration of the problems encountered in ensuring that all workers complied with required operating procedures, assumed increasing importance. For the first time the public concerns, which were evident following the Three Mile Island accident, and had became much more acute after Chernobyl, led to a considerable amount of attention being devoted to techniques for communicating with the public. To compensate for this, less attention was paid to the work which it was by then assumed would normally be carried out by a health physics technician, and to the development of specialised health physics services such as personal monitoring and whole body counting which had begun to become readily available from commercial suppliers.

Further such changes have gradually continued over the last decade, and have tended to mark the evolution of the role of the radiation safety program manager from that of an operating scientist to one which has become largely program management. In the most recent course with which I have been involved it was found necessary to begin to reduce the attention given to the three fundamental sciences of anatomy, physiology and biochemistry to make room for an extended treatment of risk assessment, risk communication, and risk acceptability. Communication with both the public and employees assumed a very high importance and much more attention needed to be paid to legal issues including probability of causation. The documentation required of a typical organization has mushroomed out of all proportion, a considerable amount of time now needed to be spent both in reviewing these requirements and in considering how best to meet them. Major organizations now have to establish much more complex health physics programs than in the past, and this means that program direction and management has now become an important topic in its own right.

Future Directions in Health Physics and in Health Physics Training

The most critical question which is likely to arise before the end of this century is probably how the somewhat rigid structure that has been developed for radiation safety can best adapt to the implications both of new research and of the changing expectations of society. Examples of such issues are the possible development of techniques for the identification of individuals with abnormally high radiation sensitivity, and the conflicting expectations of some women's groups concerned about risks during pregnancy with those of others more concerned about the impact of pregnancy dose restrictions on their career prospects. Risk communication will lie at the heart of such societal decision making processes. Similarly increasing sensitivity to all forms of pollution in the environment is likely to lead to increasing importance being attached to the effective communication of information about the relative significance of all the associated risks. Answers to such questions will demand familiarity with an extremely broad range of scientific expertise. Society is now being faced with recognition that world energy needs are increasing dramatically, and that the greenhouse effect is a serious threat. This will necessitate a re-examination of the future role of nuclear power. The decisions on all such issues will ultimately have to be made by the public following extensive discussions in the media, and later in legislative assemblies. The professionally trained health physicist will inevitably be at the centre of such discussions. This strongly suggests that the most important professional credential will probably be ability to communicate effectively with the public. The role of the typical health physicist will then have completely reversed from that of a scientist essentially working alone to that of an administrator working largely in the area of public communication.

ASSESSMENT AND EVALUATION OF NURSES TRAINING PROGRAM ON RADIATION

Yuko Bessho[1] and Tomoko Kusama[2]
[1]Fukui Medical School, Fukui, Japan
[2]The University of Tokyo, Tokyo, Japan

INTRODUCTION

Many nurses in hospitals and clinics are concerned about the care of patients diagnosed or treated with radiation. Knowledge about radiation effects and radiological protection was in limited supply among nurses. Some nurses are anxious about the effects of occupational radiation, and they have not appropriately coped with their patients' questions about radiation effects of medical exposure.

We investigated the level of knowledge about radiation among nurses and required knowledge for nurses in hospitals and clinics. Based on the results of the investigation, we designed an education and training program of lectures and practice for nurses in hospitals. After the education and training by our program was done, we evaluated the effects of the education and training with an interview and a questionnaire for each nurse.

METHODS

Proper knowledge about radiation and radiation effects and the level of knowledge on those among nurses were investigated with questionnaires. A questionnaire with the following three categories of questions was prepared; a) degree of nurses' anxiety about radiation, b) frequently asked questions from patients about radiation and radiation diagnosis/treatment, and c) information about radiation needed for nurses in the clinical field. The questionnaires were distributed to 319 nurses of 17 departments in two university hospitals. A total number of 303 nurses (95.0%) replied to questionnaires. Based on the result, we prepared a program of the education and training for nurses worked in all hospital departments except the department of radiology . A lecture and practice by our program were performed in two hospitals.

RESULTS

A total number of 214 nurses (70.6%) had experienced taking care of radiological patients. Sixty nurses were registered as radiation workers, and their average annual effective dose in 1994 was only 0.05 (0-0.6) mSv. Two hundred and seventeen nurses (71.6%) had felt anxiety about occupational radiation exposure. Major anxieties about radiation were biological effects such as carcinogenesis and hereditary effects. Two hundred and thirteen (70.3%) nurses had an experience of being questioned by the patients. The frequently asked questions from patients were biological effects such as side effects (60.9%) of the medical exposure.

