The annual intake of radionuclides (I) and the corresponding committed (and committed effective) dose equivalents (CDE and CEDE) are the main safety limits for occupational internal exposure. They are defined by monitoring an individual occupational intake of radioactive material and assessing the resulting dose. A routine monitoring programme usually consists in a set of measurements of the radiation emitted from the body or the radioactive materials contained in biological samples such as urine or feces during the calendar year. The required frequency of measurements in a routine monitoring programme depends upon the retention and excretion of the radionuclide, the sensitivity of the measurement techniques available, and the acceptable uncertainty in the estimate of intake and committed effective dose (ICRP 1997). The procedure for assessing doses on the basis of routine monitoring results includes use of standard model parameter values for the dose calculation and at least simple estimation of the associated uncertainty due to uncertainty of the worker exposure conditions, the uncertainty in the time of intake and the uncertainty of the measured bioassay quantity method. If the upper value on assessed dose exceeds the reference limit (annual dose limit for workers or part of it) a special monitoring procedure is required.

The special monitoring procedure consist in performing additional in vivo and in vitro bioassay measurements to increase the reliability of the dose assessment by obtaining better information on the model parameter values and by using statistical methods for the calculation of the associated uncertainty. Inhalation is the most often route of intake for workers and the exposure conditions in this case are characterized by the particle size distribution of the aerosol, as described by the Activity Median Aerodynamic Diameter (AMAD) and the absorption characteristics of the material, as described by the absorption classification (Type M or S for cobalt compounds). Numerical statistical methods find an increasing application for the interpretation of internal exposure monitoring data for atomic industry workers. This is due to increasing potentialities of modern computers allowing a direct modeling of biophysical processes of the radionuclide intake, retention, excretion and measurement in a human using Monte Carlo simulating technique.

The aim of the paper is to present the results of a numerical method application (Molokanov et al. 2010) for the interpretation of in vivo and in vitro bioassay measurements of Co-60 performed during special monitoring of four nuclear power-plant workers.

Material and methods

The assessment of dose from intakes of radionuclides is a stepped process of measurement and computation that is in essence a virtual biophysical experiment where computation is the process of connecting and ordering of known data by means of relations based on theory or established models in order to create new data and to reveal new insight (Siebert 2006). Our virtual biophysical experiment is aimed to find a relation between a measured quantity and a desired quantity on basis of ICRP biokinetic model. Any physical quantity used in the biokinetic model can be considered as a desired quantity such as organ absorbed dose versus time, committed and committed effective dose equivalents, organ activity and any parameter of the model including the aerosol absorption type and AMAD. For such a biophysical experiment the model can be formulated as a cause-effect relation where a single intake at time τ is a cause and quantities M and X are effects:

$$\frac{M(t_M)}{X(t_X)} = \frac{I \cdot m(t_M - \tau, \xi(\tau))}{I \cdot x(t_X - \tau, \xi(\tau))} = m_{M/X}(t_M, t_X, \tau, \xi_i(\tau)) \tag{1}$$

where I is a value of a single intake of a radionuclide occurred at time τ; $m(t-\tau, \xi)$ and $x(t-\tau, \xi)$ are functions of time t derived from ICRP model; t_M is the measurement (or sampling) time; t_X is the desired quantity fixed time; $\xi_i(\tau)$ is a set of the model parameter values at time of the intake.

Two tasks can be considered using the model described by equation (1): evaluation of quantity X and evaluation of the model specific parameter $\xi_i(\tau)$. In the first case we analyze quantity M/X in the second case we analyze quantity M_1 / M_2 where M_1 and M_2 are two independent measurement results that may define the parameter $\xi_i(\tau)$. In the case of a single inhalation intake of Co-60 the following equations sequent to equation (1) will be used.

For the dose and intake calculation:

$$\sum_{n=1}^{N} M_L(t_n) = \sum_{n=1}^{N} X \cdot m_{M_L/X}(t_n - \tau, w, AMAD) = \Phi(X) \quad (2)$$

where $M_L(t_n)$ are result of Co-60 measurement in the worker lungs at time t_n; X –the intake or the dose value; w is a parameter, characterizing absorption type (fraction of type S compound in a mixture of M and S), N is the number of measurements during the observation period.

For absorption type investigation:

$$\sum_{j=1}^{N-1}\sum_{n=j+1}^{N} M_L(t_j)/M_L(t_n) = \sum_{j=1}^{N-1}\sum_{n=j+1}^{N} m_L(t_j - \tau, w, AMAD)/m_L(t_n - \tau, w, AMAD) = \Phi_L(w) \quad (3)$$

For AMAD investigation:

$$\sum_{n=1}^{N}\sum_{k=1}^{K} M_L(t_n)/M_U(t_k) = \sum_{n=1}^{N}\sum_{k=1}^{K} m_L(t_n - \tau, w, AMAD)/m_U(t_k - \tau, w, AMAD) = \Phi_{L/U}(AMAD) \quad (4)$$

and

$$\sum_{z=1}^{Z}\sum_{k=1}^{K} M_F(t_z)/M_U(t_k) = \sum_{z=1}^{Z}\sum_{k=1}^{K} m_F(t_z - \tau, w, AMAD)/m_U(t_k - \tau, w, AMAD) = \Phi_{F/U}(AMAD) \quad (5)$$

where $M_U(t_k)$ and $M_F(t_z)$ are results of Co-60 measurement in urine and feces of a worker at time t_k and t_z correspondingly; $m_L(t, w, AMAD)$, $m_U(t, w, AMAD)$ and $m_F(t, w, AMAD)$ are functions, derived from ICRP model showing the activity value in the lungs, daily urine and feces samples correspondingly versus time t after a single inhalation intake of the radionuclide.

Equations (2) - (5) give experimental value of the measured quantities or their combination – left side, and a theoretical value of the measured quantities or their combination according to ICRP model – right side of the equation.

For determination of the desired quantity value (intake, dose, *w* and AMAD) the result of measurement (or the combination of the measurement results) is compared with the theoretical values of the measured quantity or a combination of the measured quantities calculated using equations (2) - (5) for the set of the desired quantity values and fixed values of the other parameters of the model. Namely, $\Phi(X)$ in equation (2) is calculated for the set of X_1, X_2, ..., X_j values, $\Phi_L(w)$ in equation (3) is calculated for the set of w_1, w_2, ..., w_j values and $\Phi_{L/U}(AMAD)$ in equation (4) and $\Phi_{F/U}(AMAD)$ in equation (5) are calculated for the set of $AMAD_1$, $AMAD_2$, ..., $AMAD_j$ values. The value of a parameter at which the calculated theoretical value of the measured quantity agrees with the measured experimental value represents the estimate of the parameter according to the accepted ICRP model.

In fact, the measured quantity values are variables and the model parameter values are not known exactly. In this case a likelihood function is used to describe the probable value of the quantity that was measured and the probability density function (PDF) is used to describe probable values of the model parameters. Likelihood function, $L(M|X,\xi_i)$, describes the probability of observing a value M provided the values X and ξ_i are known. Values of the likelihood function can be calculated numerically using Monte Carlo integration technique. For that at the first step the model parameter values, ξ_i, are sampled from their PDFs and the value of the measured quantity M or a combination of the measured quantities $\Phi(M_n)$ is calculated using the likelihood function(s), $L(M_n|X,\xi_i)$ and a fixed value of the desired quantity X. Repeating this procedure many times a set of the measured quantity values $\{M_k\}$ or $\{\Phi_k(M_n)\}$ is generated. A frequency distribution of these quantities is found By sorting $\{M_k\}$ or $\{\Phi_k(M_n)\}$ that represents a random sample of the likelihood function $L(M|X)$ or $L(\Phi(M_n)|X)$ for the measured quantity M or a combination $\Phi(M_n)$.

Thus, the theoretical values of the measured quantity or a combination of the measured quantities are represented as the likelihood function $L(M|X)$ or $L(\Phi(M_n)|X)$, where M or M_n are arguments and the desired quantity X is a parameter. In this case the experimental value M_0 or a combination of the experimental values $(\Phi(M_{n0})$ are compared with a set of the likelihood functions $L(M|X)$ or $L(\Phi(M_n)|X)$ for a set of desired quantity values $X_1, X_2, \ldots, X_j$. The value X_α at which fulfills a condition:

$$\int_0^{M_0} L(M\,|\,X_\alpha)\cdot dM = 1-\alpha \quad \text{or} \quad \int_0^{\Phi(M_{n0})} L(\Phi(M_n)\,|\,X_\alpha)\cdot d\Phi(M_n) = 1-\alpha \qquad (6)$$

represents the estimate of the parameter with a confidence level α (Neyman 1937, Yao W.-M. et al. 2006) according to the accepted ICRP model, the model parameter assumptions and the assumed likelihood function for the measured quantities.

Results

Special monitoring measurements of four nuclear power-plant workers consisted of in vivo measurements of Co-60 in lungs during 200 days after an acute intake and several in vitro measurements of urine and feces samples performed 200 days after an acute intake that occurred 05.02.2009. The results of the measurements are presented in tables 1 and 2.

Table 1. Results of in vivo measurements of Co-60 in lungs for four nuclear power-plant workers during a year 2009, Bq/Lungs.

Wor-ker	Date of measurement										
	26.02	11.03	16.03	23.03	24.03	30.03	03.04	06.04	29.07	10.08	24.08

Uncertainty of in vivo measurements of Co-60 in lungs presented in table 1 has two components: type A and Type B. Type A uncertainty arises from the statistics of counting measurements and described using the Poisson distribution. Type B uncertainty includes variability of the measurement geometry and uncertainty of the calibration. Type A uncertainty for the observed activity levels did not exceed 1 % and Type B uncertainty was described by lognormal PDF with geometric standard deviation equal 1.2 (Doerfel et al. 2006).

Uncertainty of in vitro measurements of urine and feces samples presented in table 2 also has two components: type A and Type B. Type A uncertainty for the observed sample activity levels was about 20 %. Type B uncertainty due to variation of excretion rate is usually described by lognormal PDF with geometric standard deviation equal 1.3 – 1.8 for urine and 1.5 – 5 for feces /6/ . Using table 2 data we estimated variation of urine excretion by the value of 1.4 and feces excretion by the value of 1.5.

Results of absorption type investigation using equation (3) and the results of measurements of four nuclear power-plant workers presented in table 1 are shown in figure 1.

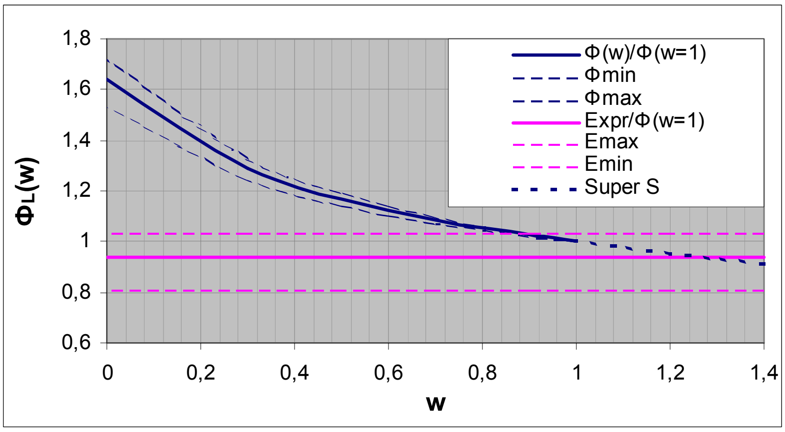

Fig. 1. Theoretical value of function $\Phi_L(w)/\Phi_L(w=1)$, calculated using equation (3) versus parameter *w* in comparison with values $\sum_{j=1}^{N-1}\sum_{n=j+1}^{N} M_L(t_j)/M_L(t_n)$ obtained in experiment.

Absorption characteristics of the material in case of cobalt compounds classified by two types: M and S. We introduced a parameter w to characterize a fraction of type S compound in a mixture of M and S compounds. In figure 1 a theoretical value of the ratio $\Phi_L(w)/\Phi_L(w=1)$ is presented as a function of w. Horizontal lines are the values of the combination of measured results $\sum_{j=1}^{N-1}\sum_{n=j+1}^{N} M_L(t_j)/M_L(t_n)$ normalized to $\Phi_L(w=1)$. Average, maximum and minimum values of the above quantitities for four workers and different values of AMAD in the range 0.1 – 10 microns are presented in figure 1. It follows from figure 1 that the most probable value of the parameter w is w >1. It means that Type S compound is not slow enough to describe the retention of the radionuclide Co-60 in lungs in the case under study and a slower type like super S is needed. But from the two compounds used in the ICRP model type S is the best option.

Results of the Activity Median Aerodynamic Diameter (AMAD) investigation using equations (4) and (5) and the results of measurements of four nuclear power-plant workers presented in table 1 and 2 are shown in figures 2 and 3.

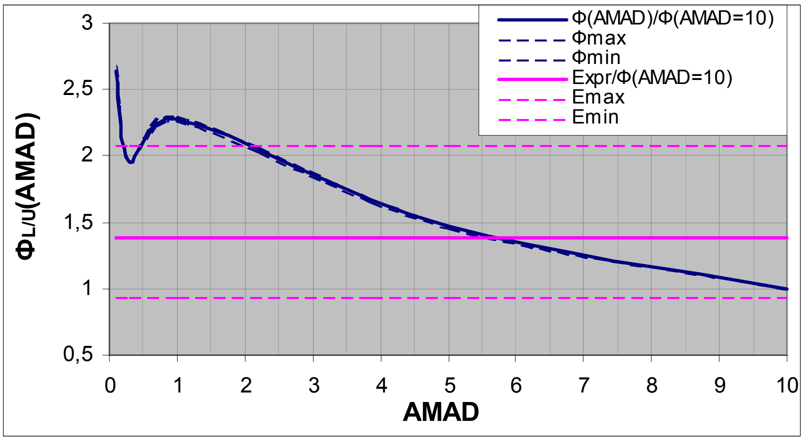

Fig. 2. Theoretical value of function $\Phi_{L/U}$(AMAD)/$\Phi_{L/U}$(AMAD=10), calculated using equation (4) versus parameter AMAD in comparison with values $\sum_{n=1}^{N}\sum_{k=1}^{K} M_L(t_n)/M_U(t_k)$ obtained in experiment.

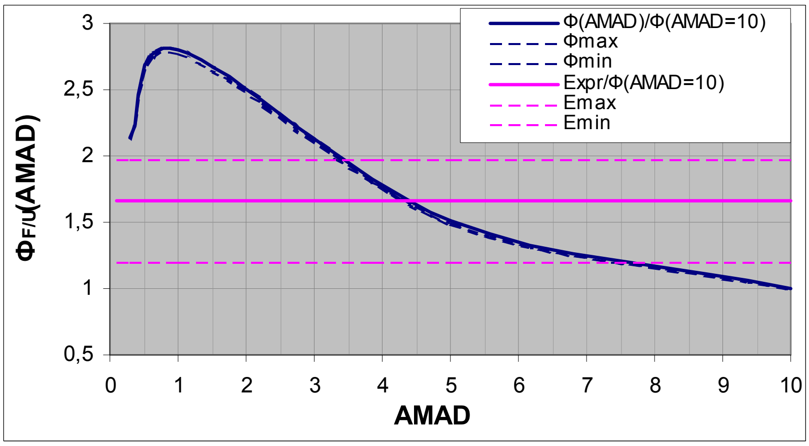

Fig. 3. Theoretical value of function $\Phi_{F/U}$(AMAD)/$\Phi_{F/U}$(AMAD=10), calculated using equation (5) versus parameter AMAD in comparison with values $\sum_{z=1}^{Z}\sum_{k=1}^{K} M_F(t_z)/M_U(t_k)$ obtained in experiment.

Parameter AMAD in working area vary in the range from 0.1 to 20 microns. Aerosols of desintegration usually have AMAD more than 1 micron and condensation aerosols - less than 1 micron. In figure 2 and 3 a theoretical value of the ratios $\Phi_{L/U}$(AMAD)/$\Phi_{L/U}$(AMAD=10) and $\Phi_{F/U}$(AMAD)/$\Phi_{F/U}$(AMAD=10) are presented as a function of AMAD. Horizontal lines are the values of the combination of measured results $\sum_{n=1}^{N}\sum_{k=1}^{K} M_L(t_n)/M_U(t_k)$ and $\sum_{z=1}^{Z}\sum_{k=1}^{K} M_F(t_z)/M_U(t_k)$ normalized to $\Phi_{L/U}$(AMAD=10) or $\Phi_{F/U}$(AMAD=10). Average, maximum and minimum values of the above quantitities for four workers are presented in figures 2 and 3. In all cases type S compound was used. It follows from the figures 2 and 3 that the avarage value of AMAD is in the range (4,5 - 5,5) microns and figure 3 data show a smaller range of (3-8) microns.

Results of the committed effective dose calculation for the four nuclear power-plant workers using equations (2) and (6) are presented in table 3.

Table 3. Results of the committed effective dose calculation for the four nuclear power-plant workers, mSv.

Worker	Dose estimate E_{50} (α=0,50)	Confidence interval		$(E_{max}-E_{50})/E_{50}$, %
		E_{min} (α=0,025)	E_{max} (α=0,975)	
W1	30.8 (20)	25.7 (5.2)	35.9 (51)	17 (155)
W2	13.6 (8)	11.1 (2)	16.8 (20)	24 (150)
W3	10.4 (7.1)	8.15 (1.8)	13.0 (17.3)	25 (144)
W4	17.9 (12.5)	13.9 (3.3)	23.0 (31)	28 (150)

For the dose calculation only in vivo measurements of Co-60 in lungs were used and the following assumptions were taken: Type A uncertainty for the in vivo measurements of Co-60 in lungs equals 1%, Type B uncertainty is described by lognormal PDF with geometric standard deviation equal 1.2, absorption type is characterized by the type S compound, AMAD vary in the range 3-8 microns with uniform probability. Normal PDF is taken as a likelihood function. In table 3 the estimate with a confidence level α=0.5 is taken as the dose estimate and the estimates with confidence levels α=0.025 and α=0.975 are taken as lower and upper limits of the confidence interval. In brackets the same estimates are shown but calculated using the first measurement only and assuming that absorption type is unknown (M or S) and AMAD varies in the range 0.1 – 10 microns.

Conclusions

The presented example of a numerical method application for the interpretation of bioassay measurements of Co-60 performed during special monitoring of four nuclear power-plant workers showed a possibility of improving the dose assessment by obtaining better information on the model parameter values and by using statistical methods for the calculation of the associated uncertainty. From the two compounds used in the ICRP model for cobalt the type S was taken as the best option and the range of AMAD values was reduced from (0,1 до 20) to (3 – 8) microns. This result in the reduction the uncertainty of the dose assessment from (144-155) % to (17-28) %.

The presented committed effective doses for the nuclear plant workers are the estimates with a confidence level α calculated in accordance with the ICRP model and with the assumptions of the model parameter values and the assumed likelihood function for the measured quantities.

On the other hand the parameter model investigation showed that absorption type S compound is not slow enough to describe the retention of the radionuclide Co-60 in lungs in the case under study and a slower type like super S is needed.

Comparison of the three most recent biokinetic models for plutonium

Klein, Wolfgang; Breustedt, Bastian; Urban, Manfred
Institut für Strahlenforschung (ISF), Forschungszentrum Karlsruhe GmbH, GERMANY

Abstract

Biokinetic models for the assessment of individual internal doses represent the physiological processes in the human body which affect the internal distribution of the radionuclide of interest. The International Commission on Radiological Protection (ICRP) recommends compartment models which emerge from a development and refinement of originally crude approximations. The three most recent systemic models for plutonium were studied: the ICRP67 model, the model proposed by Luciani (Luciani and Polig) and the Leggett model (Leggett et al.), which will find its way in future ICRP recommendations.

The three models represent the physiological processes of a standardized human. The flow from one compartment into another is specified by transfer rates, which may diverge from person to person. The sensitivity of a model regarding changes in one transfer rate can be analysed with Monte Carlo simulations. Simulations show that only few transfer rates have an impact on the measurable excretion rates. The influence of a changed transfer rate on the excretion rates is time dependent and can cause a large variation once, while it is without big effects at other times.

For dose assessment with unknown incorporation scenario the variation of the amount of incorporated plutonium was estimated with Bayes methods using excretion rates for the three models and considering individual variations. Incorrect presumptions about particle diameters, f1-values, solubility, wound category … were assumed for inhalation, ingestion and invulneration. They result in considerable different incorporations and consequently different doses. Thus the effort to determine correct incorporation conditions should not be neglected.

Introduction

For the assessment of individual internal doses of occupationally exposed workers and for members of the public the International Commission on Radiological Protection (ICRP) proposes biokinetic models. The most important component of internal exposure for workers is often provided by plutonium and other actinides. Beside the recommended model for plutonium (ICRP 67, published 1993) there are two newer models: the Luciani model and the Leggett model (Fig.1). Luciani modified the ICRP 67 model eliminating unphysiological assumptions and changing the bone model to the more realistic model from Polig. In the year 2005 Leggett improved the ICRP67 model to reflect later developed data. His model will find its way in future ICRP recommendations.

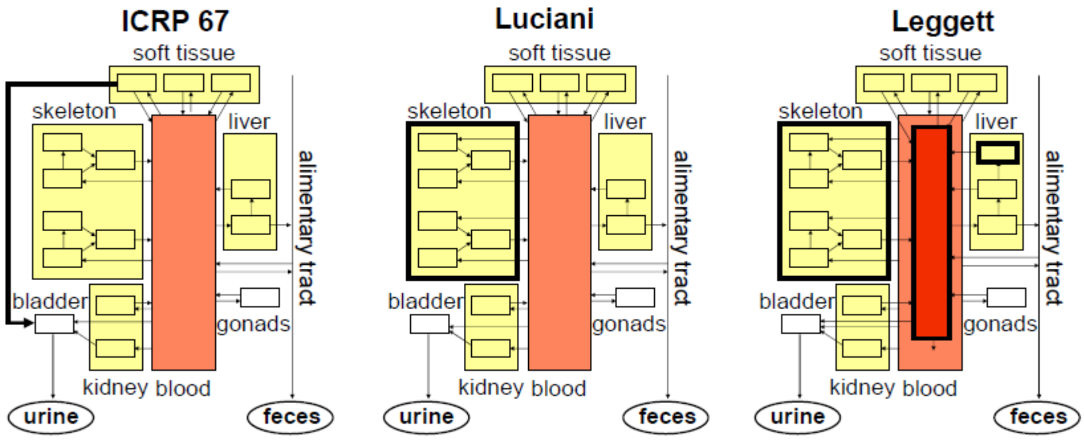

Fig. 1. Model structure of Pu-models from ICRP 67, Luciani and Leggett.

Air sampling and in vivo measurements can provide information on plutonium intakes, but in most cases the primary source of information is bioassay data obtained from urine and faecal analysis. In order to deduce intakes from excretion data, it is necessary to compare the measured amount of plutonium found in urine and feces with the model predictions (Fig. 2). Biokinetic models represent the physiological processes of a standardized human. In general the metabolism of an individual differs from the standardized one. Differences can be modelled with changes in model parameter values. Studies of the effect of these changes on the data of interest is called sensitivity analysis and can give some hints on critical model parameters and best date for excretion monitoring for dose assessment. If the incorporation scenario is unknown assumptions about the intake modalities have the main impact on dose assessment. Incorrect presumptions about particle diameters, f1-values, solubility, wound category … for inhalation, ingestion and invulneration lead to major errors in the estimation of occurred intake.

Material and methods

For sensitivity analysis transfer rates were generated to quantify the impact of changes in one transfer rate on the plutonium excretion within 10,000 days with Monte Carlo methods. As most of the measurable body parameters (e.g. body size, …) are lognormally distributed over the whole population a lognormal distribution was assumed also for transfer parameters. Previous studies indicated that independent variations of all transfer rates with a coefficient of variation of about 60% are able to represent the inter-individual variation for the biokinetic plutonium model best. Thus for the simulations of the sensitivity analysis each transfer rate fluctuates separately according to a lognormal distributions with the mean from the biokinetic model and a coefficient of variation of 60%. In this case Monte Carlo simulations lead to distributions for the predicted excretion rates with time variant statistical spread.

In real plutonium cases most intakes occur accidentally. Then in addition to the individual transfer rates the modalities of incorporation are uncertain as well. The effects of incorrect assumptions about particle diameters, f1-values, solubility, wound category … can also be examined with Monte Carlo methods. They can exceed effects from inter-individual differences by far. A 10,000 days monitoring period after incorporation was chosen. Virtual monitoring data was created exponential distributed during this period with at least 5 datasets. Incorporation modalities were chosen randomly (e.g. AMAD 1, AMAD 2, AMAD 5, AMAD 10 respectively solubility S, M, F) while the intake was calculated with standard assumptions (inhalation: AMAD 5, solubility M) and lognormally distributed transfer rates with coefficient of variations of 60%.

Results

As the decay of Plutonium produces mainly alpha particle with low penetration depth incorporated Plutonium commonly cannot be detected outside the human body. Thus dose assessment bases on bioassay data from urinary and fecal excretions and most human data derives from there. Therefore a correct reproduction of the observed excretion data is one of the most important aims of the biokinetic models. As a consequence the different models show only small differences in their charts for excretion rates of the standardizes (medium) subject while the observed data differs with a coefficient of variation of about 60-80% due to inter-individual variation (Fig.2).

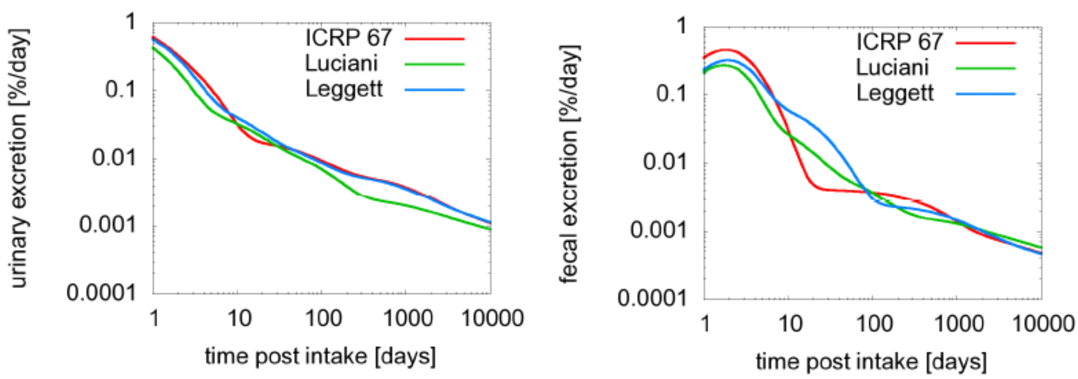

Fig. 2. Differences in model predictions for urinary and fecal excretions.

These individual differences can be modeled with changes in model parameter values. Parameter distributions and variations are unknown for the different models. As physiological parameters are distributed lognormally in the majority of cases, it can be assumed that the transfer rates of biokinetic models fluctuate according to lognormal distributions as well. Previous studies indicated that the observed inter-individual variation can be attained with independent variation of all transfer rates with a coefficient of variation of 60%. As it is unlikely that all parameters fluctuate similarly the influence of single parameters on the excretion rates should be studied in so-called sensitivity analysis. Therefore simulations for each transfer rate fluctuating separately according to a lognormal distributions with the mean from the biokinetic model and a coefficient of variation of 60% were compared with the standardized model. The study showed that only few model parameters determine the variation of the complete model while the contribution of other parameters can be neglected (Fig.3). The influence of the parameters is highly time variant. While one transfer rate determines the total variation of the excretion rate for one time it can be subordinate at other times.

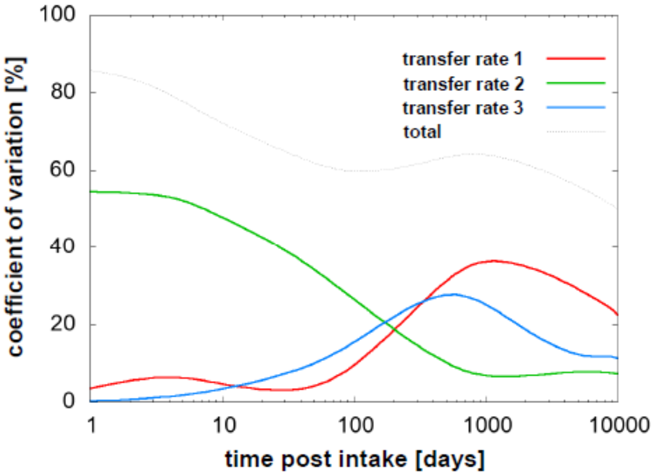

Fig. 1. Sensitivity analysis of the ICRP 67 model for urinary excretion.

In addition to the individual transfer rates the modalities of incorporation are often uncertain as well. The effects of incorrect incorporation assumptions exceed normally the effects of individual differences on excretion rates and thus on dose assessment. They can also be examined with Monte Carlo methods. Therefore intake calculation based on standard assumptions while excretion datasets were generated with different assumptions taking inter-individual variation in account.

The resorption in the alimentary tract is an example for a well studied parameter, which depends on the chemical form and on individual metabolism. Under experimental conditions (identical chemical form) values between $2 \cdot 10^{-3}$ and $12 \cdot 10^{-3}$ were observed for plutonium. The biokinetic models assume a medium of $5 \cdot 10^{-3}$. Dose assessment with Bayes methods shows a large under-/overestimation depending on the biokinetic model (Tab. 1).

Table 1. Influence of resorption fraction f_1 differing from standard value ($5 \cdot 10^{-3}$) on dose estimation.

model \ f_1	$2 \cdot 10^{-3}$	$12 \cdot 10^{-3}$
ICRP 67	-50%	+170%
Luciani	-60%	+150%
Leggett	-60%	+170%

For inhalation cases the particle diameters of the aerosol is an import parameter for the deposition of activity and the particle transport in the respiratory tract. It is specified as activity median aerodynamic diameter (AMAD). For reference workers the recommended value is AMAD = 5 µm (AMAD 5) if no further information about the particle size is available. Obviously the deposition and particle transport has an influence on the absorption into the body and consequently on the excretion rates and dose assessment. Nevertheless the effect on dose assessment is relatively small (Tab. 2). Monte Carlo simulations show a maximum mean difference of 21% for wrong particle size assumptions.

Table 2. Influence of aerosol particle size differing from standard value (AMAD 5) on dose estimation.

Particle size / model	AMAD 1	AMAD2	AMAD 10
ICRP 67	+3%	+10%	-18%
Luciani	+3%	+11%	-16%
Leggett	+13%	+16%	-21%

In contrast to the small influence of the particle size the correct assumption about solubility is crucial for dose estimation (Tab. 3). Different chemical forms are subdivided in only three solubility classes. The difference between estimated dose and true value lies in a range of -95% to +510% with wrong assumptions.

Table 3. Influence of solubility class differing from standard solubility class M on dose estimation.

Solubility / model	F	S
ICRP 67	+500%	-95%
Luciani	+510%	-95%
Leggett	+430%	-95%

Conclusions

Uncertainties in dose estimation have been calculated for the three latest biokinetic models for plutonium. In a first step the most sensitive transfer rates for urinary and faecal excretions were identified. The effort to determine individual transfer rates should concentrate mainly on these few parameters. In a second step the influence of individual variations and incorrect presumptions about particle diameters, f1-values and solubility were studied. The different sources of uncertainties lead to small under- respectively overestimates for the particle size (-21% to +13%) and bigger ones for the resorption in the alimentary tract (-60% to +170%) and the solubility class (-95% to 510%). Correct assignment of model parameters linked to the incorporation scenario like solubility, resorption and particle size can be much more important for dose estimation than the exact determination of the individual transfer rates of the systemic biokinetic model.

Biokinetic models
Analysis of a numerical technique

Bento, Joana; Oliveira, Augusto; Teles, Pedro
Instituto Tecnológico e Nuclear, PORTUGAL

Abstract

Occupational exposure leading to intakes of internally incorporated radionuclides can occur as a result of various activities. This includes work associated with the use of radioactive sources in medicine, scientific research, agriculture and industry, and occupations which involve exposure to enhanced levels of naturally occurring radionuclides. The application of biokinetic models are a fundamental issue in estimation of doses and risks associated with incorporation of radionuclides within the human body. In biokinetic models of radionuclides, there are several techniques available to solve the systems of first-order differential equations. Here we present a straightforward implementation of the difference equations using an available computational spreadsheet like the EXCEL from Microsoft. It was chosen a well known model as a reference, allowing us to check the rigor of the technique. The main scope of this work is to make a detailed computational analysis of the role of all the parameters involved in this methodology. We obtained an accurate insight of the implemented technique, which validates its application in more complex biokinetic models where reference solutions are non-existing or difficult to obtain. In this technique of difference equations there are specific parameters such as time step values and compartment values for each time step that need to be well defined and well understood. Using appropriate algorithms, we developed techniques to optimise those parameters in order to obtain accurate solutions of complex compartment models. Moreover, in the scope of the Internal Dosimetry group activities at the ITN this tool will be of extreme value in order to estimate dose of measured personnel. Finally, another aim of this work is to provide a flexible tool that allows the study of biokinetic models with fast and easy addition or removal of compartments in any given model under analysis.

A methodology for studying cerium biokinetics using stable tracers and Thermal Ionisation Mass Spectroscopy

Keiser, Teresa; Höllriegl, Vera; Giussani, Augusto; Oeh, Uwe
Helmholtz Zentrum München, GERMANY

Abstract

The double tracer technique as introduced in the 60s is a potent method to investigate the biokinetics of elements in humans. The technique was modified and applied over the last years to various elements of interest for radiation protection in order to validate and improve the available biokinetic models of ICRP. One project currently running at Helmholtz Zentrum München aims at studying the biokinetics of cerium in humans using stable, i.e non-radioactive tracers. For this purpose a methodology needs to be developed which enables to measure simultaneously different stable cerium isotopes in human body fluids such as blood and urine Thermal Ionisation Mass Spectroscopy (TIMS) using the instrument "Triton" from Thermo Scientific GmbH, Bremen, Germany. The measurement protocol was developed using cerium standard solutions with different concentrations and different combinations of filament materials. The best results were achieved adopting the double filament configuration and using the tantalum filaments. The optimal current for the ionisation filament is about 4700 mA and for the evaporation filament between 1250 mA, the temperature is around 1700°C. Under these experimental conditions the measured standard ratios agree within 1% with the IUPAC values. For measuring biological samples with TIMS a chemical treatment is necessary because it is not possible to coat the sample holder directly with the sample. A chemical method for eliminating all elements except cerium was therefore established, consisting in two steps: first blood plasma and urine samples are subjected to microwave-assisted acidic pressure digestion, and then cerium is extracted by column chromatography to obtain pure cerium salts, which can be optimally ionised in the TIMS ion source without interfering elements. The methodology was applied to biological samples collected during tracerkinetic studies in humans and preliminary results of urine excretion and plasma clearance of cerium will be presented.

First international intercomparison for Serbian Institute of Occupational Health EURADOS IC2008

Marinkovic, Olivera[1]; Spasic Jokic, Vesna[2]
[1] Serbian Institute of Occupational Health “Dr Dragomir Karajovic”, Belgrade, SERBIA
[2] Faculty of Technical Sciences, University of Novi Sad, SERBIA

Abstract
Laboratory for personal dosimetry (LPD) in the Serbian Institute of Occupational Health, Belgrade (SIOH), has taken part for the first time in international intercomparison EURADOS IC2008. At the same time it was the first participation for any Serbian dosimetry service outside Serbia. LPD had participated in national intercomparisons organized in Former Yugoslavia during last twenty years.

The aim of this paper is to open the discussion on applying method, which usually stays hidden behind results.

Introduction
Preliminary results Intercomparison 2008 as presented at participants meeting, Braunschweig, 27 January 2009 (Figure 1) was free for access at EURADOS web site.

SIOH LPD is 38th participant.

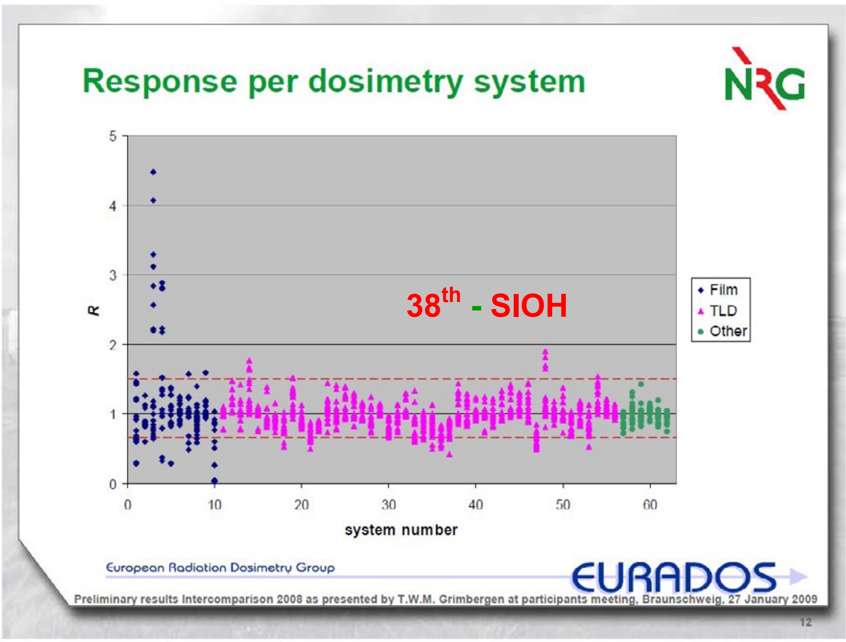

Figure 1. EURADOS IC2008 preliminary results for all participants.

Results

SIOH LPD reported results are given in Table 1, columns S7 and S8 together with important intermediary results.

TLD has two crystals. The first step is to read-out dosemeters using calibration factors for S-Cs (columns S1 and S2). In the aim to estimate applied quality, inverse calculation gives signal intensity in *nC* (columns S3 and S4). Present calibration for quality appraisal is based upon results given in column S5. Column S6 represent estimation particularly important for Hp(0.07) calculation.

The biggest error of quality estimation was missing cobalt. Why? It is not yet answered.

Examples of good estimation are dosemeters ID 12694 and 12707. Nevertheless that was reported the same quality (S-Cs+N60-0^o) of irradiation for those two dosemeters the reference value ratio Hp(0.07)/Hp(10) 0.98 and 0.95 (Table 2.) indicates different qualities. It is possible that S-Cs and N60 quotum in these two irradiations were different. This is very close to estimation in Table 1: irradiation quality for ID 12694 Cs (Hp(0.07)/Hp(10)=1); for ID 12707 N60 (Hp(0.07)/Hp(10)=0.94).

Table 2. Comparison of LPD results and reference values

		Hp(10)			Hp(0.07)

Six dosemeters (grey rows, Table 1) had average dose 0.17 *mSv*. According routine practice background has not been subtracted.

It was possible to recalculate Hp(10) after quality estimation using adequate calibration factors (column S7) as well as Hp(0.07) (column S8) given in Table 1.

Discussion

Here is present only an example of many open issues for discussion and improvement.

International intercomparison involving a lot of dosimetry services should be great opportunity for experience exchanging.

Conclusions

Besides the prime aim to reach results inside trumpet curve and being in accordance with standards international intercomparison gives chance to find solutions for many open dilemma in everyday practice.

Research and applications in the Laboratory for Environmental and Personnel dosimetry

Stochioiu, Ana; Tudor, Ion; Gheorghiu, Adriana
"Horia Hulubei" National Institute of Research and Development for Physics and Nuclear Engineering, IFIN-HH, POB MG-6, 077125 Bucharest, ROMANIA

Abstract

This paper presents the activity of the Laboratory for Environmental and Personnel Dosimetry. This laboratory is a part of the Department of Life and Environmental Science from IFIN-HH.

The laboratory has 4 units; each is dealing with a specific activity:

– the dosimetric surveying unit which uses thermoluminiscent dosemeters for personnel (USD-TL). In USD-TL unit, the personnel monitoring is performed with thermoluminescent dosimetric system SD-TL which uses TL-detectors of LiF: Mg, Cu, and P with the measuring range 10µSv – 100mSv;
– the unit for gammaspectrometrical analyses;
– the unit for measuring the environmental radioactivity where the environmental samples (soil, surface and underground water, vegetal, aerosols and atmospheric sediments) are analyzed from the point of view of the gross alpha, beta and gamma activity. In the same unit, the environmental monitoring is performed also by TL system SDTM type with LiF: Mg, Cu, P detectors;
– the unit for photodosimetrical survey.

All these units are working according to the ISO/IEC: 17025:2005 requirements. They are recognized by the Romanian Nuclear Authority (The National Commission for the Control of the Nuclear Activity – CNCAN) and accredited by the RENAR (The National Accreditation Body).

The R&D activity of the laboratory is focused on the personnel and environment dosimetry:

– the development of survey methods for personnel using in TL dosimetry for the extremities;
– the behavior of the TL detectors in ultra-low radiation background in the salt mines in Romania and intercomparisons of the TL-measuring systems.

Introduction

Horia Hulubei National Institute of R&D for Physics and Nuclear Engineering, IFIN-HH, is deeply involved in nuclear physics research and technical nuclear activities. Important nuclear installations, such as: the UVVRS Reactor- under decommissionning, the U-120 Cyclotrone, the Van der Graaf Accelerator-Tandem, the Radioisotope

Production Centre, the Radioactive Waste Treatment Station, and the Multipurpose Irradiator-IRASM are situated on its site. A significant number of professionals are implied in the nuclear activities as workers. Consequently, the radiological survey of the personnel and environment of IFIN-HH and its neighbouring zone of influence, are a priority. A dedicated laboratory for this activity, as well as for developing new systems and methods was set up many years ago. At the present time the laboratory, known as the Laboratory for Dosimetry of Personal and Environment (LDPM), is a part of the Department of Life Physics and Environment (DFVM).

The basic and continuous LDPM activities are: (i) the personnel dosimetrical monitoring, both by the use of the thermoluminescent dosimeters (TLD) and photographic films; (ii) monitoring of the environmental radioactivity: directly, by the measurement of the radioactive content of air, water, fallout, soil and vegetation samples, and indirectly, by continuous dosimetrical monitoring by using high sensitivity TLD. The high quality of equipment and the refined methods of prelevement and measurement allowed for developing new special applications, such as: measurement of ultralow level background in underground laboratories, or in special radiological areas of interest.

The laboratory succeeded in accomplishment of requirements of the quality standard EN ISO/IEC 17025:2005, "General requirements for the competence of testing and calibration laboratories", being accredited by the national accreditation body RENAR, and designed as a notified testing laboratory by the nuclear authority, CNCAN; this implies the periodical verification of the quality of testing methods by the participation in intercomparisons or proficiency testing. This paper describes the activities developed in LDPM as a whole.

Material and methods

LDPM description

The LDPM is officially organized in 4 distinct units:

- The Unit for the dosimetrical survey of the personnel by using the Thermoluminescent Dosimeters (TLD);
- The Unit for Photodosimetric survey;
- The Unit for the measurement of the activity of the environmental and food samples by the gamma ray spectrometry;
- The unit for the measurement of the gross alpha, beta and gamma activity of environmental samples and gross gamma activity of air samples. A parallel continuous dosimetric monitoring is performed with a high sensitivity TLD system with LiF: Mg, Cu, P detectors, Model SDTM.

Dosimetrical survey of personnel with thermoluminescent dosimeters

Our system is used for the measurement of the dose equivalent within the interval: 10μSv 100mSv. It consists from:

- A TL reader type READER 770A
- The dosimetrical coded case, containing the TL detectors type LiF: Mg, Cu, P.The dosimeters are worn by the persons along a one month period on the breast zone. The integral dose equivalent is registered [1]. Then they are brought in the

laboratory, and the information is obtained from the TL READER. It is delivered both as a Hard Copy Dosimetrical Bulletin, delivered to the user, and as a Protected Stock File in the Personal Computer and as CD. It contains the following data: the person's name, the TL case code, the survey period, the value of the dose equivalent with its uncertainty for a k = 2 interval, [2] equivalent to the former 95% confidence level. Two times per year the results are reported to the CNCAN. The system is implemented for the whole staff of IFIN-HH.

The Unit for Photodosimetry

This monitoring is accomplished by the use of dosimeters with AGFA films [3, 4].

The measurement interval of dose equivalent with this system is: 0.2 mSv-1000 mSv for gamma-rays with energy within the interval 30-3000 keV, and 0.1mSv-1000 mSv with energies of 30-200 keV. In IFIN-HH, the system is used as a redundant means of survey, doubling the TLD basic system, but it is still used as the sole survey mean for the workers belonging to about 30 external Romanian units, outside our Institute.

Gamma ray spectrometry Unit

The gamma ray spectrometry system type provided with a HPGe detector and a software Model ORTEC DigiDART are used. In this laboratory, gamma spectrometry of the environmental samples, foods and underground areas measurements are done. His work and results are beyond the scope of this paper.

The Unit for the measurement of gross alpha, beta, gamma activity

The monitoring of the environmental radioactivity in the IFIN-HH and in its influence area consists from the prelevement, processing and measurement of environmental samples of: soil, surface and subterranean waters, spontaneous and cultivated vegetation, aerosols, rain and atmospheric fallout. The specified prelevement points and their frequency are established in agreement with the Monitoring Program of the Environmental Radioactivity approved by the CNCAN. The points are representative for the radiological characterization of the zone of interest. They are placed inside IFIN-HH area and outside it, on a radius of 5 km, preponderantly distributed on the direction NE towards SW, where the population representing the critical group lives. The prelevement is made by a qualified personnel, according to the technical procedures elaborated in the laboratory. All the samples are weighted by using the analytical balance Model WAX 220, 0.1-220 mg weighing interval. The processing of samples generally consists from the concentration of the specific sample activity by: evaporation, drying, roasting, depending of its physical shape.

After the processing, the samples are measured in terms of the gross alpha, beta, gamma activity. The equipments used for these measurements are:

– Installation for the measurement of gross alpha and beta activity in ultralow level background. Model 9300 PC-6 FL Soft VISTA 2000.
– Gross alpha/beta/gamma with low background and automatic sample changer Model S5 XLB- 6e, Soft ECLIPSE.