Based on the results of the investigation with the questionnaire, we planned an education and training program. Matters of interest were listed in Table 1, and these items were arranged to form a lecture and practice as shown in Table 2. The lecture and the practice in our program were applied to 95 nurses and 12 nurses, respectively.

Two weeks after the lecture and the practice, we asked all participants to tell what they had learned from the program. The results of the investigation of the effects of the lectures and

Table 1. Matters of interest

Biological effects	
Relationship between dose and biological effects	(78.8%)
Doses of patients and workers	(46.7%)
Practical protection procedure	
Protection procedure	(40.5%)
Regulation	(40.5%)
Measurement of dose	(23.0%)
Nature of radiation	
Characteristics of radiation	(41.9%)
Physical, chemical and biological action in the body	(25.1%)
Medical use of radiation	
How radiation is used in medicine	(22.7%)
Equipments and apparatuses	(15.5%)

Table 2. Subjects in the lecture and the practice

Lecture (90 min.)
Biological effects of radiation
exposure doses and dose limits
Basic procedure for radiation protection
Patient doses and optimization
Practice (60 min.)
How to use a survey-meter
Measurement of radiation in daily life
Relationship between dose and distance
Shielding effects of some materials (density, thickness)

practice are shown in Figures 1 and 2. More than 95 % of the nurses understood radiation and radiation effects through the lecture. Among the items of the lecture, the basic procedure of radiation protection was easily understood for nurses while the biological effects of radiation were difficult to understand. The useful items of the lecture for nurses were; understanding the level of occupational exposure (31.4%), practically detailed procedure to reduce external doses(18.6%), basic procedure to reduce external doses (17.1%), and biological effects of radiation (14.3%).

Of the 12 nurses who attended the practice, 7 nurses answered that the experimental practice for the shielding effect of some materials was very interesting. Also, 11 nurses answered that they understood radiation in everyday life such as radiation from luminous clocks and natural radiation.

*Radioisotope Laboratory, School of Pharmacy and Biochemistry, University of Buenos Aires, Buenos Aires, Argentina.

**Argentine National Nuclear Regulatory Authority, Buenos Aires, Argentina.

INTRODUCTION

The advancement of knowledge in molecular and cell biology, biochemistry, medicine and pharmacology, which has taken place during the last 50 years, after World War II finalization, is really outstanding. It can be safely said that this fact is principally due to the application of radioisotope techniques. The research on metabolisms, biodistribution of pharmaceuticals, pharmacodynamics, etc., is mostly carried out by means of techniques employing radioactive materials. Radioisotopes and radiation are frequently used in medicine both as diagnostic and therapeutic tools. The radioimmunoanalysis is today a routine method in endocrinology and in general clinical medicine. The receptor determination and characterisation is a steadily growing methodology used in clinical biochemistry, pharmacology and medicine. The use of radiopharmaceuticals and radiation of different origins, for therapeutic purposes, should not be overlooked.

For these reasons, the importance to teach radioisotope methodology is steadily growing. This is principally the case for specialisation at the post-graduate level but at the pre graduate curriculum it is worthwhile to give some elementary theoretical and practical notions on this subject. These observations are justified by a more than 30 years teaching experience at both levels at the School of Pharmacy and Biochemistry of the University of Buenos Aires, Argentina. In 1960 we began to teach Physics III, an obligatory pre graduate course for biochemistry students, in which some elementary notions of radioactivity and measurement techniques were given. Successive modifications of the biochemistry pre graduate curriculum incorporated Radiochemistry as an elective subject and since 1978, Radioisotope Methodology, as obligatory subject for biochemistry students. This subject is given at the Radioisotope Laboratory during the first semester of each year and its objective is to provide theoretical and practical knowledge to the biochemistry students, even though this knowledge does not imply any possibility to obtain a license to work with radioactive material. Pharmacy students receive since 1975 some very elementary notions of radioactivity in the Physics courses in the same Department and some notions of Radiopharmacy are given in Pharmaceutical Technology.

Since 1962 we are giving every year during a complete semester in the second half of the year, at the same Radioisotope Laboratory of the School of Pharmacy and Biochemistry, the Radioisotope Methodology Course for professionals mostly engaged in the health area. Its objective is to provide a throughout theoretical and practical knowledge for the utilisation of radioactive materials in different disciplines, particularly those related to health. The experience obtained in this course is sufficient to obtain a license from the National Regulatory Authority to manipulate radioactive material "*in vitro*".

COURSE ORGANISATION

The teaching experience acquired during successive courses given since 1962, allowed us to define a well settled complete theoretical and practical program embodying 222 training hours, 122 being theoretical and the remaining 100 are personal and intensive experimental work. It should be added that each graduate has to study for each practical activity and make a report of the obtained results; this activity is not taken into account in the foregoing chronogram. In order to estimate the degree of knowledge, the practical activities are evaluated; we take two partial examinations and a final, written and oral examination. Radioprotection aspects have a relative weighting in the evaluations of approximately 50 per cent.The program includes a first part of basic and general concepts. In the second part all the specific applications of radioisotopes to the biomedical area are included and as new methodologies appear they are incorporated. The titles of each chapter of the program are:

Nuclear stability. Binding Energy. Nuclear models. Radioactive decay mechanisms and kinetic equations. Particles and radiation interaction mechanisms. Instrumentation: ionisation chamber, proportional counters, Geiger-Müller tubes, mono and bidimensional radiochromatogram analysers, solid and liquid scintillation spectrometry, solid state detectors, radioautography (whole sample, histology, cellular), absolute activity determination. Detection efficiency. Statistics in the radioactivity measurements. Production of radioisotopes and radiopharmaceuticals. Purity control and criteria. Activation analysis. Biochemical

applications of radioisotopes: radioimmunoanalysis, receptors, radioautography, precursors and others. Medical applications: image diagnosis and radiopharmaceuticals. Radiotherapy: internal and external. Notions.

Since the objective of this paper is radioprotection, we shall analyse these points of the program with more detail. Radioprotection is one of the most important chapters of the course, since it is our experience that professionals having passed the final examination frequently will be responsible for the radioprotection aspects in his/hers work place. We emphasise from the very beginning that a throughout knowledge of radioprotection is essential for a good professional practice. The theoretical subjects are approximately a 30 per cent of the classes and include:

Definitions, magnitudes and units of: dose, dose equivalent, collective dose equivalent, committed dose equivalent, exposure and their respective rates. Internal and external sources. Shielding. General aspects of radioprotection: justification, optimisation and dose limitation. Biological effects of ionising radiation. Radiobiology. Classification of working areas. Occupational radiological protection. Internal and external contamination. Monitoring. Instruments for radioprotection. Regulation for the transportation of radioactive materials. Regulations for the utilisation of radioactive material in Argentina.

Even though the specific practical activity related to this chapter is only a 10 per cent of the total practical training, in all these activities radioprotection regulations are taken into account and discussed permanently with the graduate students. Specifically in the first practical work the rules to work safely with radioisotopes are given and discussed with the trainees and afterwards problems and shielding calculations are carried out. At the end of the course a substantial part of the final examination is the planning of an experiment with radioisotopes, taking into account radioprotection regulations as well as all the other knowledge throughout the course. The main idea of stressing the importance of radioprotection considerations is to take for granted that, at least in principle, any professional having passed the final examination and consequently licensed by the Regulatory Authority, should be capable to act as security officer.

The objective of the training in radioprotection consists in the acquisition of criteria for the adequate application of the radioprotection *philosophy*, independently on the previous university training of the graduate students participating in the course. The global synthesis include:

Planning of professional practices with an adequate *training* of the personnel involved in order to keep the doses as low as it is reasonably possible and *calculation* of the doses absorbed by the personnel during the practices. At the same time we emphasise those aspects related to the specific future activities of the graduates assisting to the course, principally ^{125}I for biochemists mainly interested in radioimmunoanalysis. In the case of physicians interested in future radioisotope applications to their profession, ^{99m}Tc is the mostly used radionuclide in Argentina. Even as its Γ value is 0.08 Rm^2/hCi, quite similar to that of ^{125}I, in the ^{99m}Tc case activities of 0.5 to 1 Ci are used, which obviously increase the dose due to irradiation.