The systems are calibrated in terms of detection efficiency with standard sources, as follows. For the gross alpha activity measurement a ^{241}Am and respectively for beta activity a ^{90}(Sr+Y) standard sources are used. They are provided by the Radionuclide Metrology Laboratory from IFIN-HH, accredited and notified calibration laboratory, according to the EN ISO/IEC 17025:2005 standard, traceable to the International System of Units (SI).

Our laboratory participated also at two international proficiency testing exercises, organized by the National Physical Laboratory (NPL), UK, organized in 2008 and 2009, regarding the measurements of gamma-ray spectrometry, gross alpha,beta and gamma activity in solid and liquid samples. An extensive paper describing the monitoring of the radioactivity concentration in air was published in [3].

The environmental radioactivity survey by the sensitive TLD system

The measurement of the integral ambient dose equivalent [mSv] for a given monitoring period and the calculation of the ambient dose equivalent rate [nSv h^{-1}], due to the gamma radiations of the radionuclides present in the environment inside IFIN-HH and its influence area is done by using the Environmental TLD system. It was qualified and authorized by the CNCAN to be used as an official monitoring mean. It is similar to the personal survey system, but it is more sensitive. It is composed from the following parts:

– A TL reader type Analyzer RA'94
– The dosimeter for the environment monitoring. It is in shape of a plastic cylindrical container with external dimensions: Φ=50 mm and h = 9 mm and contains a three TL detectors based on LiF:Mg, Cu, P.

A detailed description of its dosimetrical characteristics is given in the paper [6].

The system was extensively used for monitoring of IFIN-HH area and its influence zone. The results are reported to the CNCAN as a component of the official Environment Survey Report. The results of a one year monitoring of IFIN-HH is also presented in paper [6].

This system was also used for special measurements, such as: (i) The monitoring of special places of interest in IFIN-HH [7] ; (ii) The measurement of the very low level background values in underground laboratories: the mine salt Slanic Prahova-Romania [8,9] and Praid Mures –Romania mine [10].

Results

The paper presents two types of results: (i) Results obtained by using the equipment for gross alpha, beta, gamma activity and (ii) Results in the validation of the Environmental TLD system used for environmental radioactivity survey.

(i) The results obtained for one year follow of the samples preleved, processed and reported in the Unit for the measurement of gross alpha, beta, gamma activity

The results, obtained according to the use of the equipment and procedures of the Unit, are presented in Table 1, as mean values of gross activity concentrations, for various samples.

Table 1. Mean values of gross activity concentrations, during the year 2008

Type of sample	Gross alpha	Gross beta	Gross gamma
Evacuation channel of water	-	(0.81±0.22 Bq/L)	-
Points in amonte and in aval of the evacuation channel to the river	-	(0.75±0.08) Bq/L	-
Drinking water	(0.030±0.008) Bq/L	(0.25±0.05) Bq/L	(0.10±0.02) Bq/L
Underground waters	-	(0.55±0.15) Bq/L	(0.21±0.08) Bq/L
Sediment	-	(710±90) Bq/kg	(280±36) Bq/kg
Soil	-	(810±135) Bq/kg	(250±50) Bq/kg
Spontaneous vegetation	-	(100±15) Bq/kg	(15±4) Bq/kg
Cultivated vegetation	-	(85±10) Bq/kg	(10±13) Bq/kg

(ii) Results in the validation of the Environmental TLD system, by participation in the intercomparison with the NPP Cernavada TLD system

The inercomparison consisted in the placement of a pair of dosimeters, one Model SDTM, IFIN-HH and another Model Panasonic- belonging to the Laboratory for Environmental Survey of the NPP Cernavoda. Ten points of interest, situated outside the NPP area, but inside of its influence area, were chosen. Both dosimeters were placed at a height of 1 m from the ground level and the integral ambient dose equivalent was registered for a period of 1 month. At the end of the exposition period thy were read separately in the two laboratories with the respective TL-READERS and the results, expressed in terms of ambient dose equivalent, H*(10) [mSv], were compared.

The mean values obtained for monitorized ten points have the following values:

– for the laboratory from IFIN-HH: 0.105±0.013 mSv;
– for the laboratory from NPP: 0.096±0.020mSv.

The combined standard uncertainty of the IFIN-HH measured values was 12% (k=1) and was calculated from the standard deviation of the 3 detectors' readings and the system calibration uncertainty, 7.5%. The uncertainty of the NPP values is expected to be the same. In order to establish the quality of comparison, the u-statistic Test, defined in [11] was applied.

$$u - statistic = \frac{|result\,1 - result\,2|}{\sqrt{uncerta\,\mathrm{int}\,y1^2 + uncerta\,\mathrm{int}\,y2^2}} = \frac{|result\,1 - result\,2|\%}{21.5\%} \qquad (1)$$

For these kinds of low level measurements for environment, the u-test is applied in the judgment of the agreement of results states that two result are in agreement if:

$$u - statistic \leq 3.29 \qquad (2)$$

In this comparison the maximum allowed difference is: (result 1 - result 2) =55.7%. That means that the reported values are in good agreement.

Discussion

The results presented above referred only to two types of measurements: direct measurement of the gross environmental radioactivity and indirect measurement by the high sensitivity TLD system, as other results were extensively presented in the following references .

(i) The results obtained for one year follow of the radioactivity concentration.

The final result of the measurements is the judgement on the accomplishment of the Legal limits of the Maximum Admitted Concentrations (MAC) . From the reported results, such limits are established for: (a) Surface waters: gross beta activity, less than 1.85 Bq/L; (b) drinking water: gross alpha: less than 0.1 Bq/L and gross beta: 1.00 Bq/L.

Such as it can be seen from Table 1, the reported values are under these legal limits. Regarding the other reported values: for gross beta and gamma, they are mainly due to the natural ^{40}K and uranium series, as well as to the remaining ^{137}Cs from the Chernobyl accident.

(ii) Validation of the Environmental TLD system in an intercomparison

The statistical analysis of the two independent results demonstrated that the reported values are in good agreement.

On the other hand, if one takes into account a 30 days =720 hours of exposition, from above mean values one calculates the mean values of the ambient dose equivalent rate for all locations , dH*(10)/dt, [nSv/h]: IFIN-HH value =145.83 nSv/h and NPP value =133.33 nSv/h. These two mean values are in very good agreement, difference 9.4%.

It is very interesting to compare these values with other reported literature data. They are a little higher that the world and Romania mean reported values for outdoor rates, 59 nSv/h [10,11] and comparable with previousely values reported for IFIN-HH area, respectively: (127±14) nSv/h in 2006, (107±11) nSv/h in 2007, (113±12) nSv/h in 2008 and (110±10) nSv/h in 2009. The explanation is that in Bucharest area, the contribution of radon is superior to Cernavoda, such as reported for the Bucharest area in general.

Conclusions

– A general presentation of the Laboratory for Dosimetry of Personal and Environment (LDPM) is done. It includes also the main fields of monitoring of the personnel and environment, the main equipment and the work procedures.
– The measurement results are in agreement with the legal imposed limits for the environmental radioactivity
– The quality of work is demonstrated by the accreditation and notification of the laboratory obtained and by the good results obtained in intercomparison with similar system in the case of environmental TLD measurements

Mean energy required to form an ion pair (W value) for various ionizing particles in air

Krajcar Bronić, Ines
Rudjer Bošković Institute, Department of Experimental Physics, CROATIA

Abstract

The mean energy required to form an ion pair (W value) is defined as the mean energy spent by the incident particle of energy E for the formation of an electron – ion pairs after complete dissipation of the initial energy, W = E/N, where N is the total number of produced electron-ion pairs. For high-energy particles in thin media, when only a fraction of the particle energy (dE) is deposited in a medium, it is necessary to consider the differential w value, w = dE/dN. For sufficiently high incident energy, W value is approximately constant, and w = W is a good approximation. Available data on W or w are often fragmented, dispersed, and missing systematic. Several compilations and reviews, such as ICRU Report 31 and IAEA TECDOC 799, provide a basis for assessing the present knowledge of W values for different charged particles in various gases. Most available data exist for electrons. The W value for high-energy electrons (>10 keV) in dry air is well defined, 33.97 ± 0.05 eV, and also a dependence on air humidity has been studied. W and w values for high-energy protons (>20 MeV) have been also carefully analyzed. The value of 34.23 eV, with ± 0.4%, has been recommended. The existing W or w data for heavy ions used in radiotherapy (He, C, Ne, Si, Ar) are fragmentary and most of them are measured for relatively low energies (< 1 MeV/amu) where major variations in energy dependence are observed. There is a lack of experimental data at energies > 1 MeV/amu of interest for radiotherapy. For carbon ions a few sets of experimental data on W exist at low energies and have been recently extended to higher energies. The average W value for C ions at energies > 10 MeV/amu is 34.7 ± 0.9 eV, which is slightly higher than the recommended value (34.5 ± 0.5 eV) for all ions at energies > 1 MeV/amu. There is a need for new W value measurements for heavy-ions in air at energies > 10 keV/amu, and especially for C ions of several hundreds of MeV/amu that are of interest in carbon-ion therapy.

Comparison of local ion density determined by recombination chambers with biophysical models

Golnik, Natalia[1]; Zielczyñski, Mieczysław[2]
[1] Warsaw University of Technology, Institute of Metrology and Biomedical Engineering, POLAND
[2] Institute of Atomic Energy, POLAND

Abstract

The basic parameter characterizing initial recombination of ions in ionization chambers is local ion density μ, defined here as a density of ions averaged over a short segment of an ionising particle track. It can be determined with a recombination chamber, which is. tissue equivalent, high-pressure ionization chamber operating under conditions of initial recombination of ions. It was deduced from theoretical models, that the length of the segment mentioned above or the size of cluster of ions in recombination chambers is equivalent to about 70 nm of unit density tissue. For practical reasons, the values of μ in the ion recombination models were often approximated by restricted LET, in order to correlate ion collection efficiency in the chamber with radiation quality factor.

In 2004 we published the values of μ, measured for low-LET radiations of energies from about 30 keV up to ^{60}Co gamma rays. More recently, D. Harder and co-authors considered the role of electron track-ends for dicentrics formation in human blood lymphocytes and published the curve showing the Monte-Carlo calculated number of correlated track-end groups per unit dose, relative to ^{60}Co gamma rays. There is striking similarity between this curve and μ(E) curve, especially when results of our new measurements, extending the range of E to lower energies are taken into account. The similarity can be easy explained because both phenomena- in the chromosoms and in the gas – depends on the distances between the points of ion formation. In our opinion, expressed also in earlier papers, μ is a physical, measurable parameter, associated with track segments of the length similar to important distances within the cell. The paper will present the reconsidered model of μ(E) dependence, for low and high-LET radiations, with track-ends taken into account, the set of μ values determined for different kinds of radiation and short comparison with biophysical models of dicentrics formation.

Energy and angular dependence of radiation monitors in standard X radiation beams

Nonato, B. C. Fernanda; Vivolo, Vitor; Caldas, V. E. Linda
Instituto de Pesquisas Energéticas e Nucleares, IPEN – CNEN/SP, BRASIL

Abstract
In Brazil, most of the monitoring instruments are calibrated in terms of exposure rate and dose rate in X, gamma and beta radiations, using reference systems calibrated at primary and secondary standard laboratories. In this work, the ionization chambers were calibrated in standard X radiation beams with the objective to study their response in relation to the energy and angular dependence in the operational quantity ambient dose equivalent H*(10), as recommended by the International Organization for Standardization (ISO 4037). For the energy dependence study, the ionization chambers were tested in standard beams, at the distance of 2.5 m from the tube. The X-rays system utilized was a Pantak/Seifert equipment, model MXR-160/22, with effective energies of 48, 65, 83 and 118keV, respectively for the N-60, N-180, N-100 and N-150 radiation qualities. For the angular response of the detectors, a special holder was made of PMMA with a goniometer for the monitor rotation. The results obtained were satisfactory, according to the international standards ISO 4037-1(ISO, 1996) and ISO 4037-3 (ISO,1999) and to the Brazilian standard ABNT-NBR 10011 (ABNT, 1987).

Introduction
Since the discovery of X-rays, the use of ionizing radiation has been intensified and expanded in several areas of applications, as in medicine and in industry. Many investments have been applied in research and technology. All this innovation requires the use of irradiators, X-ray equipment, particle accelerators, and radioactive sources. To regulate the use of ionization radiation, the International Commission on Radiation Units and Measurements (ICRU) and the International Commission on Radiological Protection (ICRP) established standards with the objective of the risk perception and optimization of radiation protection, using the ALARA principle ("as low as reasonably achievable"). One form of ionizing radiation control is through the use of measurement instruments such as dosimeters in the clinical area, and portable detectors, which quantify and qualify radiations. There are some types of clinical dosimeters made of various materials as well as different types of radiation detectors such as Geiger-Müller detectors, scintillation detectors, proportional detectors, semiconductor detectors, ionization chambers. Working with portable area detectors requires a quality control that is guaranteed in part by the calibration, which certifies the good functionality of the

equipment and offers reliability in their measurements. The instrument calibration can ensure if it is working properly and determines the indication of an instrument as a function of the measurement (the quantity intended to be measured).

In this work, the radiation monitors were calibrated at the Calibration Laboratory of IPEN which offers calibration services of gamma, X, beta and alpha radiation detectors. The objective was to study the energy dependence of radiation monitors for low and medium energy X-rays, using the ambient dose equivalent quantity, $H^*(d)$ and the angular dependence. Theses tests can show if the instrument is working correctly.

Materials and methods

The system of X radiation, in the Calibration Laboratory of IPEN, consists of a Pantak / Seifert, ISOVOLT HS 160, model 160, equipament with mean energies of 48 keV to 118 keV. The characteristics of the X radiation beams, used in this work, are described in Table 1. The caractrization of the X radiation beams, radioprotection level, was performed using the ionization chamber PTW, model w32002 – 35, calibrated at the German Laboratory Deutscher Kalibrierdienst (DKD) for the radiation qualities N-60, N-80, N-100, N-150, N-200 and N-250 (DKD, 1995). This ionization chamber has an expanded uncertainty of 3.0%, and it was used with the electrometer PTW UNIDOS, model 10001, with an uncertainty estimated as 0.5%, composing a measurement system with a total uncertainty of 3.5% for the value corresponding to the calibration factor. The uncertainties were determined according to the recommendations of the ISO 15572 (ISO 1998) and Brazilian standards (ISO 2003) for a coverage factor k = 2 and confidence level of 95.45%.

Table 1. Characteristics of X radiation beams (series of narrow spectrum), radiation protection levels established in the Pantak/Seifert system.

Radiation quality	Mean energy (keV)	Voltage (kV)	Half-value layer (HVL) (mmCu)	Additional filtration (mm)
N-60	48	60	0.25	0.6(Cu)
N-80	65	80	0.61	2.0(Cu)
N-100	83	100	1.14	5.0(Cu)
N-150	118	150	2.40	2.5(Sn)

Twenty one ionization chambers of six manufactures and eleven different models were tested in X radiation beams. Of the twenty one ionization chambers, nineteen were studied in relation to their energy dependence and four of them were tested in relation to their angular dependence.

Initially, the measurements of the exposure rates and air kerma rates were converted to ambient dose equivalent rates. The conversion coefficients from air kerma to ambient dose equivalent are presented in Table 2.

Table 2. Conversion coefficients from air kerma to ambient dose equivalent for the radiation qualities of ISO 4037-3 (ISO, 1999), at the reference distance of 2m.

Radiation quality	Conversion coefficients (Sv/Gy)
N-60	1.59
N-80	1.73
N-100	1.71
N-150	1.58

Then, the calibrations factors, C_f, were determined. The calibration factor is the ratio between the conventional true value (reference), C_{TV}, and the measured (indicated value), M, by the radiation detector, for the N-60, N-80, N-100 and N-150 radiation qualities (narrow beams), according to Equation 1.

$$C_f = \frac{C_{TV}}{M} \qquad \text{Equation 1}$$

For the angular response of the detectors, a special holder, Figure 1, was made of PMMA with a goniometer for the monitor rotation. The response of the ionization chambers in relation to the angular dependence was taken for the angles 0^0, $\pm\,15^0$, $\pm\,30^0$, $\pm\,45^0$, $\pm\,60^0$ and $\pm\,90^0$.

The characteristics of the ionization chambers tested in this work are presented in Table 3.

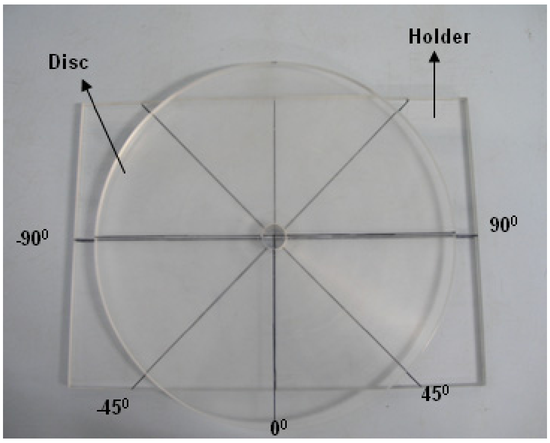

Fig.1. Goniometer for the angular dependence study of the ionization chambers.

	451B	J1...J4	α, β, gamma, X	0 a 50 R/h
	451P	K1...K3	gamma, X	0 a 5 R/h ou 0 a 50 mSv/h

Results and discussion

The calibration factors of the ionization chambers in standard X-ray beams were determined, and the results are presented in Table 4.

Table 4. Calibration factors of the ionization chambers for X radiation.

Chamber code	C_f: Calibration factor			
	(N – 60)	*(N – 80)*	*(N – 100)*	*(N – 150)*
A1	1.01	1.03	1.00	0.90
B1	0.88	0.81	0.78	0.81
B2	0.99	0.99	0.97	1.05
C1	1.09	1.05	1.05	0.91
C2	1.30	1.26	1.20	1.01
D1	0.96	0.93	0.95	0.99
E1	1.00	1.03	1.09	1.05
E2	0.98	1.01	1.08	1.06
E3	1.01	1.04	1.11	1.06
E4	0.98	1.01	1.09	1.06
F1	0.97	1.00	1.07	1.06
G1	1.01	1.04	1.09	1.04
H1	1.03	1.13	1.10	0.98
I1	1.20	1.14	1.15	0.91
J1	1.05	0.98	1.02	0.93
J2	1.11	1.00	0.96	0.82
K1	1.15	1.08	1.07	0.94
K2	1.12	1.07	1.07	0.95
K3	0.96	0.93	0.95	0.99

The calibration factor shall not be higher than 1,2 (IRD, 2004). In this case, the ionization chamber B2 would not be able to measure radiation intensity in the radiation quality N-100 and the ionization chamber C2 would not be able to measure the radiation intensity in the qualities N-60 and N-80.

The data of Table 4 can be visualized in Figures 2, 3 and 4. In the case of the ionization chambers D1 and H1, the response was presented for the radiation energies of the ^{137}Cs and ^{60}Co sources too.

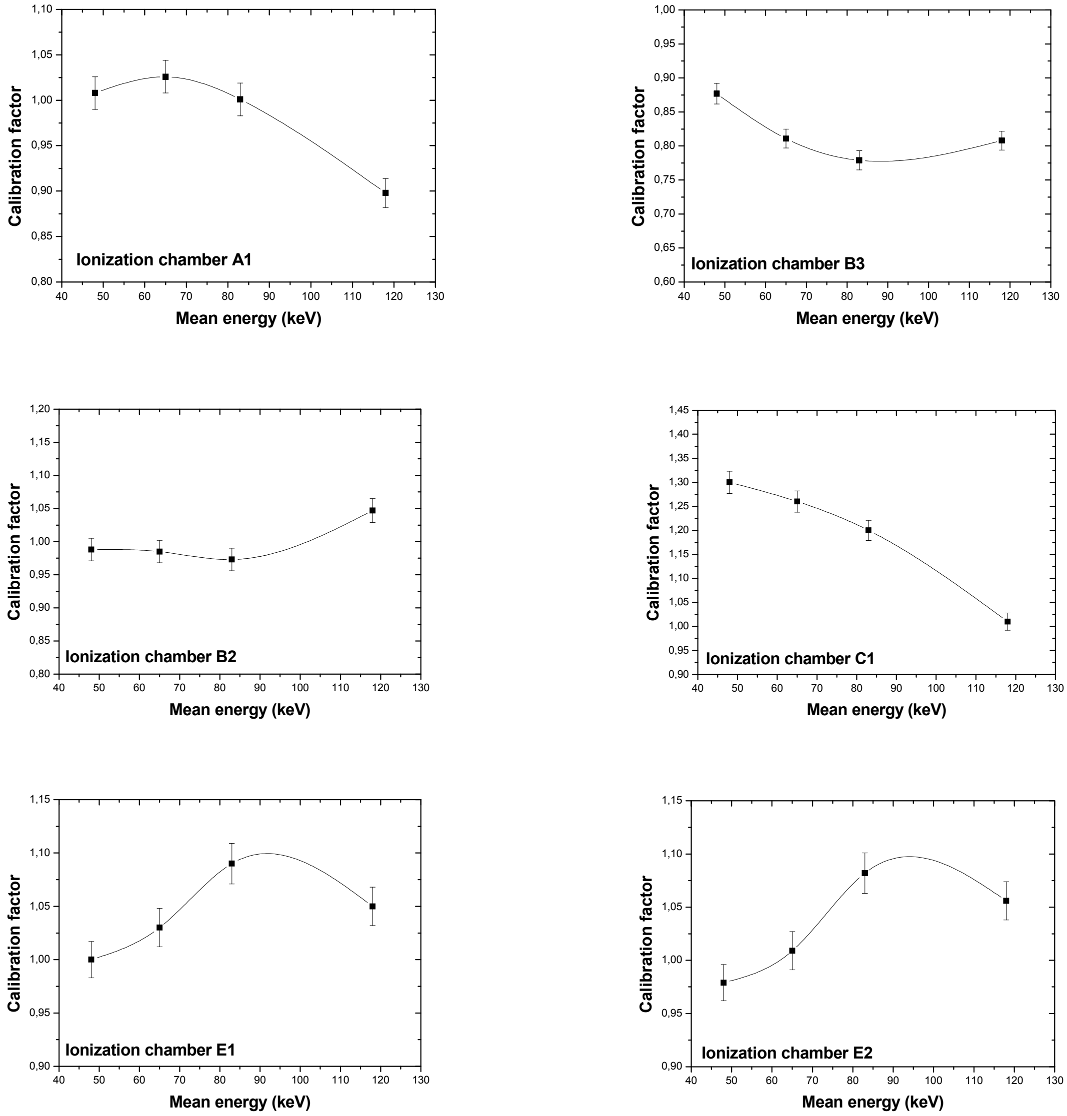

Fig.2. Calibration factors of the ionization chambers: A1, B1, B2, C1, E1 and E2 for different X radiation qualities.

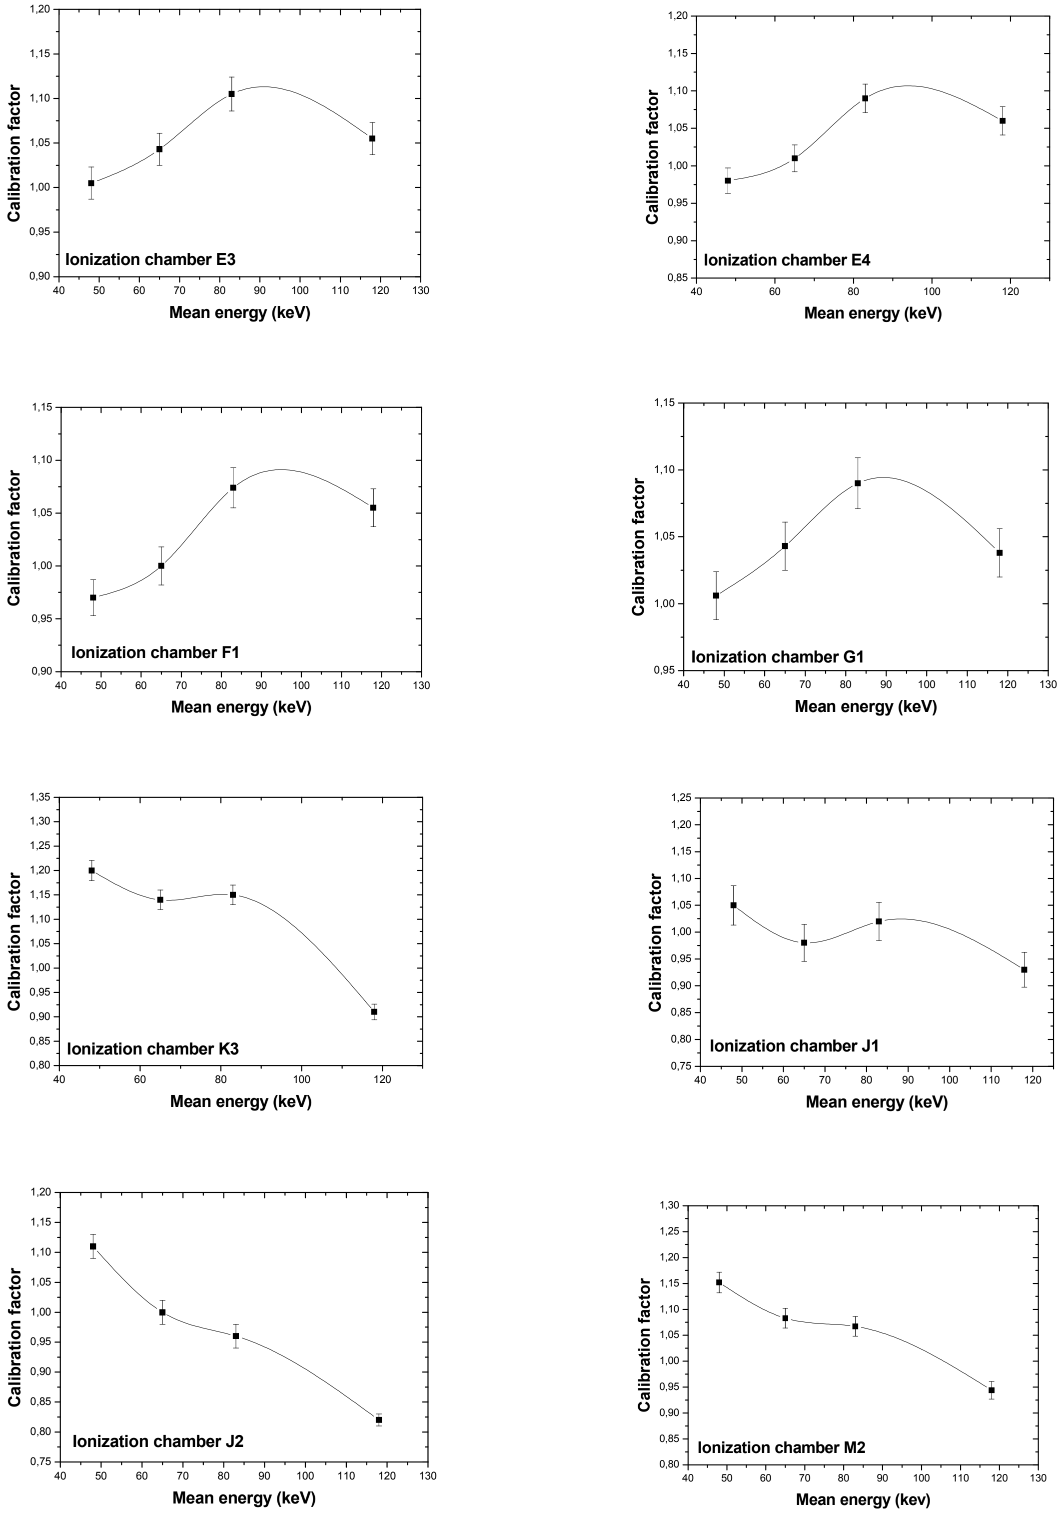

Fig.3. Calibration factors of the ionization chambers: E3, E4, F1, G1, I1, J1, J2 and K1 for different X radiation qualities.

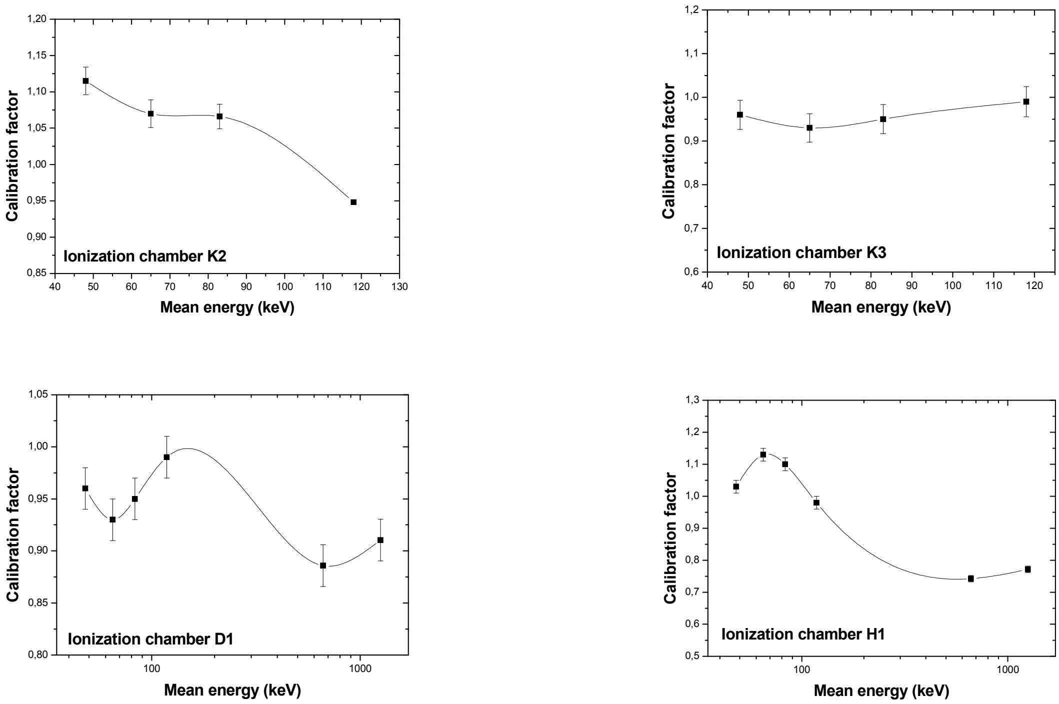

Fig.4. Calibration factors of the ionization chambers: K2 and K3 for different X radiation qualities; and D1 and H1 for gamma and X radiation qualities.

Different behaviors are observed in the response of the ionization chambers of different models. When comparing the curves, the behavior of the response of ionization chambers of the same model is quite similar, such as in the case of E1, E2, E3 and E4 ionization chambers. The curves obtained for the ionization chambers D1 and H1 in Figure 4 show that the calibration factors for X radiation is higher than the calibration factors for gamma radiation.

The energy dependence of these monitors is presented in Table 5, using the calibration factor data presented in Table 4.

Table 5. Energy dependence of the ionization chambers, radiation protection level, for X-rays (48keV-118 kev).

Chamber code	Energy dependence	Expanded uncertainty (U)
A1	1.14	0.07
B1	1.13	0.06
B2	1.08	0.06
C1	1.20	0.07
C2	1.29	0.06
D1	1.06	0.06
E1	1.09	0.06
E2	1.10	0.06
E3	1.10	0.06
E4	1.11	0.06
F1	1.10	0.06
G1	1.08	0.06
H1	1.15	0.06
I1	1.32	0.07
J1	1.13	0.06
J2	1.35	0.08
K1	1.22	0.07
K2	1.18	0.07
K3	1.06	0.06

The energy dependence of the ionization chambers varied between 6% and 35% (Table 5), according to the ionization chambers K3 and J2, which respectively showed energy dependence of (1.06 ± 0.06) and (1.35 ± 0.08). Monitors utilized at radioprotection level are divided into different classes, according to ABNT 10011 (ABNT, 1987). In this standard, the ionization chambers studied in this work are within the definition of Class II, where the maximum variation may be ± 25%. Only the ionization chamber J2 showed no agreement with the standard.

The angular dependence was obtained for the ionization chambers A1, C2, J3 and J4 without changing the measurement quantity to dose equivalent ambient. The two last models were not tested in relation to the energy dependence. The angle variation was from 0^0 to $\pm 90^o$ and only the radiation quality N-150 was utilized. The curves are presented in Figure 5.

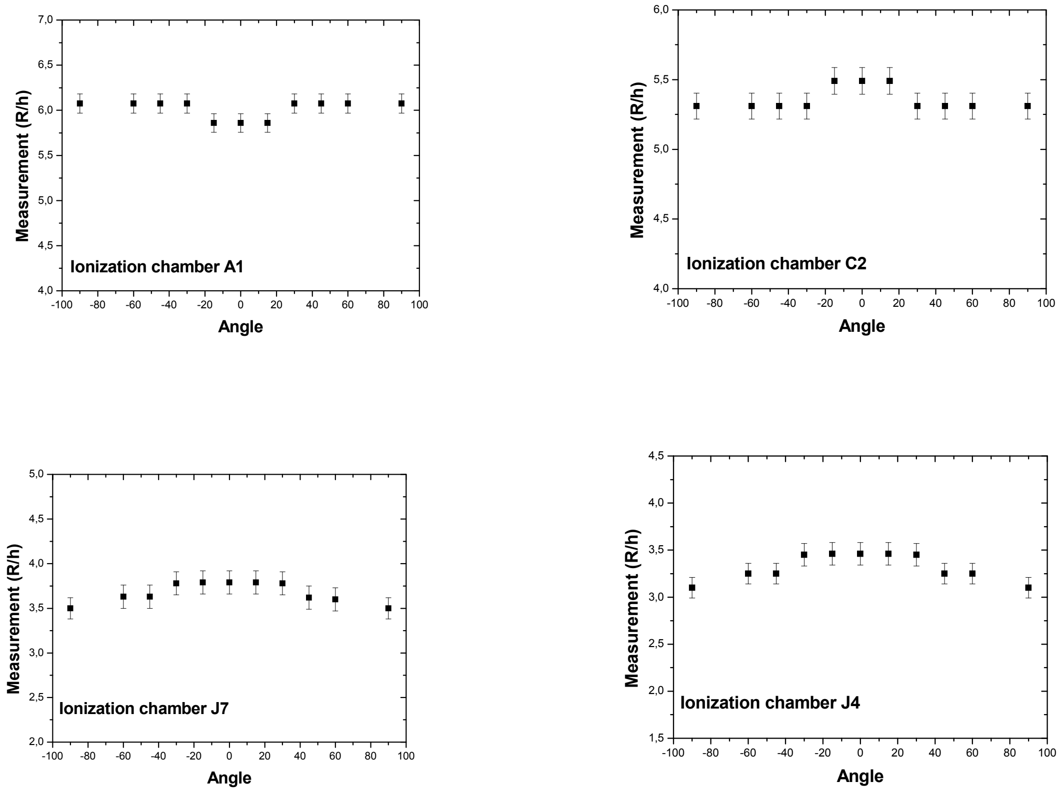

Fig.5. Angular dependence of the ionization chambers: A1, C2, J3 and J4; radiation quality: N-150.

The ionization chambers (Figure 5) presented low or almost no angular dependence for certain angle intervals. Their measurements are stable when varying the positioning of the ionization chamber in relation to the beam incidence. The ionization chambers J3 and J4 present higher angular dependence than models A1 and C2, because of their radiation entrance windows. The ionization chamber A1 has just an external wall (protection cap for build-up), but during the calibration with X-rays it is not utilized. The ionization chamber C2 is pressurized, and does not have an entrance window. All ionization chambers with x-rays agree with the standard EN 60846 (EN, 2004) that determines that the angular dependence may vary up to 40%.

Conclusions

The results obtained for the calibration factors and energy dependence for the ionization chambers were satisfactory, according to the ISO-4037-1 (ISO,1996); ISO-4037-3 (ISO,1999) and IAEA SRS16 (IAEA, 2000) recommendations. Only one of all nineteen ionization chambers presented an energy dependence higher than 25%. The energy dependence curves presented differents behaivors, depending on the ionization chamber model. The angular dependence of the monitors showed agreement with the standard EN 60846 (EN, 2004).

A simplified OSL-algorithm for low-dose retrospective dosimetry using household salt

Christiansson, Maria; Mattsson, Sören; Rääf, Christopher L.
Medical Radiation Physics, Malmö, Department of Clinical Sciences Malmö, Lund University, Skåne University Hospital Malmö, SWEDEN

Abstract
In retrospective dosimetry and for the purpose of geological and archaeological dating by optically stimulated luminescence (OSL) in materials such as quartz and feldspar, the single-aliquot regenerative-dose (SAR) protocol is widely used. This protocol is designed to account for the non-linear dose response between OSL-response and absorbed dose in e.g. quarts. The SAR-protocol normally involves five regeneration doses with subsequent read-out to be used for a signal-to-dose plot, enabling a calculation of the original absorbed dose in the sample. Currently the SAR-protocol is being optimised for NaCl and various brands of household salt, to be used as potential environmental and personal dosemeters. In this particular study we have investigated if only the initial part of the SAR protocol can be used for household salt, in an attempt to find a more rapid read-out protocol in case of nuclear and radiological emergencies. Stopping at only two regeneration doses appears to yield the same result within 2% as the full SAR-protocol for household salt, while at the same time saving up to 50% of read-out time per sample.

Introduction
Optically stimulated luminescence (OSL) has in the past few years been considered for retrospective dosimetry after nuclear emergencies [Bailiff 1997, Bøtter-Jensen and Jungner 1999, Thomsen et. al. 2002, Bernhardsson et. al. 2009]. The technique has for example been used for reconstruction of absorbed dose to human habitats after the Chernobyl accident [Bøtter-Jensen et. al. 2000]. In these events, burnt building materials such as bricks and tiles, containing quartz and feldspar crystals, have been used to retrospectively determine the absorbed dose. The sample preparation and measurements for OSL dosimetry of building materials are, however, altogether a laborious process. The minimum detectable absorbed dose (MDD) is estimated to be in the order of 30 mGy. It has been found that the MDD for OSL-determination of absorbed dose in household salt is much lower, down to 1 mGy [Thomsen et. al. 2002], and for some brands of salts even as low as 0.2 mGy [Bernhardsson et. al. 2009]. In combination with its relatively easy handling before OSL-read-out it has been suggested as an emergency dosemeter in case of nuclear and radiological accidents.

The OSL-response for various types of household salt and chemically pure NaCl has been investigated in Malmö using a TL/OSL reader (TL/OSL-DA-15; Risø National Laboratory, Roskilde, Denmark). In an on-going study, the SAR protocol originally used for quartz is now being modified to better fit the OSL-response and luminescence characteristics of household salt [Christiansson et al., 2010; Bernhardsson et al., 2009].

In the SAR protocol, a known additional dose, a so-called regeneration dose, is given to the sample after the optical destruction of the original OSL-signal in the sample, and the OSL-read-out is repeated. In all, five regeneration doses are given to the sample to determine the unknown dose. One problem with regeneration protocols using quartz and feldspar is the sensitivity changes in the sample when re-using the aliquot. This has been solved using a so-called test-dose after read-out of the regeneration dose. By normalizing the luminescence from each generation dose to that of the subsequent test dose, sensitivity changes during the process are compensated for. The SAR-protocol then makes use of the linear relationship between the detected luminescence and the given doses, and fits a linear expression to the dose-luminescence plot. From this linear expression the original luminescence of the sample is translated into an absorbed dose. A drawback of this method is the prolonged read-out times for the salt samples leading to a slow through-put of samples and delayed assessment of collected samples from e.g. an accident site. Our aim has been to test whether the initial part of the SAR-protocol can be used as a rapid substitute for the established SAR-protocol, provided the absorbed dose can be determined with sufficient accuracy (within 20% 1 SD).

Material and methods

The OSL measurements have been carried out using a TL/OSL reader (TL/OSL-DA-15; Risø National Laboratory, Roskilde, Denmark). The reader is equipped with an internal beta source ($^{90}Sr/^{90}Y$) of 20 MBq, which irradiates the sample at an absorbed dose rate of 0.9 mGy s^{-1} at the sample position. The stimulation light source was the 28 blue LEDs which are divided into four clusters, with a peak emission at 470 nm and a maximum power of 50 mW cm^{-2}. To detect the light from the stimulated sample, the reader contains a light detection system, which includes a PM-tube and light filters. The PM-tube is an EMI 9235QA PMT that has maximum detection efficiency around 400 nm. The light filters consist of a GG-420 long-pass filter that reduces contributions from the low end of the emission peak, and a 7.5 mm Hoya U-340 that reduces scattered light from the LEDs that reach the PMT. The reader is also equipped with a heater that can increase the sample temperature to any point between room temperature and 700°C.

In this part of the study we have specifically tested a salt brand that previously has shown the highest luminescence yield per unit given absorbed dose using a read-out algorithm based on the SAR-protocol. The salt is a mine salt (Falksalt fint bergssalt) aimed for household use. Before the measurements, the salt was bleached by exposing the salt to sunlight and fluorescent lamp-light for at least 24 hours, in order to reduce the background luminescence originating from e.g. prior exposure to background radiation. The salt was then sieved using “test sieves” (Retsch GmbH, Haan, Germany) to receive grains in the size range 100–400 µm. Upon the irradiation experiments the salt samples were divided into three subgroups which were subjected to an absorbed dose corresponding to 20, 50 and 100 s of irradiation by the internal ^{90}Sr-source, respectively.

The test dose read-outs were preceded with pre-heat temperatures ranging from 140°C to 200°C for 10 s, while the OSL-read-outs of the regeneration doses were preceded with a 220°C pre-heat for 10 s. All the OSL measurements were performed with a constant stimulation power (continuous wave) at 100°C for 40 s at 40% of the maximal stimulation power.

Results

The ratio between the dose measured and calculated with the SAR-protocol and the absorbed dose given to the samples (which are the regeneration dose of a given order 1st, 3rd and 5th) is plotted in Figure 1 for various pre-heat temperatures of the test dose. The pre-heat temperature at 140°C will not give the accurate dose value for one, three or five regeneration doses.

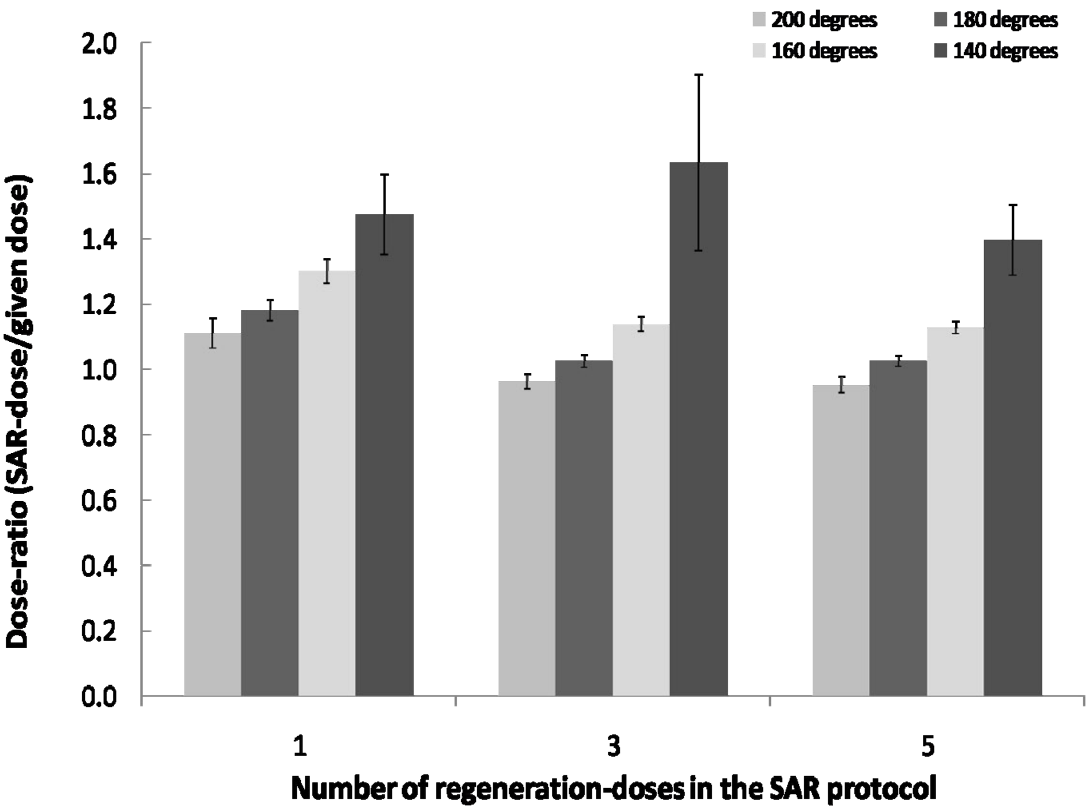

Fig. 1. The ratio between the dose measured with the SAR-protocol and the absorbed dose given to the samples of the investigated brand of household salt which are the regeneration dose of a given order (1st, 3rd and 5th). Different pre-heat temperatures ranging from 140 to 200°C have been used.

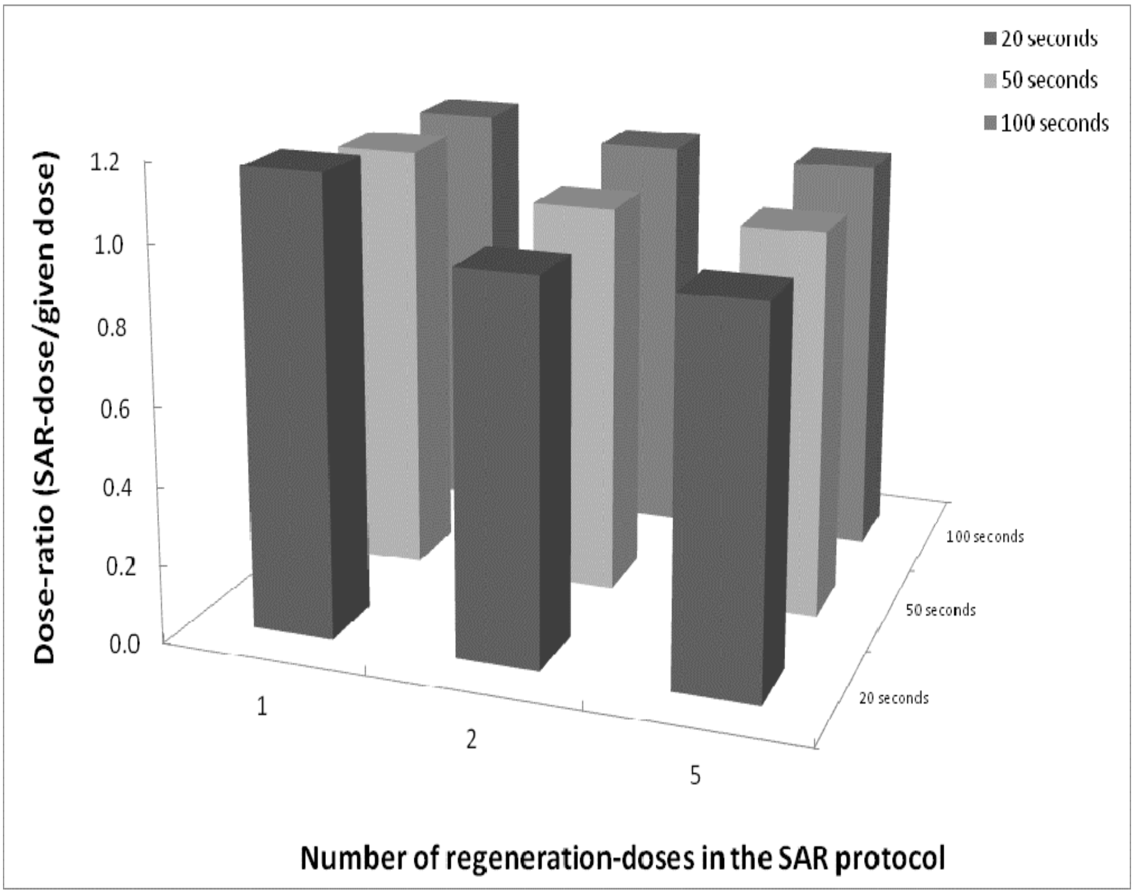

Fig. 2. The ratio between the dose measured with the SAR-protocol and the absorbed dose given to the samples is plotted for the pre-heat temperature 200°C. The given dose is received during 20, 50 or 100 seconds.

In figure 2 the ratio between the dose measured and calculated with the SAR-protocol and the absorbed dose given to the samples (which are the regeneration dose of a given order 1st to 5th) is plotted for the pre-heat temperature 200°C. In the latter figure it can be seen that at the second read-out, the ratio between the measured SAR-dose and the given dose appears to be sufficiently close to unity, and further regeneration will not improve this ratio drastically. Numerically the second regeneration dose protocol gives values that coincide within 2% of the ones from the full SAR-protocol.

Conclusions

With an optimised value of 200°C for the pre-heat temperature at the OSL-read-out protocol of household salt, two regeneration doses will give an adequate estimate of the given absorbed dose within 2% compared with the complete SAR-protocol of 5 regeneration doses. Employing the two-regeneration-dose protocol saves up to 50% of the reading time. Thus, this simplified SAR-protocol is recommended for use in case of a large nuclear or radiological accident involving many individual cases of exposures that need to be reconstructed.

Uncertainty analysis of internal dosimetry using expert judgment and probabilistic inversion

Hato, Shinji[1]; Homma, Toshimitsu[2]
[1] Visible Information Center, Inc., JAPAN
[2] Japan Atomic Energy Agency, JAPAN

Abstract

The uncertainty of internal dose coefficient was analysed using expert judgment implemented by joint activity of U.S. Nuclear Regulatory Commission and European Community. In this study, the transfer coefficients in biokinetics model were taken to sources of uncertainty, and their probability distributions were estimated by iteration PARFUM of probabilistic inversion method with expert judgment. Their transfer coefficients sampled from their distribution were substituted into internal dosimerty model, and the uncertainty of dose coefficient for ingestion of ^{137}Cs by adult was analysed. The uncertainty factor (95%/ 5%) was approximately 5.1.

Introduction

The direct measurements of internal dose are difficult in most of cases. Then, the internal dose is estimated using both indirect measurements (e.g., bioassay and environmental concentration) and mathematical models which simulate metabolism and dose of radionuclides in body. The estimated internal dose includes errors of measurements and uncertainties of input parameters substituted to model which were estimated by human and laboratory animal data. In this study, the uncertainty of internal dose coefficient is analysed through propagation of uncertainty in input parameters.

The probabilistic distribution of input parameters is needed for implementing the uncertainty analysis of internal dose. Since their distribution cannot be obtained in most of cases, the method of expert judgment is applied to set probabilistic distribution of input parameters (Cooke et al., 1999). This expert judgment is subjective probability and is consisted of 5th, 50th and 95th percentiles which the quantity is well known by experts. The expert judgments do not always correspond to input parameters. Therefore probabilistic distribution of input parameters is estimated by probabilistic inversion with expert judgment. This study used the probabilistic inversion developed by Du et al. (2006).

The goal of the study is an estimation of uncertainty in internal dose coefficient for ingestion of ^{137}Cs by adult recommended by International Commission on Radiological Protection (ICRP). To implement this, the probabilistic distributions of transfer coefficients in biokinetics model of cesium are estimated by probabilistic inversion with expert judgment given Jones et al. (2001).

In this paper, it is described that the method of uncertainty for internal dose coefficient with expert judgment and the result of uncertainty of internal dose coefficient for ingestion of ^{137}Cs by adult.

Material and methods

In this study, the probabilistic distributions of the transfer coefficients in biokinetics model of cesium are estimated by probabilistic inversion with expert judgment. This section describes the biokinetics model, expert judgment, probabilistic inversion and analytical procedure.

Biokinetics model of cesium

The biokinetics model of cesium refers to model recommended by current ICRP. As illustrated in figure 1, this model is consisted of two compartments which are named Body Tissue A and Body Tissue B. Each compartments represent short and long retention.

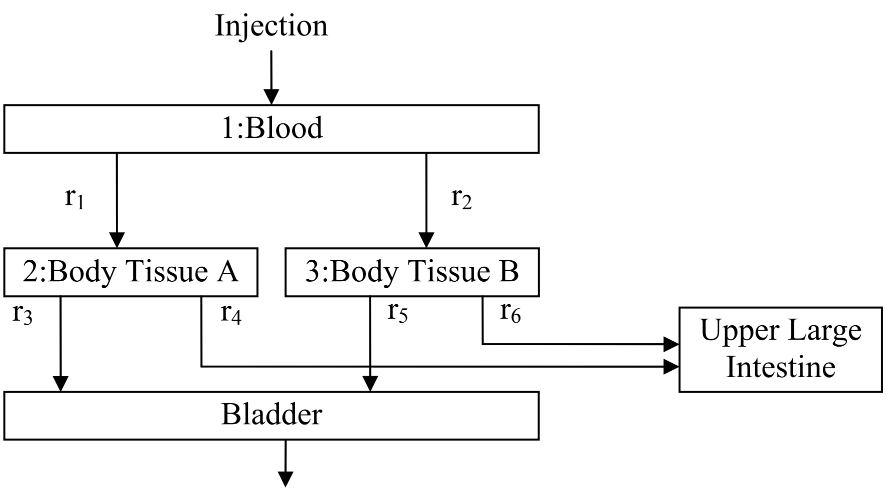

Fig. 1. Structure of ICRP's biokinetics model for cesium (r_i: transfer coefficients).

The retention of cesium in this model is described by first order kinetics. Suppose q_i is retention and r_i is transfer coefficient, the first kinetics is given by equation (1). When the initial conditions are $q_1(0)=1$ and $q_2(0)=q_3(0)=0$, their solutions are given by equation (2).

$$\begin{aligned}\frac{dq_1}{dt} &= -(r_1 + r_2)q_1 \\ \frac{dq_2}{dt} &= r_1 q_1 - (r_3 + r_4)q_2 \\ \frac{dq_3}{dt} &= r_2 q_1 - (r_5 + r_6)q_3\end{aligned} \tag{1}$$

$$\begin{aligned}q_1 &= e^{-(r_1+r_2)t} \\ q_2 &= \frac{r_1}{(r_3 + r_4) - (r_1 + r_2)}\left\{e^{-(r_2+r_2)t} - e^{-(r_3+r_4)t}\right\} \\ q_3 &= \frac{r_2}{(r_5 + r_6) - (r_1 + r_2)}\left\{e^{-(r_1+r_2)t} - e^{-(r_5+r_6)t}\right\}\end{aligned} \tag{2}$$

Expert judgment

The expert judgment of biokinetics model for cesium is illustrated in table 1. This expert judgment was given in Jones et al. (2001) and was represented by 5th, 50th and 95th percentiles which were retention fraction of body tissues by injection of cesium.

Table 1. Expert judgment of biokinetics model for cesium.

Time after Intake	Retention fraction of body tissues by injection of Cs		
	5%	50%	95%
1 day	8.70E-01	9.62E-01	9.92E-01
1 week	7.45E-01	8.59E-01	9.43E-01
1 month	5.45E-01	7.24E-01	8.93E-01
1 year	2.38E-03	6.48E-02	2.64E-01
5 years	1.21E-10	1.08E-05	6.30E-03

Probabilistic inversion

The probabilistic distributions of input parameters are needed to analyse uncertainty of dose coefficient through input parameters in biokinetics model of cesium. Their distributions cannot be obtained from data of measurements in most of cases. In such cases, the expert judgment of subjective probability is applied to uncertainty analysis. Since this expert judgment constructed quantity that experts well know, it does not always agree to input parameters. Therefore, the distributions of input parameters are needed to produce by probabilistic inversion from expert judgment. Though there were a few methods of probabilistic inversion, this study applied the method developed by Du et al. (2006). The uncertainty parameter of target refers to target variable and the variable asked to experts refers to elicitation variable.

In this study, the target variables are six transfer coefficients (r_1,...,r_6 in figure 1) and the elicitation variables are five retention fractions of body tissues at 1 day, 1 week, 1 month, 1year and 5 years. The 6-dimension space for target variables and 5-dimension space for elicitation variables are formed. The probabilistic inversion estimates the marginal distributions of space in target variables from the marginal distributions of space in elicitation variables. Since the target and elicitation variables are related to model equations and they are one-to-one mapping, the joint distribution in space of target variables is automatically evaluated if the joint distribution in space of elicitation variables is estimated. As a result, the marginal distributions of targets are evaluated from the joint distribution.

Since it is difficult to show figure of more than 3 dimensions, the probabilistic inversion for 2 dimensions about each of target and elicitation variables is explained as illustrated figure 2. The procedure of probabilistic inversion is as follows.

Step1 The analyst sets an appropriate sampling range of target variables and assumes uniform distribution as initial probability. The N sets are sampled from this region.

Step2 The sampled target variables are substituted for model equation and the obtained model values are mapped in space of elicitation variables. The N images are made in space of elicitation variables.

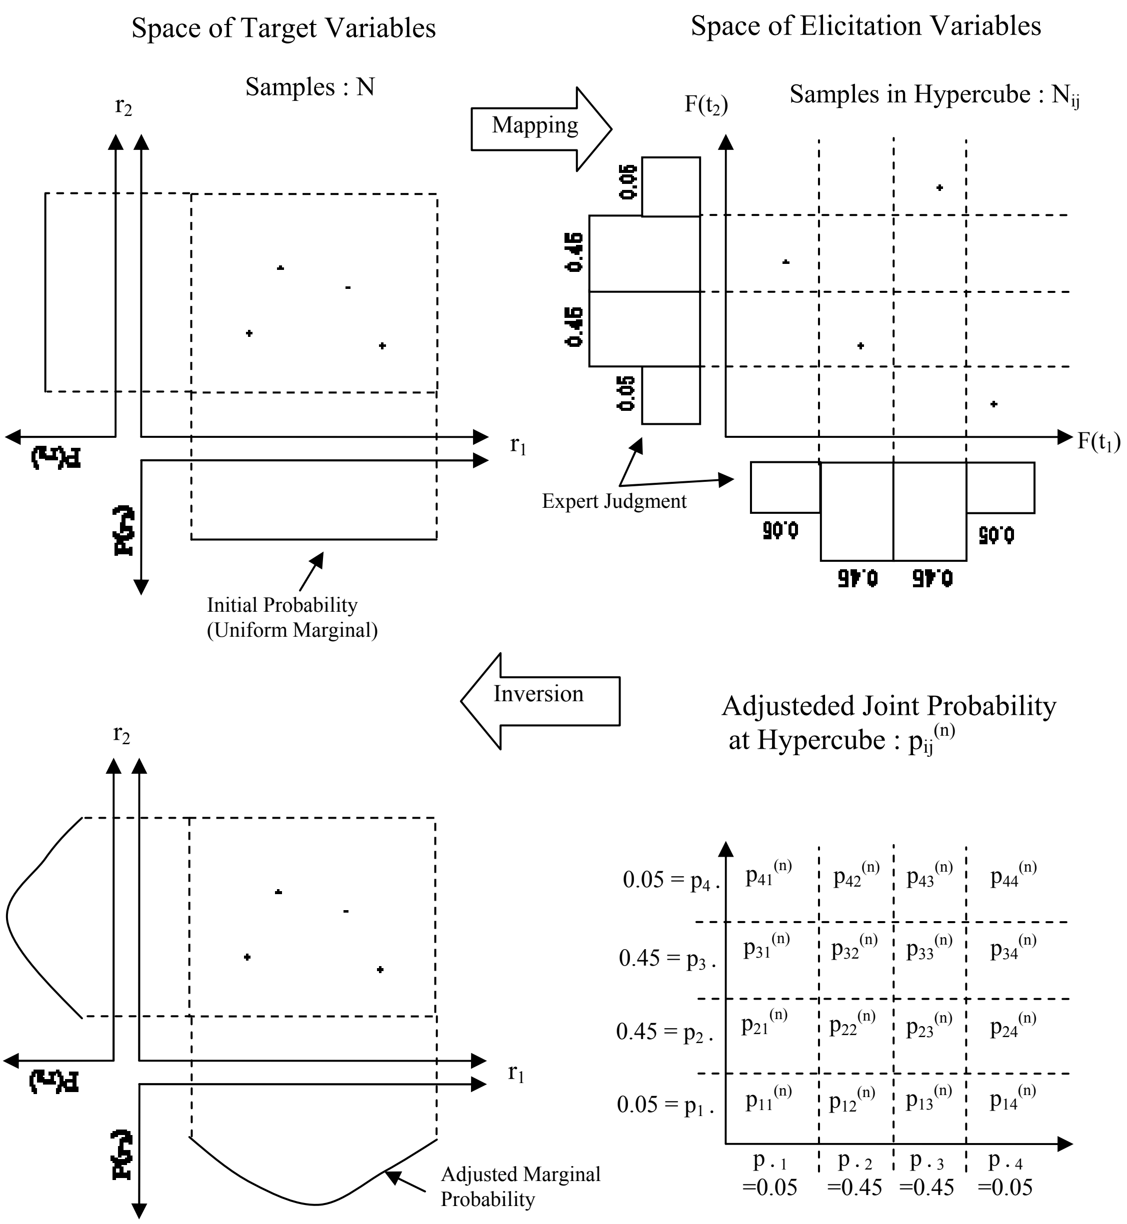
Step3 Counting number of points (N_{ij}, i,j=1,2,3,4) in hypercube partitioned 5th, 50th and 95th percentiles in space of elicitation variables.

Step4 The initial joint probability of hypercube are set to $p_{ij}^{(0)} = N_{ij} / N$. The iteration PARFUM is projected in n cycles and the joint probability of hypercube is adjusted as fitting to marginal distribution ($p_{i\cdot}$, $p_{\cdot j}$) of expert judgment.

Iteration PARFUM $$p_{ij}^{(n)} = \frac{1}{2}\left(p_{ij}^{(n-1)} \times \frac{p_{i\cdot}}{p_{i\cdot}^{(n-1)}} + p_{ij}^{(n-1)} \times \frac{p_{\cdot j}}{p_{\cdot j}^{(n-1)}} \right)$$

Step5 If the joint probability $p_{ij}^{(n)}$ could be evaluated, the probability of each points in hypercube is evaluated as $p_{ij}^{(n)} / N_{ij}$. Their probabilities are inversed to space of target variables and the joint probability of target variables is set up.

Step6 Consequently, marginal probability of target variables can be calculated from joint probability.



$$p_{ij}^{(n)} = \frac{1}{2}\left(p_{ij}^{(n-1)} \times \frac{p_{i\cdot}}{p_{i\cdot}^{(n-1)}} + p_{ij}^{(n-1)} \times \frac{p_{\cdot j}}{p_{\cdot j}^{(n-1)}} \right)$$

$$p_{ij}^{(0)} = \frac{N_{ij}}{N}$$

Fig. 2. Procedure of probabilistic inversion.

Analytical procedure for uncertainty of internal dose coefficient

The analytical procedure for uncertainty of model output caused by uncertainty of model input is shown to figure 3. The uncertainty analysis consists of two parts in this study.

The first part is that probabilistic distributions of model inputs are estimated by probabilistic inversion with expert judgment. The target variables are sampled by initial probability assumed uniform distribution. The PREP code (Homma et al., 1991) was used for sampling of target variables in this study. When Kullback-Leibler divergence with respect to initial probability of adjusted probability was evaluated after first probabilistic inversion, it is more than zero for inconsistent initial and adjusted distributions. The initial probability is replaced by adjusted probability and the probabilistic inversion is repeated to come closer zero. When the PREP code is used to sampling, their distributions approximate piecewise uniform distribution as illustrated in figure 3. When Kullback-Leibler divergence comes closer to zero, the distributions are set to final distribution.

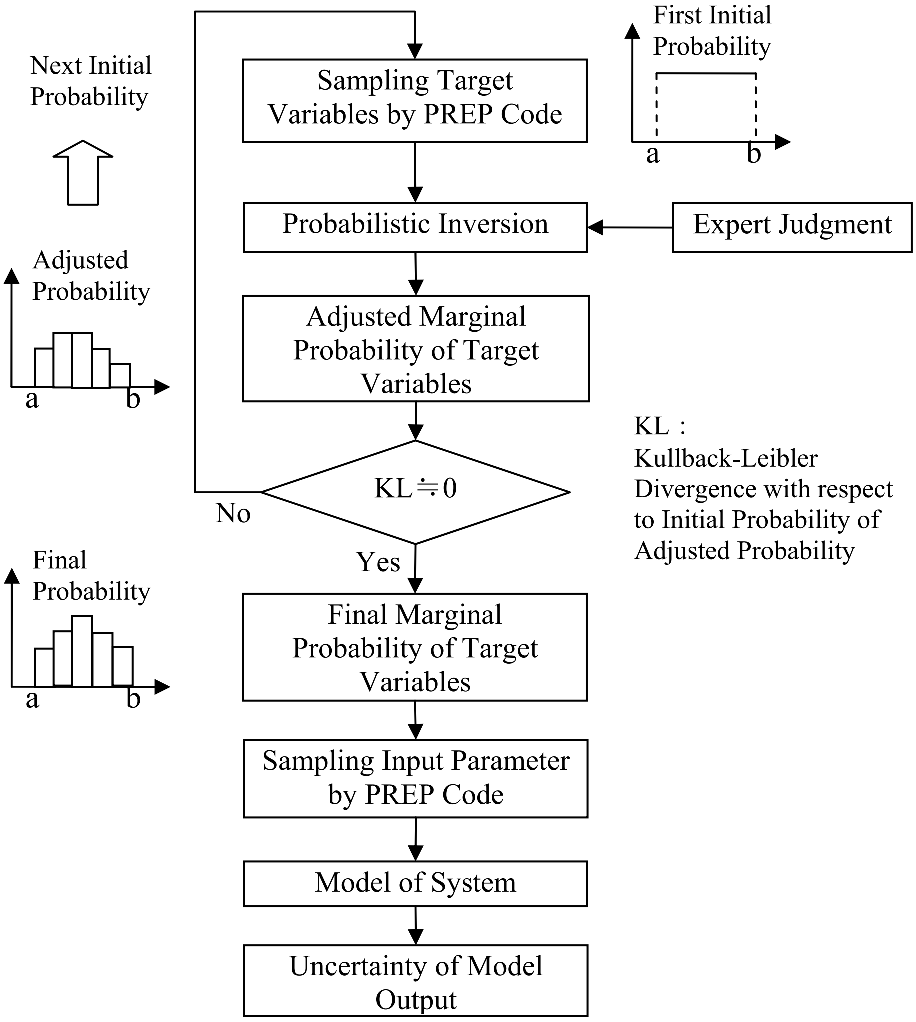


Fig. 3. Analytical procedure for uncertainty of model output caused by uncertainty of model input.

The second part is to analyse the uncertainty of model output. The input parameters are sampled with PREP code by estimated marginal distributions and outputs of model are evaluated by substituting their parameters to model equation. The uncertainty of dose coefficients for ingestion of cesium as illustrated in figure 4 is estimated by uncertainty of transfer coefficients in biokinetics model of cesium.

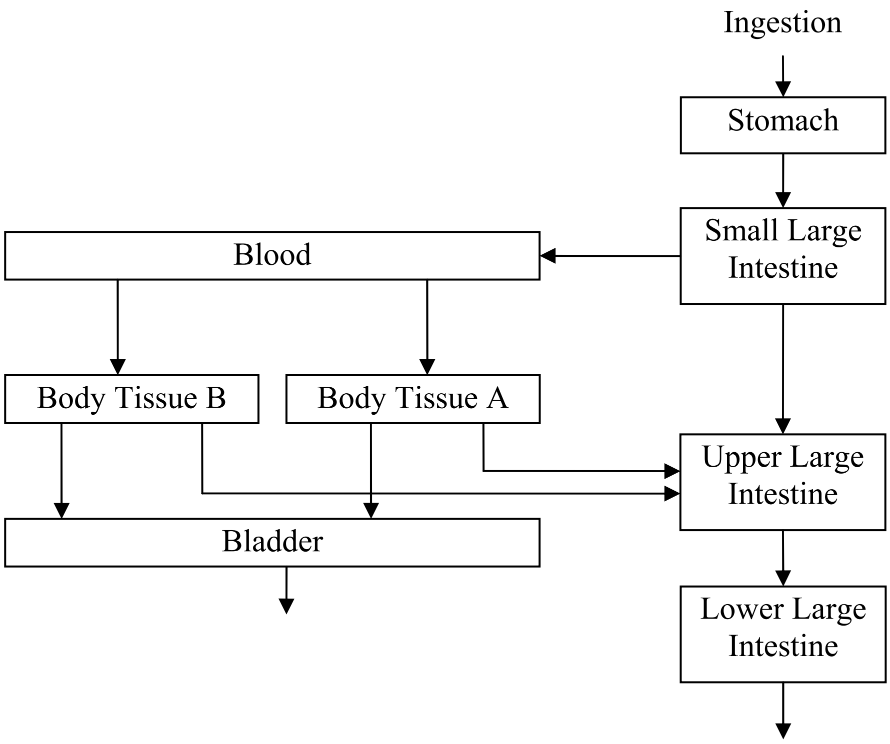

Fig. 4. Internal dosimetry model for ingestion of cesium.

Results

The probabilistic distributions for transfer coefficients in biokinetcs model of cesium estimated by probabilistic inversion and the uncertainty of dose coefficient for ingestion of ^{137}Cs by adult will be described in this section.

Probabilistic inversion

The six transfer coefficients were estimated by probabilistic inversion with expert judgment as illustrated in table 1 if the samples were 50000, the iterations of the iteration PARFUM were 200 and the iterations of probabilistic inversion were 10. In the results, the Kullback-Leibler divergence with respect to initial probability of adjusted probability was 6.04 and 0.38 in first and tenth probabilistic inversion, respectively. The probabilistic distributions of six transfer coefficients were shown in figure 5 as cumulative probabilistic distribution. This figure shows the first assumed uniform distribution, tenth adjusted probability and transfer coefficient recommended by ICRP. The 5th, 50th and 95th percentiles for retention fraction of body tissues by injection of Cs were illustrated in table 2 among expert judgment, 1th and 10th initial probability.

The first initial probability was very different from expert judgment, but the tenth adjusted probability resembled to expert judgment.

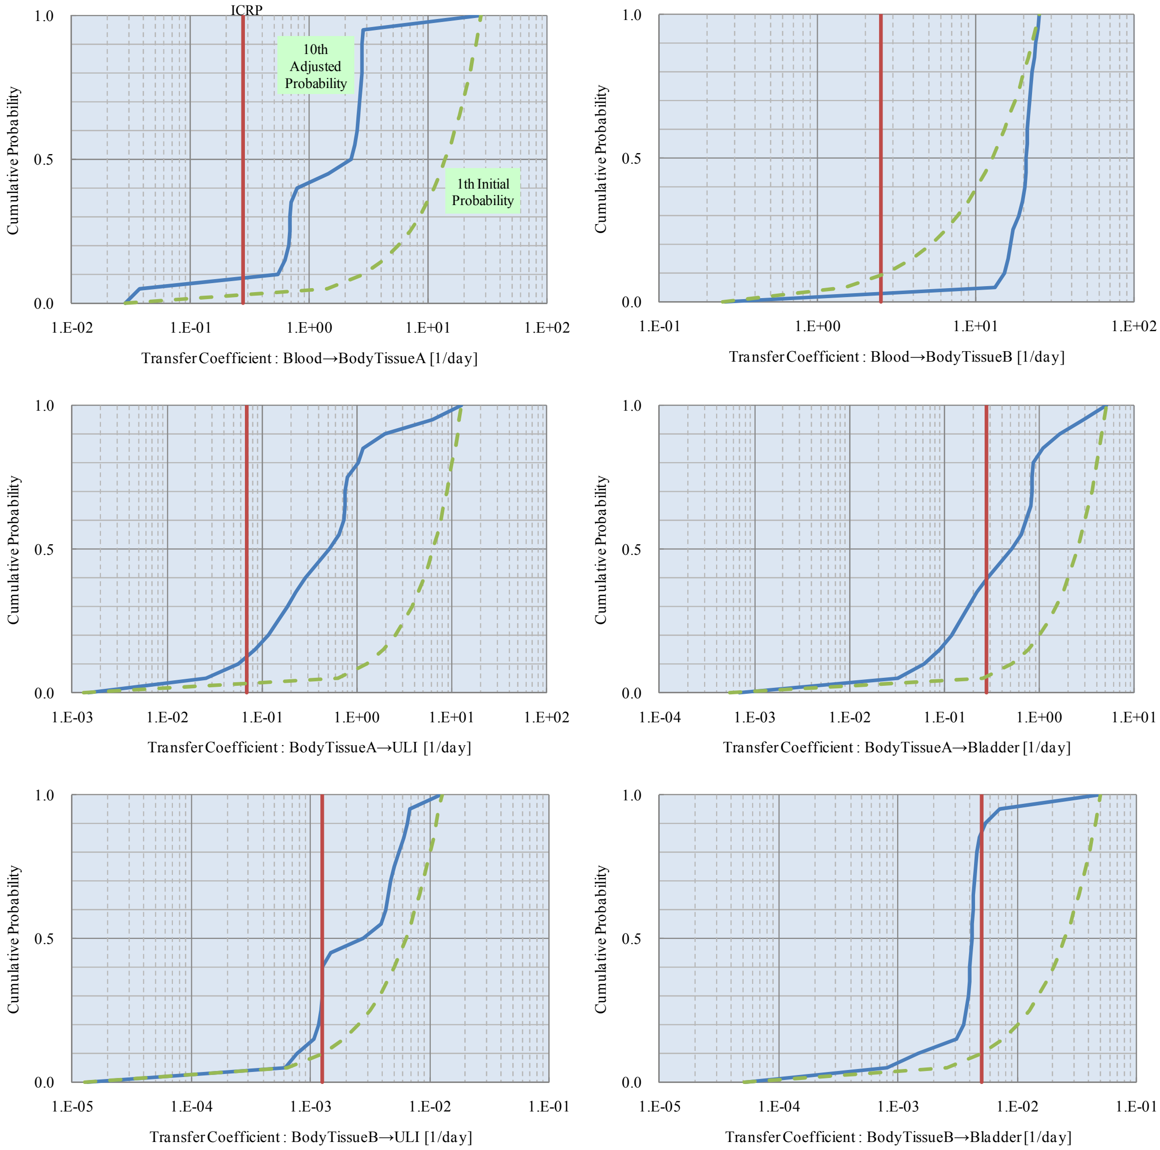

Fig. 5. Cumulative probabilistic distributions of six transfer coefficients in biokinetics model of cesium estimated by probabilistic inversion with expert judgment.

Table 2. 5th, 50th and 95th percentiles for retention fraction of body tissues by injection of Cs, for expert judgment, first initial probability and tenth adjusted probability.

Retention fraction of body tissues by injection of Cs		1day	1week	1month	1year	5years
5%	Expert Judgment	8.70E-01	7.45E-01	5.45E-01	2.38E-03	1.21E-10
	1th Initial Prob.	1.02E-01	7.66E-02	3.37E-02	7.60E-10	1.31E-44
	10th Adjusted Prob.	8.70E-01	7.46E-01	5.43E-01	5.55E-03	9.62E-12
50%	Expert Judgment	9.62E-01	8.59E-01	7.24E-01	6.48E-02	1.08E-05
	1th Initial Prob.	4.71E-01	3.80E-01	1.74E-01	4.18E-06	4.38E-26
	10th Adjusted Prob.	9.62E-01	8.59E-01	7.24E-01	7.07E-02	5.86E-06
95%	Expert Judgment	9.92E-01	9.43E-01	8.93E-01	2.64E-01	6.30E-03
	1th Initial Prob.	8.75E-01	7.33E-01	4.89E-01	2.15E-02	1.22E-07
	10th Adjusted Prob.	9.91E-01	9.52E-01	8.84E-01	2.93E-01	4.43E-03

Uncertainty of dose coefficient

The uncertainty distribution of effective dose coefficient for ingestion of ^{137}Cs by adult was shown in the figure 6. This uncertainty distribution was produced by estimated probabilistic distribution of transfer coefficients in biokinetics model of cesium. This figure also shows recommendation of ICRP, 5th and 95th percentiles. The statistics of uncertainty were shown in table 3. The recommendation of ICRP was equivalent to median and less than mean. The uncertainty factor of ratio of 95% to 5% was 5.1.

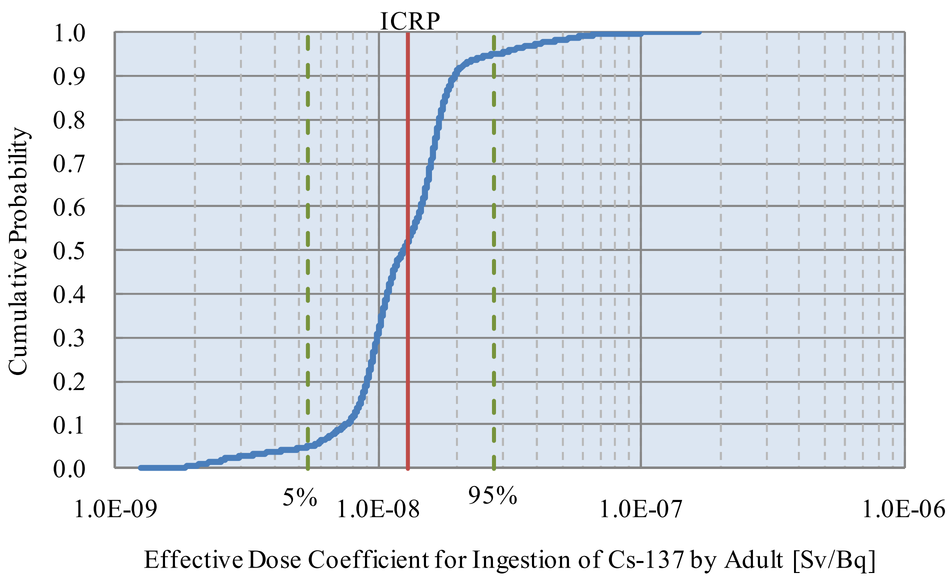

Fig. 6. Uncertainty distribution of effective dose coefficient for ingestion of ^{137}Cs by adult.

Table 3. Statistics of uncertainty of effective dose coefficient for ingestion of ^{137}Cs by adult.

Effectiv Dose Coefficient for Ingestion of ^{137}Cs by Adult	Value
Recommendation by ICRP	1.3×10^{-8} [Sv/Bq]
Mean	1.4×10^{-8} [Sv/Bq]
Median	1.3×10^{-8} [Sv/Bq]
5th percentile	5.4×10^{-9} [Sv/Bq]
95th percentile	2.7×10^{-8} [Sv/Bq]
Uncertainty Factor (95%/5%)	5.1

Conclusions

The uncertainty of internal dose coefficient was analysed with expert judgment. In this study, the expert judgment of Probabilistic Accident Consequence Uncertainty Assessment (Cooke et al., 1999) was applied. The probabilistic distributions of transfer coefficients in biokinetics model of cesium were estimated by probabilistic inversion. The uncertainty of dose coefficient for ingestion of ^{137}Cs by adult was analysed with estimated distributions of transfer coefficients.

In the result, the recommendation of ICRP was equivalent to median and less than mean. The uncertainty factor of ratio of 95% to 5% was 5.1, and its value was thought relatively small. It is thought a reason that the transfer coefficients in biokinetics model are taken as sources of uncertainty. The uncertainties of gastrointestinal model are also need to take as sources of uncertainty in dose coefficient for ingestion.

Internal and external dosimetry organization in the Joint Research Centre of Ispra

Minchillo, Gianfranco; Bielewski, Marek; Vanetti, Silvia;
Giuffrida, Daniele; Osimani, Celso et al.
Radiation Protection Sector, Nuclear Decommissioning Unit, European Commission,
I- 21027 Ispra (VA), ITALY

Abstract

The Joint Research Centre of Ispra, one of the research Sites belonging to the European Commission, Directorate General JRC, was created in the late '50s, in order to steer European research on nuclear industry. It hosts numerous nuclear facilities, some of which are maintained in operation, while others were shutdown in past years, namely: two research nuclear reactors, hot cells facilities, radiochemical laboratories, one Cyclotron (still in operation), facilities for studies on fissile material (in operation), and some facilities for the treatment and storage of liquid and solid waste (in operation).

The JRC accounts for 21 nuclear licences, 14 Controlled Zones and 12 main Surveilled Zones, on its Ispra Site.

The Radiation Protection Sector employs the services of some internal laboratories for the assessment of external and internal doses: the "Dosimetry" Laboratory (for personal and ambient TLDs), the Whole Body Count Laboratory, the Radiotoxicological Laboratory (for analyses on excreta), the Radiation Protection Sector itself (for ambient dose and contamination reporting, and electronic personal dosimeters readings).

Some of these Services are open also to the external market, and JRC-Ispra is among the few being able to provide, in Italy, either for internal and external dosimetric services to Customers.

The paper will discuss the organization and the structure of the Dosimetry and the Whole Body Count Laboratories, and their functions in the management of daily Radiation Protection tasks at the JRC.

Moreover, in order to follow-up and control Personnel radiation doses, the Radiation Protection Sector has developed and put in place, in 2007, the "**Unified Dosimetry System**", a wide and flexible *database* centralizing all dosimetric data and making them on-line available to JRC Radiation Protection experts and to the JRC Qualified Expert.

The "Dosimetry" Laboratory

Today, the mission of the JRC Ispra Dosimetry Service, belonging to the Radiation Protection Sector, is:

- preparation and distribution of personal and environmental TLD dosemeters;
- dosemeter reading and data processing;
- communication of dosimetric data to the Qualified Expert.

The number of dosemeters processed in the year 2009, with their monitoring frequencies, are shown in Table 1.

Table 1. Capability of JRC-Ispra Dosimetry Service.

Type of dosemeter	Number of dosemeters processed in the year 2009	Monitoring frequency
Whole body	4500	Monthly
Extremity - Ring	500	Monthly
Extremity - Wrist	1000	Monthly
Environmental	1000	Quarterly

Dosemeters' description: structure and composition

The Whole body dosemeter is sensitive to beta, neutronic, X and γ radiation. It consists of a transparent plastic outer casing (of dimensions 50x50x14 mm) with two Panasonic TLD badges; the first is of UD-802A series and is located at the top; the second is of UD813-A6 series and is contained within a capsule of B4C ("albedo capsule"), inserted at the bottom. Each badge contains four thermoluminescent detectors coated with different protective material and/or shielding. The choice of thickness and front and rear construction of the dosimeter serves the purpose of providing a more selective response to radiation of different nature and energy. Table 2. shows the composition of each thermoluminescent detector and the overall front and rear thickness of the different materials that shield each of them.

Table 2. Whole body dosemeter: structure and composition.

Badge series	Detector	Composition	Overall front filtration (mg/cm^2)	Overall rear filtration (mg/cm^2)
UD-802A	1	$^{n}Li_2B_4O_7$:Cu	Plastic: 14	Plastic: 28
	2	$^{n}Li_2B_4O_7$:Cu	Plastic: 303	Plastic: 303
	3	$CaSO_4$:Tm	Plastic: 303	Plastic: 303
	4	$CaSO_4$:Tm	Plastic: 143 – Lead: 874	Plastic: 143 – Lead: 874
UD-813-A6	5	$^{6}Li_2{}^{10}B_4O_7$:Cu	Plastic: 80	Plastic: 165 – B_4C: 450
	6	$^{7}Li_2{}^{11}B_4O_7$:Cu	Plastic: 80	Plastic: 165 – B_4C: 450
	7	$^{7}Li_2{}^{11}B_4O_7$:Cu	Plastic: 165 – B_4C: 450	Plastic: 165
	8	$^{6}Li_2{}^{10}B_4O_7$:Cu	Plastic: 165 – B_4C: 450	Plastic: 165

The ring dosemeter is made of plastic with flexible brackets to fit any finger size. The thermoluminescent detector is $^{n}Li_2B_4O_7$:Cu (Panasonic UD-807 series). Front filtration: 11 mg/cm^2 – Rear filtration: 28 mg/cm^2. The dosimeter does not allow selectivity in radiation of different nature and energy.

The wrist dosemeter is the Panasonic UD-802A badge inserted in a strip of clear plastic of adjustable length. The front and rear filtrations have characteristics of the standard Panasonic badge. The dosemeter is characterized by a selective response to radiation of different nature and energy.

The Panasonic UD-802A badge is also an environmental dosemeter, but inserted in a double plastic tube; the first tube (diameter 2 cm – height 5 cm) guarantees weather protection of the dosemeter in all weather conditions; the second allows the dosemeter correct positioning (diameter 4 cm – height 14 cm).

Starting in 2010, ambient Radon dosimetry service will officially be offered in the JRC. CR-39 detectors will be employed, and specific measurement campaigns will be started both in JRC nuclear facilities and in all underground working places.

Fig. 1. Personal dosemeters at the JRC: wrist, whole body and ring.

Dosemeters' calibration

Dosemeters are irradiated at the JRC Ispra Calibration Centre which is an accredited SIT ("*Servizio di taratura in Italia*": SIT is one of the signatories to the Mutual Recognition Agreement EA-MLA and ILAC-MRA for calibration certificates), using radiation sources (X and gamma) specified in ISO 4037-1 and in accordance with ISO 4037-3 (irradiations performed on ISO phantoms for personal dosemeter and in air for environmental dosemeter).

Calibration is performed for each new batch of detectors and, afterwords, with annual periodicity. Each thermoluminescent detector is characterized by a sensitivity factor every year.

For each monitoring period and for all types of dosimeters a calibration curve is read together with the associated dosimeter.

The dosemeters are read via a Panasonic UD-716 AGL automatic reader.

Performance of JRC personal dosemeters

Since 1986 the JRC-Ispra Dosimetry Service has successfully participated in the technical *audits* promoted by the national working group ENEA-EDP, for the whole body TL dosimetric system. From 2000 on, the national working group ENEA-EDP is no longer active, and in Italy new legislation to regulate the matter is pending.

According to the main standards in this field, the JRC-Ispra Dosimetry Service tested its dosemeters. Irradiations were performed at the Calibration Centre of the JRC Ispra. Table 3. and Fig. 2. show some of the test results.

Table 3. The standard requires that the detection threshold shall not exceed 0,1 mSv.

Type of dosemeters	Detection threshold (mSv)
Whole body	0.05
Extremity - Ring	0.07
Extremity - Wrist	0.03

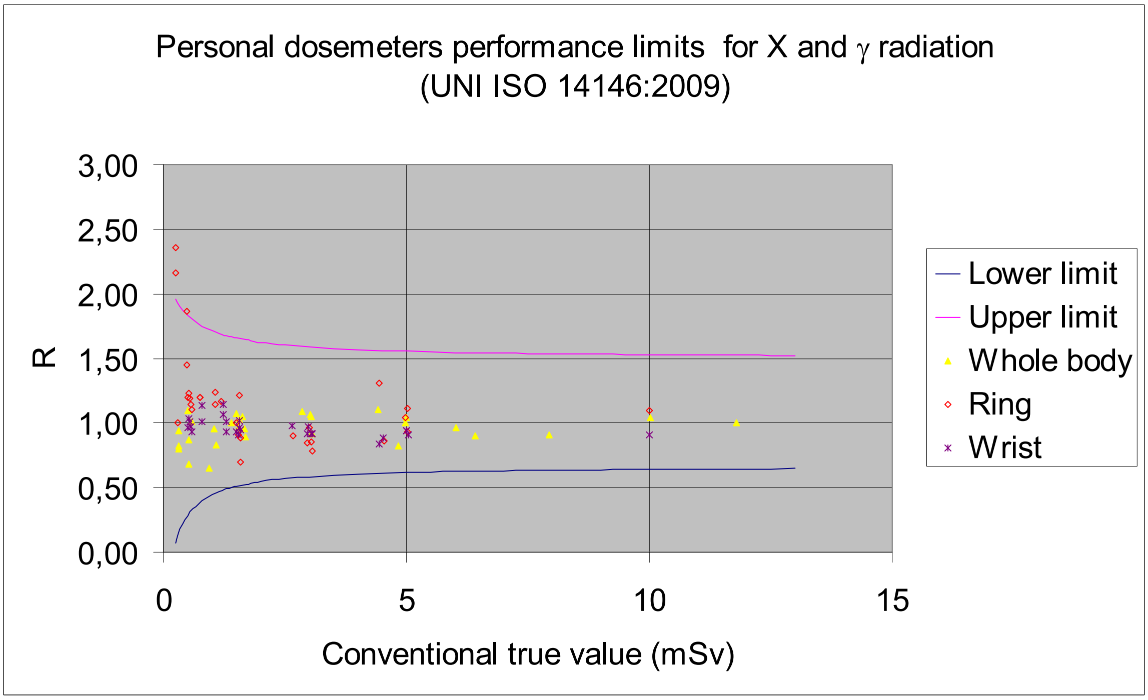

Fig. 2. Performance limits – R : ratio between measured dose and conventional true value.

The “Whole Body Count” Laboratory

The mission and the scope of Whole Body Counting (WBC) service of the JRC Ispra Radiation Protection Sector is:

- to conduct measurements of internal radioactivity of the human body on routine basis;
- to conduct measurements of internal radioactivity of the human body in special cases, like work missions outside JRC, in case of incidents etc.;
- identification of the radionuclide, and if possible its distribution within the body;
- communication of acquired data to JRC Qualified Expert.

The statistics of WBC examination performed in the year 2009 is presented in Table 4.

Table 4. Statistics of WBC measurements in the year 2009.

	Number of examinations performed in the year 2009
WBC total	599
WBC - JRC	361
WBC - external	238
no artificial radiation found	563
^{60}Co	6
^{137}Cs	26
^{125}I	1 (localized in thyroid)
^{18}F	2
^{99m}Tc	1 (undeclared medical examination)

WBC laboratory description

The internal contamination of the human body is measured by a "direct method": gamma rays emitted by radioactive nuclides from inside the body are detected using an appropriate detector, allowing determination of the quantity of incorporated activity and, in certain cases, the localisation of a radionuclide (e.g. lungs or thyroid).

For this reason the very good shielding of the measurement room against background radiation is a prerequisite. To achieve this, both, the special materials and a specific construction of rooms and equipment are employed:

- the laboratory is located in the building's basement, in order to reduce cosmic radiation,
- the 40 cm thick walls are made of low activity concrete providing additional shielding of the room,
- the floor of the room is made of marble poor in potassium (presence of 40K) and other naturally occurring radionuclides,
- the measurement room is shielded with a multilayer absorber consisting of:
  - bricks of purified lead, 10 cm thick, providing the outer shielding,
  - 1 mm thick cadmium sheets,
  - 2 mm of copper cover inside, to absorb fluorescence radiation from lead.
- A "maze" shape in the entrance of the measurement room
- the room is well ventilated and supply of fresh air through air filters is realized to reduce the radiation from radon and products of its decay present in ambient air,
- careful choice of other components of room equipment and spectrometer parts, containing low residual activity,
- low noise electronics.

With use the all above listed measures, an environmental radioactivity background as low as 10 nSv/h was obtained in the WBC measurement room.

WBC spectrometer description

The spectrometer of the WBC laboratory is equipped with three gamma detectors, one NaI(Tl) scintillation detector, commonly used for whole body counting and two HPGe detectors dedicated for lungs counting. Each detector is associated with separate spectrometric electronics - Multi Channel Analyser (MCA) and all three can work simultaneously. The spectra collected are processed and stored on the hard disk of dedicated PC, specifically intended for data analysis and archiving. Each spectrometric line dedicated for whole body counting or lung counting, except dedicated detector consists of:

- NIM module – Ortec 556 high voltage power supply,
- NIM module – Ortec 672 spectroscopy amplifier,
- NIM module – Canberra Multiport II multichannel analyser,
- PC (common for all three lines)on which the software is installed,
- software – Gennie 2000,
- software – ABACOS.

The scintillation detector is based on single crystal of NaI(Tl) with the diameter of 20 cm and 10 cm height, with an aluminium window and equipped with four independent photomultipliers. The energy resolution of this detector is 50.5 keV at 662 keV (^{137}Cs line) and 76.6 keV at 1461 keV (^{40}K line). Due to the high density of the crystal (3.67 $g \cdot cm^{-3}$) and its relatively high effective atomic number, the detector may detect electromagnetic radiation in the energy range from 50 keV up to around 2500 keV. The electronics associated is of high quality, in order to minimize noise and therefore ensure higher sensibility, accuracy, precision and overall performance of the system.