RESULTS

Since the beginning of the course until 1995, a total of 1106 professionals have passed their examinations. It should be mentioned that the graduates are chosen not only taking into account their academic profiles but also considering the necessity of their respective working places to have well trained personnel in radioisotope techniques. We receive mainly biochemists, physicians, chemists, biologists, engineers, pharmacists and others. In the Figure 1 we show the proportion of the main professions in periods of five years as a function of time. The preponderance of biochemists and physicians is evident. Another interesting point to be noted is the increasing tendency of the number of professionals as a function of time. In the last years the number of physicians is growing steadily. This is due to the increasing expansion of medical diagnosis with radioisotopes, principally in cardiology.

The participating professionals live principally (88 per cent) in Buenos Aires and its surroundings. In the last few years the proportion of graduates from the provinces is increasing. This fact should be due to a growing interest in smaller cities to have, at least, certain minimal radioisotope using health care practices, both in medicine and biochemistry. During these years 10 professionals from different Latin-American countries (Peru, Venezuela, Colombia, Brazil and Uruguay) have passed their examinations.

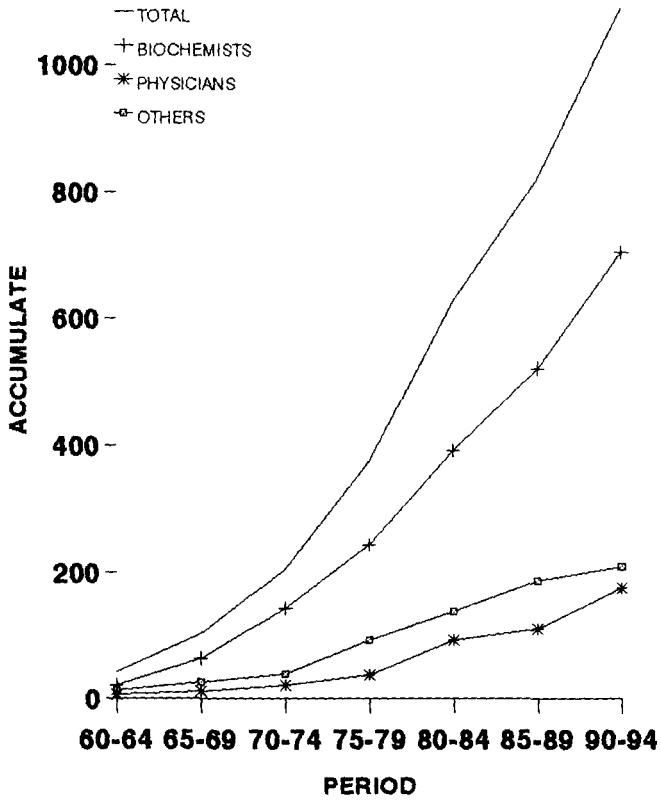

Fig. 1.- Number of professionals trained from 1960 to 1994.

CONCLUSIONS.

The application of radioisotopes and radiation to different professional activities is already a common practice in modern science and technology. However, these activities are only possible in a framework of radiological safety, if adequately trained personnel is employed. The course we describe in the present paper is organised and conceived with this purpose in mind, with a background of more than 30 years of permanent and actualised teaching activity.

RCA - A REGIONAL APPROACH TO RADIATION PROTECTION

Richard Griffith and John Easey
International Atomic Energy Agency, A-1400 Vienna, Austria

INTRODUCTION

The Regional Cooperative Agreement (RCA) for Asia and Oceania is the oldest of four International Atomic Energy Agency Member State regional programs. Organized in 1972, 17 countries are now members of RCA - Australia, Bangladesh, Peoples Republic of China, India, Indonesia, Japan, Republic of Korea, Malaysia, Mongolia, Myanmar, New Zealand, Pakistan, Philippines, Singapore, Sri Lanka, Thailand, and Viet Nam. A number of projects related to the application of a wide range of nuclear technologies are conducted through RCA. The program is established by national coordinators for each project area, in consultation with IAEA technical officers. Most of the funding comes directly from RCA regional donor countries, with about one third supplied through the IAEA Technical Cooperation program.

In 1986, following the Chernobyl accident, national coordinators and the IAEA staff recognized the value of establishing an RCA project aimed at strengthening regional radiation protection programs. The potential importance of RCA involvement in radiation protection is underscored by the fact that its member states comprise more than half of the world's population.

The regional approach to addressing radiation protection issues allows member states to take advantage of regional resources to solve common regional problems. RCA provides the opportunity for specialists who may have few professional colleagues in their country to develop valuable contacts with regional radiation protection experts. In a very real way, specialists can network with their neighbors, often establishing bilateral programs outside of the RCA auspices.