The two HPGe detectors are based on crystals of 5.1 cm in diameter and 2 cm height, with beryllium windows allowing the detection of low energy photons. The energy resolution of the detectors is in the range of 0.55 keV for 60 keV radiation and of 0.88 keV for the energy of 350 keV. Due to the high energy resolution and efficiency characteristics is more suitable for detection of the low energy photons, especially in the range 10 – 300 keV. The HPGe detectors are also connected to high quality electronics.

WBC calibration

Prior to WBC contamination measurement, system calibrations with specially designed, certified sources (phantoms) are needed. The WBC Laboratory has employed a Bottle Manikin Absorption (BOMAB) phantom for efficiency calibration of NaI(Tl) detector (commonly used for whole body radioactivity measurements). The BOMAB phantoms consists of 10 sealed bottles simulating shape of the human body and containing selected radionuclides homogeneously distributed inside the matrix (absorbing radiation in a similar way to a human body). The two HPGe detectors (used for lungs counting) are calibrated with a Livermore Phantom. This kind of phantom consists of plastic elements simulating the body and its internal organs. Such construction allows calibrating the system in order to measure the radioactivity localised in single organs (e.g. lungs). The calibration of HPGE detectors for lungs counting is shown in Fig. 3.

Since the WBC examination involves spectrometric measurements, also the energy calibration is performed on regular basis in order to allow nuclide identification. This process employs the measurements of radiation emitted by selected sources in order to assign radiation energy to channel number of MCA and is generally identical for all detectors.

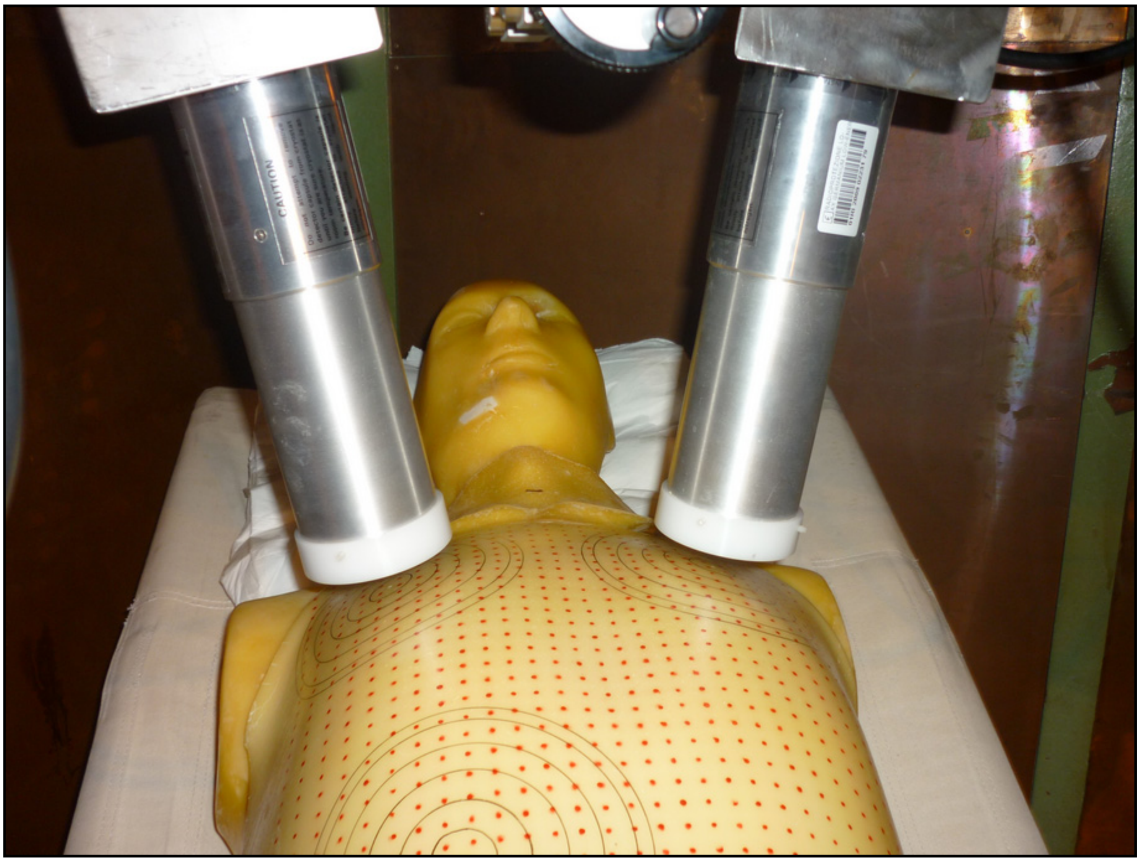

Fig. 3. The efficiency calibration of HPGe detectors with Livermore Phantom equipped with contaminated lungs.

WBC measurement

The WBC measurements are executed on a routine basis on JRC Exposed Workers, and also at start (or closure) of job contract with the JRC or related external company. The measurements are also performed on *ad hoc* basis in urgent cases (like suspicion of contamination of workers) or prior and after work missions. The duration of the measurement is between 10 minutes for standard check, up to 45 minutes in special cases. The collected spectra are evaluated ant the results are communicated to the JRC Qualified Expert.

The "UNIFIED DOSIMETRY SYSTEM"

The Radiation Protection Sector (RPS) introduced the "**Unified Dosimetry System**" (UDS) in 2007. This wide database is collecting all exposed Personnel's dosimetric data. It is also the current way of managing the TLD and WBC data, either for storage and for examination/evaluation by the JRC Qualified Expert.

The JRC accounts, on its Ispra Site, in 2010, for 21 nuclear licences, 14 Controlled Zones and 12 main Surveilled Zones.

On JRC classified zones, during the last 12 months, a considerable number of JRC exposed workers have been employed (for a total of 180 JRC exposed workers), as well as 190 external companies' exposed workers, belonging to around 30 different Companies. In the last 12 months, more than 50.000 passages of Personnel have been registered by the Electronics Dosimeters' System, inwards JRC Controlled Zones, among which almost 4.500 passages with non-zero dose (i.e., associated with a registered "electronic" dose higher than zero).

The RPS has developed and first put in operation the UDS aiming the follow-up and control of radiation doses received either by JRC Personnel intervening in nuclear facilities' operation (and during future decommissioning activities).

The Italian Legislation, implementing relevant European Directives, requires that personal doses be evaluated, recorded and registered. For some aspects, though, Italian Radiation Protection Legislation is stricter than the Directives from which it comes from, reflecting the peculiar attention granted to nuclear industry in Italy.

The main role in the management of doses and of exposed workers risks is a responsibility assigned, by Law, to the Radiation Protection Qualified Expert (QE).

It is the QE's responsibility, among many others, to inform the Employer about radiation risks, to perform radiation measurements and samplings, and to suggest the prescription of PPEs, personal dosimeters and additional controls and verifications that may result necessary.

Moreover, the QE is the sole responsible for evaluating workers' effective doses, unlike what happens in other EU countries, in which an approved dosimetric service may assign and communicate doses to the Employer (and not only dosimeters' readings).

In the case of workers of Category B, the Italian legislation requests that the evaluation of external exposure may be based on ambient dosimeters, but, for workers of Category A, personal dosimeters must always be assigned to workers[1].

Each worker automatically turns on and off his/her EPD at the entrance/exit of the specific Controlled Zone, making dose collection automatic and quicker. Moreover, "task codes" have been identified for some specific work activities, which allow to separate and track doses pertaining to long-lasting projects or to planned repetitive operation and decommissioning activities on JRC nuclear facilities.

[1] For workers of category A, proper *in vivo* and *in vitro* methods must be employed for the evaluation of internal exposure.

At present, active task codes are:
1. Radiation protection (for RP assistance activities all throughout the JRC)
2. Research activities at the JRC Cyclotron (IHCP Institute)
3. Radiopharmaceutical commercial production at the JRC Cyclotron (IHCP Institute)
4. Research activities concerning fissile material (IPSC Institute)
5. Decommissioning activities
6. Licensing and operation of JRC facilities
7. Maintenance activities on JRC facilities
8. Management of nuclear material
9. Visitors

To overcome the need for the Qualified Expert to manually treat all data relating to internal and external dosimetry (some of which are normally made available with some weeks of delay) and other radiation protection archives data (medical aptitude, previous dose records, training, passports, missions, etc.), the need for a very more complex database has been felt. The UDS database, in fact, needs to be able to store a huge number of data, namely:

- Personal workers' data (name, birth date, address, company, category, last medical visit, medical aptitude, previous doses, etc.)
- Access data (identification of controlled zone reader, date and hour of entry, date and hour of exit, errors in communication with the reader, etc.)
- Data related to doses (integrated dose (either gamma and neutron) between entry and exit, average dose (either gamma and neutron), dose or dose rate threshold exceeded, dose and dose rate alarm, integrated dose alarm (on a time period basis), etc.)
- Data related to "task codes" (task code typed in during entrance)
- Informatics data

This informatics tool has been specifically developed in order to comprise also:

- Workers' personal data archive, recording personal ID, arrival date to the JRC, category of exposure, medical visits and aptitude, doses received in previous activities (if present), working location, appointed QE, training information, emission of certificates and radiation passport, etc.
- Workers' calendar, presenting milestones in the worker's personal history (general RP training date, specific RP training date, medical aptitude date, in vivo and in vitro examinations dates, incidents and contamination dates and references, etc.)
- The dosimetric archive, either for TLD personal dosimeters, for EPDs and for TLD ambient dosimeters, importing and regrouping raw dose data coming from the Dosimetric Service and the RP Sector
- The radio-toxicological in vitro archive, importing and regrouping data from Medical Service examinations
- The WBC in vivo archive, importing and regrouping data from Whole Body Count examinations
- The Qualified Expert evaluations archive, regrouping evaluations of internal and external doses and other QE's official acts

- The dose communications' archive, regrouping the official dose communications from the Employer to workers and the communications of dosimeters' readings to Outside Companies

The functions of the UDS include the possibility to issue personal radiation sheets, signalling doses and intakes from the last months/years, and indicating additional information on medical aptitude and RP training. Finally, as dose evaluations must regularly be communicated to the Employer and the Workers, as requested by Law: the data for communications are easily obtained via the UDS, regrouping raw data and Qualified Expert's evaluations in a single view.

At present, the UDS incorporates the possibility to issue the dose evaluation document itself, inserting individual evaluations in a standard format letter, which is used for JRC dose communications, workers' dose evaluations and other data.

The "Unified Dosimetry System", is a wide and flexible tool, which allows a thorough follow-up of regulatory personal dosimetric data, as well as statistical analyses over dosimetric data. It is based on the integration of dosimetric data of different origin: either the use of both regulatory TLD passive dosimeters (either personal and area monitoring TLDs) and operational active electronic dosimeters (EPDs); and also data of internal dosimetric evaluations, both direct (WBC) and indirect (RTX).

The UDS allows the printout of dose communications, with the aim, in the future, to replace the paper ones, according to the requests of Italian Legislation.

The UDS is also a system of workers' dose control, in an ALARA perspective, and will be of paramount importance during future decommissioning works, for which a much higher collective dosimetry is expected.

Abstract

In some cases extraordinary high monthly radiation doses have been determined by the PTPA for radiation workers of the Department of Nuclear Medicine of the General Hospital Vienna. These values only could be explained to be caused by contaminations of the cover of the dosimeters (badges). These incidents were the motive for the presented study, with the aim to find out the amount of radioactivity sufficient to produce a monthly dose of 1.67 mSv, derived from the maximum permissible annual dose (20 mSv).

For this reason 50 badges (UD-802A) have been contaminated systematically with calibrated radioactive solutions, using a 10µL-pipette. The drops have been placed on the resin cover above one of the four TL phosphors respectively in order to consider different spots of possible contaminations. The badges have been shielded by lead to avoid irradiating each other. They were stored for one month at most and evaluated afterwards. The procedure was performed with the nuclides F-18, P-32, Tc-99m, In-111, I-123, I-125 and I-131. In order to consider different times of contamination the results of the measurements were converted for 2, 14 and 30 days respectively before the evaluations.

As a result just low amounts of radioactivity are causing relative high doses. Due to the radionuclide and – for nuclides of longer half lives in addition due to the moment when a contamination occurred – the values differ significantly. Our study shows, that possible contaminations of the badges can be considered to be the reason for conspicuous high evaluated doses.

Introduction

In some cases extraordinary high monthly radiation doses have been determined by the PTPA for radiation workers of the Department of Nuclear Medicine of the General Hospital of Vienna. These values only could be explained to be caused by contaminations of the cover of the dosimeters (badges). The incidents were the motive for the presented study, with the aim to find out the amount of radioactivity sufficient to produce a monthly dose of 1.67 mSv, derived from the maximum permissible annual dose (20 mSv) [1].

Material and method

Thermoluminescence dosimeters (TL-badges; Panasonic UD-802A) were contaminated systematically with calibrated radioactive solutions, using a 10µL-pipette. The drops were placed on the resin cover above one of the four TL phosphors respectively, in order to consider different spots of possible contaminations. The procedure was performed altogether more than 300 times, with the nuclides F-18, P-32, Tc-99m, In-111, I-123, I-125 and I-131.

The contaminated dosimeters were covered with 2mm lead to avoid exposure towards each other. In the case of P-32 a cylindrical shielding of 8mm acryl with an additional cover of 1mm lead was used. The dosimeters thereafter were stored for a month at most, at a place with low radiation background before they were evaluated by the PTPA.

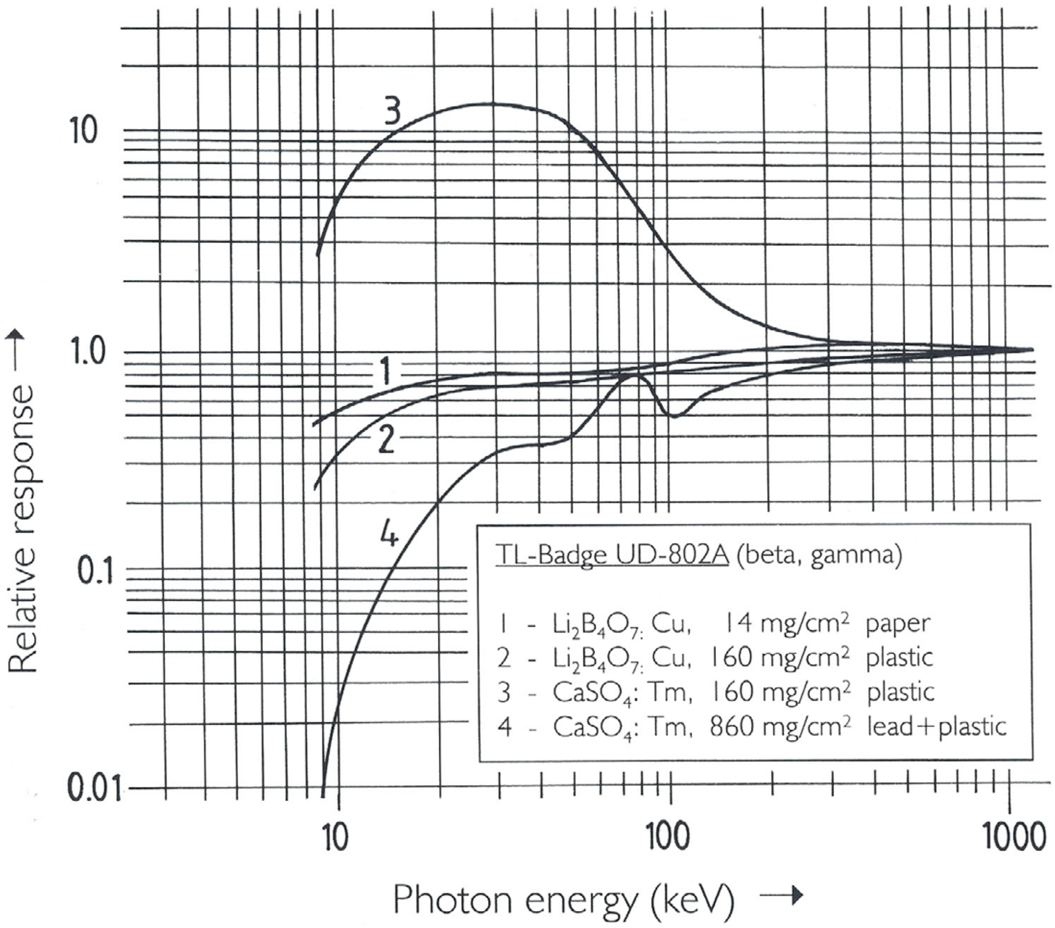

Fig. 3: Efficiancy curves of the four TL phosphors between the diverse filters [2].

Results

The results are summarized in the tables 1 to 7. They are corrected for radiation background and are normalized to an activity of 1 MBq (column 2). In order to consider different times of contamination before the time of evaluation the results of the measurements have been converted for 2, 14 and 30 days. The activities, sufficient to cause 1.67 mSv ($A_{1.67}$) are listed in column 3 to 5 of the tables. The respective irradiation times are indicated in parentheses.

Meaning of the terms in the first column of the tables:
"phosphor #1": contamination over the first Phosphor; mean of 7 values
(just as for "Phosphor #2" to "Phosphor #4")
"Ph. 1-4, mean": mean of the values "Phosphor #1" to "Phosphor #4"
"Ph. 1-4, uniform: uniform distributed contamination over the four Phosphors (singular values)

Discussion

Just low amounts of radioactivity are causing relative high doses. Contaminations with less than 1 kBq of the nuclides P-32, I-125 or I-131 are sufficient to exceed the maximum permissible monthly dose. Compared to these nuclides, about 100 kBq of Tc-99m are necessary to reach this dose.

For nuclides with longer half-lives (P-32, I-125, I-131) the values differ significantly, depending on the moment of contamination. As expected this does not apply to nuclides with short half-lives (F-18, Tc-99m, I-123).

The evaluated doses depend on the radiation energy, on the half-life of the radionuclide and consequently on the cumulated activity $\tilde{A}$ (number of decays during the irradiation time). For example $\tilde{A}$ for an irradiation time of 14 days for P-32 is about hundred times higher than that for F-18. Due to the position of the contamination on the dosimeter the doses differ from 1:8.5 (In-111) to 1:1.300 (P-32). The mean values "Ph. 1-4, mean", written in bold letters, are the most evident results. In most cases they are similar to the values "Ph. uniform".

The doses for P-32 seem to be surprisingly high, but are explainable with the relative long half-life and with the fact, that the Phosphors #1 und #2 are within the range of the beta radiation and that adjacent phosphors can be reached by the slanting rays.

Furthermore, the results are due to the evaluation algorithm for the TL-dosimeters, generally intended for uniform external irradiation rather than for contaminations.

Conclusion

Our study shows, that contaminations of personal dosimeters with low amounts of radioactivity should be considered to be the reason for conspicuous high evaluated doses.

Tooth dosimetry for residents of Techa riverside territories

Abstract

The method of EPR dosimetry with teeth is practically the only method acceptable for retrospective individual dose measurements for non-occupational exposure. Application of the method for external dose reconstruction in the Techa River region (Southern Urals, Russia) is complicated by combined character of tooth exposure: internal (mostly due to $^{90}Sr/^{90}Y$ incorporated in the tooth tissues) and external radiation. The aim of the study was evaluation of the external doses for Techa riverside residents. The external dose can be assessed by subtraction of the internal dose component from a total EPR-measured dose in the tooth enamel. The internal dose in the enamel was estimated based on TL contact beta detection of the radionuclides incorporated in the tooth tissues. About 300 teeth obtained from 170 Techa riverside residents permanently lived in different settlements along the river stream were investigated by EPR. For many of them parallel TL-measurements of ^{90}Sr concentration were performed. The paper present results of tooth dosimetry accumulated during 10 years of extensive measurements.

Introduction

The extensive increase in plutonium production in the Mayak Production Association (Southern Urals, Russia) during 1948–1955, as well as the absence of reliable waste-management technology, resulted in significant releases of liquid radioactive effluent into the rather small Techa River. This resulted in chronic external and internal exposure of about 30,000 residents of riverside communities (Vorobiova et al. 1999). Since 1992, EPR tooth dosimetry is used for the Urals region for external dose estimation. Eleven EPR methods applied in 7 different laboratories were used under this 18 years study. Different methods had unequal quality that should be taken into account under combined analysis. Additional problem of EPR data interpretation is the presence of ^{90}Sr in the tooth tissues. ^{90}Sr and his daughter ^{90}Y are bone seeking beta emitters responsible for additional internal exposure of enamel. Moreover some of donors were treated by x-ray medical exposure influenced on the total enamel dose. Therefore, the following steps are required to evaluate the external doses from EPR measurements performed by different methods during long-term study:

- unification and harmonization of available EPR data obtained by different methods, including:
  * adjustment for systematic bias by estimation and subtraction of background doses, that consists from both the dose due to environmental exposure and possible systematic error;
  * decision on data processing below the detection limit;
  * algorithm for averaging of repeated measurements performed for the same tooth and/or different teeth of the same donor by different methods;
- estimation of internal dose due to 90Sr incorporated into the tooth tissues
- estimation of medical doses that could have contributed to the dose in the tooth enamel
- evaluation of the individual external dose according Fig1.

As it can be seen from Fig. 1 the individual external dose is evaluated from weighted EPR measurement (in case of several measurements for the same donor) by subtraction of average background, internal dose fraction and individual medical dose.

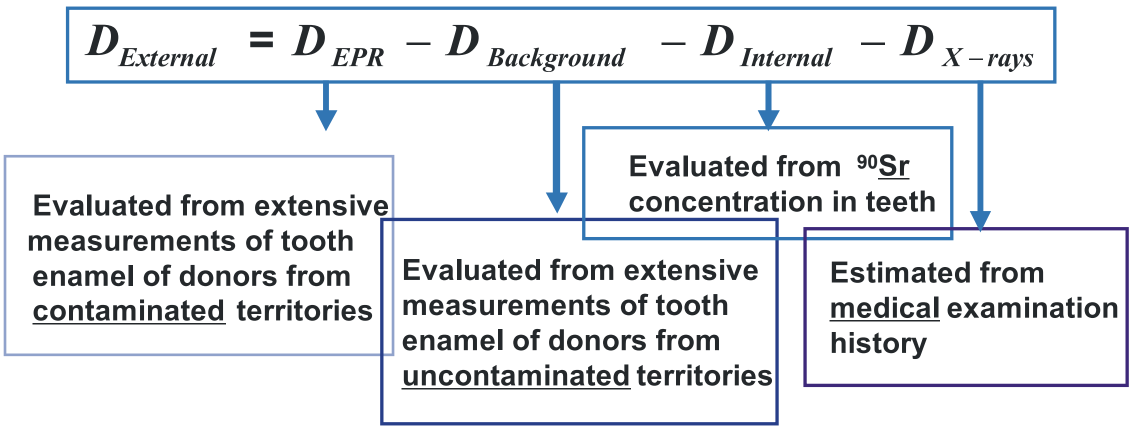

Figure 1. Illustration of assessment of the external dose for Techa river residents from EPR measurements.

Material and methods

The investigated teeth were all extracted because of medical indications at local dental clinics. Tooth donors were identified to allow matching with the roster of exposed persons (Vyushkova et al. 1996). During long-term study teeth were measured at 7 different laboratories using 11 different methods (with different accuracy and precision). The following laboratories participated this long term study: Institute of Metal Physics (IMP, Russia); Helmholtz Centrum Munich (HMGU, Germany); Institute of Chemical Physics (ICP, Russia); Institute of Biophysics (IBP, Russia); National Institute of Standards and Technology (NIST, USA); Medical Radiobiological Research Center (MRRC, Russia); Istituto Superiore di Sanità (ISS, Italy).

Table 1 represents description of the EPR data accumulated in the long-term study and available for analysis. Currently 973 results of EPR measurements for exposed and unexposed population is available in URCRM database. Moreover about 10% of teeth from exposed population were measured twice by different methods and 30% donors donated more than 1 tooth. Teeth from unexposed population were collected in the Urals rural territories from donors with the life style and diet similar to exposed population. Enamel dose obtained as a result of X-ray examinations of tooth donors at the URCRM clinic were estimated from personal medical histories. In total 152 persons with EPR measurements were identified as medically exposed. Calculations of medical doses were done using a method that will be published soon (Wieser et al, to be published). Internal doses from incorporated ^{90}Sr in the teeth were calculated with the method described in Shishkina et. al. (2010).

Results

Unification and harmonization of available EPR data

Pooled analysis of exposed samples has required adjustment of EPR results for proper background levels. The results of EPR measurements for unexposed population have demonstrated that the background level depends on EPR measurement protocol (due to possible bias) and differs for anterior and posterior teeth. In turn, lateral and lingual parts of incisors' enamel have different background doses. Thus, average background dose was calculated for each combination of the methods of sample preparation and EPR measurement separately for anterior and posterior teeth. For some EPR methods tmeasurements of background doses were not conducted (see Table 1) and the decision about background was made from the results of interlaboratory comparisons (Wieser et al., 2000a; Wieser et al., 2000b). Background doses for incisors were calculated separately for lingual and lateral fractions. Some incisors where measured in IMP without separation of lateral and lingual fraction. However it was found no significant difference between whole enamel and lateral fraction. This is reasonable because most fraction of incisor enamel is lateral. Therefore we combined measurements of lateral and whole enamel together for estimation of background doses.

Only one method (method 3 in Table 2) demonstrated the reliable age dependence in background level. For all the EPR methods, most of background doses were below the method detection limit. Therefore average background doses do not reflect real environmental exposure and corresponds to systematic bias. Therefore the average background dose can be assumed as adjustment for systematic bias (parameter for data harmonization).

All measurements of doses in the tooth enamel of exposed individuals which are below the detection limit should be replaced with a value of mathematical expectation of radiation dose. For each method, such value was calculated using the comparison of measurement results that were below the detection limit (DL) for exposed and unexposed donors. Figure 2 illustrates the approach for estimation of dose ascribed to EPR results below the DL. The obtained results are shown in the Tab. 2. These values are also harmonization parameters.

Table 2. Parameters of data harmonization.

EPR method	Years of measurements	Dose ascribed to EPR results below the DL (Δ), mGy	Adjustment for systematic bias ±st.dev, mGy		
			Posterior teeth	Anterior teeth	
				Whole enamel/lateral enamel	Lingual enamel
1	1996–2007	4	110±90	200±130	110±90

8, 9, 10	1992–1994, 2000–2001	4	110±90	200±130	110±90
11	2001	4	120±90	230±110	200±150

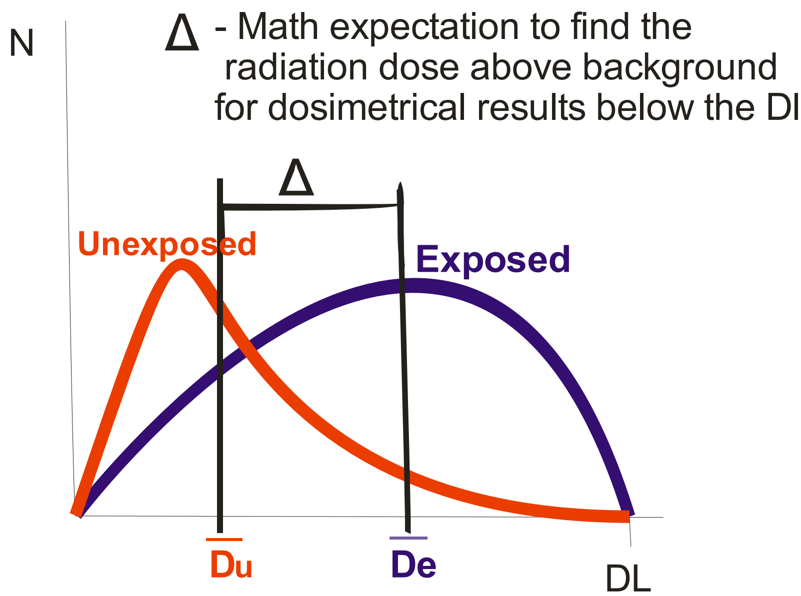

Figure 2. Illustration of the algorithm for estimation the mathematical expectation for dose of incidental exposure which attributes to results of EPR dosimetry below the DL. Du is the average dose in the sample group from unexposed population. De is the average dose in the sample group from exposed population.

The algorithm for pooling data obtained by different methods together for combined analysis was done according to scheme presented in Figure 3, where D is the background dose; Δ is mathematical expectation of incidental dose for measurements below the DL. Doses for teeth which have been measured several times by different methods were averaged accounting for different uncertainties of the methods (δ) and repeatability of the measurement (σ). Doses estimated for different teeth of the same donor were also averaged. As a result, a set of doses for individuals was available for analysis. Conversion of EPR dose in a tooth into external dose ($D_{tooth} \rightarrow D_{tooth\ external}$) was done by subtraction of individual medical exposure and internal dose component.

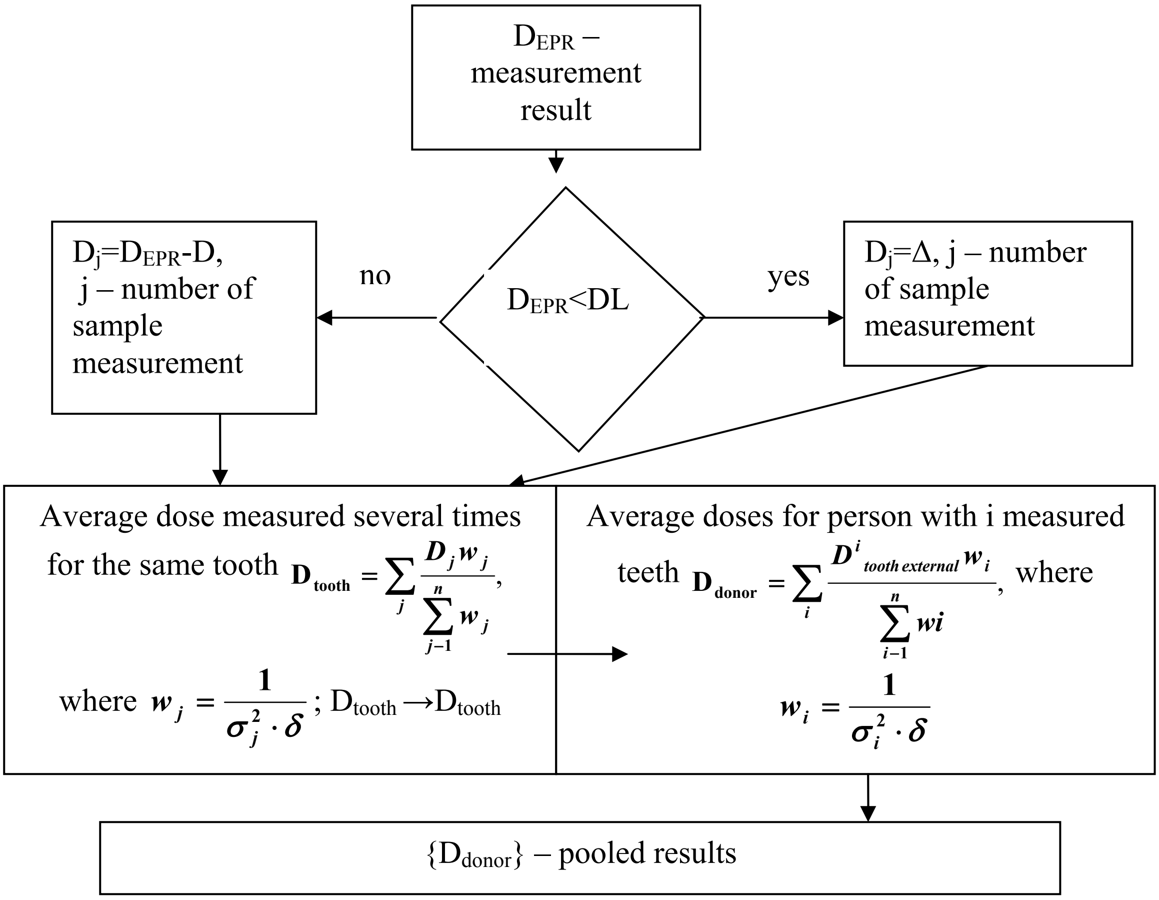

Figure 3. Scheme of data unification for combined analysis. Averaging are performed with weighting factors *w*.

Internal enamel doses due to ^{90}Sr incorporated into the tooth tissues

In Shishkina et al. (2010) it was shown that current levels of ^{90}Sr concentration in different tooth tissues of Techa riverside donors are age-dependent. It was shown that for external dosimetry only teeth aged more than T ≥ 6 years in 1951 can be used for the external dosimetry. The average current concentration of ^{90}Sr in enamel is 0.14±0.12 Bq/g. Additionally some influence on enamel dose of adjasted dentine existes. Based on the model of radionuclide contamination in different tooth tissues and dose conversion factors described in Shishkina et al. (2010) the expected average levels of internal doses were calculated for different tooth age (Table 3). For teeth with known individual contamination of ^{90}Sr internal dose component was calculated individually.

Table 3. Expected age-dependent average levels of ^{90}Sr concentration in the tooth tissues and correspondent cumulative internal doses

Tooth age, years	Concentration of ^{90}Sr, Bq/g			Internal dose in the enamel, mGy
	Enamel	Crown dentin	Root	
6	0.14±0.12	7±5	21±24	120±80
10	0.14±0.12	3±2	15±17	80±50
15	0.14±0.12	1.02±0.40	7±8	42±30
25	0.14±0.12	1.02±0.40	0.4±0.4	40±27

Doses of medical exposure

Medical histories of patients of URCRM clinic were investigated. Table 4 shows the information on X-ray examinations that resulted in additional exposure of tooth enamel, including statistics for donors who have EPR measurements on teeth. The last two columns include the enamel doses expected to be accumulated in the anterior and posterior teeth due to medical observations.

Table 4. X-ray observations and typical doses cumulated in the enamel

Tested organ	Total number of persons	Number of persons with EPR measurements	Average dose in enamel, mGy	
			Posterior teeth	Anterior teeth
Teeth/jaw	496	7	12	64
Skull	1071	34	10	9
Nosal cavities	1365	49	2	1
Neck-bone	1417	61	12	23

The results of individual dose calculation indicated that for 96% of cases of X-ray examinations of donors the additional medical doses in tooth enamel were below 50 mGy. Contribution of medical exposure was subtracted from the EPR dose for all persons who had X-ray examinations to adjust enamel dose estimates for this source of confounding exposure.

External doses for Techa riverside population depend on residence

External enamel doses were estimated from EPR measurements for 170 permanent residents of Techa riverside whose teeth were totally completed at the beginning of exposure. Each donor lived permanently at the same settlement during the period of maximum radioactive release: from 1950 through 1952. Individual EPR-based doses have been grouped according to a person residence site. Figure 4 illustrates group-average doses for residents lived in settlements located at different distances from the release site.

As can be seen, average external dose in tooth enamel was about 200-520 mGy at distances up to 50 km from the release site (individual doses reached 2.3 Gy). Two distinct peaks are visible in this length corresponding to residents of Metlino (located at

7 km frome release site) and Nadyrovo (located at 50 km). Also, large variations of individual external doses for residents of the upper Techa River require continuation of EPR measurements for more reliable conclusions.

At the distances of about 60-90 km from the site of releases the external dose decreased to 120-130 mGy, and was about 50 mGy for those who lived at distancesmore than 100 km downstream from the release site.

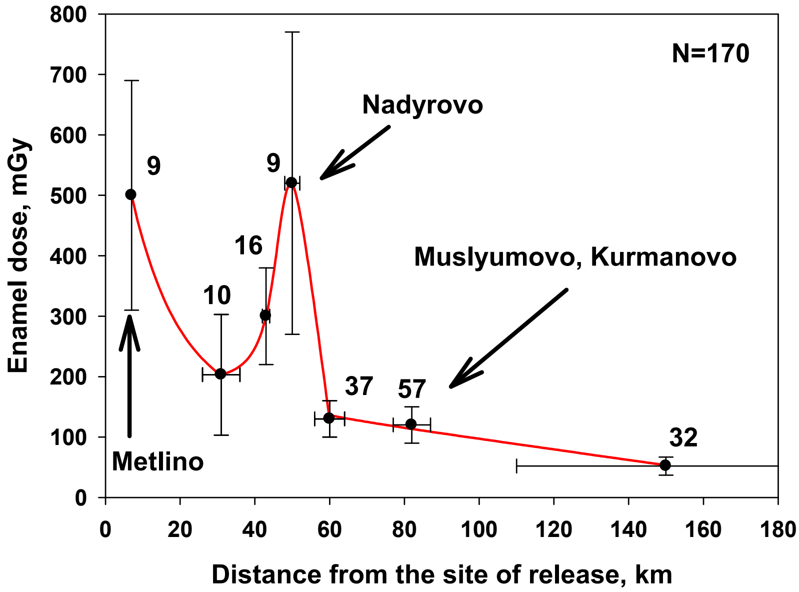

Figure 4. Average EPR-based external dose for permanent residents of the Techa River settlements dependent on the distance from the site of release. Bares indicate standard errors.

Discussion

The EPR-based estimates of individual external dose are used for validation of the external dose calculation made using the Techa River Dosimetry System (TRDS, Degteva et. al. 1998)). The Techa River cohort contains about 30,000 residents and some of them died. Therefore physical retrospective dosimetry with EPR is not sufficient to evaluate the doses for the whole cohort, and mathematical modeling is the only way for estimation of individual external doses. However the models used in TRDS include some assumptions which cand be validated with EPR.

In this connection the peak in external doses observed in Nadyrovo (Fig. 4) is not predicted with the current version of TRDS. This peak could be explained by exposure conditions specific to this part of the Techa River and should be considered more carefully in the further study. The obtained results of EPR external dosimetry will be used for improvement in external dose calculation in TRDS.

Conclusions

1. Algorithm for harmonization of available EPR data obtained by different methods during long-term study was elaborated. Parameters for harmonization were evaluated.
2. Internal doses were estimated. Average internal doses in the enamel for teeth with completed crown are in the range from 40 to 120 mGy

3. The influence of medical examinations on the total enamel dose was evaluated. 96% of doses due to medical exposure was found below 50 mGy.
4. Individual external doses in the Techa River region evaluated based on EPR tooth dosimetry are following:
   - average external dose in tooth enamel was about 200-520 mGy at distances up to 50 km from the release site (individual doses reached 2.3 Gy);
   - at the distances of about 60-90 km from the site of releases the external dose decreased to 120-130 mGy;
   - the doses are about 50 mGy for those who lived at distances more than 100 km downstream from the release site;
   - highest individual doses (up to about 2 Gy) were found in two sites: Metlino (7 km) and Nadyrovo (50 km)

The obtained results of EPR external dosimetry will be used for improvement in external dose calculation in TRDS.

Acknowledgments

This work was done under financial support of SOLO projectand also under common fondation of Russian Federal Medical and Biological Agency and Department of Energy of USA (Russian-American Program 1.1). Authors also are very thankful for IAEA for provision to present the study in the Regional International Radiation Protection Association (IRPA) Congresses. Spetial acknowlegmen is for Shagina NB (URCRM, Russia) for fruitfull discussions.

Finland’s approach to licensing and regulatory control of geological repository for spent nuclear fuel

Varjoranta, Tero; Paltemaa, Risto
Radiation and Nuclear Safety Authority, STUK, P.O.Box 14, FI-0881 Helsinki, FINLAND

Abstract
Finland’s program for the disposal of spent nuclear fuel is among the most advanced in the world. The first licensing step, the Decision-in-Principle, which sealed public acceptance on local and national level, was taken in 2000-2001. Site confirmation studies, the construction of an underground rock characterization facility and the development of the safety case for the facility are ongoing and the program is approaching the next step, the submittal of construction license application, expected in 2012. All this was preceded by more than 30 years of work with a long-term goal. In this review, the approaches to licensing and regulatory control of the facility are presented.

Introduction
There are four nuclear reactor units in operation in Finland, two VVER-440/213-type pressurized water reactors (488MW each) in Loviisa and two ASEA-Atom boiling water reactors (860MWe each) in Olkiluoto. The reactors were commissioned between 1977 and 1980. One reactor unit, a 1600MW EPR, is under construction at Olkiluoto. There are applications pending for new reactors by three companies, on four candidate sites. Currently, about one third of the electricity consumption in Finland is produced by nuclear reactors.

From an early stage in the Finnish reactor program, it was considered that the whole nuclear fuel cycle needs to be taken into account when addressing the safety of nuclear energy production. Over 30 years of systematic research and development has been carried out to select a site, to develop engineered barriers and the safety case and, in parallel, a stepwise regulatory approach for the disposal of spent nuclear fuel produced in Finland.

These activities have been done following Government’s long term strategies since 1983. As the first regulatory step, public acceptance at local, Governmental and Parliament levels was gained in the Decision-in-Principle (DiP) in 2000 to locate the repository at Olkiluoto.

The operators of nuclear facilities/producers of nuclear waste, now Fortum Oyj and Teollisuuden Voima Oyj, have full responsibility for nuclear safety, including the safety of disposal of spent nuclear fuel. For the implementation of the disposal, the NPP operators have formed a jointly owned company, Posiva Oy. The Ministry of Employment and the Economy is responsible for the supreme command and control of nuclear matters, while the Radiation and Nuclear Safety Authority (STUK) is responsible for the supervision of safe use of nuclear energy. STUK is an independent regulatory body with broad authorities to ensure that nuclear power is produced in a safe manner, and to give necessary orders for this purpose.

An application for a Construction License of the disposal facility is expected to be submitted at the end of 2012 and operation of the facility to begin in 2020.

Stepwise licensing

In Finland, licensing a nuclear facility proceeds in three steps:

Decision-in-principle

Construction of a nuclear facility of considerable general significance requires a Government Decision-in-Principle on that the construction project is "in line with the overall good of society". Nuclear facilities deemed to be of considerable general significance include nuclear waste disposal facilities.

The Decision-in-Principle is the major political decision on the societal acceptability of the project. An Environmental Impact Assessment process with public consultation and stakeholder involvement must be performed. As a prerequisite for the decision, the Government must obtain the consent of the host municipality and a preliminary safety evaluation by STUK indicating that "no facts indicating a lack of sufficient prerequisites for constructing a nuclear facility have arisen".

The Decision-in Principle is made by the Government and endorsed or reversed by the Parliament.

Construction license

The license to construct a nuclear facility is granted by the Government. It requires an application which must include the justification of safety for the facility, the Safety Case of the designed facility. Based on the application, STUK makes a safety evaluation, which must be positive for the construction license to be granted.

Operating license

The license to operate a nuclear facility is also granted by the Government. The Safety Case of the constructed facility is reviewed by STUK and a positive safety evaluation is required for the Government to grant the licence.

Regulatory control

From a regulatory viewpoint, the Olkiluoto spent fuel disposal project can be divided into the following main phases:

1. Research phase from the late 1970's to the Decision-in-Principle licensing phase (DiP),
2. Research, development and design phase including construction of an underground rock characterization facility (from DiP to Construction Licence),
3. Construction phase (from Construction Licence to Operating Licence),

4. Operating phase
5. Decommissioning and closure phase.

Before the DiP, the progress in siting and research and developed were followed by annual reporting with STUK's statements to the ministry.

In the year 2000, the Government made the Decision-in-Principle. The decision also authorized the construction of an underground rock characterization facility, now called ONKALO, in Olkiluoto. The facility may be later used as the access tunnel to the disposal facility and is therefore constructed under full regulatory control.

In addition, research, development and design work by Posiva continued with the aim to arrive at a facility design and a Safety Case for the next licensing stage by 2012. STUK has reviewed Posiva's plans and evolving drafts of Safety Case documentation, commenting on their adequacy compared to regulator's expectations.

Construction of ONKALO

For long term safety, the main safety functions of the Olkiluoto disposal facility are ensuring the integrity of the engineered containment of the disposed waste and maintaining sub-criticality. The secondary safety functions are the limitation and retardation of the release of radioactive nuclides and isolation of the engineered barrier system from external impacts.

Therefore, it is important that such chemical and mechanical conditions are maintained in the bedrock that the safety functions are not jeopardized over a long period of time in a variety of normal and abnormal circumstances.

Construction of ONKALO to the planned disposal depth (-427m) disturbs the geo-environment and conditions in a variety of ways. The purpose of STUK's regulatory control of ONKALO construction is primarily to ensure that the design, location, orientation and construction are carried out in such a manner that the geo-environment retains its favourable characteristics and conditions needed for the safety functions.

In particular, this implies the minimization of

- host rock responses to excavation, the excavation disturbed zone,
- groundwater leakages to the tunnels and shafts, and
- introduction of foreign, potentially harmful, substances to ONKALO during excavation and operation (cement and other grouting materials, reinforcement materials, explosives etc.).

STUK's regulatory activities (approvals, review and assessment, inspection) of ONKALO are implemented in a graded approach. All structures, systems, components are classified based on their assessed significance to safety.

Posiva's management system is also subject to STUK's regulatory control. STUK primarily inspects safety and quality management of Posiva's organization and reviews Posiva's self assessment of safety culture.

As a basis for review and assessment, STUK requested from Posiva a plan of the documents to be submitted for information or approval. The plan was an adaptation of that defined in the regulatory guide for nuclear facilities. The documents that must be submitted include description of the constructing organization, staff competences, regulations, codes and standards to be used in the construction, quality system documentation, design data, drawings, construction documentation, etc.

In addition, Posiva was required to submit to STUK a plan describing how the company intends to communicate to STUK the progress of the construction work. The purpose of this document is to facilitate well planned and timely regulatory activities.

In STUK's review and assessment of ONKALO construction, requirements in current regulatory guides (for nuclear facilities) are used, as applicable, but in many cases they can only be used as a model and new requirements and criteria suitable for this part of the underground disposal facility have to be created.

ONKALO inspection activities cover all areas of STUK's responsibilities. Inspections are carried out in order to ensure that Posiva is in compliance with regulations, conditions and approvals of STUK. Inspection activities can be divided into:

- Construction Inspection Program,
- Inspections concerning the readiness to begin excavation and work phases, and
- Inspection on construction works on site.

From the Construction Inspection Program, five to ten inspections are performed annually. The inspection program has a three-level hierarchy:

- Level A, Management system: safety management, organization, safety culture, quality assurance, competence of staff, communication with STUK,
- Level B, Main Operations: construction project management and resources, safety issues, quality assurance for construction work, monitoring program, related R&D,
- Level C, Functions and Activities: Posiva's inspections and QC, excavation and excavation disturbed zone, drillings, mapping of features, construction impacts (to geochemistry, rock mechanics, hydrogeology, groundwater leakages to tunnels and shafts, introduction of foreign materials, grouting, enforcement works and materials), physical protection and emergency preparedness.

ONKALO construction is divided into different phases. The purpose of the inspections concerning the readiness to begin excavation and work phases is to ensure that all the arrangements and conditions at the construction site are in order for the next construction phase to start (previous phase is properly completed).

Examples of this type of inspections are inspecting the preparedness to begin shotcreting a specified tunnel section, and inspecting the preparedness to start a new excavation piece-work.

Inspections on construction works on site, carried out at least once in two weeks, focus on work processes, methods and practices, and their quality and compliance with approvals.

Posiva's research, development and design activities

During this period between the DiP and the submittal of Construction License application, STUK's regulatory control of Posiva's RD&D activities focuses primarily on the gradually evolving facility design and the drafts of Safety Case documentation.

Posiva has a program of producing the documentation for the long-term Safety Case, 10 main reports, in a several advancing versions, before final versions submitted with the Construction License application. STUK has reviewed these reports and commented on them, compared with regulatory expectations, and identified safety questions that need to be resolved before the next licensing phase.

As a required maturity test, Posiva submitted recently the current drafts of their Construction License application material to STUK and Ministry of Employment and the Economy. This material includes the draft Preliminary Safety Analysis Report and drafts of most reports included in the long-term Safety Case. The regulators review if the pre-license application demonstrates sufficient readiness from scientific, technological and safety viewpoint to justify the actual construction licensing process to start in 2012.

Regulations, guides and regulatory decisions are developed and taken in parallel with the proceeding RD&D work.

In support of its regulatory staff, STUK has organized the three international experts groups for

- Olkiluoto site safety investigations,
- Engineered Barrier System and Technology, and
- Safety Assessment.

Nuclear Safeguards

As ONKALO is foreseen to become a part of the disposal facility for spent nuclear fuel, STUK decided in 2003 to start to require the application of nuclear safeguards measures to ONKALO. Posiva was obliged to implement safeguards procedures from the beginning of the excavation to the closure of the disposal facility site. As required by STUK, Posiva has prepared and documented all necessary safeguards procedures and measures in their "Safeguards Handbook" and submitted it regularly to STUK for review and approval.

Safeguards activities for spent fuel disposal in Finland have four main objectives:

- to ensure that all safeguards relevant information about the final disposal facility will be available in due time;
- to be able to confirm that there are no undeclared activities relevant to safeguards at or near the final disposal site;
- to enable the IAEA to perform integrated safeguards in Finland;
- to enable the IAEA and the European Commission to plan for their future safeguards activities.

STUK's current safeguards activities consist of auditing Posiva's safeguards implementation, reviewing Posiva's safeguards relevant reports and confirming by on-site inspections that ONKALO is in compliance with Posiva's as-built documentation.

STUK's audit of Posiva's safeguards implementation includes review of the documented results and the observations made throughout the year in connection with report reviews and on-site inspections. Result of STUK audits are fed back to STUK's regulatory process and to Posiva.

Conclusions

Finland's program for the disposal of spent nuclear fuel is approaching the construction license phase. In parallel with the progress of the disposal project, an approach to regulatory control has been developed, as described in this paper.

Preliminary results on Cernavoda NPP operation impact on terrestrial and aquatic biota

Bobric, Elena[1]; Varlam, Carmen[2]; Popescu, Ion[1]; Simionov, Vasile[1]
[1] Cernavoda NPP, Health Physics Department, ROMANIA
[2] National Institute R&D for Cryogenic and Isotopic Technologies, Rm. Valcea, ROMANIA

Abstract

Recently, the awareness of the vulnerability of the environment has increased and the need to protect it against industrial pollutants has been recognized. The concept of sustainable development, requires new and developing international policies for environmental protection. (Protection of the environment from the effects of ionizing radiation. IAEA-TECDOC-1091. International Atomic Energy Agency, Vienna.). As it is recommended in "Cernavoda Unit #2 NPP Environmental Impact Assessment it is Cernavoda NPP responsibility to conduct an Ecological Risk Assessment study, mainly to assess the impact of Nuclear power plant operation on terrestrial and aquatic biota. Long records from normal operation of Cernavoda Unit 1, wind pattern, meteorological conditions, and upgread source terms data were used to evaluate areas of interest for environmental impact, conducting to a circle of 20 km radius around mentioned nuclear objective. The screening campaign established tritium level (because Cernavoda NPP is a CANDU type reactor, and tritium is the most important radioisotope evacuated in the environment) in air, water, soil and vegetation, focusing the interest area on particular ecosystem. Using these primary data it was evaluated which are the monitored ecological receptors and which are the measurement endpoints. This paper presents the Ecological Risk Assessment at Cernavoda NPP technical requirements, and the preliminary results of evaluating criteria for representative ecosystem components at Cernavoda NPP.

Optimization of management of radioactive waste generated in research and education centres

Macias, Mª Teresa[1]; **Pulido, Juan**[2]; **Pérez, Jorge**[2]; **Sastre, Guillermo**[2]; **Sánchez, Angeles**[3]; **Usera, Fernando**[4]

[1] Instituto de Investigaciones Biomédicas Alberto Sols (CSIC-UAM), SPAIN

[4] Centro Nacional de Biotecnología Severo Ochoa (CSIC), SPAIN

Abstract

The radioactive waste generated in biological research has low specific activity and it is candidate for clearance from regulatory control. Some issues of the management of this waste could be technically improved. With the aim, it has been initiated a research project with a grant of ENRESA.

The objectives are: 1) Characterization of radioactive waste generated; 2) To propose criteria for the management of mixed waste (scintillation vials full of scintillation solution); 3) To suggest clearance values for liquid waste; 4) To propose criteria for the management of uranyle and thorium salts wastes. 1) We suggests to measure the activity of liquid and mixed wastes and to estimate the amount of solid waste. The radiological characterization of selected radiosotopic techniques applying this new protocol has begun. Also, we are complying information about chemical characterization of the waste. 2)-3) It has been considered the incineration as the final way for the mixed waste. This waste can be characterized attending their specific activity and it can be applied the clearance levels for solid waste. Therefore, it is necessary to determine the released activity airborne and the activity burnt to ashes. These calculations are being carried out at this moment. Regarding the organic liquid waste, the final way is also the incineration if the radioactive concentration is below the clearance values.

However, for the aqueous liquid waste, the final way is the discharge via the sewer system. To determine the maximum discharge concentration, the calculations are being carried out taking into account the water flow of the sewer systems and the Annual Limit on intake for ingestion applying the committed effective dose per unit-intake for the ingested radionuclide. The results obtained allow confirming that it will be possible to obtain a final document to serve as a guide to simplify and to standardize the management procedure of radioactive waste generated in biological research.

Introduction

The radioactive installations of Research and Education Centres generate residual materials with radioactive content, they are very heterogeneous and, generally with low activity. Therefore they are mainly clearance. The International Agency of Energy Atomic (IAEA) names this waste as low and medium activity waste. It is necessary that these radioactive installations have an adequate management program for this waste, with technical and administrative actions to control these materials, to optimize their management and to minimize its radiological impact of human health and the environment. Some technical documents, of international reference, have been recently published, to improve the management of this waste in the installations of Research and Education (IAEA-TECDOC-1000 1998, Krieger et al. 2002, IAEA WS-G-2.7. 2005, IAEA-TECDOC-1528 2006).

Two technical guidelines were published in Spain in order to optimize the management of this waste. The first document (Castell et al. 1996) defines the basic components of general management system for this waste. The second document (Macías et al. 2002) developed the theoretical and practical aspects of the first document, in order to propose a Radiological Characterization Protocol presenting the results of radiological characterization of different techniques. The radiological characterization of this waste is a fundamental action to establish the most adequate disposal ways: conventional evacuation or transfer to authorized company. However, the acquired experience during the application of this second document (Macias et al. 2002) highlighted some difficulties due to the fact that the Radiological Characterization Protocol proposed is too complex. On the other hand, some issues related to liquid and mixed waste and other materials have not been resolved and others could be technically improved.

With the aim to try resolving these issues four important research and education centres started a research project with a Grant of ENRESA (National Company of radioactive waste in Spain). It began in July 2008 and it will finalize in December of this year. The centres are Universidad de Alcalá de Henares, Instituto de Investigaciones Biomédicas "Alberto Sols" (Consejo Superior de Investigaciones Científicas -CSIC- and Universidad Autónoma de Madrid -UAM), Centro de Biología Molecular "Severo Ochoa" (CSIC-UAM) and Centro Nacional de Biotecnología (CSIC). These centres have approximately 600 radioexposure workers. The main object of this project is to show significant improvement in the management procedures of radioactive waste just as to achieve homogeneous waste management programs in the radioactive installations of Research and Education. In order to develop this project and to take the technical guideline of 2002 (Macías et al. 2002), as a starting point, the following objectives have been proposed: 1) Radiological and chemical characterization of radioactive waste generated in different radioisotopic techniques. 2) To propose criteria for a homogenous and adequate management of mixed waste (composed of scintillation vials full of scintillation liquid). 3)To suggest reference Levels for liquid waste in accordance with the values propose in different national and international technical documents. 4) To propose a correct management of wastes generated in electronic microscopic techniques.

Material and methods

Gathering and classification of radioisotopic techniques

In order to obtain the data of the techniques performed in the indicated centres, a written form has been applied for, it contains the following information: technical name, frequency of realization and radioactive compound data used.

This process has been carried out in the radiological areas of 101 laboratories of the indicated centres. The obtained data have allowed to identify and to classify the radioisotopic techniques performed actually, taking into account the initial classification in technical groups and subtechniques used by Macías et al. 2002. Ten groups of generic techniques have been established: nº 1. Enzymatic Assays nº 2. Cellular culture Assays; nº 3. Nucleic Acid Hybridisation; Nº 4. Nucleic Acid Characterization; nº 5. Radioinmunoassay; nº 6. Binding assay; nº 7. Radioiodination; nº 8. Radiolabelling of animals; nº 9. *in vitro* transcription ; nº 10. *in vitro* translation. Each group has different subtechniques performed with several radionuclides.

Radiological Characterization Protocol of residual materials with radioactive content

Taking into account the experience acquired with technical Guideline of 2002 (Macías et al. 2002) as a starting point, a new Radiological Characterization Protocol has been developed. It is easier and more functional and it allows a fast characterization of the generated waste in a specific technical. The methodology applied is as follows:

- Acquisition of previous information of the radioisotopic technique to characterize using a data format.
- Weighing all material that will be generated as solid and mixed radioactive waste in each technique.
- Measurement of the radioactive concentration of liquid and mixed waste, and estimation of specific activity of solid waste taking into account:
  - Total activity used in each technique or initial activity.
  - Activity measured in liquid waste and calculations of the radioactive concentration taking into account the whole volume of liquid waste.
  - Activity measured in mixed waste and calculations of the specific activity considering the whole weight generated.
  - Estimated total activity of solid waste applying the expression 1

    A sólid = A initial – (A líquid + A mix) Expressión 1

    A solid: Estimated total activity of solid

    A liquid: total activity measured in liquid waste

    A mixed: total activity measured in mixed waste

  Likewise, the activity percentages of solid, liquid and mixed waste have been calculated with regard to the initial activity used in the assay.

  All these data are collected in a specific form of collection of results.
- Number of characterization for each technique: this paper proposes to carry out twice the radiological characterization at least.
- Measurement procedures: they are indicated in Macías et al. 2002.

Bibliographical revisions

The bibliographical revisions have been carried out using search engines in the web as the ISI Web of Knowledge, Scirus, Google Scholar o Live Search Aca-demic. At the same time, different documents and web pages of international institutions of Radiation Protection, with special attention to management radio-active waste have been consulted, as the IAEA, NEA and UNSCEAR. Further-more, web pages of the Regulatory Bodies as CSN and NRPB.

Calculations of Reference Levels

The necessary calculations have been carried out to propose the Reference Levels applicable to the incineration of residual materials with radioactive content (scintillation vials) and those corresponding to the activity concentration levels in the initial point of discharge to the normal sewerage system

Results

Radiological and chemicals characterization of radioactive waste generated in different radioisotopic techniques

The selection of techniques to characterize have been performed according to the following criteria: high frequency of use, generation of mixed waste and subtechniques belonging to a technique group which did not was characterized in the Guideline of Macias et al. 2002. Table I shows the results of characterization of some characterized subtechiques according to the indicated criteria, applying the described protocol.

Table I. Percentage distribution of activity of generated waste in the characterized techniques (number in brackets indicates the corresponding technique group)

Subthecnique	% in Solid	% in líquid	% in mixed
^{3}H- Adenilil cyclase activity (1)	84.88 ± 0.97	-	15.14 ± 0.98
^{32}P- Ceramides determination (2)	12.37 ± 2.91	87.18 ± 2.94	0.16 ± 0.03

^{32}P- Northern blot (3)	93.41 ± 2.30	6.59 ± 0.03	-
^{14}C- Etanolamine kinase activity (1)	19.50 ± 1.25	77.72 ± 2.76	2.78 ± 0.12

To confirm the validity of new protocol, some techniques characterized and described in the Guideline Macias et al. 2002 have been characterized with the new document. The results (they are not presented in this paper) demonstrate that the significant differences in the assignation of activities do not exist. At the present, the characterization of remaining techniques is finalising.

In relation with the chemical characterization of liquid and mixed waste, the gathering of chemical compounds of this waste is being carried out. The final results are not available at the moment.

Management of mixed waste with radioactive content

The bibliographical revision performed regarding the management of mixed waste (vials with scintillation solution) has allowed to obtain the following results: 1) The mixed waste is not considered as a defined typology of waste (they are not specifically classified); 2) Very often, the term mixed waste refers to the dangerous or biological waste but not to the vials full of scintillation solutions. (IAEA-TECDOC-1183 2000); 3) Some technical documents suggest the incineration as disposal way (IAEA-WS-G-2.7. 2005). Other minority documents, propose the emptying out of scintillation vials and to dispose the scintillation solution in the specific sink (Northumbria University, 2007).

Quantification of the weights and volume of mixed waste.

The percentage distribution of solid and liquid material in the mixed waste has been determined, weighing the empty and full scintillation vials and applying the scintillation solution density used. The results show 62% of solid content and 38% of liquid content in this waste.

Reference levels applicable for incineration of scintillation solution vials

To propose the reference levels for the possible incineration of scintillation vials two different situations have been contemplated: a) all radioactive content escape as gaseous effluents after incineration; b) some part of the radioactive content remain in the ashes after the incineration. The results shown in this paper derive from the calculations performed by the authors and the study carried out in the Unit of Environmental Radioactivity (CIEMAT), spanish reference laboratory in this field (Mora y Robles 2010).

a) Assessment of the activity that will produce an effective dose of 10 µSv per year in an individual after the incineration of mixed waste

Twenty four hours daily have been considered during which the individual may be exposed to the disposal, considering this during 365 days of the year. The breathing rate applied for the public is shown in table II (ICRP-66, 1994).

Table II. Breathing rate for age groups.

<1 year	1-2 years	2-7 years	7-12 years	12-17 years	>17 years
1043.9	1883.4	3182.8	5584.5	7336.5	8103

The presented calculations have been carried with normal atmospheric conditions and a procedure, previously, established (Mora y Robles 2010).

- For ^{3}H the expression 2 is used:

$$(C_A)_{X1}^{\max} = \frac{(X)_{X1}^{\max}}{(H)_{X1}} \quad \text{expression 2}$$

$(C_A)_{X1}^{\max}$ is the tritium concentration in stationary phase as water vapour, at a distance x1 from the point of gaseous discharge, $(X)_{X1}^{\max}$ is the tritium concentration obtained in air previously and $(H\ )_{X1}$ is the absolute humidity in the atmosphere. It is recommended to use of 6 x 10^{-3} l m^{-3} (IAEA- Safety Reports Series 19; 2001) for the last value.

To obtain the effective dose of 10 μSv/year it is necessary a continual emission of 3.9 x 10^{11} Bq/year of Tritium.

- For the ^{14}C the expression 3 is used

$$(A)_X^{\max} = \frac{(X)_X^{\max}}{(C)_X} \quad \text{expression 3}$$

$(X)_X^{\max}$ is the calculated concentration initially due to the dispersion of Gaussian plume, $(A)_X^{\max}$ is the specific activity of ^{14}C in relation to the total carbon and $(C)_X$ is the Carbon concentration in the air (IAEA-Safety Reports Series 19, 2001).

To obtain the effective dose of 10 μSv/year it is necessary a continual emission of 5.4 x 10^9 Bq/year of ^{14}C.

- When a mixture of both radionuclides is incinerated, the expression 4 must fulfill

$$A(^3H) + 72\ A(^{14}C) \leq 3.9 \times 10^{11} \quad \text{expression 4}$$

Where A(^{3}H) and A(^{14}C) are the eliminated activities (Bq/year) by the chimney.

b) Assesment of the activity that will produce a effective dose of 10 µSv per year in an individual due to the ashes

Considering that the 4.74 % is the percentage in weight of ashes generated in the incineration of scintillation vials (Cañadas et al. 1991) and taking into account that neither the 10^6 Bq/g for Tritium nor the 10^4 Bq/g for the ^{14}C must not exceed if both radionuclides are in the ashes (Spanish Order ECO/1449/2003), the expression 5 must be accomplished.

$$A(^3H) + 100\ A(^{14}C) \leq 10^6 \quad \text{expressión 5}$$

In this case A(^{3}H) and A(^{14}C) are expressed in terms of specific activities (Bq/g) contained in the ashes.

Management of liquid waste with radioactive content

The bibliographical revision carried out allows identifying the necessity of, initially, knowing the chemical composition of the liquid waste to establish the suitable management.

Management of organic liquid waste:

This waste, considering its chemical composition, will always be transferred to an authorized company for radioactive o dangerous waste. If the activity of this waste is lower than the indicated results for scintillation vials (they contain organic liquid) incineration, this paper proposes its transference to the dangerous waste company and subsequent incineration. Moreover, the organic liquid waste with activity more than the indicated values (point 2.2) and its half-life is greater of 100 days; it must be transferred to the radioactive waste company (in Spain ENRESA)

Management of aqueous liquid waste:

The aqueous liquid waste could be directly discharged to the normal sewerage system whenever they can be clearance._Therefore, their radioactive concentration must be lower than the activity concentration levels in the initial point of discharge to the normal sewerage system.

Activity concentration levels in the initial point of discharge to the normal sewerage system. To propose these levels it is necessary to calculate:

- The Annual Limits on Intake (ALI_{ing})
- Maximum limit of concentration of activity in the final point of the the normal sewerage system (CV_{max})
- Maximum limit of concentration of activity of the waste to discharge in the initial point of the normal sewerage system (Cv_{PI})..

a) Calculation of Annual Limits on Intake (ALI_{ing}):
Applying the committed effective dose equivalent of 1mSv by one year for members of the public, 1 mSv (RPSCRI, Real Decreto 783/2001; IAEA-TECDOC-1183. 2000) and the dose coefficient per unit intake for ingestion $e(g)_j$ Sv/Bq for members of the public (age group older than 17 years). (RPSCRI, Real Decreto 783/2001; IAEA-TECDOC-1183; 2000).

b) Calculation of the maximum limit of concentration of activity in the final point of the normal sewerage system CV_{max}, applying the expression 6

$$CV_{\max} = \frac{LIA_{ing}}{600}\frac{Bq}{l} \quad \text{expression 6}$$

The annual ingestion rate of water for adult individual, 600 l (ICRP-23;1975) has been used

c) Calculation of the maximum limit of concentration of activity of the waste to discharge in the initial point of the normal sewerage system (CvPI).
Cv_{PI} : is the maximum limit of concentration of activity of radionuclide in the container (initial point of discharge)

$$Cv_{PI} = \frac{CV_{\max} \times (V_c + V_{ec})}{V_c} \quad \text{expression 7}$$

V_{ec} is the water volume released in the centre daily

Table III shows the results of ^3H y ^{14}C for a centre that releases 45,000 l daily.

Table III. Values of concentration of activity for ^3H y ^{14}C in the initial point normal sewerage system.

Radioinuclide	Compound	ALI (Bq)	*CVmx* (kBq/l)	Cv_{PI} (kBq/l)
^3H	H_2O tritiated	$5.56 \cdot 10^7$	92.593	138,981.48
	OBT	$2.38 \cdot 10^7$	39.683	59,563.49
^{14}C		$1.72 \cdot 10^6$	2.874	4,313.22

When it is necessary to discharge a mixture of radionuclides the expression 8 must be applied.

$$\sum_{i=1}^{n} \frac{Cv_i}{Cv_{PI\,i}} \leq 1 \quad \text{expression 8}$$

These values may be considered as Reference Levels to clearance of aqueous liquid waste, with the approval of the Regulatory Body.

The Consejo de Seguridad Nuclear (CSN), Regulatory Body in Spain, limit the annual amount of discharge to the normal sewerage system to a maximum of 10 GBq of ^{3}H, 1 GBq of ^{14}C and 1 GBq as the sum of the rest of radionuclides, ensuring that in the final point of discharge the concentration of activity does not exceed the concentration limits obtained between the ALI_{ing} (age group older than 17 years) and the annual ingestion rate of water for the adult individual, 600 l (ICRP-23; 1975). This criterion is reflected in the Operation Authorization of the radioactive installations.

Management of waste with Uranyl Acetate salt

In relation to the management of waste with uranyl acetate salt, the gathering to characterize the waste generated in electronic microscope techniques have been carried out. The values of specific activity of Uranyl Acetate salt used are well known, the same as the technique protocol applied. The characterization of this waste has begun. They are, basically, solid and liquid waste and the rest of Uranyl Acetate salt have not been used, in the commercial containers.

The preliminary results are available. They indicate that the total activity of some solid waste and liquid waste is lower than exemption levels (IS-05 – CSN; 2003). Therefore, this waste could be a candidate to clearance and transfer to Hazardous Waste Company.

Table IV. Exemption Levels for U235 / U238

Radionúclide	Activity (Bq)	Concentration (KBq/Kg)
U^{235} / U^{238}	10^{4}	10

However, in some cases the specific activity of solid waste exceed the exemption levels shown in table IV, in this case it will be necessary its transfer to the radioactive waste company.

Discussion and conclusions

We can consider, by the data shown, several comments. Firstly, the application of new Characterization Protocol derived from the indicated project has allowed the easy and fast radiological characterization of the waste. The comparative analysis of obtained results to characterize the same technique applying both protocols supports the suitability of this document. Nevertheless, to determine the waste activity in each step of the technique, it is recommended to apply the characterization protocol described in Macias et al. 2002.

On the basis of the gathering carried out to classify the techniques it is possible to confirm that the amount of mixed waste is low in relation with the solid and liquid waste generated.

The percentage distribution of activity shown in table I indicates that the activity of mixed waste exceeds 10% of initial activity only in one technique, the rest of techniques have very low levels of radioactivity (it is not a significant activity).

The mixed waste is not always considered as a determined type of residual material with radioactive content, in accordance to the bibliographical revision. However, to establish its management it is necessary to classify them correctly. Taking into account its solid content in relation with its liquid content, the mixed waste is considered as solid waste in this project. Therefore, to propose a suitable disposal way for this waste, the clearance levels for solid waste (Order ECO/1449/2003) may be applied. Considering the percentage of activity of this waste shown in table I, it is possible suggest its clearance. However, taking into account its chemical composition (scintillation solution) its disposal as conventional solid waste is not possible, making necessary its transfer to hazardous waste company, the final treatment of which will be incineration. To propose the incineration as management way for this waste, according to IAEA WS-G-2.7, the necessary calculations have been performed to determine the reference levels applicable to the incineration of scintillation vials. Two different scenarios, very conservative, have been considered. In both situations, so the activity that will produce an effective dose of 10 **µSv** per year in an individual after the incineration (390 GBq /año de H-3 and 5,4 GBq/año de C-14) as in the amount of radioactivity that will produce an effective dose of 10 **µSv** per year in an individual due to the ashes are much higher than the used activities in the radioactive installations of research and education.

In relation with the organic liquid waste, regarding the results shown, the more suitable management may be the incineration.

It is possible to confirm that all mixed and organic liquid waste generated in radioactive installations of research and education are clearly candidates to clearance, using as final disposal way the incineration. With regard to the activities, weights and volume of generated waste susceptible for the incineration, the theoretical model used shown that the public dose will be two o three magnitude orders lower than the public dose of 10 µSv to year.

For the aqueous liquid waste, the discharge to the normal sewerage system whenever their radioactive concentration is lower than the activity concentration levels of discharge authorized, it is suggest. Different approximations have been carried out to define these values; finally the calculation of the maximum concentration of activity levels in the initial point of discharge was selected. This approximation has been chosen in relation with others since it is as conservative as the others, but the calculations to identify the clearance waste in each discharge are made easier. The maximum concentration of activity levels in the initial point of discharge, proposed in this paper, must be authorized by Regulatory Body, before its application. Likewise, the discharge limit to the normal sewerage system proposed by the CSN, is adequate for the management of aqueous liquid waste.

Waste generated in electronic microscope techniques, as it has been mentioned, is the most part clearance. However, as happens with the mixed and organic liquid waste, attending to its chemical composition, they might be transferred to the hazardous waste company.

Finally, considering the incineration as the most suitable disposal way for the mixed, organic liquid and Uranyl Acetate salt waste, it is necessary to provide rules and/or technical documents to the hazardous waste companies to facilitate the removal of this waste of the installations.

Radiation Protection organization in radioactive waste management at the Joint Research Centre of Ispra

Accorsi, Roberto; Giuffrida, Daniele; Osimani, Celso
European Commission, Joint Research Centre of Ispra, Ispra Site Management, Nuclear Decommissioning Unit, ITALY

Abstract
The Joint Research Centre of Ispra, one of the research Sites belonging to the European Commission, Directorate General JRC, was created in the late '50s, in order to steer European research on nuclear industry. It hosts numerous nuclear facilities, some of which are maintained in operation, while others were shutdown in past years, namely: two research nuclear reactors, hot cells facilities, radiochemical laboratories, one Cyclotron (still in operation), facilities for studies on fissile material (in operation), and some facilities for the treatment and storage of liquid and solid waste (in operation).

The JRC accounts for 21 nuclear licences, 14 Controlled Zones and 12 main Surveilled Zones, on its Ispra Site.

This paper will discuss the organization which has been developed, during the years, and put in place to guarantee highest safety levels in all radiation work activities at the JRC-Ispra, with an emphasis on radioactive waste management.

The present strategy for waste management at the JRC will be briefly discussed, and its major facilities will be introduced in detail.

Processes discussed will include:

1. Decontamination of surfaces via Abrasive Blasting Unit (ABU)
2. Measurements of materials in the Material Clearance Facility (MCF)
3. Radiological characterisation of waste (active and passive, XDRS and WCF)
4. Radioactive transports and accountancy
5. Interim storage at the JRC

Introduction

Historical background
The European Commission is responsible for the management of its nuclear installations present on the Ispra site of its Joint Research Centre throughout their life by mandate of the Euratom Treaty and the Agreement with Italy.

JRC-Ispra is thus required to safely conserve and subsequently decommission its shutdown installations and to manage the associated radioactive waste. These post-operational activities, together with the management of existing radioactive waste, are the Commission's so-called "Historical Liabilities" at JRC-Ispra. The Nuclear Decommissioning Unit of the Ispra Site Management is responsible for managing these liabilities.

AREA 40, a small nuclear island in the north-eastern corner of the Ispra site, was born in the early 1960s as the nucleus of radioactive waste management services for the site. AREA 40 was initially conceived to provide routine services including temporary and long-term storage of a variety of radioactive wastes originating from the nuclear research and development activities underway at the site. At that point in time, no provisions had yet been made for the support of decommissioning activities, and AREA 40's development proceeded accordingly. By the mid 1990s, the capacity and potential of the waste management infrastructure remained limited for the scope of a full scale decommissioning activity.

In the late 1990s the overall decommissioning and waste management policy underwent a transition from safe shut-down and delayed decommissioning to an accelerated reduction of JRC-Ispra's historical liabilities. This policy change resulted in a sudden need for significant improvements in AREA 40's infrastructure and its management practices: many development and planning projects were launched, soon followed by a first wave of investments and construction activities. This phase is now nearing completion as many important facilities are becoming operational.

Material and methods

JRC-Ispra’s waste management policy

At the highest level, the prioritization of waste management activities is guided by the needs of the decommissioning program and the applicable legislation. The latter can also be considered a prioritization of the safety of both the population and the environment since the evolving legislation is mainly driven by continuous demands to reduce and manage such risks.

At the waste management level, prioritisation follows the natural logic of implementation of a decommissioning program, according to which facilities are first realised and then operated. JRC-Ispra's waste management strategy choices are largely based on the foundations set by many internal and external studies and their critical assessment by JRC-Ispra's hierarchy. Feasibility studies have been conducted that covered the decommissioning and waste management of critical facilities, including JRC-Ispra's two main reactors (Ispra 1 and Essor) and the waste management infrastructure, including a super-compactor, the upgrade to an old cementation facility and a new storage facility. The prioritization of the implementation of these projects is determined by a critical path analysis. In practice, the Interim Storage Facility (ISF) and the definition of a Final Waste Package (FWP) turned out to be the highest priority projects. Other projects are being undertaken as material and human resources become available.

In some cases the range of strategy options has been pre-constrained by external stakeholder's opinions, such as Italian Control Authorities and Italian Regional and

Provincial Government. In this respect, it should be noted that Italian regulations sometimes set stricter criteria than those of related European Directives or their associated technical documents, an example being interregional radioactive waste transport. In particular, JRC-Ispra's general waste management policy is based on the criteria listed in the national guide for waste management, Guida Tecnica 26. These criteria are:

- radiological and environmental protection, as stated by the ALARA principle, i.e. including social and economic factors as well as the impact of the activities on future generations and the environment;
- waste volume reduction at the origin and by implementation of specific treatment and by optimization of waste management processes; and
- classification of waste into three different categories based on the present radioisotopes and their quantity, leading to different confinement times and waste management strategies.

The volume reduction criterion is translated into three further principles specific to the Ispra site:

- minimisation of the amount of un-irradiated nuclear materials and other obsolete materials by recycling them within the nuclear industry;
- maximisation of the quantity of material, either simply suspect or following its decontamination, that is removed from regulatory control; and released from the Site;
- reduction, where practical, of the volume of remaining radioactive waste for temporary storage on the Ispra site.

AREA 40 is intended only to provide interim - not long-term storage - of radioactive waste, since JRC-Ispra's radioactive waste and nuclear material are ultimately destined for a “final national repository”. Accordingly, it is the policy of JRC-Ispra’s to also harmonise, whenever practical, its waste management activities with current and evolving national guidelines. The general waste management strategy adopted by the Nuclear Decommissioning Unit of the JRC-Ispra is based on the application of these principles within the constraints posed by safety and economic considerations.

AREA 40's mission of providing waste management support for JRC-Ispra's decommissioning and waste management program translates into three strategic objectives:

- acquire appropriate waste management capability (internal or external, and on-site and/or off-site, as appropriate);
- manage existing wastes (including, where necessary, their re-conditioning); and
- manage future decommissioning wastes and materials.

Due to the necessity of significant upgrading of the existing waste management infrastructure the waste management activity is initially concentrated in the construction and refurbishment of the needed infrastructure. As the facilities are commissioned and become available for operation, this activity will give way to routine waste processing activities. Although the variety of waste is comparable even with large scale research centres, the actual quantities of waste are relatively small. Hence, what might have been obvious strategic investments for larger establishments was not necessarily the optimal approach for JRC-Ispra, especially over the time horizon of the Decommissioning and waste management Programme established in the Communication to the European Council and Parliament. JRC-Ispra has considered a range of technical solutions as well as their possible provision according to the following the four criteria:

- incur minimal technical risk;
- ease of licensing;
- cost effectiveness; and
- public acceptance.

The waste delivered to AREA 40 for processing and storage must comply with well-defined Waste Acceptance Criteria (WAC) in order to ensure their compatibility with the services offered.

Since plans for a long-term national repository are not yet finalised in Italy, it is assumed that such a repository will be accepting waste starting in 2023 and that all of JRC-Ispra's waste could be transferred by 2028.

Waste management facilities

The waste management plant (*Stazione Gestione Rifiuti Radioattivi*, SGRR) comprises buildings and installations located in AREA 40 and a Post Operational Clear Out (POCO) waste buffer. The eastern part of AREA 40 is used to store radioactive waste; the western to process it. All buildings in the controlled zone of AREA 40 are inside a fenced zone to which both personnel and vehicle access is limited and controlled. The whole area is covered by a fire prevention certificate thoroughly revised after the first wave of infrastructure development. Those buildings that are served by specific Heating and Ventilation (H&V) Systems are limited to the controlled area of building 40 and, more recently, the pair of buildings 41/41c. These buildings are served by a dubious liquid effluent collection network that drains to suitable collection tanks located inside building 40b integrated with the liquid effluents treatment station (Stazione Trattamento Effluenti Liquidi, STEL). Improvements are underway to expand the network to service installations such as a wash cabin.

The routine services offered cover the whole spectrum of radioactive waste management with the exception of waste disposal and are listed and summarised below following the natural time sequence of waste management operation:

- <u>Transport</u>: operations associated with the movement of radioactive waste material on the Ispra site. The main means of transport are forklifts, tractor trailers, vans and a truck with appropriate ADR-certifications.
- <u>Characterization</u>: determination of the physical, chemical and radiological properties of waste to establish its future management. The main installations are the waste Characterization Facility (WCF), the Radioanalytical Analysis Process Laboratory (RAPL), the Waste Characterization Laboratory (WCL) and the X-ray Digital Radiographic System (XDRS).
- <u>Pre-treatment</u>: operations prior to waste treatment, such as collection, segregation, and decontamination. The main installation is the Abrasive

Blasting Unit (ABU). In the near future, other supporting pre-treatment areas like wash and cutting cabins will be refurbished in the hot wing of building 40.

- Treatment: operations such as volume reduction, removal of radionuclides from liquid waste (decontamination), and change of composition that intend to benefit safety, economy or both. The main existing plant on site is STEL; some other capacity for solid waste, such as a sorting cabin and a compactor, might be refurbished or added based on operational experience.
- Conditioning: operations that produce a waste package suitable for handling, transportation, storage and disposal. The existing installation (RWCP, Radioactive Waste Cementation Plant) is presently in standby until a definite strategy, a qualified FWP and validated grouting and solidification methods will be established. Once these aspects will have been defined and necessary authorizations obtained, refurbishment of the existing RWCP or realization of one or more new installations can be undertaken.
- Material clearance: removal of radioactive materials or radioactive objects within authorised practices from any further radiological control by the regulatory body. The main installation is the MCF (Material Clearance Facility).
- Storage: safe and secure conservation of waste in a nuclear facility where confinement, environmental protection and human control are provided. The main installations will be the ISF, the Tank Farm Facility (TFF) and the POCO Buffer Store (PBS);
- Inventory and tracking: maintaining records of waste packages including e.g. data on their physical location, contents and classification. The main tools are the Electronic Transport Module (ETM) and Waste Information and Tracking System (WITS).

Waste infrastructure

This section presents a brief description of the infrastructure development

- Final Waste Packages (FWP): the process of optimisation of the ISF involves the standardisation of waste containers. JRC-Ispra adopted 440-l drums and 5.2 m^3 boxes as the (UNI CC-440 and CP-5.2) as the containers for final category I and II waste packages. The former will be used for sludge, the latter for grouted waste. Precise plans for category III waste packaging and storage are currently on hold while national guidelines are under redefinition.
- Waste Transport: the transport fleet has been designed on the basis of the FWP and will consist of fork lift trucks (3, 7 and 20 tons for the transport, respectively, of 4 × 200-l drums, 4 × 440-l drums, and CP-5.2), a flatbed truck and a tractor trailer equipped with two tanks for liquid effluents. Roads will be upgraded to allow the passage of heavy loads; the upgrade will minimise the use of asphalt in anticipation of the problems that might be involved in its disposal.

- Interim Storage Facility (ISF): Since the availability of a national repository is not expected before 2023, JRC-Ispra has made plans to develop its own interim storage facility to service its decommissioning and waste management activities. This is a lightweight structure to be built in AREA 40 by the end of 2011.
- Post-Operational Clear Out (POCO) Waste Buffer: low-level technological waste will be centralised in a suitably authorised building outside AREA 40 until the ISF will become available.
- Supercompaction: preliminary studies have shown the economic case for a mobile supercompactor, the specifications of which are under definition.
- Grouting: the immobilisation of waste in CC-440 and CP-5.2 FWPs will take place in a new grouting facility that will replace the existing facility, which was designed to treat waste packages no longer compatible with the evolving normative guidance.
- Solidification: due to insurmountable difficulties involved in the authorisation process for the off-site transport, cementation of the about 150 m^3 of treated effluents will take place in a new, on-site solidification installation.
- On-site radiochemical analysis laboratories: JRC-Ispra's current in-house radiochemical analysis capabilities are limited in scope (nuclide and matrix composition) and activity range (very low). A new laboratory for managing samples arising from decommissioning and waste management activities must be developed to extend these capabilities and allow the refocusing of the current laboratory on its original core activity of environmental sample analysis. Plans to develop two laboratories are underway: one for clearable material and low-activity samples, the other for samples needing glove box handling and separate working areas to avoid cross-contamination.

Waste streams

This section presents a brief description of the waste streams and their planned treatment and pre-conditioning.

- Intermediate Level Liquid Waste (ILLW): research and development activities on fuel and high level waste reprocessing resulted in a small quantity of liquid waste essentially comprised of a solution in nitric acid of irradiated fuel. If treated and conditioned alone, the waste would fall under the scope of category III as defined in Guida Tecnica 26 (highest concentration waste). A significant effort has been spent exploring processing options. Off-site options are significantly limited by authorisation questions; on-site options are limited by economic justification of a small-scale intervention. At the present time, the most feasible alternative seems to blend the liquid with the sludge present on site if this should result in category II waste (intermediate concentration waste).
- Sludge: two batches exist on site. The first, currently held in a tank, carries α contamination (210 Bq/g ^{241}Am); the second is stored in drums. Both batches will be centralised in the two new tanks of the TFF designed to store all sludge on the site. Drums will be emptied and washed in a glove

box equipped with a custom-built interface to connect safely to the drums. The empty, used drums will be either washed, cut and possibly blasted in ABU or supercompacted. The sludge will be solidified in 440 l FWP with a suitable cementation recipe. FWPs will be characterised at the WCF and transferred in pallets hosting six drums each to the ISF.

- Orphan sources: AREA 40 stores disused radioactive sources. High activity sources still have industrial interest and their liability is being transferred to third parties, effectively recycling both their active and shielding components within the nuclear industry. It is planned that smaller sources will be characterised (which might involve the on-site laboratory), grouted and packaged in 440 l FWP.
- Bituminised drums: more than 6000 drums of various bituminised wastes are present on site, buried in trenches. The drums will be retrieved, characterised in the WCF and, where necessary, invasively, prior to their transfer and grouting into FWP for storage in the ISF. Compaction of the drums before grouting is also being considered.
- Roman Pits: in the late 60s and early 70s, fifteen Roman Pits built from prefabricated concrete rings superimposed on one another were filled with waste, mostly activated metals, and sealed with concrete. Recovering the pits entails inserting a sleeve around each pit after excavating the surrounding ground and immobilising the sleeve with cement to allow lifting the pit from its burial hole. Once out of the ground, the pits will be laid down in an existing temporary facility. Following the extraction of the pits, the terrain will be radiologically mapped to confirm that no dispersion of radioactivity has occurred either during the thirty years of underground storage, nor during their extraction. Once extracted, a non destructive γ scanning campaign will be undertaken to characterise the pits. Samples will be taken where indicated if possible. The reference strategy is not to treat the pits prior to their conditioning, unless the results of the analyses should give indications to the contrary. In preparation for their shipment to the national repository, the pits will be inserted in special transport containers (essentially stainless steel liners) and grouted. Slicing the 7-m tall pits to allow transportation with conventional means is being evaluated in light of the justification and optimization principles.
- Specific wastes (e.g. soil, wood, asphalt): over the years about 100 m^3 of contaminated soil, wood and leaves were collected in drums and, where contamination was very low, in plastic boxes. Whereas a study has indicated that decontamination by chemical leaching would be feasible and potentially allow the release of 90% of the material, the relatively small volume involved does not justify the construction of a decontamination facility, the cost of which is projected to exceed supercompaction or even direct packaging in FWP. Materials will be characterised in the WCF.
- Concrete blocks: during the 1980s various waste conditioning activities resulted in the production of 570 m^3 in concrete blocks, for a total activity of about 62 TBq mostly from activation isotopes but with significant α content as well as exotic materials. It is assumed that non destructive

characterisation will provide satisfactory verification of existing inventories. The current treatment and pre-conditioning strategy entails packaging and grouting for direct shipment to the national repository.

- Decay pool aqueous effluents: the Essor decay pool have been measured to contain a low level of βγ nuclides (50 Bq/g) and no chemical contaminants. The Ispra 1 decay pool, on the other hand, may contain chemicals that inhibit the precipitation and flocculation process of STEL, thus creating the need for a pre-treatment step currently under investigation, after which the effluent will be sent to STEL. Evaporation may be used to bring the effluent closer to STEL's acceptance limit of (400 Bq/g), thus reducing the effluent volume. STEL's liquid effluent will follow the path via characterisation at the onsite lab to discharge in the environment; the sludge will be treated in the TFF (see Sludge above); and filters and other technological waste will be supercompacted and packaged appropriately for storage in the ISF.
- Reactor graphite: Ispra 1 contains about 22.4 m^3 of graphite which was used as moderator and reflector. The presence of significant quantities of ^{14}C, ^{36}Cl and ^{166m}Ho can be expected and will be defined by a characterisation campaign. Treatment and conditioning will be defined according to specific guidance of the control authority.
- Metallic waste: metallic radioactive waste resulting from both historical liabilities and decommissioning activities is contaminated mostly with ^{60}Co and ^{137}Cs. In some cases ^{3}H cannot be excluded. Most waste is steel and its alloys but lead and aluminium are also found. Pre-treatment will include segregation and cutting; parts that can be potentially decontaminated by blasting will be sent to the wash cabin and ABU. Non-releasable parts will be packaged, grouted and sent to ISF. On-site supercompaction has the potential to offer volume savings and is also being considered as a possible treatment option that, however, could be limited to a part of the waste by the presence of α contamination.
- Demolition waste: the biological shields of both Ispra 1 and Essor and the shavings of all contaminated areas make up most demolition waste. Expected activation products are ^{133}Ba, ^{152}Eu ^{154}Eu and ^{3}H, ^{14}C and ^{41}Ca must also be considered along with ^{60}Co and ^{137}Cs and α contamination. The biological shields will be cut to fit into CP-5.2 FWP. Characterisation will be performed by in situ γ spectrometry and sample analysis. FWPs will be transferred to AREA 40 for grouting. If significant α contamination should be found, the waste will be packaged into Category III FWP, characterised in the WCF and grouted following the guidance of the control authority.
- Combustible waste: this stream includes technological and process waste as well as some specific waste such as wood, leaves, carcasses and oil for a total of up to 110 m^3 from historical liabilities and an additional 500 tons from decommissioning. Due to authorisation difficulties, on-site incineration has been ruled out, and the volume of most combustible waste will be reduced by supercompaction. Other streams, such as oil, solvents and biodegradable waste, will be sent to an external provider after the

necessary characterisation. Return ashes will be packaged for storage in the ISF.

- Compactable waste: this stream includes mainly technological and process waste and potentially metallic parts, building rubble, contaminated soil and ashes. Until a supercompaction service will be available on site, volumes can be managed in the interim with a simple 3-ton press that will be used to compact waste in 220-l drums. These drums may be supercompacted later.
- Liquid effluents: decontamination and cutting operations are expected to produce about 100 m^3 of liquid aqueous effluents that will be treated in STEL, along with reactor pool effluents.

Potentially clearable waste

JRC-Ispra's waste management strategy calls for the maximisation of the quantity that can be cleared as conventional waste. The essential elements for clearance are:

- maximisation of the use of historical information;
- optimising in-situ pre-clearance measurements;
- minimisation of samples and scope of the analysis;
- maximisation of waste material handling and flow;
- optimisation of clearance measurements; and
- efficient application of quality assurance and control procedures.

If, e.g. on the basis of historical information, contamination of waste material is suspected, or if it has been decontaminated, 100% radiometric controls will be implemented to assess the homogeneity of the activity distribution where practical. Samples will be taken to assess the presence of emitters not detectable with field detectors. If the stream will result homogeneous, further analysis will produce the nuclide vector of a sample. The waste will then be routed to clearance measurements. 0.7-m^3 containers were chosen as a compromise between handling and measurement needs. The maximum averaging volume and mass allowed by normative guidelines were also important factors in the choice. The Material Clearance System includes two total gamma and a gamma spectrometry measurement chain. These measurements are complemented with sample-based data. A characterisation plan, addressing the qualification of the verification measurements will be submitted for evaluation, comment and, eventually, approval by the regulatory authority.

Radiation Protection organisation

All operational activities in Waste Management area are covered by permanent assistance by the JRC-ISPRA Radiation Protection Sector (RPS). This Sector, providing services also to operating facilities and during pre-decommissioning works, is presently composed of 15 Permanent Agents (Civil Servants of the European Commission) and is supported by an external Radiation Protection Assistance Contract.

The RPS is involved in the evaluation and discussion of all projects related to waste management, and is providing operation assistance on a daily basis.