The current five year RCA ***Project to Strengthen Radiation Protection Infrastructures***, with the IAEA designation - RAS/9/006, will be completed at the end of 1997. The project was developed to address five major areas of activity: Off-site emergency response; Individual monitoring, internal and external; Characterization of the physical, anatomical, physiological and metabolic characteristics of the Asian populations; Regulations, with emphasis on implementation of the new International Basic Safety Standards; and Training and Education.

OFF-SITE EMERGENCY RESPONSE

The objective of this project area is to support establishment of national capabilities in RCA Member States for off-site emergency response to accidents involving radiation sources, nuclear power stations and research reactors. This need was highlighted following the Chernobyl accident. Although only four RCA Member States (China, India, Japan and Korea) and Taiwan (not an IAEA Member) have currently have operating nuclear power plants, an accident within the region is likely to have an impact on regional neighbors. Moreover, other countries within the region are currently developing plans for national nuclear power programs.

The need for an emergency response capability is not limited to nuclear power issues. World wide experience over the last few years has shown that improper use or loss of control of large sources can have fatal consequences, sometimes involving the public. Therefore, RCA work on emergency response is intended to address the potential for large source accidents as well.

The emergency response project has been established by the RCA national coordinators to address three major topics areas or outputs: Recommendations on the regulatory control, safe handling, storage and disposal of sealed sources based on IAEA Safety Series guidance (covering medical uses, nuclear gauges, irradiation facilities, and decommissioning, dismantling, storage and disposal); Development of national capabilities for handling off-site emergency plans and countermeasures; and Establishing a regional network to assist in emergency situations.

The mechanisms identified to achieve the emergency response objectives include:

- conduct of regional consultants meetings on formulation of legal requirements and development of national services to produce procedures and guidance on assistance in the event of an accident.
- workshops for national specialists on recommendations on the regulatory control, safe handling, storage and disposal of sealed sources; preparation of off-site emergency plans and counter measures assessment of dose arising from a radiological accident.

- training courses on licensing and control of sealed sources and recent developments in basic radiation protection
- intercomparison program for measurement of environmental radioactivity

On an individual basis, support for the upgrade of emergency response capabilities is provided through recruitment of experts, either from the region or outside the region, to advise on specific areas of need, and fellowships which allow people having national responsibilities to receive on-the-job experience in neighboring countries. It is often through individual contacts such as these that on-going, bilateral relationships are established with the RCA region.

INDIVIDUAL MONITORING

A major objective of the RCA project to strengthen radiation protection infrastructures is to promote the harmonization and upgrading of individual monitoring programs for occupational protection. This is seen as an area where regional cooperation can be particularly effective. The tasks under the current project address both external and internal dose assessment. For external monitoring, the program is particularly timely in that it provides an opportunity to stimulate introduction and use of the operational quantities defined by the International Commission on Radiation Protection and Units (ICRU) and endorsed in the ***International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources*** (BSS) for demonstration of compliance with the prescribed dose limits.

RAS/9/006 primarily addresses dosimetry needs through regional intercomparisons and workshops. Intercomparisons offer the participants access to a number of resources for calibration and assessment of their measurement systems that would not otherwise be available to them. This, for example, may include the opportunity for calibration using x-ray fields that can provide information on the energy response characteristics of their dosimetry systems. Participants compare the performance of their systems with their regional colleagues, which can help them identify areas for improvement.

The first RCA regional personal dosimetry intercomparison for photons was conducted in three phases over three years during the period 1990 to 1992. Seventeen dosimetry service organizations from 14 member states participated in the programs. Irradiations and data compilation were conducted by Japan Atomic Energy Research Institute (JAERI). Progress over the three phases demonstrated clear improvement in the participants' understanding of the concepts and their ability to carry out dose assessment. The second intercomparison is currently underway with 37 participating services from 15 Member States. The Australian Radiation Laboratory, JAERI, Japanese Power Reactor and Nuclear Fuel Development Corporation (PNC), and the New Zealand National Radiation Laboratory are providing irradiations. Emphasis is being given to calibration in terms of the ICRU operational quantities, including use of the 30cm x 30cm x 15cm water filled backscatter phantom now being recommended in draft guidance of the International Standards Organization (ISO).

Regional workshops bring together experts and those responsible for establishing and managing various elements of occupational monitoring programs. In 1994, RAS/9/006 sponsored two highly effective workshops on external dose assessment and calibration techniques for external photon irradiations. Again, a major thrust of these workshops was calibration and individual monitoring in terms of the ICRU operational quantities. Expert presentations, laboratory exercises and open discussions with participants helped clarify the principles involved in use of the "new" quantities and allay fears about their implementation. In particular, the workshops were valuable precursors to the second RCA regional intercomparison for individual monitoring. In 1996, another workshop is planned on contamination monitoring.

Additional RCA regional activities include tasks intended to address internal dosimetry and biological dosimetry. One task is aimed at the need to establish regionally harmonized measurement techniques and dosimetry for radon and thoron. A workshop on use of physical phantoms and mathematical models for occupational radiation protection is also being planned for 1997.

REFERENCE ASIAN MAN

Remembering that the RCA Asian Member States represent more than half of the world's population, the national coordinators identified the need to compile a database on the physical, anatomical, physiological and metabolic characteristics of the Asian populations for radiation protection purposes. The compilation process was initiated as an IAEA Coordinated Research Program (CRP) in 1988 under funding by the Japanese government. Eleven RCA Member States participated in the CRP, collecting national data in four major areas:

- Anthropomorphic measurements
- Organ mass measurements
- Nutritional and dietary intake
- Pulmonary function and water balance

Data was compiled on over 1,000,000 people. Results show a range in anthropomorphic and organ mass characteristics within the Asian region that is nearly as great as the difference between the Asian and western populations. Moreover, in some countries such as India there is a wide national diversity due to contributions of ethnic sub-populations, while others such as Japan are quite homogeneous. It is clear that each country in the region will need to analyze its own situation and use the available data as appropriate to national needs.

The extent and quality of data on nutritional and dietary intake, and pulmonary function and water balance were not as extensive and complete as for the anatomical parameters. This has led to initiation of a second CRP which will focus on analysis of trace elements important to radiation protection in national dietary samples and selected tissues. A more detailed report on the CRP appears elsewhere in this proceedings.

REGULATIONS

Publication of the ***International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources*** has brought a focus on the requirement to harmonize implementation of the new recommendations. The RCA offers an excellent mechanism to address this need in the Asian region through regional workshops, seminars and training programs. A specific task has been established to facilitate BSS implementation with the objective of assisting Member States in understanding and implementing the recommendations of BSS in the region. Activities under this task include: Regional training on implementation of the Basic Safety Standards and National seminars on the consequences of the introduction of the BSS and their implementation on a national and regional basis.

TRAINING

The RCA program for strengthening radiation protection infrastructures offers the opportunity to develop and upgrade the quality of RCA Member State training and education programs on a regional basis. The major activity in this area is the development of distance learning materials for radiation protection. The distance learning material program, which has been, developed by the Australian Nuclear Science and Technology Organization (ANSTO) and supported by the Australian government, recognizes the difficulty that is often encountered in providing effective national training in countries where resources are separated from those who need the training by great distances. The distance learning materials have been developed in a modular format to enhance flexibility in their use. Topics range from basic radiation interaction and detection principles to transport of radioactive material and waste management. Each module includes question sets to assess the student's comprehension. The materials are designed to be used and administered by a facilitator or mentor.

Recently, a regional seminar to promote education and training in radiation protection and nuclear safety was conducted under joint sponsorship of the RCA and the regular IAEA Technical Cooperation training program. Although not strictly an RCA activity, the regional seminar brought together training specialists from RCA member states to discuss national training needs, approaches and solutions. A clear outcome of the seminar was the potential for using a regional approach to meet training needs.

SUMMARY

The IAEA/RCA ***Project to Strengthen Radiation Protection Infrastructures*** brings together 17 countries in Asia and Oceania to address radiation protection issues of common interest on a regional basis. Activities within the Project combine technical resources from within the region and interregional expertise to conduct training activities, workshops, Co-ordinated Research Programs (CRPs), expert advisory group meetings etc. Emphasis is placed on use of regional radiation protection experts to respond to RCA country needs, and local host institutions for fellowship training. Although RCA communications begin with the network of national coordinators, networks of specific technical specialists have evolved to expedite information exchange in emergency response and dosimetry. The RCA has become an excellent vehicle for developing a regionally harmonized approach to implementation of the International Basic Safety Standards.