The RPS is structured upon some main pillars:

1. an **Operational Radiation Protection group**, subdivided in three Teams, providing operational assistance on a daily basis, dose and contamination measurements on controlled areas, pre-clearance spot checks on materials, routine dose and contamination mapping, air contamination evaluations, workers' electronic dosimetry readings, etc., and proving guidance and support to workers;
2. the **Dosimetry Laboratory**, providing TLDs for whole body, finger and wrist dose evaluations, gamma, neutron and radon dosimetry;
3. the **Whole Body Count Laboratory**, providing direct measurements of internal contamination, either on a routine or incidental basis;
4. the **Electronics Laboratory**, dedicated to the management and maintenance of the over 1.000 fixed and portable radiation measuring equipments in the JRC-ISPRA;
5. the **Transport & Accountancy group**, intended to account for presence, movements and uses of radioactive material (sources, fissile material, waste, etc.) in the JRC-ISPRA, and managing the JRC "*Committee for Fissile and Radioactive Materials*";
6. the **SIT Calibration Laboratory**, a certified centre for the calibration of radiation measuring equipments in the JRC-ISPRA
7. the **nuclear emergency** preparedness and response group;
8. the **Radiation Protection Archives**, managing all workers' dosimetric data (WBC, RTX, TLDs, EPDs, medical reports and aptitudes, training, etc.)
9. a **Documental group**, managing the drafting and diffusion of technical procedures and documents, and managing Radiation Protection training actions in the JRC-ISPRA;
10. the **Radiation Protection Assistance contract**, providing assistance in operational and Laboratory activities (25 individuals in 2010)
11. the **Qualified Expert**, an internal Advisor, appointed by the Ispra Site Management Director, who is legally responsible for the correct management of Radiation Protection issues on Site.

The safe decommissioning of two plutonium contaminated facilities at Dounreay

Thompson, Peter; White, Simon
Dounreay Site Restoration Limited, Dounreay, Caithness KW14 7TZ, U.K.

Abstract
The Dounreay site is situated on the north coast of Scotland, mainland United Kingdom, and is operated under contract to the UK's Nuclear Decommissioning Authority (NDA) by Dounreay Site Restoration Limited (DSRL), a wholly-owned subsidiary of UKAEA Limited. Dounreay was instrumental in fast breeder research and fuel reprocessing plant development. The site's business is now one of safe decommissioning and remediation.

This paper discusses the decommissioning of a plutonium criticality test facility and an experimental pulsed column technology solvent extraction facility. There is a detailed discussion of the radiation protection aspects of the decommissioning and the evaluation and implementation of novel, as well as "tried and tested" radiological protection controls within plutonium contaminated environments.

The paper concludes with a review of the radiation protection challenges and successes of the decommissioning techniques used, from a radiological protection perspective, and the lessons learned in successfully completing these challenging decommissioning projects.

Introduction
The Dounreay site was instrumental in fast breeder research and fuel reprocessing plant development. The site's business is now one of safe decommissioning and remediation. This paper discusses the decommissioning of a plutonium criticality test facility and an experimental pulsed column technology solvent extraction facility.

Decommissioning the Criticality Test Facility
The Criticality Test Facility was a laboratory (Fig. 1.) built in the late 1950s to provide data on solid and liquid plutonium criticalities in support of reprocessing plant design and development. The criticality cell (Fig. 2.) comprised a seven metre high by eight metre diameter domed cylindrical steel pressure vessel. This was surrounded by a 1.5 metre thick hexagonal concrete biological shield.

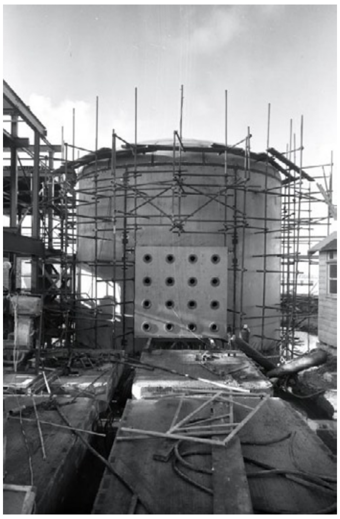

Fig. 1. The Criticality Cell during construction

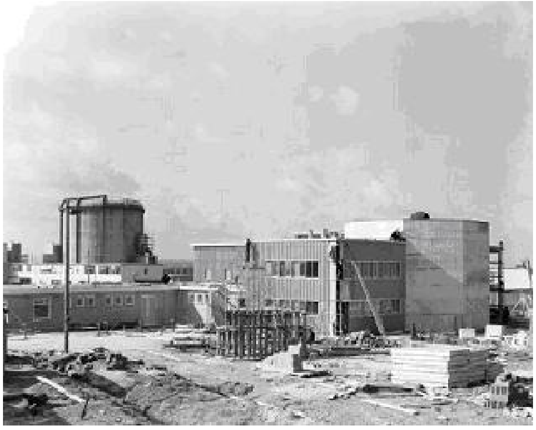

Fig. 2. The Criticality Test Facility

By 1994 most of the plutonium inventory process vessels had been decommissioned. The radiological protection aspects of this initial work have been documented in Nicol 1994. The work after this involved the removal of the highly contaminated criticality test cell and decontamination of the building structure before demolition to “brown field” status. This started in 1999 and involved carefully planned pressurised suit entries into the plutonium contaminated criticality cell. The radiological protection aspects of the early phase of this work were reported in Thompson 2002.

Unfortunately the cell contained a large amount of historical waste that had been left over from previous work. This waste was successfully size reduced, packaged and sentenced to the appropriate waste route. The cell’s internal structure (approximately $300m^2$) was decontaminated using the “sponge jet” technique. This successfully reduced the steel liner from Intermediate Level Waste (ILW) to Low Level Waste (LLW).

Installation of a new ventilation system (designed to be easily removed) was completed to allow the decommissioning of the now 50 year old ventilation system, whilst still providing the required ventilation capability for the remainder of the plants decommissioning. This also involved re-sealing the criticality cell to allow the ventilation capacity to be diverted to support decommissioning of other rooms within the facility. This work was carried out on a room by room basis. On some walls, particularly at locations where wet systems were located, the contamination had penetrated deep into the structure and required complete demolition, as decontamination via scabbling and other methods was not viable. To reduce manual handling, and mitigate radiological and industrial safety hazards much of the demolition was carried out using a Brokk robotic machine (Fig. 3. and Fig. 4.).

Fig. 3. Demolition of internal walls with a Brokk **Fig. 4. Completed internal wall removal**

On the remaining walls and support structures a thin sodium iodide detector was used to detect the low energy X-rays from the plutonium isotopes, to assess whether there was significant contamination below paint and within the structures. This allowed a decision to be made about whether further decontamination was required before demolition. This type of detector arrangement has been used successfully during a number of projects at Dounreay, to identify areas of plutonium contamination which could not be found using conventional surface contamination monitoring techniques.

Following a re-configuration of the ventilation system, attention then reverted back to the removal of the 13 mm thick steel pressure vessel of the criticality cell. Following an option study, work to remove the vessel was carried out using hand held oxy gas cutting equipment by operatives gaining access from an extensive scaffold structure (Fig. 5. and Fig. 6.). Essential preparatory work included the local monitoring and decontamination of all the cut lines, to ensure that contamination did not migrate with the highly mobile cutting fume. The monitoring included checking of the steel surface with the thin sodium iodide detector to provide confidence that contamination, undetectable with conventional instrumentation, was not present in the surface of the metal. This was backed up by laboratory analysis of samples of the metal. This process additionally prevented the inside surface of the bio shield from becoming contaminated.

Fig. 5. and Fig. 6. Hot work to remove the Criticality Cell liner and pit

The work culminated in a complete radiological survey of the building which included conventional health physics monitoring, plutonium X-ray monitoring and sampling of the building structure before the building was declassified and freed for demolition. Demolition was completed using conventional techniques (Fig. 7.).

The completion of this challenging project removed a significant liability from the site (Fig. 8.) and was a very significant success story for the Dounreay site.

Fig. 7. Demolition of the Criticality Test Facility

Fig. 8. The completed project

Decommissioning the Pulsed Column Laboratory

The Pulsed Column Laboratory (PCL) was built for full scale reprocessing flow sheet trials, using pulsed column technology (Fig. 9), which was a more efficient solvent extraction process and a replacement for "mixer settler" solvent extraction technology. The laboratory housed a large sectional glass pulsed column rig inside a glovebox with dimensions of 11.5 metres (high) by 6.5 metres (wide) and 1.2 metres (deep) which extended up four floor levels within the building (Fig. 10.).

Fig. 9. Pulsed Columns

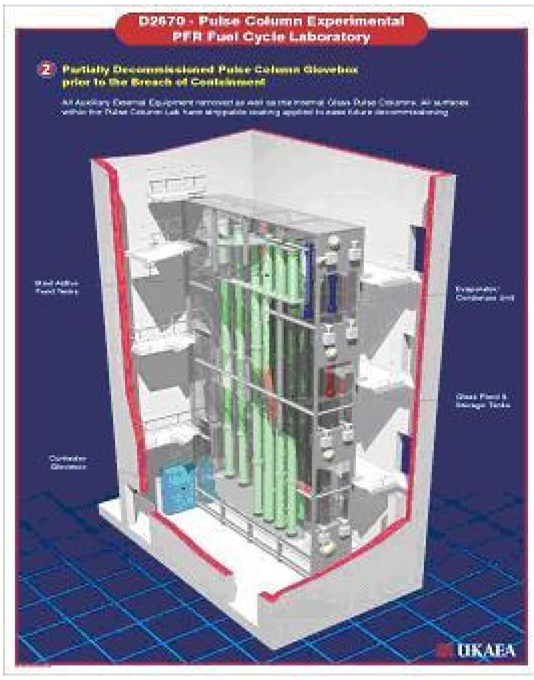

Fig. 10. The Pulsed Column Laboratory

During the early stages of the decommissioning work (Thompson 2001, Thompson 2002) in the PCL there were a number of low level intakes of radioactive material identified following the provision of nose blow samples. The contamination in the nose blow samples was not accompanied by significant surface contamination or airborne activity monitoring results.

A thorough investigation into the intakes highlighted that the contaminant was likely to be of very small particle size (sub micron) and that this was proving to be a significant challenge to the containment and ventilation system that had been installed for the decommissioning work.

The initial strategy involved breaching the glovebox to remove its internal glassware and services which were then size reduced in a purpose designed glass crusher before being disposed of as ILW. This resulted in a spread of contamination to the laboratory. Although tie down materials and decontamination campaigns were regularly undertaken, the laboratory effectively became the primary containment. It was clear that the contamination in the laboratory was providing a challenge to the ventilation system. To address this, a significant change in strategy was implemented with the fundamental principle being to regain and retain the glovebox as the primary containment.

The following text discusses the improvements that were made to the decommissioning strategy, containment, ventilation and access arrangements.

Ventilation and access/egress arrangements

The original ventilation design was set up to draw air through each of the four pressurised suit access corridors to the laboratory. The effectiveness of the ventilation system to provide adequate containment velocities at the containment barriers was sensitive to prevailing external weather conditions and internal movement (opening of doors, etc.) within the facility.

These access arrangements (Fig. 11.) were also convoluted causing problems with turbulent airflow at the containment barriers and curtains. This created a significant challenge to the dynamic containment of the facility, due to poor consistency of face velocities at barriers and turbulence at barriers and barrier curtains.

To improve this situation a number of significant modifications (Fig. 12.) to barrier arrangements and the supply ventilation flow distribution were implemented, including:

- Sealing of two access floors, which reduced the volumetric flow through these areas. This provided increased ventilation capacity to support dynamic containment at the two remaining access barriers and increased the volumetric airflow rate through these access areas. The increased volumetric flow rate also allowed the removal of the barrier curtains and barriers without any reduction in the required containment velocity of ~1m/s.
- Using prefabricated 'oval' doorways (without curtains) and profiling to streamline corners, etc. This reduced the amount of turbulence in the access arrangements and the fluctuating air flows noted during previous decommissioning entries as curtains are opened and closed (Fig. 12.). Furthermore, this modification eliminated the risk of contamination spread onto curtains.

- Modification of supply ductwork was necessary to implement improvements to airflow in the main change area, where original duct arrangements resulted in air being blown across the face of the barrier rather than evenly over it. A new supply grill and baffle plate was installed to deliver supply air to the ground floor sub change area and to promote an even flow pattern in the sub change areas.
- New supply ducting and ventilation grills were installed to the space ahead of the main change barrier to increase supply volume to the main change area and to promote an even flow pattern over that barrier. To feed these new supply points supply air was transferred from the closed off floors to the ground floor.

Fig. 11. The original PCL access corridor

Fig. 12. The improved PCL access corridors

Following implementation of the above, an extensive study of the airflow pattern involving smoke tests, recording and graphing of airflow velocities was carried out. Whilst the barrier flows improved, there was still a need for further improvement. To increase the total extract the power cabling and components for the duty and standby fans were uprated, this included the replacement of the two extract fan motors (duty and standby). To safely take advantage of the increased fan motor power, additional extract capacity was utilised by permanently using all four extract filter banks, as the original plant set up was to use three duty and one standby.

Further inspections and measurements were carried out after the fans were commissioned. Barrier flows were visually inspected using smoke tests generated by an industrial generator. This allowed visual confirmation that the access modifications had resulted in the smoothing of airflow profiles and subsequent much reduced turbulent eddies in the flow characteristics. The smoke tests were replicated with an operator standing at the oval door way which demonstrated that the air flowed past the operator without any significant backflow being induced. This exercise also proved to be a useful demonstration to the operators of what had been achieved.

Containment

The completion of the access arrangements and ventilation improvements allowed re-entry to the laboratory to be made under better conditions. Work to decontaminate the laboratory and re-instate the glovebox containment could now begin. This was achieved by installing a purpose made cover and bag posting arrangements (Fig. 13.) to the open glovebox. This and further covers were installed progressively as the glovebox was emptied and decommissioned (Fig. 14.). Material posted out of the glovebox was via installed bagging ports (Fig. 15.) to be either sentenced as ILW or transferred to the Dounreay decontamination facility for cleaning and disposal as LLW.

Fig. 13. Installation of the PCL Top Hat

Fig. 14. Installed posting ports for the removal of glovebox internals

Fig. 15. Posting operations within the PCL

Development of a new pressurised suit

As part of the thorough review of the arrangements at the PCL it was acknowledged that there is a period in the airline suit undressing process, when respiratory protection has to be removed and personnel are not fully protected. To alleviate this issue, a new single use suit with an air fed respirator integrated within the suit was developed (Thompson 2008). This new suit (Fig. 16.) offers the following features:

- An air fed respirator integrated within the suit, offering continuous protection both within the suit and following suit removal.
- Disposable, offering single use and minimising cross contamination potential.
- Improved wearer comfort, when worn with new moisture wicking undergarments.
- User involvement (and importantly ‘buy in’) in suit development.
- Less folds, creases and therefore contamination traps than the two piece suit that had been used previously.
- Easy to remove, minimising disturbance of the air and potentially contamination on removal.

The suits were used for the rest of the decommissioning work and proved to be very popular with the operators. They are very straightforward to put on and remove. It was novel in the United Kingdom for operators to wear respirators inside a pressurised suit, but feedback from the operators has been very favourable as the air fed respirator provides a good flow of air to the head area and has not caused problems with perspiration.

Fig. 16. The new pressurised suit with integrated air fed respirator.

The work to remove the PCL Glovebox and decontaminate the laboratory was completed in March 2010 (Fig. 17.), removing a significant hazard by employing innovative techniques to enable the safe decommissioning of the largest glovebox on the Dounreay Site.

Fig. 17. The PCL Glovebox is decommissioned

Conclusions

Our experience with the decommissioning of these two highly plutonium contaminated facilities, has provided a number of lessons, including:

- New facilities should be designed with decommissioning in mind.
- Containment of contamination at source is paramount in the safe decommissioning of plutonium contaminated facilities. Restricting the spread of contamination to the “work area” reduces the challenge to the ventilation system and the pressurised suit access areas.

- Glove boxes should be Post Operative Cleaned Out (POCO) immediately after cessation of work.

- Facilities should not be left in care and maintenance for long periods before decommissioning as facility specific knowledge and experience can be lost.

- Ventilation system requirements for the decommissioning of plutonium facilities should take into account potential routine and accidental airborne contamination challenges to the working area. The challenge posed by sub-micron particulate to the containment must be considered. The ventilation system should also be constructed with contingency beyond the minimum calculated requirement to ensure that there is additional capacity available.

- To enable unrestricted movement of personnel in and out of the high-risk area, without a significant cross-contamination potential, the space available for ingress and egress should be adequately sized and not convoluted. The addition of barriers and convoluted access ways can also lead to turbulence and the instance of turbulent eddies and back-flow.

- A considerable amount of time and effort should be allowed for the final surveys and decontamination of facilities. The use of instrumentation that measures the low energy X-rays from the plutonium isotopes to assess whether there was significant contamination below paint and within the walls and support structures etc can be extremely useful in the declassification process.

Radiation protection issues related to the decommissioning of the DR3 research reactor

Søgaard-Hansen, Jens; Hedemann Jensen, Per
Section of Radiation and Nuclear Safety, Danish Decommissioning, Frederiksborgvej 399, DK-4000 Roskilde, DENMARK

Abstract
The research reactor DR3 was closed in 2000 after 40 years of operation. It was a Pluto type reactor operated at 10 MW (thermal power). It was heavy water cooled and heavy water moderated and it had a graphite reflector. The reactor was used for neutron physics experiments and isotope production. At present the reactor fuel has been removed and most of the peripheral systems have been dismantled. The main construction parts will be decommissioned from 2012 to 2016. The planning of the decommissioning is made by a group of former reactor engineers, mechanical engineers, reactor physicists, technicians and health physicists. Through discussions in the group possible schemes have evolved on how to decommissioning the reactor. Some of the main constructions parts have high contents of activity e.g. many GBq of ^{60}Co and they are posing a major challenge regarding external exposure during dismantling. Graphite dust containing ^{14}C and primary tritiated heavy water leaked into the graphite and concrete are potential sources of internal exposure. A characterization study of the reactor components together with constructional and operational information is the basis for dose rate calculations related to the future dismantling operations. Examples of calculated dose rates anticipated in some of the critical decommissioning operations are presented together with other important radiation protection issues.

1. Introduction
The DR3 research reactor was a Pluto type reactor supplied by the English company Head Wrightson Processes in 1960. It was in almost continuous operation at 10 MW until 2000 where it was permanently shut down. The reactor was moderated and cooled by heavy water and had a graphite reflector. The reactor was primarily used for physics research (neutron scattering), radionuclide production and silicon doping. 18 experimental tubes gave access to positions close to the core position. Neutrons (thermal and cold neutrons) were guided out of four openings in two horizontal tubes and dispersed to several spectrometers. Figure 1 shows a schematic cross section of the reactor construction.

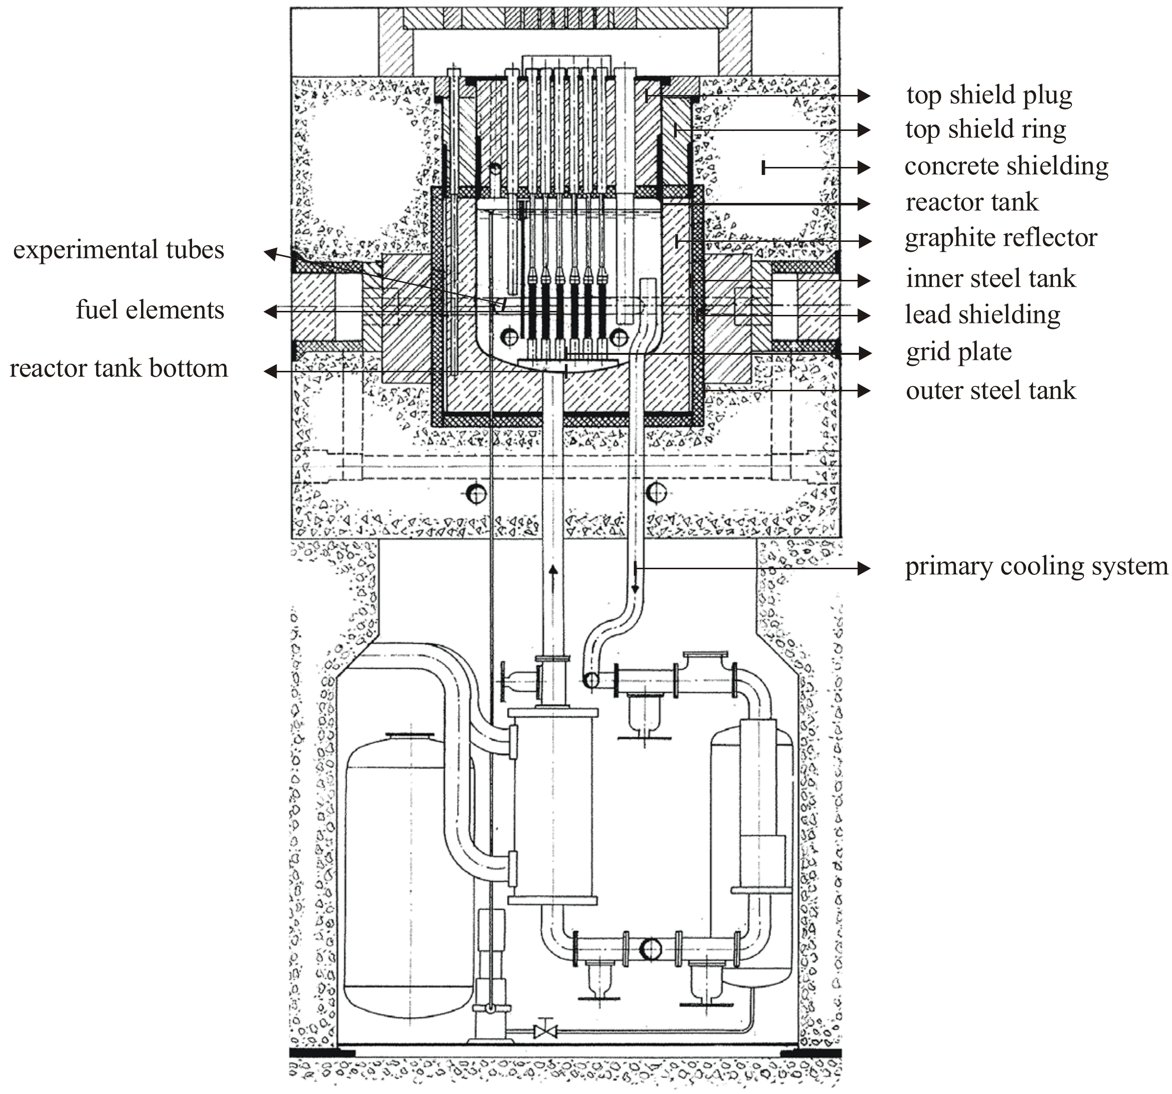

Fig. 1. Schematic cross section of the DR 3 reactor construction. The reactor aluminium tank contains the core and the heavy water moderator. Outside the tank the graphite reflector is situated in the inner steel tank. Outside the steel tank a lead and Boral shielding are situated in another, outer steel tank. Outermost is the concrete biological shielding. The reactor aluminium tank is closed at the top by a top shield plug (TSP) and likewise the steel tank with the graphite reflector is closed by a top shield ring (TSR). Below the reactor construction is the heavy water room containing the pumps for the primary cooling circuit.

The reactor block is placed in a steel containment which has an entrance for persons and an entrance for trucks. An auxiliary building used for active handling and storage of radioactive items is connected to the containment building at the truck entrance.

2. Preparing for decommissioning

Shortly after the final shut down the fuel was removed and the heavy water was drained from the primary and secondary systems. In 2003 the Danish parliament decided that DR 3 (along with the other nuclear facilities at the Risø site) should be decommissioned, preferable to a 'green field' status and a state company Danish Decommissioning (DD) was established with a core of personnel from the former nuclear safety department at the Risø National Laboratory.

In 2004 to 2005 a characterization project was carried out [Ølgaard 2006] with the aim of determining the amount of activity in the primary reactor systems and in the concrete in the reactor block.

From 2005 to 2006 another characterization project [Ølgaard et al. 2007] characterized the activity contents in components situated in the DR 3 storage facilities.

From 2006 and to the end of 2010 the peripheral reactor systems i.e. systems outside the reactor block are or will be dismantled and removed, leaving the bare reactor block and equipment necessary for the decommissioning e.g. the crane in the containment.

The decommissioning planning for the DR 3 started in 2008 and will continue until the actual decommissioning takes place from 2012 to 2016. Experience gained from the decommissioning of the DR 1 and DR 2 reactor will be used (Ingemann Larsen et al. 2008).

3. Radiation protection issues

Many radiation protection issues will arise during the decommissioning of the DR 3 reactor. Below some of the most important issues are addressed.

3.1 Radiation protection personnel

The Section of Radiation and Nuclear Safety at DD includes four health physicists (HP) and 11 health physics technicians (HPT). The personnel have a comprehensive education and training in radiation protection (Lauridsen 2009). Several have experience from former reactor operation and most have experience from the decommissioning of the DR 1 and the DR 2 reactors that were on the site.

The section serves all radiation protection works at DD including a 24 hour on site presence of a HPT. During the preparatory and planning phase 1.5 HP and 1 HPT has been allocated directly to the DR 3 decommissioning project. Additional manpower has been used for clearance measurements on equipment from the peripheral system parts. When the DR 3 decommissioning starts it is foreseen that 2 HP and 2-3 HPT will be allocated.

3.2 Sources of radiation and contamination

From the characterization project and some additional measurements the activity concentration and total activity content in the different reactor components have been assessed. Table 1 gives the values of ^{60}Co (which is the dominating source of external exposure) in some of the components primo 2012. The uncertainties on the values are estimated to be 20-200%, as they are obtained by sampling, which need not to be fully representative.

Table 1. Assessed average activity concentrations and total activity of ^{60}Co in selected reactor component primo 2012.

Component	Average activity concentration [MBq/kg]	Total activity [GBq]
Reactor tank (Al), lower part	80	30
Reactor tank (Al), bottom part	55	10
Experimental tubes	55	15
Grid plate	80	10
Graphite reflector	5	65
Inner steel tank, lower part	23	190
Outer steel tank, lower part	2.3	6.6
Top shield plug, bottom iron plate	7300	2200
Top shield ring, bottom iron plate	1300	300

3.3 Planning

A group of 10 people including one HP is responsible for the decommissioning planning. This group has expertise within reactor operation, reactor physics, mechanical engineering, radiation protection and decommissioning. All the group members have a basic understanding of radiation protection. The group has held one meeting every month from the end of 2007 and two meetings every month from the end of 2008.

Based on knowledge of the reactor construction and the activity contents in the construction parts, critical radiation protection elements in the project have been identified. Some of these have required additional sampling and measurements.

The group has produced preliminary plans for major steps in the decommissioning of the reactor some of which are alternative ways of dismantling. When the preliminary plans have been evaluated, the group will decide for a final decommissioning scheme and a detailed plan will then be made. The planning group will also participate in the actual decommissioning.

Plans are discussed and presented within the Dido Group which has members from other nuclear facilities with a Dido or a Pluto type reactor (Harwell, Dounray, Jülich and Ansto). Also an international expert panel has commented on some of the preliminary plans and will look thoroughly on the final overall plan as will the Danish radiation protection authorities.

3.4 External exposure

To assist the planning and evaluation of plans in terms of dose and shielding costs, radiation transport calculations have been made using the Monte Carlo method (MCNP) and the point kernel method (summation of point source responses). In cases where both methods have been used good agreements have been obtained. Figure 1 and Figure 2 show MCNP-calculated dose rates primo 2012 at different heights above the bottom of an open reactor pit, with only the top shield plug removed. Dose rates are shown as a function of distance to the central reactor axis. In the Figure 1 calculations air was in the reactor tank while in the Figure 2 calculations water filled up most of the reactor tank. It is seen from the two figures that filling up the reactor tank reduce dose rates by roughly an order of magnitude.

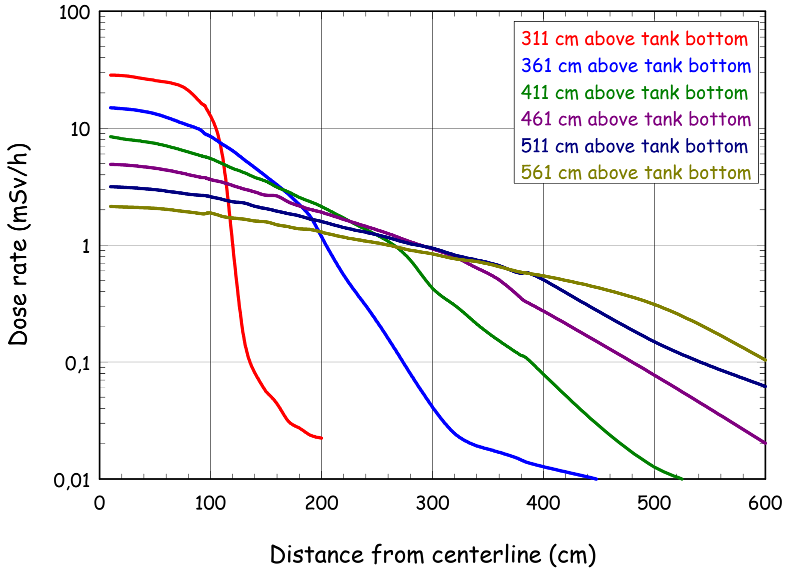

Fig. 1. Calculated dose rates primo 2012 at different heights above the bottom of an open reactor pit with only the top shield plug removed. Dose rates are shown as a function of distance to the central reactor axis. Top of the reactor is 311 cm above bottom.

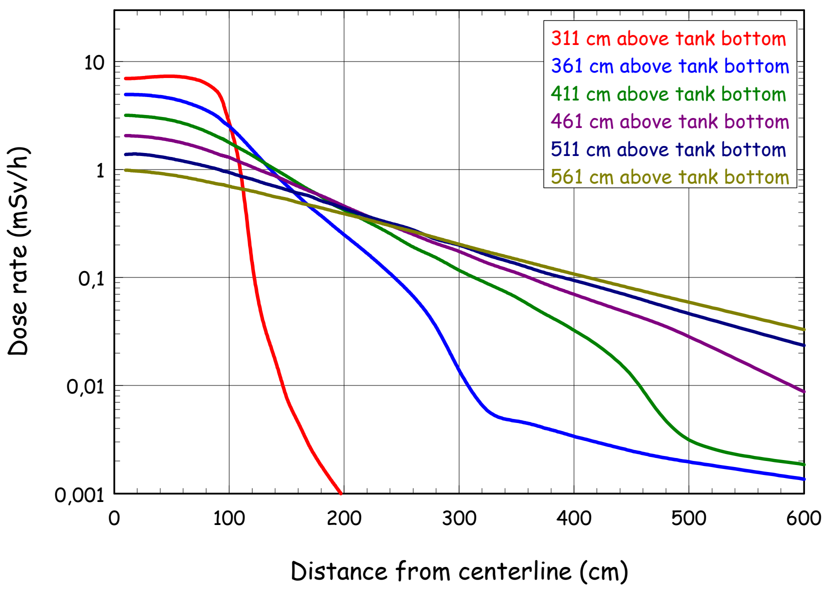

Fig. 2. Calculated dose rates primo 2012 at different heights above the bottom of an open reactor pit with only the top shield plug removed and with water in the tank. Dose rates are shown as a function of distance to the central reactor axis. Top of the reactor is 311 cm above bottom.

3.5 Internal exposure

The induced activity contents in the reactor components constitute sources of internal exposure as the dismantling will require the use of cutting tools. In addition a leak in the primary cooling system has supposedly coursed a widespread contamination with tritiated heavy water in especially the graphite and the concrete shielding. Also it is expected that graphite dust is already present some places in the graphite. From the estimated contents of radionuclides in the different reactor components the potential for internal exposure has been calculated. Table 2 gives the mass concentration in air equivalent to an effective dose rate of 1 µSv/h. Conservative activity to effective dose conversion factors have been used and tritium contents due to leakage has not been taking into account. For materials containing more than one radionuclide, the equivalent masse concentration is calculated as:

$$\left(\sum_i \frac{C_i}{dc_i}\right)^{-1}$$

where C_i is the concentration of nuclide i in the material (Bq/kg) and dc_i is the activity concentration in air (Bq/m^3) of nuclide i which is equivalent to an effective dose rate of 1 µSv/h.

Table 2. Mass concentrations in air of different reactor materials equivalent to a dose rate of 1µSv/h.

Reactor material	Equivalent mass concentration in air (µkg/m^3)
Graphite reflector	1.4
Al reactor tank	0.4
Steel inner tank	1.4
Concrete shielding	30
Primary heavy water	0.2

3.6 Dose constrains and acceptable doses

Dose constrains will be set for individual doses for each of the years the decommissioning takes place. The dose constrain for effective dose will be in the interval 5-10 mSv pr. year depending on the operations planned for the particular year. For all years the equivalent dose to the eyes will be constrained to 15 mSv/year and the equivalent dose to skin and to extremities will be constrained to 150 mSv/year.

Due to the inherent associated large uncertainties in determining internal doses, planning should strive to entirely avoiding internal exposure with tritium as an exception.

Radiation doses below the dose constrains should be as low as reasonably achievable. To assist the more detailed planning in controlling exposure for individual operations a guideline on “acceptable doses” has been made. Table 3 gives values of acceptable doses for operations with different benefit and frequency.

Table 3. Guideline for "acceptable doses" from working operations.

Benefit from operation and frequency of operation (pr. year)	"Acceptable" effective dose	"Acceptable" equivalent dose to eyes	"Acceptable" equivalent dose to skin and extremities
Small benefit, high frequency	up to 10-20 µSv	up to 30-60 µSv	up to 300-600 µSv
Medium benefit, high frequency	up to 50 µSv	up to 150 µSv	Up to 1500 µSv
Large benefit, low frequency	up to 100-200 µSv	up to 300-600 µSv	Up to 3000-6000 µSv
Very large benefit, A few operations	Up to 500 µSv	up to 1500 µSv	up to 15000 µSv
Very large benefit, one operation	Up to 2000 µSv	up to 6000 µSv	up to 60000 µSv

3.7 Clearance

An infrastructure for clearance called the Clearance Function has been established within the Section of Radiation and Nuclear Safety. This Function comprises laboratory facilities, measuring equipment, measuring procedures, waste handling software, software for clearance related calculations and trained personnel (Søgaard-Hansen et al 2008). The Clearance Function was granted an accreditation in 2007 from the accreditation body, DANAK, according to the standard ISO/IEC 17025 (ISO 2005). The accreditation process was completed over a period of approximately one year. Many of the items from the peripheral systems have been classified as candidates for clearance measurements and have subsequently been cleared; in contrast all materials within the reactor block are to be considered as radioactive waste.

4. Conclusions

The Section of Radiation and Nuclear Safety at DD which has been in existence since the days of reactor commissioning will be responsible for the radiation protection guidance during the decommissioning project. Procedures used during reactor operation such as participation of health physics personnel in planning and execution of operations which involve high dose rates and/or risk of contamination and health physics classification of areas will be continued during the decommissioning phase.

From the assessed activity contents the radiation exposure during the various operations will be calculated and used in the planning of the operations, with adequate considerations taken to allow for large uncertainties on the activity estimates. Calculations will, when possible, be checked with measurements.

A guideline for acceptable doses has been communicated to the planning group to help the detailed planning in ensuring that the dose constrains are respected.

[2] LAINSA S.A.U, SPAIN
[3] MONCOBRA S.A.U , SPAIN

Abstract
The irradiated fuel reprocessing plant MTR type was designed to treat fuel elements plate type from reactor JEN-1 (Ciemat). This facility (M-1 Plant) also served to develop fuel reprocessing processes.

Dismantling Works, which have been conducted by ENRESA, were carried out by MONCASA-LAINSA (MONLAIN) , the most experienced Spanish joint venture in dismantling nuclear facilities.

The dismantling of M-1 plant was performed from 2007 until the beginning of 2008.

This paper presents the performed dismantling works of the three M-1 Plant main systems:

♦ Hot Cell M-1.
♦ Glove Boxes Assembly L-1.
♦ Radioactive Liquid Waste Storage Cell (F-1).

The dismantling of these systems required methodical tasks planning, development of specific execution processes, execution of Alara studies and detailed safety plans.

Development of specific tools for dismantling tasks, containment auxiliary systems design, namely ventilated tents with local extraction systems and HEPA filters, operation assembly for equipment and components' extraction represent ones of the examples presented in this work.

A multidisciplinary team formed by the two companies joint venture, working together on an equipment designed by ENRESA, has carried out a unique work in Spain, executed with efficiency, optimizing resources and wastes, and minimizing the dose in accordance with the Alara criteria.

Introduction
The pilot plant for reprocessing of irradiated fuel type MTR (Plant M-1) is located in the eastern part of CIEMAT, in Building 18. It was designed to treat plaque-type fuel elements of the JEN-1 reactor and for the development of fuel reprocessing processes.

After two campaigns of treatment of irradiated fuels the Plant was shut down.

The dismantling of the facilities of the Plant M-1 has been performed in the frame of the Integrated Plan for the Improvement of the Facilities of the Ciemat (PIMIC

The dismantling of these systems has needed careful planning of tasks, development of specific execution procedures, and performance of Alara studies and detailed Safety Plans.

Description of the plant

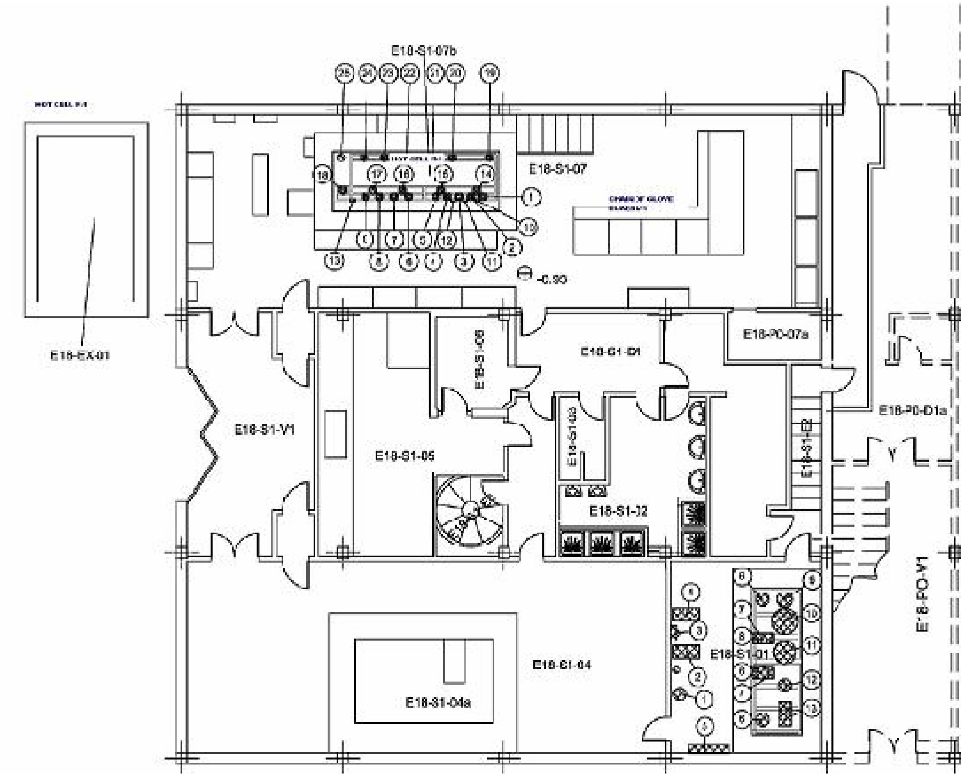

Fig. 1. Layout of the M1 Plant.

The pilot plant for reprocessing of irradiated fuel type MTR (Plant M-1) is a building of 352 m^2 and 6 m high, divided into three modules, with two floors in the central module.

The areas of interest for this paper are on the ground floor and northern area (Figure 1): Glove box chain L-1 and M1 Hot cell and outside the building 18, F-1 cell, Liquid Radioactive Waste Storage.

Glove Box Chain L-1

It contains the medium and low activity process equipment. The glove box chain L-1 has an "L" shape with seven separate modules. The second and the third are joined in a unique module.

The modules are divided in two parts. The low part of the second, third and sixth modules are not a part of the glove box and were used for the installation of auxiliary material. Each module is made of a metal profile structure to which panels of methyl-methacrylate (Plexiglas) of 8 mm of thickness are mate and constitute the side faces, as well as the separation between modules. The funds, roofs and separations between areas of modules are sheets of steel of 5 mm thick.

Cell M-1

Inside the cell the equipment for the first cycle of uranium and plutonium separation is found. Having dimensions of 1.60 x 4.80 x 2.40 m. The ceiling and walls of the cell M-1 are composed of reinforced concrete with a thickness of 65 cm. Part of the front wall (1.2 x 4 m) is shielded with three layers of lead bricks 50 mm thick. In the right side wall of the cell there is an opening that gives access to the interior with a free surface of 1.70 x 0.70 m, which is closed by a staggered shape door made of 60 cm thick barite concrete.

The M-1 cell contains diverse equipments of the first purifying fuel cycle, including tanks, mixers, settlers, valves and interconnecting tubing, mainly.

On the roof of the cell M-1 are found: the shielded glove box (sampling system of the cell deposits) and shielded cubicle C-1 (filtration system of the main process) and C-2 (volumetric pumps remote heads feeding radioactive solutions to process equipment).

Cell F-1

The F-1 cell for the reception and temporary storage of radioactive liquid waste is an underground cell of 2.6 x 4.5 x 4 m with reinforced 40 cm thick concrete walls. The roof is 20 cm above the street level and consists of 6 concrete slabs of 40 cm thick, which allows access to the interior.

The cell is divided internally into two areas, by means of barite concrete blocks (density 3.3 g / cm ^{3}) with a thickness of 50 cm, in order to separate the reception and storage of high and intermediate liquid effluents activity to the reception and storage of those of low activity.

The storage area of high and intermediate liquid effluents activity contains the tank A-1 (high activity), A-2 and A-3 (intermediate activity). The area of low activity includes tanks B-1 and B-2.

Dismantling Works

Planning for decommissioning has been carried out with reference to data provided ENRESA in the technical specification. The work was divided into units of intervention and for each of them a dismantling card was prepared to collect data related to the radiation risks, radioactive inventory, list of materials depending on their typology, estimate of waste, radiation protection and safety, equipment, components and systems, etc.

The first stage consisted of preparing the auxiliary facilities, in particular containment enclosures, called SAS (Figure 2). Due to the risk of alpha contamination the need to use a double barrier of containment was considered. This SAS consisted of a double enclosure, internal and external SAS, with an exhaust system that ensured an air flow towards the interior and that was complemented by a HEPA filtering system.

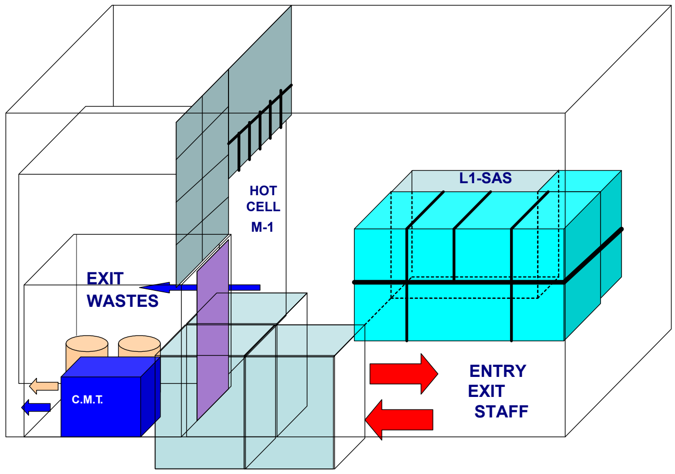

Fig. 2. SAS of Glove Boxes L-1.

The internal SAS had rectangular form and covered all the glove boxes L1 for both sides. It consisted of a metallic structure covered by methacrylate in the lower and not protected areas.

The external SAS covered the half of the room where there were the glove boxes L1 and the entry of the M1 cell. It was placed, partly, on the cell M1 and the rest in the corridor between M1 cell and the south wall. It had a metallic structure and it was covered in most cases by methacrylate. It is necessary to clarify that in the low part a door of methacrylate was enabled to allow the access to the waste management area.

That area had two methacrylate doors: one of them, in the East side, allowed the entrance of the wastes and the other was in the West side where the waste left. A rotary alarm with a door blocking system was placed to avoid the two doors were opened at the same time.

The system of assisted breathable air for the pressurized suits of the staff was located at the entrance area from inside the room, in the SAS of staff.

Dismantling of glove boxes L-1.

First, ancillary equipment (mixer-settler) located at the bottom of the modules C2, C3 and C6 was removed. The retrieval of these elements to the metallic containers was done by double bagging.

Next, sampling systems, glass columns (filled with silica gel), elements of ventilation and separate items mounted inside the box in the upper level of the modules C2, C3, C4, C5 and C6 were dismantled.

The method used to extract these systems from the inside of the glove boxes was the bagging.

Then dismantling of ducts, capping and closure of the holes, and connections with the lower level boxes C2, C3 and C6, was done.

Once emptied out the items with the previous method, and sealing the connections pipes, we proceeded to clean the inside (mopped) prior to the implementation of fixing paint inside the boxes.

Then we proceeded to the dismantling of the conduits located on the roof of the glove boxes L1, using cutting techniques such as confined cutting or sealed cutting with polyurethane foam.

Once the boxes were painted, the fastening pieces and methacrylate sheets were removed and cut to adapt them to the size of the metallic container.

Tanks on the lower level of each of the glove boxes were cleared.

Funds, ceilings, separating plates of 5 mm thick steel, and metal profiles were dismantled by cold cutting.

Hot Cell M-1

Once the Glove Box L-1 dismantled, it was necessary to restructure the SAS (see figure 3), to adapt it for the dismantling of the Cell M1.

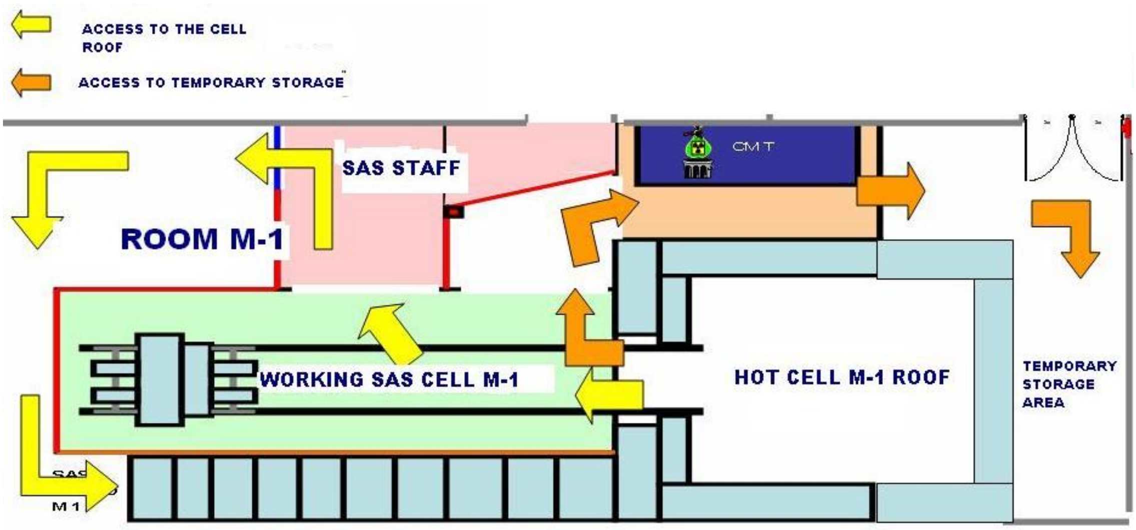

Fig. 3. SAS of Hot Cell M-1.

Given that the there was little room inside the Cell and the expected dose rates in certain systems, it was necessary to plan the works in detail attending on the ALARA principle.

An inventory of the equipments and systems of the interior of the Cell was performed, and a few cards reflecting the relevant information of every component (radiological characteristics, situational scheme inside the cell) were prepared.

A few auxiliary systems were prepared:

- Vacuum of particles.
- Decontamination.
- Collection of liquids
- Plasticized and bagging.
- Shielding.
- Mechanical manipulation of loads.
- Supply of breathable air.

The main methods of work used were:

- First vacuum. Adaptable canes of aspiration to the geometry of the environment of work. Periodic warnings in the filters of the system of collection of dust.
- Cutting and dismantling of pipes. Hydraulic shears that allows a rapid and clean cut. It cuts carbon steel as much as stainless steel.
- Dismounting of tanks, components and shieldings. Manual tools, nut-cutter, loosen bolts.
- Retreat of pipes. Double bagging and transport to a container (CMT).
- Retreat of tanks. Manual or with hoist according to the weight. Previous retreat of liquid from the inside of tanks.
- Cutting of work surfaces and supports. Hydraulic shears.

Cell F-1

The dismantling of the underground Cell F-1 had to be planned meticulously due to the risk of radiation and contamination, in addition to the little available room.

As in case of the Cell M1 it was necessary to build a specific ventilated SAS, but with an auxiliary installation that would allow removing the tanks (figure 4).

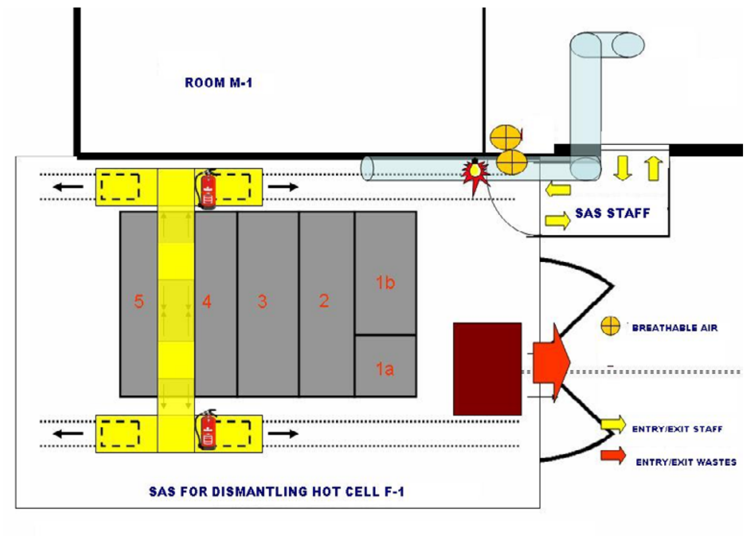

Fig. 4 . SAS for dismantling Hot Cell F-1.

This installation consisted of a bridge crane with a rail that allowed the movement across the SAS. The design of the SAS and of the bridge crane were thought to extract all the elements of the Cell, included the tank of discharged waste, which complexity was made clear along the works.

The sequence of the main activities was:

A. Opening and movement of concrete slabs.

B. **Dismantling of the Low Activity Tanks**

- Dismantling of valves and pumps.
- Cleaning of the outer tank walls.

- Cutting of pipes and supports of the tanks.
- Application of fixed paint on accessible surfaces of the tank.
- Hoisted of the tanks.
- Application of fixed paint in the rest of tank surfaces.
- Partial cutting of tanks inside the cell and the rest of cuttings outside. With vacuum hood system.
- Vacuum and cleaning inside the cell.

C. **Dismantling of Intermediate Activity Tanks**

- Extraction of side wall of concrete blocks adjacent to High Activity tanks.
- Dismantling of the roof blocks and cutting of feeding pipes of the tanks.
- Sealed-cutting of drainage pipes.
- Hoisted tank. Application of the first layer of fixation.
- Application of the second layer of fixation. Plasticized.
- Hoisted and laying in CMT of the tanks.

D. **Dismantling of the High activity tank**

- Extraction and dismantling of concrete blocks and cutting of feeding pipes.
- Opening a hollow and refilled with a layer of concrete the bottom of the tank.
- Fastening and hoisting the tank a little. Application of the first layer of fixation.
- Application of the second layer of fixation and covering with plastic.
- Hoisted of the tank and laying in shuttle.
- Introduction in spécial container CE2A.

Results

Next there the most important results, related to the work load, the dose and the management of materials are presented.

Work load

A whole of 4.427 hours x person has been used to achieve the three activities described previously. That indicates the difficulty of the above mentioned works. The percentage distribution of the hours is shown in figure 6. The percentages are very similar in the Cell M1 and in the F-1 and there do not move away too much of those of the glove boxes. Although the radiation risks glove boxes were very lower than those of other systems, certain time was used in the preparatory works, principally in the assembly of the SAS. In case of the Cell M1, the construction of the SAS did not take so much time, since the principal part, the separation in two halves of the Room M1 was already done in the previous phase.

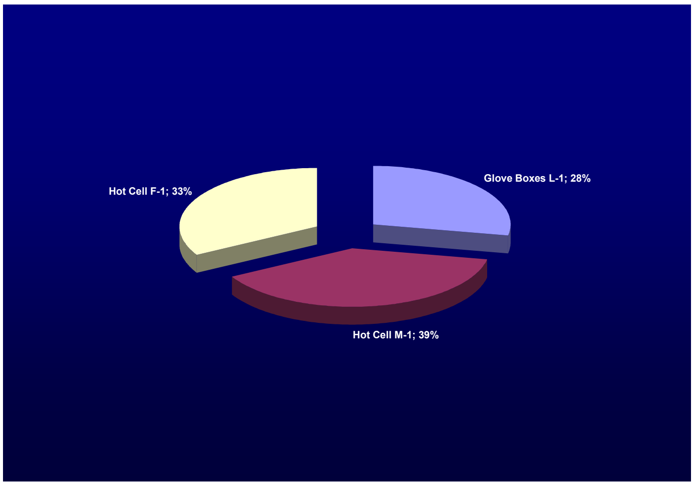

Fig. 5 . Work Load Breakdown.

Management of materials

Table 1. Balance of materials.

	CLEARENCE Materials	RADIAOCTIVE WASTES
Glove Boxes L-1	60 %	15 %
Hot Cell M-1	39%	40 %
Hot Cell F-1	1 %	45 %
Total	100 %	100 %

The whole of treated materials has been 62 Tm approximately. Table 1 shows the percentage distribution between the glove boxes and the cells for the potentially clearance materials and the radioactive wastes. 17 per cent of the materials have separated as clearance and therefore they have had to surrender to a process of measurement in the box counter, to perform a detailed radiological characterization and to decide his final destination. 83 % remaining has been considered to be radioactive residues, which is coherent with the type of elements on those who have been worked.

As it was expected the percentage of clearance materials for L-1 compared to those the Cells has been very higher. The biggest percentage of residues has been of the Cell F-1, due to the weight of the tanks and to that it has not been possible to segregate any more clearance components, due to the high dose rate inside the Cell.

Dosimetry

The activities with important collective dose have been the ones related to the Cell M-1 and the Cell F-1, since in case of the glove boxes L-1, the biggest risk was that of contamination. In this sense, there has been nor external contamination of the personnel neither internal contamination due to the applied confinement and protection measures. Photograph 4 shows the exit of personnel of the SAS of the Cell M1.

The biggest percentage of the collective dose has been allocated to the dismantling of the Cell F-1, as it was expected, since the levels of radiation were high.

Next the Cell M-1, since although the area dose rate was not too high, nevertheless it was certain equipments having points with high values.

The total collective dose in the Cell M1 has been 6 mSv x person approximately. This dose is 3 times lower than what had been foreseen in the Alara studies. We can find the cause of this deviation in the reduction of the time of execution, for what the exposition has diminished considerably. The detailed planning previous to the works has been a key point in this sense.

In case of the Cell F-1, the total collective dose has been 10 mSv x person. It represents approximately twice less than the expected one. In this case the attenuation of the term source, by means of shieldings and the meticulous planning of the works have been the main reasons.

Conclusions

The intervention of a multidisciplinary team of two constituent companies of the JV, collaborating with the team designated by ENRESA, has reached very good results in a work in Spain considered as unique. This work has been performed in an efficient and effective form, optimizing resources and residues and minimizing the doses in accordance with the Alara principle.

This work had not been possible without the fundamental support of the CIEMAT in the execution of the operations.

Protocol for the clearance and release for metal materials from SLAC National Accelerator Laboratory – Application to BaBar Detector Dismantling

Liu, James[1]; Fasso, Alberto[1]; Kerimbaev, Emil[1]; Rokni, Sayed[1]; Sabourov, Amanda[1]; Vollaire, Joachim[1]; Yamanishi, Hirokuni[2]
[1] SLAC National Accelerator Laboratory, UNITED STATES
[2] National Institute for Fusion Science, JAPAN

Abstract

In 2000, the DOE announced a suspension on unrestricted releases of any metals that have been inside a radiological area. SLAC is an electron accelerator facility which has many valuable metal components for off-site reuse or recycling. BaBar is a particle physics detector currently being dismantling for that purpose. Based on the DOE relief process, a protocol for unrestrictive release of non-radioactive metals is developed for BaBar dismantling.

At electron accelerators, surface contamination is very unlikely and volume activation is the main interest. The BaBar protocol can be generalized for other applications at SLAC or other electron accelerators. The SLAC protocol consists of an evaluation to determine the potential radioactivity of metal components based on process knowledge, calculations and measurements, as well as a technical basis for unrestrictive release.

Facility operations (beam or non-beam related) that can potentially contaminate or activate property are evaluated as follows: 1) obtaining process knowledge such as BaBar historical operational models and beam losses, 2) radioactivity calculations using the FLUKA Monte Carlo code, which allows a zoning approach to classify the components as radioactive or not for the purposes of planning, radiological control, and measurements, and 3) gross beta-gamma field survey on all surfaces of every item. Gamma spectroscopy measurements are conducted on pre-determined critical items to compare with FLUKA results.

The technical basis for the protocol consists of determining the detection limits of the measurement methods. Survey procedures and release criteria are developed based on the DOE Order 5400.5, MARSSIM, and ANSI standard N13.12. The SLAC instrument's detection limit is 10 times lower than the N13.12 clearance level for volumetrically activated materials based on the dose of 1 mrem/yr. Only items that have non-detectable radioactivity from both calculations and measurements will be released.

Development of radiochemical analytical method for the determination of radionuclides difficult to measure for decommissioning of nuclear facilities

Hou, Xiaolin
Technical University of Denmark, Risø National Laboratory for Sustainable Energy, DENMARK

Abstract

The decommissioning of a nuclear facility requires estimating the total inventory of radioactivity in various materials and its variation with time, which has to be carried out by the determination of the radioactivity of various radionuclides presented in the materials. The neutron activation products of components and impurity in the materials, such as ^{3}H, ^{14}C, ^{36}Cl, ^{41}Ca, ^{60}Co, ^{55}Fe, ^{63}Ni, ^{133}Ba, ^{152}Eu, ^{154}Eu, and some transuranics, are the main contributors to the total radioactivity. But some fission products, such as ^{90}Sr, ^{99}Tc, ^{129}I, and ^{137}Cs, may also exist in the materials due to the contamination of the leaked nuclear fuel. Of these radionuclides, the beta and alpha emitters including ^{3}H, ^{14}C, ^{36}Cl, ^{41}Ca, ^{55}Fe, ^{63}Ni, and some transuranics, have to be determined by radiochemical analysis including a completely separation of individual radionuclides from matrix and other radionuclides before measurement by beta counting, alpha spectrometry or mass spectrometry. This work presents various radiochemical analytical methods developed in the authors laboratory in the recent years for the determination of these radionuclides in various materials for the decommissioning of nuclear facilities, which includes:

1. rapid determination of tritium and ^{14}C in solid materials, such as graphite, concrete, steel, aluminium, paint, silica gel, soil, and dust;
2. determination of ^{14}C in high tritium samples, such as heavy water, waste water, and oil;
3. determination of ^{36}Cl and ^{129}I in graphite, steel, concrete, waste water, and dust;
4. determination of ^{41}Ca in concrete;
5. determination of ^{55}Fe and ^{63}Ni in graphite, concrete, steel, aluminium, sediment, sand, waste water, seawater, and lichens.

Meaning of site-specific data in dose assessment: case of concentration ratios in boreal forest

Ikonen, Ari T. K.[1]; Aro, Lasse[2]; Helin, Jani[1]
[1] Posiva Oy, Olkiluoto, FI-27160 Eurajoki, FINLAND
[2] Finnish Forest Research Institute, Parkano Unit, FI-39700 Parkano, FINLAND

Abstract

Posiva is implementing a deep repository for spent nuclear fuel in Olkiluoto, Finland. A site-specific safety case is being produced, and data has been acquired for the assessment models. However, neither site or literature data alone are sufficient for the safety case; a balanced combination is needed. The case of the concentration ratios from soil to plants in boreal forest, dominant ecosystem at the site, is discussed in this contribution.

Combining literature data with site data is not straightforward. Our approach is based on updating probability density functions (pdf). First, an *a priori* distribution is established from site-applicable literature data to contribute to the width of the distribution. Then, the pdf is updated with individual, site-relevant literature data taking into account the number of samples as a weight. Finally, the distribution is updated with the site data. In the weighting, also additional weighting factors of confidence or relevance for which quantitative measures have been established can be used. Repeating the procedure for different groupings of data, e.g. plant types, reveals whether the grouping is statistically reasonable.

The meaning of the site data is pronounced where the site data alone is not sufficient and where the literature data would have not been adequate: few site data do not necessarily reveal the entire width of the distribution, and the literature data may not span to the extremes in the site data.

Furthermore, the national forest soil inventory methodology applied required development of a concept to calculate concentration ratios from multi-layer soil data where the rooting depth is taken into account, as opposed to the conventional method of average concentration in soil core to a fixed depth. Examples of concentration ratios specific to soil layers are presented.

Introduction

Posiva is implementing a deep repository for spent nuclear fuel in Olkiluoto, Finland. A site-specific safety case is being produced to support a construction license application in 2012 (Posiva 2008), and data has been acquired for the assessment models (Hjerpe et al. 2010). In the assessment, a large amount of data is required of which only part can be produced in the site investigations with reasonable resources. Furthermore, there has been discussion on whether the site data alone would be sufficient anyway since it may not capture the entire variability relevant to the assessment (e.g. Sheppard 2005), the less the fewer the site data is. In this paper, methods to derive concentration ratios from site data and to combine site and literature data are outlined and demonstrated, and the need of site-specific and generic data is discussed based on some examples.

In Posiva's repository programme, ecosystem characterisation is an iterative process aiming to achieve an adequate site understanding, in order to evaluate the appropriateness of different models and of preliminary data to the site, and subsequently to provide data of sufficient scope and quality to underpin the safety case development (Haapanen et al. 2009). Ideally, a totally exhaustive characterisation of the properties and processes of the ecosystem could be taken as the aim. However, with any limited resources that can never be achieved, neither is it necessary to achieve to present a sufficient safety case; the extent of the ecosystem characterisation efforts needs to be in reasonable relation to the overall repository programme, the significance to the safety of the spent fuel disposal and the regulatory requirements. In practice, this means continuous improvement at a moderate level (i.e., reasonable in the context of overall repository programme) in ecosystem characterisation with a focus on issues that have significant safety relevance. Identification of key issues is not a straightforward task, but an iterative process, preferably done with feedback from the regulator and other stakeholders. During the initial overall characterisation little data has been acquired in some key nuclides and their chemical analogues – the programme is currently shifting focus from the general characterisation to these assessment-driven key issues. In the interim, information also from other programmes of similar sites or literature needs to be utilised.

Material and methods

Multi-layer approach to concentration ratios

In Posiva's biosphere assessment BSA-2009 (Hjerpe et al. 2010), the terrestrial ecosystems are represented by a compartment model shown in Figure 1. The model has been reformulated from earlier ecosystem-specific compartment models to correspond the features at the site as recognised in the biosphere description process (Haapanen et al. 2009). Following from its specific function and on the other hand its varying thickness (about 2-20 cm in the rather young sites at Olkiluoto Island, emerged from sea by post-glacial uplift only during few past millennia), the humus layer has been separated from the underlying mineral soil layers in forest objects. The compartment structure is also consistent with the available information from the various site studies, where the humus layer, the mineral soil layer of 0...30-cm depth and the subsoil are sampled separately to follow more general sampling schemes (e.g. the national forest soil inventory), and in the case of subsoil also in separate campaigns with lower spatial resolution due to the need of machinery and the disturbance to the site studied.

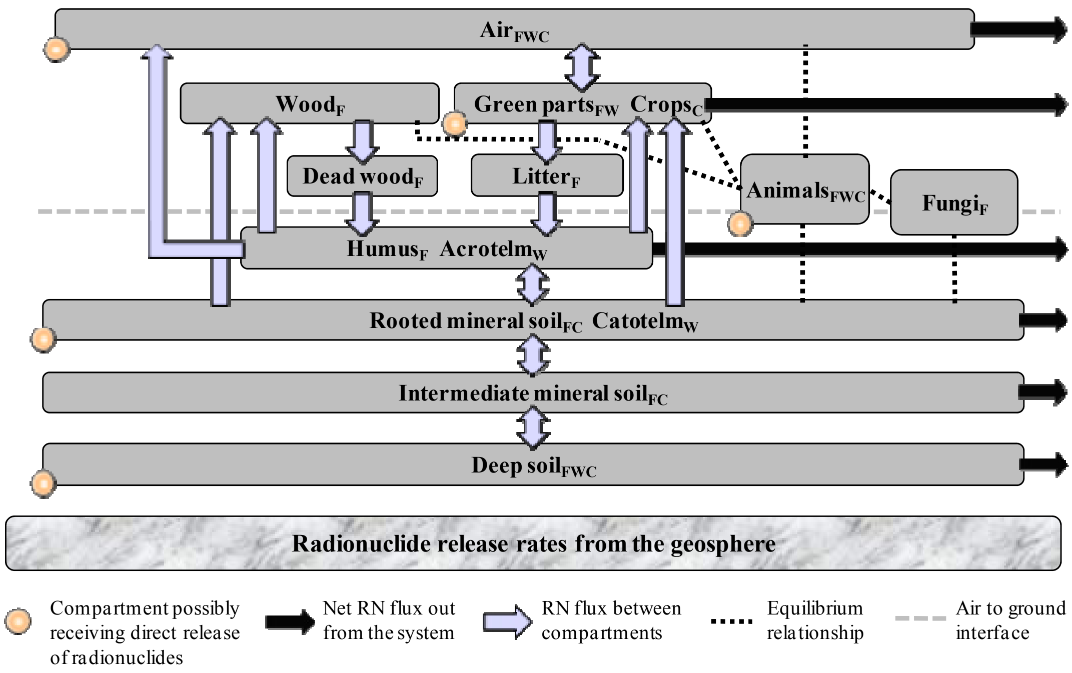

Figure 1. The conceptual radionuclide transport model for terrestrial ecosystems (Hjerpe et al. 2010). The indices in the compartment names define for which ecosystem(s) they are valid, where: F denotes forest, W wetland and C cropland.

Following the compartment division described above, concentration ratios are calculated for the transport from the humus layer and from the rooted mineral soil using the fine root biomass distribution (Table 1) as a weighting factor (Haapanen et al. 2009); it is assumed that the uptake from the compartments hosting the roots is proportional to the amount of roots in them:

$$f_i C_j = CR_{i,j} C_i$$

$$C_j = \Sigma_i\, CR_{i,j} C_i = CR_{eff} C_s$$

where f_i is the proportion of fine root biomass in soil layer i, C_j is the concentration in the recipient compartment (e.g. wood or foliage), $CR_{i,j}$ is the soil layer-specific concentration ratio from soil layer i to compartment j, and C_i is the radionuclide concentration in soil layer i. To calculate the concentration in the recipient compartment using the conventional concentration ratio (CR_{eff}), the corresponding average concentration in the soil layers relevant to the root uptake (C_s) shall be used:

$$CR_{eff} = C_j \,/\, [\, (\Sigma d_i \rho_i C_i)/(\Sigma d_i \rho_i)\,]$$

where d_i is thickness of a considered soil layer and ρ_i the respective bulk density of soil.

Certainly using the layer-specific concentration ratios is not compatible to the general definition of the concentration ratios, assuming a topsoil sample regardless of the soil layers, most often 30 cm. Thus for comparisons or combination with literature data, CR_{eff} needs to be estimated and used.

Table 1. Distribution of fine root biomass (mass-%) in humus layer and in mineral soil layer of 0-30 cm at Olkiluoto (Helmisaari et al. 2009).

Stand type	Plant group	Humus	Min. soil	Application in assessment
Pine	Trees	38	62	Pine trees
Pine	Shrubs	85	15	Shrubs in coniferous stands
Pine	Grasses	89	11	Grasses and herbs in pine stands
Spruce	Trees	59	41	Spruces and coniferous bushes
Spruce	Grasses	99	1	Grasses and herbs in spruce stands

Combination of various data sources using Bayesian updating

A Bayesian approach has been developed by Kristofer Stenberg (Facilia AB) and adopted by Posiva (Helin et al. 2010) to obtain combined probability density functions (pdf) from site measurements and literature data. The goal is to obtain pdf's that take into account the more generic data when the site data is judged insufficient and also the variability between the studies included.

As a ratio quantity, concentration ratios are expected (and thus assumed) to be lognormally distributed by the central limit theorem. Most data compilations that have studied the form of the distribution do not represent arguments against the assumption, although some other possible distributions have been derived from the data.

For small number of observations there can be large uncertainty in the estimates of mean and variance. Bayesian updating makes it possible to reduce this uncertainty by including further knowledge (prior knowledge) in the estimation: a prior distribution of the two unknown parameters is assumed and the posterior distribution, or the probability of the parameters conditioned on observed data, is given by Bayes' theorem. There are different methods of estimating the posterior distribution depending on the interpretation of the prior knowledge and thereby on the form of the prior specification. In this paper we demonstrate only combining the site and literature data with *direct updating* where they are considered equally appropriate to the site: the posterior is a combination of the observations *a priori* and the new observations, weighted with the sample sizes. This method utilises the concept of full conjugacy of the prior distribution (Gelman et al. 2003). This and the other methods, population and hierarchical updating, are described in more detail in (Helin et al. 2010).

Results

Soil-layer-specific concentration ratios from the Olkiluoto site

Table 2 lists results on concentration ratios of nickel and iodine to forest plants, derived from the data from three sampling sites at Olkiluoto in 2008: FIP4, FIP10 and

FEH914254 (Haapanen 2009). FIP (forest intensive monitoring) plots have been established to continuously follow changes taking place in the nutrient budgets and fluxes in the soil, tree stands and vegetation at both the stand and the catchment level. FIP4 is a Scots pine-dominated advanced growing stand and FIP10 is a mature Norway spruce-dominated stand. Both FIP plots are located in herb-rich heath forests. FEH plots are used for inventories of vegetation (composition, biomass, nutrient concentrations) and soil (soil profile description, physical and chemical properties) at 5–10 years intervals, in addition to regular tree stand measurements. FEH914254 is a black alder-dominated stand growing on herb-rich heath forest site.

As an example of a larger dataset, for comparison, respective concentration ratios of nickel are presented in Table 3 as derived from a forest inventory at Olkiluoto in 2005 (Tamminen et al. 2007). Further details of the calculations can be found in (Ikonen et al. 2010).

Combinations of site and literature data

To illustrate the combination of datasets using the Bayesian direct updating described above, datasets on concentration ratios of iodine to plants are used (the choice was limited by availability of literature data comparable to the site data). The site data on effective concentration ratios to understorey plants (excluding mosses) presented in Table 2 and Fig. 1 was combined with concentration ratios to generic plants derived by Sheppard et al. (2006). The latter data was converted to the dry-weight basis by assuming a dry matter content of 0.50 kg_{dw}/kg_{fw}. The combined data, still dominated by the literature data (N=80 vs. N=7 of the site data), exhibits a slightly higher geometric mean following from the update with the site data having a higher geometric mean than the literature data. The geometric standard deviation has also increased in the combination due to the difference of the datasets; in the combined one the variability of the both original datasets has been included.

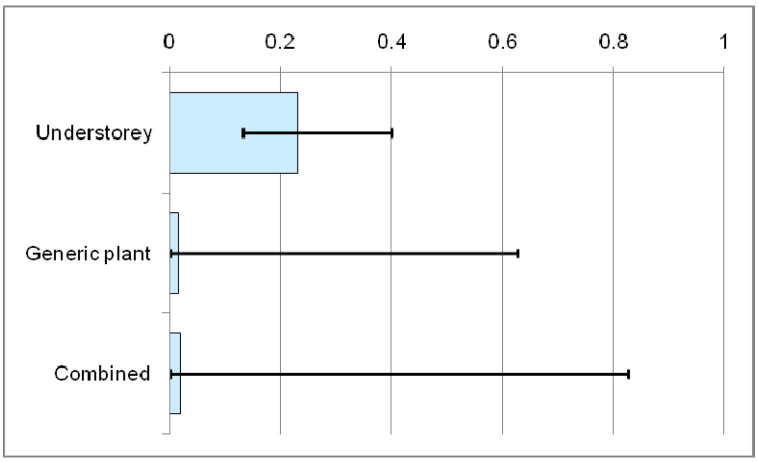

Fig. 1. Distributions of concentration ratios of iodine ([kg/kg$_{dw}$]/[kg/kg$_{dw}$]): site-specific data for understorey (CR_{eff}, Table 2), data for generic plants (Sheppard et al. 2006) and their combination derived by Bayesian direct updating. Geometric means are presented by end of the thick bars and 5th and 95th percentiles as the lines.

Table 2. Soil-layer-specific and conventional, or effective, concentration ratios ([kg/kg$_{dw}$]/[kg/kg$_{dw}$]) of nickel and iodine to forest plants at Olkiluoto in 2008, geometric mean (geometric standard deviation; number of sample pairs). The humus layer (*h*) has been taken as the actual at the sampling sites, and the mineral soil layer (*min*) includes the top 30 cm.

Generic plant	0.016	9.3	80
Combined	0.02	9.6	87

Discussion

If we consider, for example, the transport parameters, like Sheppard (2005), it is indeed nearly impossible to know whether there is an unexpected bias when there are only few data (from the site or the literature), and also to exemplify whether a species in a group is different from another, for example, is bilberry bioconcentrating more effectively than lingonberry? In any case, the more data available, the more we can know about the underlying processes and relevant differences in conditions. Since the literature data on these parameters are notoriously scarce (with compendium values usually lacking description of the range of conditions the data are derived from), the contribution of even a few site data would be useful. Still, a few site data alone could be insufficient since the inherent variability of the transport parameters is so large that site data would be significantly different only for "fairly exceptional on-site properties" (Sheppard 2005). Demonstration of such cases turned out to be more difficult in case of forest plants than foreseen; the literature data accessible with moderate effort is rather plenty in caesium data but very scarce for other nuclides, specifically of those most of interest of Posiva's assessment (Cl-36 and I-129, dominating the dose together with C-14 in the dose assessment time window of 10 000 years (YVL 8.4, YVL E-5)).

By comparing the data in Tables 2 and 3 it is notable, that when all forest types in an island of 12 km² are included in the data, the geometric standard deviation (GSD) increases significantly for the concentration ratios from the mineral soil and for the effective concentration ratios – this is the opposite to the expected situation with the humus-specific concentration ratios where the GSD decreases with more data. This is likely due to the surrogate data used to the mineral soil layers, practically assuming a default value for each soil type (Ikonen et al. 2010). In the concentration ratios specific to the humus layer this does not affect, and it can be concluded that for foliage and herbs and grasses the GSD decreases to a half with samples increasing from 3-5 to 90-123. With bilberry leaves and understorey in general the change is smaller but exists anyway. In general, it appears that in the larger dataset (Table 3) the humus-specific concentration ratio the values are on the lower end of the 5th-95th percentile range represented by the fewer samples (Table 2) – species accumulating more nickel may have been collected into the latter by chance.

Conclusions

In the repository programme the ecosystem characterisation provides with data to and supports model development in the dose assessment, and this is an iterative process where focus should be on the parameters which have the highest impact on the doses as only part of the needed input data can ever be acquired by site studies. To ensure that large enough variability is propagated through the assessment, it is necessary to try to identify any bias with help of literature data. However, as the emphasis of radioecology has been almost solely in the consequences of the Chernobyl accident, very little data is available on the radionuclides of interest in the deep geological repository – with the naturally occurring nuclides as an exception, which are on the other hand out of the dose assessment time window in the Finnish regulatory context as they may reach the biosphere only after the next glaciation when release constraints apply instead of dose limits. Furthermore, the few compendia data tend to be too general in the description, and the old original research papers are seldom available – it is difficult to judge whether a piece of literature data is appropriate to a specific site. All this emphasises the importance of extensive site studies, which should be targeted to cover the variability not only at the site itself but within the full assessment context.

To optimise use of resources, Posiva's approach has been to implement the ecosystem characterisation at the site by adopting methodologies used more widely. By this, large independent datasets become comparable. However, as the sampling and analytical protocols have not been tailored to the needs of the radionuclide transport modelling and dose assessment, some gaps remain. For example, in an extensive forest soil inventory, shovel pits are used instead of volumetric samples due to the laboriousness of the latter, and for the integrated benefits humus layer and mineral soil are sampled separately. Calculating traditional concentration ratios from the top 30 cm of soil to the plant needed thus bulk density data for calculating the average concentrations, but few of them are available from the sampling plots. To overcome these difficulties, a concept of multi-layer concentration ratios has been outlined above. With it more of the site data can be utilised, but on the other hand comparison to the traditional concentration ratios in the literature data requires surrogate to the soil density data. This is not seen as a major problem, though, since the literature data is relatively scarce for the most radionuclides of interest of a deep geological repository.

Abstract

Posiva Oy is responsible for implementing a final disposal programme in Finland for spent nuclear fuel. The next step of the nuclear licensing is by the end of 2012 submit a construction licence application for a KBS-3 type of repository at the Olkiluoto site. Currently, a safety case is produced to support this application, were a preliminary version was completed in 2009. A three-tiered graded approach was developed and applied in the dose assessment. Tier 1 and 2 are generic screening evaluations, and Tier 3 is based on site-specific state-of-the-art radionuclide transport modelling and dose assessment. The main aim of the screening evaluation is to reduce the number of radionuclides needed to be considered in Tier 3, which is especially valuable for long-term assessments that are associated with large uncertainties. This approach assures that the level of detail of the assessment is appropriate to the magnitude of the potential radiological consequences, and strengthens the confidence in the assessment and the demonstration of compliance with regulatory criteria. Tier 1 derives defensible and extremely cautious Risk Quotients, assuming that all radionuclides released from the geosphere expose one person, or a penalizing species for other biota, without any dispersion in the biosphere. Tier 2 derives defensible and cautious Risk Quotients, based on a generic model including three sub-models, a terrestrial, an aquatic, and a well. The screening evaluation was applied to the geosphere releases derived in the interim safety case. The result shows that 24 of the 35 radionuclides in the geosphere releases can be screened out. Especially noticeable is that no radionuclides in the naturally occurring decay chains need to be propagated to Tier 3. This paper presents the methodology of the graded approach, the screening models, and the results from the screening evaluation in the preliminary safety case.

Introduction

Posiva Oy (Posiva) was established in 1995 by the two Finnish nuclear power companies, Teollisuuden Voima Oyj (TVO) and Fortum Power and Heat Oy (Fortum), to implement the final disposal programme for spent nuclear fuel and to carry out the related research, technical design and development. The spent nuclear fuel is planned to be disposed of in a KBS-3 type of repository to be constructed at a depth of about 400 metres in the crystalline bedrock at the Olkiluoto site. Posiva is currently preparing for the next step of the nuclear licensing of the repository, which involves submitting the construction licence application for a spent fuel repository by the end of 2012. A safety case will be produced to support this licence application; the Posiva plan for conducting the safety case is documented in (Posiva 2008).

A key contributor to the safety case is the biosphere assessment. The overall aims of the biosphere assessment are to describe the future, present, and relevant past conditions at, and prevailing processes in, the surface environment of the Olkiluoto site; to model the transport and fate of radionuclides potentially released from the repository through the geosphere to the surface environment; and to assess possible radiological consequences to humans and other biota.

The regulatory requirements for the long-term safety are set out in detail in the Radiation and Nuclear Safety Authority's (STUK) Guide YVL E.5 (STUK 2009) on disposal of nuclear waste. STUK (2009) states that "In any assessment period, during which the radiation exposure of humans can be assessed with sufficient reliability, and which shall extend at a minimum over several millennia: 1) the annual dose to the most exposed people shall remain below the value of 0.1 mSv, and 2) the average annual doses to other people shall remain insignificantly low". Furthermore, "disposal shall not affect detrimentally to species of flora and fauna, this shall be demonstrated by assessing typical radiation exposures of terrestrial and aquatic populations in the disposal site environments".

The main approach in the biosphere assessment is to develop a fully dynamic model for the development of the surface environments, radionuclide transport and radiological consequences analysis. In the dose assessment part of the biosphere assessment, the fate of radionuclides potentially released to the biosphere is assessed with radionuclide transport models and radiological consequences are assessed by deriving radiation doses to humans and other biota. For the dose assessment, a graded approach based on three tiers has been applied. Tier 1 and 2 involve conducting generic evaluations to screen out radionuclides that have insignificant radiological consequences, using two levels of inherent pessimism, and Tier 3 is based on based on site-specific state-of-the-art radionuclide transport modelling and dose assessment. The graded approach to dose assessment has been developed for, and applied in, the recently produced interim safety case (Hjerpe et al. 2010, Posiva 2010). This paper presents the methodology used in the graded approach, the models underpinning the screening evaluation (Tier 1 and Tier 2) and results from the screening evaluation performed in the interim safety case.

Methodology

When conducting the biosphere assessment, two important goals are to ensure that the assessment is based on an appropriate level of understanding of the biosphere and its potential behaviour, and that the level of detail of the assessment is appropriate to the magnitude of the potential radiological consequences.

In the biosphere assessment performed for the interim safety case, a three-tiered graded approach is implemented to achieve the goals. The common denominator in tiered approaches is that the complexity and realism are greater for higher tiers compared with lower tiers. In the present approach, Tier 1 and Tier 2 are generic radionuclide screening evaluations, requiring a minimum of site-specific data. Tier 3, which uses the landscape model, is the most realistic. The approach is to use the results from Tiers 1 and 2 to identify radionuclides that are highly confidently expected to have insignificant radiological consequences, and do not need to be considered in Tier 3. This allows the computationally demanding landscape model used in Tier 3 to focus on key radionuclides. The approach thus avoids the need to obtain Tier 3 data, and evaluate uncertainties in these data, for radionuclides to which the overall assessment results are not sensitive. It also facilitates and strengthens confidence in the biosphere assessment and strengthens the demonstration of compliance with regulatory criteria, especially by increasing the transparency of the biosphere assessment. Furthermore, it provides an instrument for analysing model uncertainties, and providing guidance for the development of the landscape model, and the associated environmental monitoring programme. The landscape model is presented in Hjerpe et al. 2010 and the models used in the screening evaluation are described below.

The screening evaluation

This section describes the approach and the models used in the screening evaluation (Tier 1 and Tier 2). The quantity of interest in both tiers is the Risk Quotient (RQ), which is the calculated nuclide-specific dose rate divided by pre-selected Screening Dose Rates (SDR). The approach must be sufficiently cautious so that there is a high degree of confidence that the potential radiological consequences are below the relevant regulatory requirements when the RQ is below 1. The SDR itself must be assigned a value substantially below regulatory dose constraints; how much lower depends on the desired degree of conservatism in the screening evaluation. The approach here is to select the SDR low enough to allow Tier 1 and 2 to screen out individual radionuclides for which the calculated RQ is less than or equal to 1. Two SDRs are used throughout the evaluation: 10^{-5} mSv for humans, which is two orders of magnitudes below the lowest regulatory annual dose constraint, and 10 µGy/h for the other biota, which is the default generic screening absorbed dose rate in the ERICA Tier 1 (Beresford et al. 2007) and is also recommended by the PROTECT project (Andersson et al. 2008).

The procedure for the screening evaluation is similar to the one recommended in IAEA (2001) for use in assessing the impact of discharges of radioactive substances to the environment, and the models are in line with the recommendation by the ICRP (2000, 2007b) on how to conduct a dose assessment. In Tier 1, an extremely cautious approach is taken, in which it is assumed that a hypothetical individual receives the maximum exposure over one year to the whole integrated release from the geosphere. If the RQ calculated for a specific radionuclide in Tier 1 is greater than 1, then it is necessary to continue to Tier 2. In Tier 2, a screening model is applied that includes a higher degree of realism than the model used in Tier 1, but is still sufficiently cautious for screening purposes. The generic model includes two generic ecosystem-specific sub-models, one terrestrial and one aquatic, and a well sub-model. The screening model used in Tier 2 does not require site-specific parameters and therefore can be called "generic". If the RQ calculated for a specific radionuclide in Tier 2 is greater than 1, then it is necessary to consider that radionuclide in the site-specific landscape modelling (Tier 3).

Tier 1

The first tier is conceptually illustrated in Figure 1. It is designed to ensure extremely pessimistic RQs, by several orders of magnitude. Thus, radionuclides screened out at Tier 1 are indisputably insignificant for radiological consequences during the biosphere assessment time window. The evaluation regarding humans is carried out by assessing the doses due to each radionuclide in three exposure situations, where the whole integrated release from the geosphere is

- totally routed to one person for intake by ingestion,
- totally routed to one person for intake by inhalation, and
- transferred to the ground surface and exposes one person externally.

When assessing the dose due to external exposure, it is pessimistically assumed that the whole activity is transferred to one square meter of ground surface; then the external dose rate is, unrealistically, derived by multiplying the activity concentration in the contaminated surface by the dose coefficient for a source distributed over an infinite ground surface. Further, to derive the annual dose due to external exposure, it is assumed that the person is exposed to that dose rate over one year. The highest annual dose from the three exposure situations considered is then divided by the SDR, for humans, to obtain the RQ_{humans}. Thus, Tier 1 is an extension of the integrated radiotoxicity flux that may be used as an indicator of safety.

The evaluation, regarding other biota, is implemented in a somewhat different fashion. Instead of calculating absorbed dose rates to compare with the selected SDR for other biota to obtain the RQ_{biota}, the SDR is used to determine radionuclide-specific environmental media concentration limits (EMCL), based on the ERICA integrated approach (Beresford et al. 2007). The most penalising EMCL for different solid media (soil or sediment) and liquid media (freshwater and marine water) are denoted as $EMCL_{solid}$ and $EMCL_{liquid}$, respectively.

Furthermore, it is pessimistically assumed that the habitat for the worst case reference organism has an activity concentration numerically equal to the total integrated activity, for each radionuclide, in the geosphere release. For example, if the integrated activity is 100 Bq and the worst case reference organism habitat is lake water, an activity concentration of 100 Bq/L in the lake water is assumed. The RQ_{biota} is then determined as the highest ratio of the derived activity concentrations in solid media, or liquid media, and $EMCL_{solid}$, or $EMCL_{liquid}$.

In addition, to be even more certain that the RQs are not underestimated, the integrated geosphere release rates used are not corrected for any radioactive decay, but include build-up of progeny radionuclides. This is, of course, a non-physical approach. However, this is deliberate, so that there is no potential for underestimating the contribution either from the parent or from its progeny. The integration takes places over a time window of 15 000 years (from year 2 020 to year 17 020), which is 5 000 years longer than Posiva's interpretation of the biosphere assessment time window where regulatory dose constraints apply. Thus, this means that one person, or one individual of the limiting reference organism for other biota, is exposed to everything released from the geosphere up to the year 17 020.

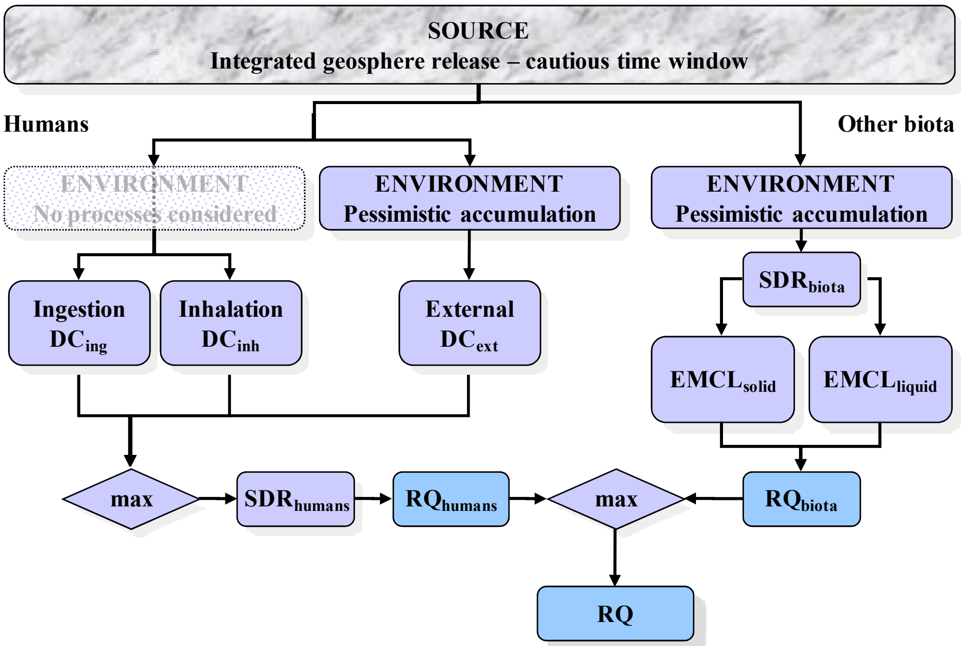

Fig. 1. Conceptual model of Tier 1. The environment box is shaded for the ingestion and inhalation pathways to emphasize that no environmental processes are considered – the source is directly inhaled/ingested (DC_{ing}, DC_{inh} and DC_{ext} are the dose coefficients for ingestion, inhalation and external exposure, respectively).

Tier 2

The second tier is illustrated in Figure 2, and is designed to ensure defensible and very cautious RQs. In contrast to Tier 1, Tier 2 takes dispersion and accumulation in the biosphere into account, and thus the degree of realism is increased. The generic model applied is still sufficiently cautious for the screening purpose, and includes generic biosphere sub-models: a cropland, a lake, and a well. These three sub-models are evaluated together, and the highest exposures by different pathways are used for deriving the RQs, which may differ for different radionuclides.

Radionuclide releases from the geosphere are directed to the well and small lake, and from the lake to a small terrestrial area (cropland) via runoff. The irrigation of vegetation with water from the lake and the well is also considered. Losses of radionuclides in the well and the lake are neglected and, therefore, the whole release reaches the terrestrial area, where radionuclides accumulate. The retention in the soil is maximised by using a high value of the distribution coefficient (Kd) in estimation of the sorption of radionuclides.

Each sub-model applies cautious assumptions regarding transport and retention. For example, the geometrical properties of the lake and cropland are selected to support exactly one person with food, and the mixing capacity of the well is cautiously selected. The parameter values are also, to as great extent as possible, cautiously selected (see Hjerpe & Broed 2010 for more details and justifications for the selected data). For example, the selected solid-liquid distribution coefficients (Kd) in soil and the concentration ratios from soil and water to biota are the 95th percentiles of internationally recommended distributions (IAEA 2009). In addition, geosphere release rate maxima are used. Tier 2 is applied over the same time window as Tier 1.

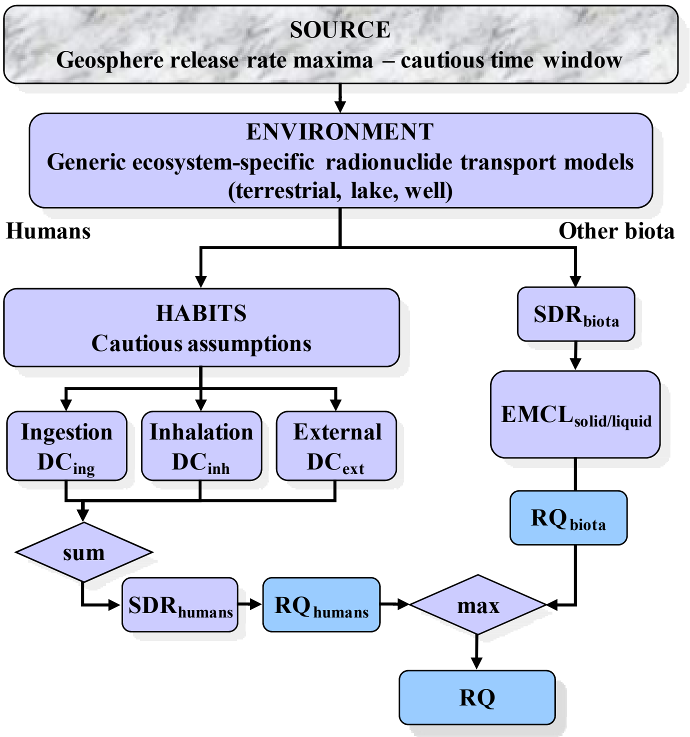

Fig. 2. Conceptual model of Tier 2 (DC_{ing}, DC_{inh} and DC_{ext} are the dose coefficients for ingestion, inhalation and external exposure, respectively).