MANAGEMENT AND TRAINING ASPECTS OF THE EMERGENCY PLAN

J R A Lakey
John Lakey Associates, Meopham, Kent, DA13 0JA, UK

INTRODUCTION

The main objectives of an emergency management system are to prevent or reduce the likelihood of consequential loss in the event of an emergency occurring. In the event of a nuclear accident the effectiveness of measures for the protection of the public will depend on the advance preparation especially in education and training. This paper reviews two recent initiatives and concludes with comments on the future development of this subject.

There is an increasing requirement in legal and moral terms for industry to inform the population of health hazards to which they are exposed. In a report (1) published by the Nuclear Energy Agency (NEA/OECD) radiation protection was described as a subject which is impenetrable to the layman and as wide as it is complex. For this and other reasons radiation hazards are perceived to exceed all others and the public appear to have a poor image of the radiation protection specialists. Communication with the public and the media is widely recognised (2) as a key part of an emergency plan. This view is supported in the European Union which has sponsored the book on "Radiation and Radiation Protection - a Course for Primary and Secondary Schools" (3) which is described in this paper.

The training of emergency teams includes the use of drills and exercises (4) to maintain skills and can also be used to test the adequacy of plans. Every effort should be made to simulate the pressure on time and resources which would occur in a real event. Radiation emergencies are fortunately rare and so there is little practical experience of these events. The emergency worker must gain some radiation protection skills and must be able to use some technical language when communicating with specialist advisors. For this reason the European Union has sponsored the book "Radiation Protection for Emergency Workers" (5) which is also described in this paper.

A COURSE FOR PRIMARY AND SECONDARY SCHOOLS

In the European Union the Council Directive (6) on public information was adopted in 1989. This emphasised that the public should understand the issues involved and be prepared in advance of the emergency. The Commission organised a Seminar (7) in 1988 and the outcome was a suggestion that teaching material on radiation protection should be developed for use in Schools of Member States. The Directorate General XI (DG XI) (8) developed a first draft of the Teacher's Manual. A "spiral curriculum" was chosen because radioactivity, ionizing radiation and non-ionizing radiation are fairly complex and abstract subjects in particular for younger and less advanced pupils. This means that items recur in a gradually more complex form. The material was set out in five levels covering ages 6 - 16. In the first three levels emphasis is placed on relating the pupils personal and every day experiences and they are made aware of the risks and benefits of ionizing radiation. In the final two levels a more detailed examination is made of the subject from both a technical and social point of view. The original text was tested by the University of Utrecht and edited into a convenient loose leaf format. A test printing of the text was produced in 1993 and presented to a group of European Communities experts together with a formal presentation of the survey results. Reports were given by

teachers involved in the testing and the two original authors responded to the comments presented their views. The course was modified in response to recommendations made at this meeting. New Chernobyl information was added and potentially confusing material on the "green house effect" was deleted. The first edition in loose leaf format was published in 1994. This will not be the end the story; success will depend crucially on the sharing of the experience gained by teachers who choose to use this book.

RADIATION PROTECTION FOR EMERGENCY WORKERS

This CEC book (4) is intended to support emergency team training and introduces the principles of radiation protection and the properties of radioactive materials. Radiation doses, their consequences and principles of radiation detection are explained. Guidelines are given for protection against radiation from external sources and from internal sources. The annex to this paper gives an example of the guidelines used in the book. A number of radiation emergencies are described to provide a basis for the lessons learned. The booklet concludes with appendices on the atom, on nuclear fission and the regulations for transport of radioactive materials. A list of radionuclides and a list of SI prefixes precedes a glossary which covers the terms used in the book and related topics.

FUTURE ACTIONS

Education. Experience of exercises and incidents occurring in the nuclear energy programme reveals that there is sometimes a gap (9) between the desired response from the engineering team and the resources available. This is where professional skills and engineering judgement are demanded, and where precisely defined training schemes and rule driven response is likely to fail. This gap probably occurs in the reponse to many other emergency situations and may be a neglected area of the engineer's education. A new syllabus has been published for an undergraduate awareness course emphasising the engineer's responsibility for health and safety of the public (10). This duty of care to the towards the public should also apply to the engineer's rôle in the response to emergencies and so an extension to this syllabus is proposed.

Performance under stress. Experience in the conduct of exercises and in real emergencies suggests that emrgency response teams do improve their performance with practice and experience. Performance under stress demands a cool heads which probably can be acquired in training. Correlation between training performance standards and the real thing is difficult, more research is needed especially in the study and alleviation of stress.

ANNEX - GUIDELINES ON PERSONAL DOSE REDUCTION *.

Emergency personnel must take precautions to protect themselves against all hazards at the site of an emergency. These guidelines are provided as an aid to the application of the ALARA principle in emergency response. Seven steps for your protection against radiation are summarised below:-

1. See the Source - make every effort to identify the type of radiation hazard. Search for the trefoil symbol, recognise the shape of standard sources and their containers, get expert advice, notify proper authorities.
2. Seek containment - do not move a damaged source, avoid breaking protective enclosures, close doors and windows. Cover all exposed skin. Do not eat, drink, smoke, rub eyes or apply skin preparations such as sun tan lotion and cosmetics.
3. Stop Spread - monitor and cover or decontaminate surfaces, do not spread activity by your own movements and set up a barrier or control line at a safe distance out of range of the source.
4. Shorten Exposure - keep exposure time as short as possible, reduce the time of working close to the source, move away into a clean or low dose rate area to think, to discuss. Rehearse all actions.
5. Step away - keep as far away as possible, never touch the source, use appliances such as long handled tongs, view the scene through a telescope, use a mirror to see round a corner. Position vehicles and command post up-wind, out of smoke and away from liquids.
6. Shadow Shield -install a radiation shield which is as thick and as heavy as possible, place it as close to the source as possible, work behind a shield, make use any available structure as a shield.
7. Self check - check your dosimeter frequently, check your own clothing for radioactive contamination at the barrier, look out for non-radiation hazards. Communicate with the controller.

Early radiation protection - the Austrian contribution

M.Tschurlovits
Atominstitute of Austrian Universities, A-1020 Vienna, Austria

Abstract

Immediately after the discovery of x-rays and radioactivity. an avalanche of applications and development developed also in Austria. Also immediately, deleterious effects of radiation were observed and hence the precursor of the profession of "radiation protection" was founded.
This paper presents some documents and information on early activities in radiation protection, as done in the countries belonging to the previous Austrian empire. The examples include information on some scientific background on radiation effects at this time, the worldwide first licensing procedure in 1899 and some early environmental radioactivity measurements. A pre-1895 epidemiological study is also shown as well as very early papers associated with the field of RADIOECOLOGY.

Radioactivity

Pre-1896, the only possible sources of radioactivity leading to an exposure with radiological consequences were daughter products of radium. As we know today, substantial concentration of radon may take place in mines, and a strange disease only among miners was described even some centuries ago. Famous names as Agricola (1500, cited by /1/) and Paracelsus (1567, cited by /2/) are reported. One area with a high concentration of valuable material and hence mining was the region "Erzgebirge" at the border between Saxony and Bohemia, where Bohemia was at this time part of the Austrian empire. Therefore, both the "Schneeberger (Saxony)" and the "Joachimstaler (Bohemia)" "Bergkrankheit, mountainous disease" were found among miners with the roughly the same incidence /3/. The disease remained unidentified until /4/ proved an enhanced incidence of lung cancer is associated with mining. Later, the relation between Radon concentration and enhanced incidence of lung tumours was proved, and numerous papers were considering this question after the discovery of radioactivity

Another very early investigations which might be considered today as roots of "radioecology" were carried out by investigations of radioactivity in air /5/ and water/6/ by scientist who become very famous later. In addition, cosmic rays were also discovered /7/

X-rays

W.C.Röntgen reported his famous discovery to a few friends before final publication. Among these friends was a Viennese scientist, and the invention was soon published in a newspaper at 5.1.1896. An avalanche of work was developed, mainly in medical application as diagnostics and therapy /8,9/. Obviously, deleterious effects of radiation were discovered immediately and were well aware to the scientific community /10/. This in turn lead to the interest of the local authorities to introduce licensing.

The worldwide first licensing procedure was started in 1898/10/. This was a formal inquiry of the administration of Lower Austria (*k.k.NÖ Statthalterey*) to the muncipiality of Vienna (*Wiener Magistrat*) to check what is going on in Drs Schröder und Ehrenfeld`s *Institute für Röntgenuntersuchungen*. This is because x-rays are still called Röntgenstrahlung in German speaking countries. This action lead after a meeting of the medical council and a statement of a medical expert, who was in a position to give a well proved statement of the deleterious effects of radiation very soon to a licence, The licence for the institute was issued in October 1899 including some *cautelen* (protective measures as not to irradiate the same part of the body frequently).

Some examples of the early documents are presented below