Doses are calculated to a hypothetical individual that spends 100% of the time on the contaminated land and is exposed via inhalation and externally. It is assumed that the exposed individual obtains 100% of the ingested water and food from the contaminated environmental media. Moreover, it is assumed that all consumed food and water have the highest calculated activity concentration values.

Results

The screening models have been applied to the derived radionuclide release rates from the geosphere to the biosphere, results from *repository calculation cases*, to screen out the radionuclides considered to be insignificant for the biosphere assessment, from a radiological consequences point of view. The repository calculation cases considered in the screening evaluation mainly originating from the most recent assessment for a KBS-3V repository (Nykyri et al. 2008); but also a few cases are selected from the KBS-3H assessment (Smith et al. 2007) and the earlier assessment for a KBS-3V repository ("TILA-99" Vieno & Nordman 1999). All repository calculation cases addressed have their origin in the same type of repository scenario – assuming releases from a single canister with an initial penetrating defect at the time of emplacement. The full descriptions of the cases are presented in the above-mentioned references. The results from the screening evaluation are presented in Hjerpe et al. (2010) and summarised here, limited to the results from the repository base cases (cases Sh1, PD-BC and SH-sal50) and the cases with the highest derived annual effective doses in the landscape modelling (cases Sh4 Q and PD-EXPELL). This limited set of calculation cases also contains all individual RQ maxima for all cases considered in the dose assessment performed in the interim safety case, thus the outcome presented below is identical to the outcome that dose assessment.

The resulting RQs from the screening evaluation, for the five repository calculation cases considered here, with Tier 1 are presented in Table 1. At this tier, 11 radionuclides are screened out. The resulting RQs from the screening evaluation, for the five repository calculation cases considered here, with Tier 2 are presented in Table 2. At this tier, an additional number of 13 radionuclides are screened out. The reaming set of radionuclides to consider in Tier 3, and their RQ maxima from the Tier 2 evaluation, are summarised in Table 3.

Discussion

The radionuclide releases from the geosphere to the biosphere, in the repository calculation cases considered, contain 35 radionuclides, some also including progeny. At Tier 1, 11 of them are screened out and 13 more are screened out Tier 2, t. The set of remaining 11 radionuclides, and their progeny, is denoted the *key set of radionuclides* for the biosphere assessment performed for the interim safety case. It is only this set of radionuclides that are considered in Tier 3: the site-specific state-of-the-art radionuclide transport modelling and dose assessment.

It is notable that all actinides and all radionuclides in the naturally occurring decay chains are excluded from the key set of radionuclides (Table 3). However, the applied screening assessment is only valid for the time window where the dose constraints are assumed to apply and for the analysed scenario with a single defective canister. Hence, this does not mean that it is only these 11 radionuclides, and their progeny radionuclides, that are important for long-term safety. A similar screening evaluation carried out beyond the dose assessment time window, or for other scenarios, such as human intrusion, would most likely return another set of radionuclides; in this case, Ra-226 and Pa-231 would certainly be regarded as key radionuclides (see for example the rock shear cases in Nykyri et al. 2008).

Conclusions

This paper has presented the methodology for the three-tiered graded approach to dose assessment adapted in the Posiva safety case. Further, results from the successful implementation of the screening evaluation part (Tiers 1 and 2) of the graded approach in the interim safety case have been presented. The outcome shows that by applying a simple screening evaluation, a significant part of the radionuclides existing in the potential releases from the geosphere do not need to be assessed with more realistic, and more complex, biosphere models. Using simple screening models it can be shown with a high confidence that these radionuclides would have insignificant radiological consequences during the time window where the regulatory dose constraints are assumed to apply.

On a simple method for proving clearance conditions for radioactive waste

Toro, Laszlo[1]; Stafie, Adrian[2]
[1] Institute of Public Health Timisoara, MateFin Ltd. Bucharest, Radiation Hygiene Department, ROMANIA
[2] Cernavoda NPP, ROMANIA

Abstract

Radioactive waste is one of the main problems of nuclear power. Any unusable material (waste) occuring in a part of a nuclear power plant is considered radioactive waste. An important part of these wastes have very low radioactivity, it may be excluded from the system of the radioactive waste regulation. Exclusion of a material from the regulation of radioactive waste is based primarily on a series of measurements to demonstrate the radioactive elements in the material are under the exclusion limits set by law. This paper presents a methodology including a series of relatively simple measurements which prevents time and human resources consuming radiochemical separation procedures. The basic idea is the fact that it is not necessary to know the exact amount of radioactivity, it is sufficient to demonstrate it is under a certain value (clearance limit). It is not necessary a complete characterization of the waste to demonstrate it meets the criteria for unconditional release. In a CANDU type radioactive waste may occur difficult to measure alpha active elements as $^{234/235/238}U$, $^{238/239/240}Pu$ and ^{241}Am; beta active elements as ^{14}C, ^{63}Ni, ^{99}Tc, ^{90}Sr and ^{90}Y and easy to measure gamma emitting nuclides as ^{54}Mn, ^{60}Co, $^{95}Zr/^{95}Nb$, ^{106}Ru, ^{110m}Ag, ^{134}Cs, ^{137}Cs, ^{144}Ce, ^{152}Eu and ^{3}H (^{3}H is considered easy to measure, the LSC technique is quite easy to apply). Determining the gross alpha and beta activity, high resolution gamma spectrometry and LSC counting can reach a well-founded conclusion the material meets all conditions for the release from the radioactive waste regulation system. The method consists of 12 stages, the theoretical basis for each stage will be presented separately. It will present the conditions under which these measurements are made and the basic properties of the equipment (background, efficiency, detection limits, stability, etc.). We will insist particularly on the need of the long-term stability of the installations used for the measurements.

A comparative overview of waste management concepts for large components

Meissner, Frank; Bauerfeind, Matthias
TÜV NORD SysTec GmbH & Co. KG, GERMANY

Abstract
During the decommissioning of nuclear power plants large metallic components like steam generators or reactor pressure vessels are playing a relevant role. Depending of their radiological properties a disposal or a further use is possible. To fulfill the requirements of the intended products, different strategies are used. These strategies are following the basic conditions like the radiological or the site situation. A relevant aspect is the possible clearance of the waste material which can be achieved after decay storage where necessary. Based on these premises different strategies are resulting. Some of these strategies are already used in practice. For example, large components can be deconstructed on site with the objective of a final storage. Other strategies are pursuing the goal of the clearance of at least a part of the large components. This can typically be achieved by an after treatment of the fragmented or entire large components, eventually including decay storage. It is within the scope of this article to show up different strategies from a point of view of practical application of dismantling. The strategies will be compared concerning their relevant advantages and disadvantages like the legal situation or radiological protection.

Introduction
Large metal components play an important role in the deconstruction of nuclear power plants. Examples of large metal components include items like steam generators, reactor pressure vessels or pressurizes. Their treatment depends on several factors: the legal framework, the respective radiological situation, the installation situation and the necessity of their removal for the deconstruction planning. These factors are building a background for the decision which strategy for disposal will be used. There are several possible paths for the disposal of large metal components or their disassembled parts: e.g. disposal as radioactive waste or release. It is also possible to use combined strategies as we will show. Via the disposal path of release, metals can be returned into the circulation of secondary resources. On the basis of these framework conditions, there can be imagined several strategies for the disposal that have already been implemented. It is to be stated, however, that these strategies form approaches only. They must be checked as to their usability in each individual case. In part, these strategies can also be combined with one another in order to guarantee optimum disposal under the existing outline conditions. The TÜV NORD SysTec GmbH & Co.

KG was and continues to be involved in many ways in such activities and had gained substantial experience with the different strategies.

Strategies

Cut and Dispose

Under the "Cut and Dispose" disassembly strategy, the large component is disassembled in its installed position. Afterwards, the disassembled parts are subject to further treatment on site or externally according to their radiological situation. This results either in disposal as radiological waste or in release. By means of methods that are well proven in nuclear engineering, it is possible to produce packages suitable for interim or final storage.

Examples of this strategy are the disassembly of the steam generator of the nuclear power plant Gundremmingen A by means of ice-sawing or the currently running disassembly of the reactor pressure tank of the nuclear power plant of Stade.

It is the advantage of this strategy that the operating staff with its experience is available during the direct deconstruction process when the deconstruction is started shortly after operation. That way, the operating history of the components is well known. That experience can be used in the disassembly process. The infrastructure available at the plant, such as lifting gear, can also be used in the disassembly of the components.

The disadvantages include a possible higher collective dose because the facilities are narrow in many cases. An installation of additional shielding may be possible, but will require additional expenditure. Moreover, an increased effort for equipment is required for a remote-controlled dismantling when tailor-made solutions for the respective component are used.

Pack and Go

Under the "Pack and Go" disassembly strategy, the large component is transported to a disposal facility not situated at the location. The further disassembly and disposal of the large component will take place there.

Examples for this strategy are the steam generators of the nuclear power plants of Obrigheim and Stade. The steam generators from Obrigheim were transported to the interim store Zwischenlager Nord, the steam generators from the KKS were transported to the firm Studsvik Radwaste in Sweden (Fig. 1 and 2).

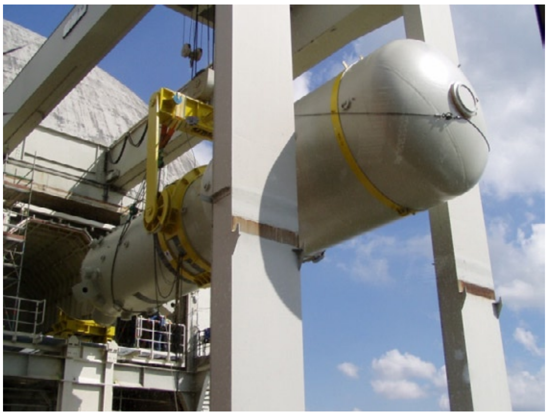

Fig. 1. Steam generator after passing material lock.

Fig. 2. Steam generator during loading on a ship.

It is the advantage of this disassembly strategy that the large components can be removed from the plant at an early stage. That creates space for further dismantling activities. Moreover, this strategy serves to accelerate the deconstruction on site.
It is the disadvantage that the large components need to be carried away in a non-disassembled condition. That requires the preparation of a transport path that allows for a smooth process free from disturbance. Moreover, the selection of the paths and means of transport depends on the possibilities of the plant to be deconstructed as well as of the receiving disposal facility.

For the internal handling of the non-disassembled large components, it must be guaranteed that the transport is possible. That refers for example to the spatial conditions or the lifting equipment available. In this concept it is beneficial that there exists worldwide substantial experience in the disassembly and transport of steam generators, as steam generators have been replaced in numerous operating nuclear power plants.

Pack and Wait

Under the "Pack and Wait" disassembly strategy, the large component is transported to an interim storage facility. There, it is disassembled after a sufficient decay period. The objective is the release of the residual materials to the largest possible degree.

Examples for this strategy are the reactor pressure tanks of the nuclear power plants of Rheinsberg and Greifswald as well as the steam generators from Greifswald (Fig. 3 and 4).

Fig. 3. Large components in the Zwischenlager Nord (ZLN).

Fig. 4. Removal of a steam generator in Greifswald (KGR).

It is the advantage of this strategy that the activity of the large components is reduced by their decay storage. That way, the collective dose for the disassembly staff is reduced. With the release, there can be achieved a higher degree of recycling. Moreover, transport on public traffic routes can be avoided when a local interim storage facility is available. The intermediately stored components are subject to the usual requirements on interim storage. The residual materials must be chemically inert and physically stable on a long-term basis.

It is the disadvantage that the interim storage facility with its infrastructure must be maintained during the decay storage for a period of several decays. That includes for example the lifting equipment, the fire protection and radiation protection installations. During the decay storage, work on the large components is not possible. In the course of the decay storage, there is to be feared a loss of knowledge with regard to the disassembly of large components from the sector of nuclear technology. Additional uncertainties result from legal aspects, e.g. in an unfavourable scenario, the release values might be changed during the decay storage, which might render the planned released more difficult.

The transports are subject to the same conditions that apply also to the "Pack and Wait" strategy. With an interim storage facility at the location, however, no difficulties of a transport on public traffic routes arise.

Pack and Dispose

Under this strategy, the components to be disposed of are directly stored at final disposal sites near the surface. For this method, a respective final disposal site must be available. This method is used in the USA for example.

The transports are subject to the same conditions that apply also to the "Pack and Go" strategy because the large component is transported in a non-disassembled condition.

Transport Paths

For the transport of non-disassembled large components, the internal transport paths as well as the public traffic routes must be taken into account.

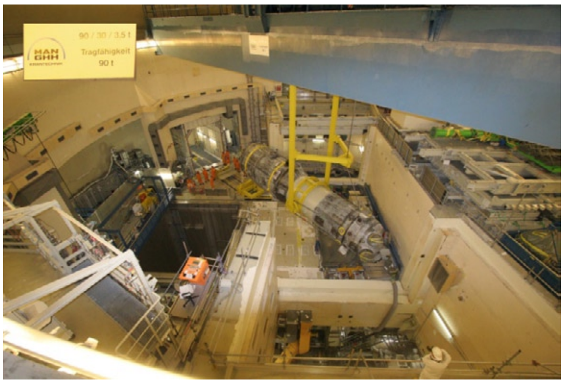

Fig. 5. Handling of a steam generator in the containment.

Fig. 6. Steam generator during loading.

The internal transports require a special consideration of the lifting equipment in many cases. As an example, the reactor-hall crane at a German nuclear power plant shall be mentioned. That crane is designed for operation according to the specifications of the German Nuclear Safety Standard KTA 3902 "Design of Lifting Equipment", Section 4.2 "Cranes, Jacks, Crane Trolleys and Load Lifting Devices with Additional Requirements". With that design, the crane is dimensioned for an operating load of 90 t. The steam generators, however, have a weight of about 180 t each. Nevertheless, it was possible to use the reactor-hall crane for these transports (Fig. 5). That was possible by examining the consequences of an assumed crash of the load. These considerations showed that the operation according to the design under KTA 3902, Section 3 "General Requirements" was possible with a mounting load of 180 t. Afterwards, the crane was recurrently checked and reclassified under KTA 3902 Section 4.2.

The transports on the state territory must meet the requirements of the legal regulations on the transport of radioactive goods. So the pipe connections of the steam generators of the nuclear power plant of Stade (KKS) were closed. The reactor pressure tanks of the nuclear power plants of Greifswald (KGR) and Rheinsberg (KRR) were enclosed in additional shielding for transport and storage.

Moreover, an optimal transport route must be selected. The requirements on the transport route result from the dimensions of the large component and from the possibilities on site. For example in Stade, it was possible to load the steam generators on a ship that took them to Sweden for further treatment (Fig. 2 and 6). The steam generators from Obrigheim (KWO) were transported by ship, too. The dimensions of the reactor pressure tank of the nuclear power plant of Rheinsberg (KRR) permitted a transport by rail. A transport by road would have been possible, too, in that case. But that possibility was rejected in favour of the technically more simple transportation by rail.

Capacities of TÜV NORD

TÜV NORD SysTec GmbH & Co. KG was and continues to be involved in many ways in a lot of such activities. As an example, we accompanied the disposal of the steam generators of the nuclear power plant of Stade from the preparation of the expert opinion up to the return transport of the radioactive waste from the disassembling facility and the release of the residual metallic materials.
Our activities comprise in particular the following fields:

- Radiological safety
- Decontamination / clearance measuring
- Evaluation of the suitability of the radioactive waste for interim storage
- Disposal of radioactive residues and waste
- Process strategy / disassembly engineering / remote-controlled dismantling
- Documentation audits

Conclusions

There are many approaches to the disposal of large components made of metal. Specific disposal strategies can be developed depending on the existing framework conditions. The framework conditions comprise for example the legal situation, the radiological situation, the spatial conditions and the planned ways of disposal. On the basis of these framework conditions, the strategies must be checked as to their applicability. All of the above mentioned strategies had been or are actually realised during the decommissioning of large metallic components according to technical feasibility or legal requirements.

Recovery from old intermediate level liquor spillage in redundant magnox waste Silo

Brown, Andrew; Doyle, Ken
Sellafield Limited, EHS&Q, UNITED KINGDOM

Abstract

A Silo at Sellafield has been used to store historic intermediate level waste from irradiated magnox fuel decanning operations undertaken from 1964 until 1991. This material is stored under water in 22 separate compartments.

In 1999, there was an event on one compartment that resulted in a liquor spill on the main silo operations floor with contact dose rates estimated at approximately 2 Sv/h in contact and general waist height dose rates of tens of mSv/h.

Retrieval of the contents from all of the Silo compartments in the building is one on the UK's most important nuclear risk reduction activities. In order to do this, it has been necessary to decontaminate and shield the affected area as far as reasonably practicable so that Silo emptying equipment can be deployed.

Detailed evaluation of the spillage was performed over the course of several years, until equipment was identified capable of removing an acceptable layer of the silo operations floor while maintaining its structural strength. Deployment of this equipment will be covered along with the ALARP processes used to identify an acceptable level of shielding for the floor area, taking account of expected future operations.

The presentation will describe the significant radiation and contamination challenges and the ALARP techniques undertaken during the course of the work. Photographs and radiological images will be used to illustrate how the project progressed through the phases of work, include a summary of the immediate follow up to the event.

A summary of the lessons learnt through this project will be presented. This will review the capability of dose prediction, suitability of the contamination control arrangements and utilisation of "radscan" imagery in an operational environment.

Efficient and environmentally sound management of radioactive waste streams from maintenance, upgrade and decommissioning

Stenmark, Anders
Studsvik Nuclear AB, SWEDEN

Abstract

Power generation of today struggle with many challenges and as the effects of global warming become obvious many countries seek alternatives to fossil fuel. The increasing interest in nuclear technology is based on its many advantages but the technology also offers challenges in how to cope with prolonged lifetime support and sustainable waste routes.

Studsvik have been processing Low Level Waste (LLW) at its licensed facility in Studsvik, Sweden since the mid-1970s. The facility has historically processed metallic and combustible waste and can today demonstrate a well defined, cost effective and robust waste volume reduction route for both the Swedish and the international nuclear industry.

Introduction

Significant volumes of Low Level Waste are today generated by the nuclear industry. Some waste has well defined routes for disposal using economically and technically efficient solutions. Other waste is temporarily stored on power plant sites waiting to be conditioned before final storage at dedicated repositories. The reasons for intermediate storage of waste may be several, such as radiological or physical complexity, and therefore on site conditioning for final repository may be technically challenging or time consuming and as such expensive.

Various technical options are available in the industry where one suitable route for waste includes external treatment by specialists. This helps the industry to minimize the cost for volume reduction and conditioning of waste before final repository. One such route includes Studsvik Nuclear AB in Sweden. With more than 60 years of experience in the nuclear industry in Sweden, Studsvik has since the 1970's treated combustible LLW and since the 1980's treated metallic LLW for the national and the international market. Today Studsvik is a leading specialist on waste volume reduction of Low Level Waste.

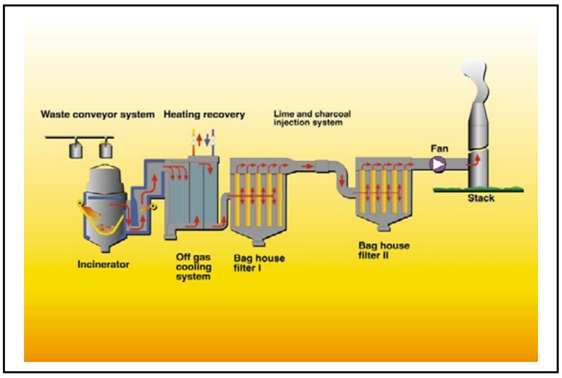
Waste treatment is also logistics and transportation. Studsvik has over the years developed a good understanding of the complexity in national and international transportation of radioactive waste. Such transports always require close cooperation with the customer as well as with regulatory authorities in both Sweden and the country of origin for non-Swedish waste.

Waste categories and methods

Studsvik focuses on treating two typical waste streams generated by the industry: low level combustible waste suitable for incineration and low level contaminated metallic scrap.

Combustibles are treated in a high temperature incinerator for maximum destruction, resulting in minimized volume and a very stable residue suitable for final repository.

Typical combustible waste is protective clothing, wood, paper, plastics, etc. According to Studsvik acceptance criteria waste is typically pre-packed by the owner into transparent plastic bags, < 25 kg to allow manual handling, sorting and inspection. This waste is typically shipped in 20-foot IP-2 containers and is well characterized for physical properties as well as radiological content (maximum dose rate and nuclide inventory).



Schematic overview of incinerator

Typical combustible waste

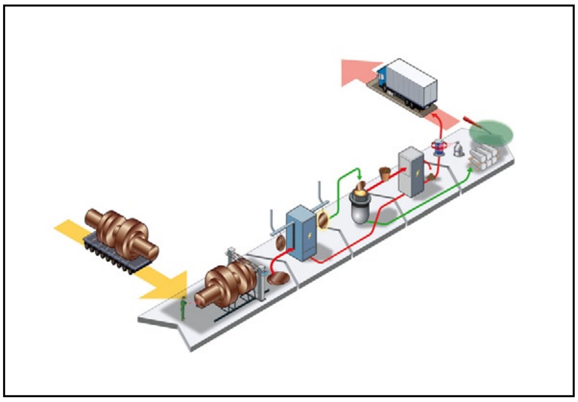
Treating combustible waste typically consists of:

- Arrival inspection and verification of transport documentation, including radiological data
- Safety inspection of all waste and an assessment of the scope of work required
- Loading waste on the conveyor system into the incinerator
- Collection of residues resulting from the treatment, ashes and fly-ash as secondary waste
- The secondary waste, including radioactive contamination, is analysed to verify that the activity content matches the original declaration by the customer to ensure all is returned back to its rightful owner
- All residual secondary waste is conditioned and shipped back with a detailed production report declaring the result of the processing

After processing the waste the remaining ash and the fly-ash accumulated in the bag house filters is collected in drums. This secondary waste is conditioned according to customer specifications and is returned to the owner together with a detailed production report.

Environmental aspects is an important part of Studsvik operations and off gas filtering is enhanced by using lime and activated char coal to minimize emissions. To further reduce the environmental impact, Studsvik is recovering energy (~1,5MW) by reusing it within the site to heat facilities.

Metal scrap is comprised of a wide variety of components such as pumps, pipes, duct work and other small waste fitting into a container. Studsvik is also capable of processing large components. This includes heat exchangers and turbine components such as housing and turbine axel, with a typical weight of 150 - 250 tonnes. Large PWR steam generators, weighing 300 tonnes or more, are successfully treated on a regular basis.



Schematic process flow for metal scrap

Typical metal scrap recycled by Studsvik consists of carbon steel, iron alloys, aluminium, lead, copper, brass, etc. Waste is delivered in transport packages such as 20-foot IP-2 containers and large components are transported under alternative arrangements according to international regulations. The acceptance criteria are well defined for physical properties as well as radiological content (maximum dose rate and nuclide inventory).

The treatment of metal waste is shown in the schematic illustration above and can be described as follows:

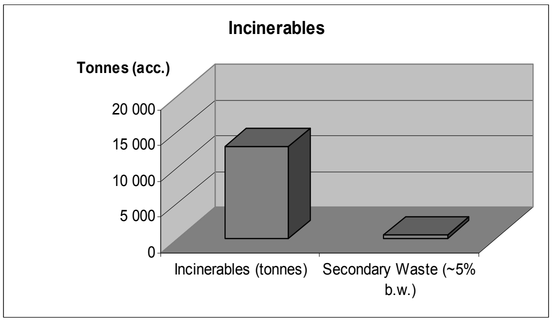
- Arrival inspection and verification of transport documentation including radiological data
- Safety inspection of all scrap and an assessment of the scope of work required
- Segmentation as needed to suitable size and weight
- Surface contamination removed by shot blasting and collected in customer isolated campaigns
- Decontaminated scrap metal is melted into ingots and analytically sampled to verify successful processing

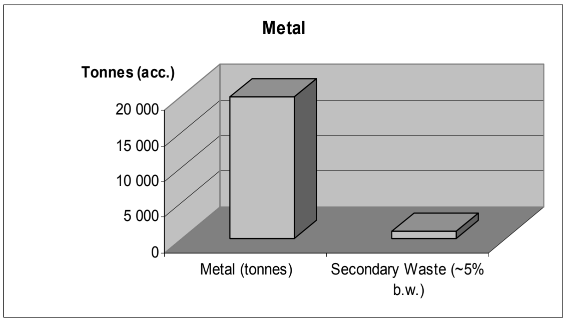
- To ensure all is returned back to its rightful owner the residual secondary process waste is analysed to verify that the activity content matches the original declaration by customer
- All residual secondary waste is conditioned and shipped back with a detailed production report declaring the result of the processing
- Metal ingots analytically verified to be in compliance with free release regulation is declared exempt by Studsvik, recycled as valuable raw material and routed back into the metal industry through internationally accepted procedures

Typical scrap metal processed at Studsvik, Sweden (Misc. scraps at left, Turbine at right)

Results

Studsvik has in total treated an excess of 10’000 tonnes of combustible material and 20’000 tonnes of metal at its site in Sweden. Today the annual processing rate is approximately 500 tonnes of combustibles and 3500 tonnes of metal with a very high rate of volume reduction, shown below in the two graphs as the average over the historical production. Specific details depend on waste character and may vary.





The resulting secondary waste is prepared according to customer specifications before it is returned. The conditioning typically includes packaging in a 200 litre drums and returning the drum back to the owner where the package undergoes final preparations before storage in a repository in the country of origin. Other forms of packaging may be required on the international market and can be arranged after individual agreement.

All final packages are analyzed and labelled, the results of which is reported in the final production report. After a completed campaign all secondary waste is returned to customer in country of origin to ensure volume reduced waste (containing the radioactive inventory) is brought back to its rightful owner for final storage.

Gamma-scanning

Exempt metal for recycling

Metal samples from each melting batch is analyzed to document data and to allow recycling as exempt metal. Metal ingots meeting exempt levels will be recycled after transfer of ownership from customer to Studsvik.

Transportation

Transport of radioactive waste is well regulated at the international level. In order to safely and compliantly transport waste for treatment a variety of regulations must be understood and applied. Studsvik has many years of experience in this field and has a detailed understanding of the regulations for land (ADR - Accord européen relatif au transport international des marchandises Dangereuses par Route), sea (IMO – International Maritime Organization) and air (Dangerous Goods Regulations) transport. Radioactive waste is, however, not transported by air freight due to several reasons, the main one being cost.

To perform a shipment of radioactive waste not only the relevant transport regulation must be complied to fulfil safety concerns but also a special transport authorization must be granted. This authorization must be given according to directive Euratom 2006/117 and approved by the competent authority in both countries. The approval operates on a system of prior notification and approval where-by the applicant (consignee) must apply to the competent authority in the country of export for consent to ship the waste internationally. They in turn seek approval from the competent authority in the country of import (and any countries transited across) prior to approving, or otherwise, the shipment. The Euratom 2006/117 system also enables the competent authorities to place conditions on the shipment such as a requirement to return the secondary waste (ash, dust, slag, etc.) to the country of origin, or to give advance notice of when the consignment will ship.

Studsvik regularly performs, in close cooperation with customers, their competent authorities, and Swedish authorities, many international transports from, and back to, countries within EU as well as other international countries. A mandatory condition in all cases is that any individual campaign must in normal cases be concluded within 24 months and all generated secondary waste (any and all waste not possible to classify as exempt and free releasable) must be returned to country of origin.

Conclusions

As nuclear power generation experiences a revival many questions on waste treatment must be answered. Prolonged lifetime and worldwide discussions of new power plant constructions highlights the obvious demand of modern, effective and safe waste treatment. Cost for storage at repositories is often volume driven and as such large savings can be obtained by volume reduction before disposal, which enables economically feasible management of waste. The process not only ensures that the volume of waste is significantly reduced but also produces a stable residue suitable for final disposal in a highly cost effective manner. This route offers clear benefits with reduced demand of required space in final repository with prolonged life time at reduced over all cost.

Effective waste treatment is also about a responsible engagement in environmental aspects. Recycling of valuable raw material and energy helps to further reduce the carbon footprint from the energy industry. By using the heat generated during incineration of combustible waste as energy (~1,5MW) to heat on site facilities the carbon foot print is dramatically reduced by replacing fossil fuel energy sources. Metal meeting exempt criteria will be circulated back into the metal industry as a valuable raw material. Reusing high quality metal saves on the environmental impact from our industry and uses limited natural sources efficiently.

Determination and quantification of NORM radionuclides

Clerckx, Tim; Pellens, Veerle; Hulshagen, Leen; Vandervelpen, Chris; Schroeyers, Wouter; Schreurs, Sonja

Abstract
This paper discusses methodologies which can be used to identify naturally occurring radionuclides in substances using automatic spectrum analysis. The possibility to use automatic spectrum analysis in order to obtain an estimation of the activity concentration of the detected radionuclides is examined. The goal is to determine whether or not the activity concentration of a measured substance meets the regulation defined in the new upcoming European Basic Safety Standards with respect to naturally occurring radioactive materials (NORM). Existing techniques which are primarily used in lab settings are applied in industrial settings and tested. These techniques include artificial neural networks and automated spectrum analysis. The methodology is assessed and a comparison is made between NaI(Tl) and LaBr(Ce) based multi-channel analysers. The methodology is applied to several NORM materials with distinct activity concentrations: zirconium, ilmenite, bauxite, and fluorspar. In this way a methodology is constructed which can be applied in situ to allow determination and quantification of naturally occurring radionuclides.

Introduction
Radionuclides of the natural radioactive series of uranium and thorium are present everywhere in the earth crust. Concentration of these nuclides is depending on the composition of the soil. Besides uranium and thorium nuclides, an amount of potassium-40 is also present. All these nuclides produce radiation doses to all human beings. In addition, industrial processes can lead to an accumulation of naturally occurring radioactive materials (NORM) due to operations in end-, by- or waste-products. The concentration of nuclides can be accumulated in such a way that radiation protection is necessary.

A uniform approach towards NORM by all European member states is a primary goal. The European Commission is therefore currently recasting Council Directives with respect to natural radiation sources (European Commission 2010). One of the new elements is the construction of a positive list of industrial activities in the non-nuclear sector that may be subject to notification. As already described in UNSCEAR 2000 and ICRP Publication 75 the acceptable dose rate threshold can be aligned with the activity concentration of materials. As a result the activity concentration will be used to determine whether regulatory authorities need a prior authorisation.

This means it is important to have a technique to determine the activity concentration of NORM. Since the activity concentration has to be measured in all the products, by-products and residues in an industrial process, a fast and usable methodology is mandatory. Nowadays the activity concentration is generally being measured by sample analysis which is a cumbersome, time and money consuming job.

In this work the objective is to construct a tool that can automatically decide in an industrial setting whether a measured substance complies with the new European Directive's activity concentration limits. This has to occur in known geometries by using a relatively cheap NaI(Tl) probe-based multichannel analyzer (MCA) connected to a tablet-PC. Custom software on the tablet steers the MCA to capture a spectrum and to interpret the spectrum straightaway. Based on the spectrum, the weight of the substance and its density, an estimation of the activity concentration is made and presented to the user.

To assess the technique proposed we captured several spectra of distinct NORM materials in a known geometry of a NORM handling company. The company stores and handles sugars, fertilizers, chemicals, minerals, iron, steel and wood products. The handling comprises bagging, repacking, sieving, sifting, weighing, mixing and conditioned storage in contamination-free warehouses. The accuracy of the tool was assessed by comparing the results with the results of an accepted method based on sample analysis.

In this work we focus on tool support. The objective is to construct a tool that can automatically decide in an industrial setting whether a measured substance complies with the new European Directive's activity concentration limits.

Tool support for determination and quantification of NORM radionuclides in industrial settings

An important goal of our current research project is to make an inventory of the issues of NORM in a NORM handling company in collaboration with the Federal Agency of Nuclear Control.

The measurement tool was designed in such a way that at the end of the project the employees of the industry can use it independently. Therefore it has to be user-friendly and applicable in distinct industrial circumstances. Software is constructed that can be easily adapted according to the environmental context: several distinct geometries are present so that the end user can select the geometry that is applicable to the current context-of-use. For example: when the substance is contained in a shipping container, this geometry can be selected and subsequently parameters with respect to a shipping container (dimensions, probe location, container wall properties etc.) can be filled out by the user. On the other hand when the substance is contained in a bigbag (common used bag in industry containing dry bulk substances) this can be selected by the user and geometry properties can be filled out by the user accordingly (diameter, circumference, etc.).

As big bags were the most common geometry in this company, the tool was at first adjusted for this model (Fig. 1). Big bags contain dry bulk substances with a mass typically between 1 and 2 ton. Activity concentrations of nuclides in big bags were determined on the side but also on the top of the bag. The measurements on the top correspond the most to the sample analysis.

In practice, the bags were placed outside the warehouse to avoid interference with radiation caused by other bags. Geometry of the bag was determined (height, net mass, perimeter, volume). Two probes (NaI(Tl) and LaBr(Ce)) were set on the top and in contact with the bags and were connected with the spectrometer and software. Measurements were repeated 10 times for 15 minutes in order to control the reproducibility of measurements. A spectrum was automatically generated and analysed.

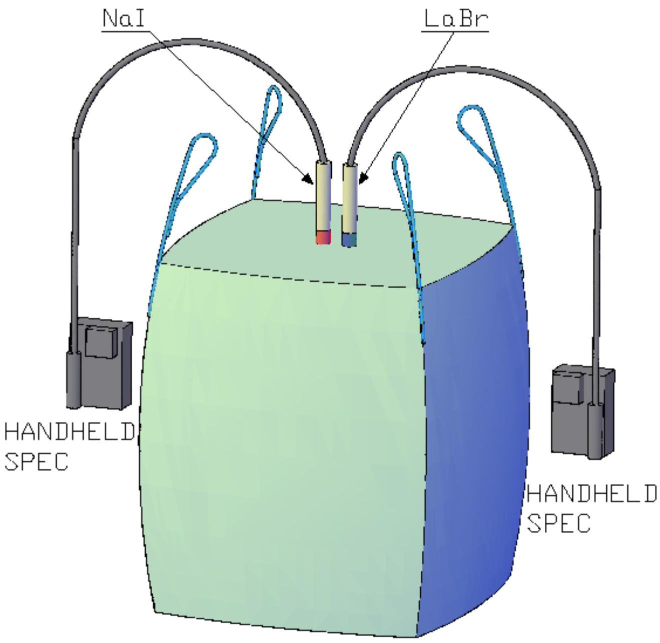

Fig. 1. A bigbag with two multi-channel analysers (NaI(Tl) and LaBr(Ce)) recording a spectrum of a known substance.

In the following sections two techniques are discussed which can be applied to identify NORM radionuclides by using Artificial Neural Networks and to quantify the activity concentration of NORM radionuclides by applying energy calibration by modelling the measured container. Both techniques make use of automated spectrum analysis of the spectra recorded in the industrial setting of the NORM handling company. The accuracy of the tool was checked by comparison of the analyses with sample analysis.

Determination of nuclides with Artificial Neural Networks (ANN)

This section elaborates on a technique to classify NORM radionuclides using artificial neural networks. The following section will discuss a technique to estimate the activity concentration.

Artificial Neural Networks for gamma-ray spectrum analysis

Artificial Neural Networks ANN simulate biological neural networks in a computational model that can be implemented in a software system. ANN already have a long history of applications in physics and chemistry in general and in nuclear science in particular with proven successful results on spectrum analysis (Long 1997) (Keller et al. 1994) (Yoshida et al. 2002) (Saritha et al. 2009). A key characteristic of ANN is the excellent performance on coping with data containing noise. Milford identified the generalization ability of ANN as the reason for this performance when increasing amounts of Gaussian noise were added to spectra (Milford 2002). Saritha et al. And Keller et al. compared a neural network to an Optimal Linear Associative Memory (OLAM) for the classification of linearly separable data (Saritha et al. 2009) and (Keller et al. 1994). While OLAM was superior to a neural network when Monte Carlo generated spectra were used, the ANN was again found to be the best solution for noisy data.

Practical Approach

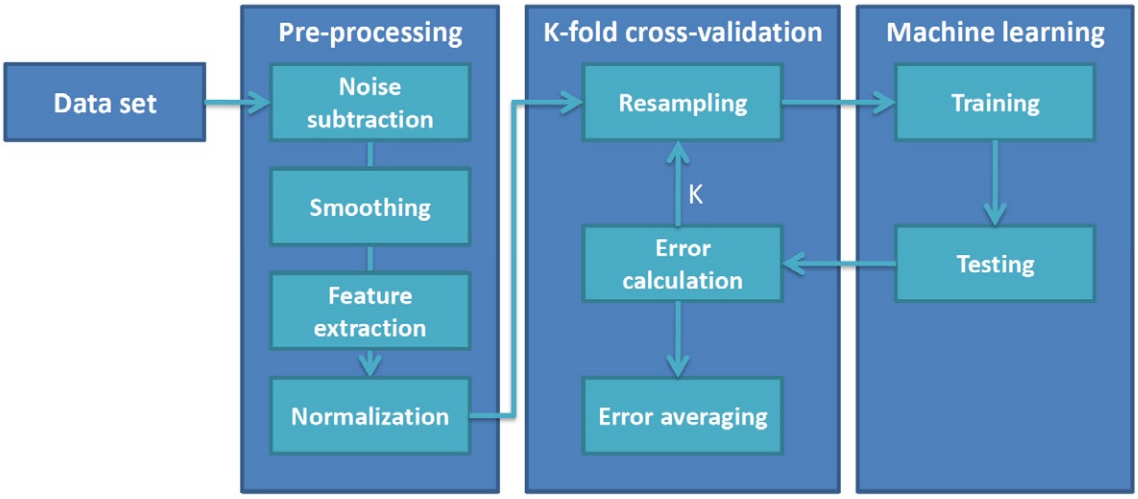

Fig. 2. Schematic overview of the machine learning sequence.

Figure 2 presents a schematic overview of the machine learning sequence of the ANN that has been implemented. The input data set is a collection of raw spectra obtained by the measurements in the industrial case study. The machine learning sequence consists of three steps: pre-processing, cross-validation, and machine learning.

Before the spectral data can be fed to the ANN a pre-processing step is applied to extract the most relevant data from the spectrum. Although this is strictly not necessary since the ANN can learn which data are irrelevant. Feeding 512 to 4096 channels used by an MCA to the ANN would be inefficient and decrease the training speed. Using trial and error the following pre-processing techniques generated the best results on the spectra recorded in the industrial case study: noise subtraction, running-average smoothing, peak-extraction based on Milford, and normalization (Milford 2002). The peak extraction algorithm investigates a specific number of channels surrounding a point to determine whether the point is a local maximum and thus a peak. This reduces the complexity of the input layer.

Figure 3 presents the implemented ANN. The ANN is a fully interconnected feed-forward network with one hidden layer. Back-propagation learning is used to train the ANN. Because of the pre-processing step, the number of input neurons is reduced to twelve, i.e. the respective position and height of six key peaks that can identify the presence of a radionuclide in the spectrum. The number of neurons in the hidden layer has to be chosen carefully in order to find a balance between the model's complexity and the generalization capacity of the ANN.

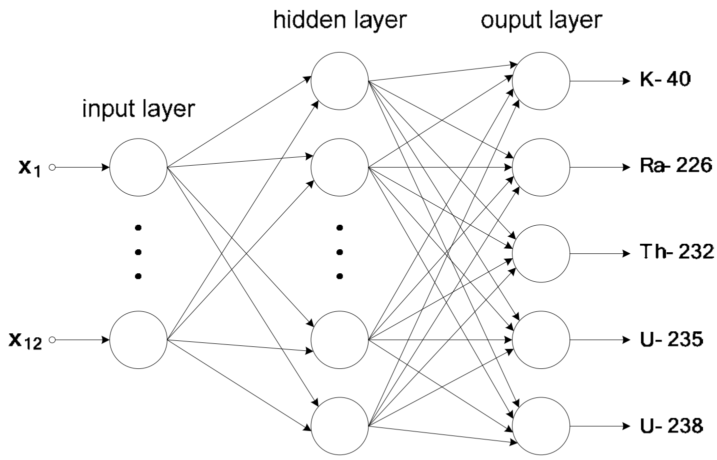

Fig. 3. Model of the implemented ANN.

To validate the ANN k-fold cross-validation was applied with k=10. This means the input data set was divided in ten equal collections of spectra from which nine are used to train the ANN and the remaining one is used for validation. Afterwards the error is calculated and the input data set is resampled for another run. This is repeated until the cross-validation error < 1%.

Results

The gamma spectra are recorded using a NaI(Tl) and LaBr(Ce) detector in the industrial environment. A training set of eighty spectral samples was used that represented all detectable isotopes (K-40, Ra-226, Th-232, U-235, and U-238) in equal numbers. The k-fold cross-validation was applied to exploit the reasonably small data set of eighty samples. A series of ten repeated 10-fold cross-validations were used to verify the performance of the ANN.

In order to optimize the performance of the network, the following parameters were isolated and compared by their accuracy, mean-squared error (MSE) and mean-absolute error (MAE):

- Momentum: scaling factor to specify to what degree the weights of the neurons change from the previous step of the learning algorithm. The momentum appeared to be acceptable with respect to the accuracy and the MSE between 0.1 and 0.3.
- Hidden-layer size: the MSE and MAE both reach a minimum when the hidden layer consists of four neurons.

Furthermore the learning rate and the number of epochs (iterations of an entire training set) were taken into account.

The results showed that the ANN classified the spectra with an accuracy of 85% on average which corresponds to an error rate of 15%. This large error was due to the problems that the ANN had with the classification of U-238. The best performance of the ANN on U-238 was 87%. The other isotopes (K-40, Ra-226, Th-232, and U-235) were classified with an accuracy of 100%.

Quantification of NORM radionuclides

In earlier work we discussed how the activity concentration of NORM radionuclides was quantified using a NaI(Tl)-based multi-channel analyser (MCA) using spectrum analyses on spectra captured in an industrial setting (Pellens et al. 2010). In this section we will compare results of spectrum analysis captured by an MCA equipped with a NaI(Tl) probe with spectra from the same substances captured in the same environmental circumstances but with an MCA equipped with a LaBr(Ce) probe. Furthermore the technique is assessed by comparing these results to the results of sample analysis performed by a certified institution.

Practical approach

The approach consists of automated spectrum analyses performed by customized software. Four substances known as NORM were measured in bigbags containing between 1000 kg and 2000 kg. The software was adapted to cope with spectra recorded by either NaI(Tl) and LaBr(Ce) probes. The final output of the software was an estimation of the activity concentration of NORM-radionuclides present in the measured substance. Measurements taken with NaI(Tl) and LaBr(Ce) are compared to results from sample analyses taken from the respective bigbags. The analyses on 250 g samples were performed by a certified lab. In the next section this comparison will be discussed.

The automated spectrum analysis was applied to ten spectra recorded on each substance. The same automated analysis algorithm was applied to the distinct substances.

Up to now, four distinct substances were considered: zirconium, ilmenite, bauxite, and fluorspar. The substances were chosen in a way that there was a variety in the respective activity concentration of the radionuclides present.

Results

The results are presented in three tables. Each table presents the results of one NORM radionuclide by comparing the automated spectrum analysis of spectra recorded with the two types of probes (Na(Tl) and LaBr(Ce)), the sample analysis by the certified lab and the recommendation as described in the reviewed basic safety standards by the European Commission. The results are presented for each of the four substances considered in this research.

Table 1. Comparison of spectral analysis results of 900s measurements using a NaI(Tl) and LaBr(Ce) probe with results of a certified lab for the Th-232 radionuclide.

Substance	NaI(Tl)		LaBr(Ce)		Certified lab SA	EC BSS
	Act Conc ($Bq·g^{-1}$)	Rel. Error (%)	Act Conc ($Bq·g^{-1}$)	Rel. Error (%)	Act Conc ($Bq·g^{-1}$)	
Zirconium	0.53	6	0.52	5	0.50	
Ilmenite	0.28	-16	0.36	6	0.34	
Bauxite	0.29	-2	0.33	12	0.30	
Fluorspar	<MDA = 0.03		0.08		<MDA = 0.02	

Table 1 presents the results of the Th-232 radionuclide. The sample analysis shows that the performance of the automated sample analysis of the zirconium spectra are nearly the same for the two different probes. There is an overestimation of 5% to 6% in comparison to the certified sample analysis. The activity concentration of Th-232 in ilmenite is performed way better with the LaBr(Ce) probe (6% overestimation) in comparison to the NaI(Tl) (underestimation of 16%). The automated analysis of bauxite presents a different picture: the analysis of the NaI(Tl) probe delivers a better result. Finally the activity concentration of fluorspar does not exceed the minimum detectable activity (MDA) for the NaI(Tl) analysis and the sample analysis. We can conclude that the automated spectrum analysis for the LaBr(Ce) probe delivers an overestimation of the activity concentration of Th-232 in comparison to the NaI(Tl) and sample analysis results. This introduces a more safe result than the NaI(Tl) which may deliver an underestimation. The last column of the table compares the results with the revised basic safety standards. None of the substances exceeds the limit of 1 $Bq·g^{-1}$ for the Th-232 series.

Table 2. Comparison of spectral analysis results of 900s measurements using a NaI(Tl) and LaBr(Ce) probe with results of a certified lab for the U-238 radionuclide.

Substance	NaI(Tl)		LaBr(Ce)		Certified lab SA	EC BSS
	Act Conc ($Bq·g^{-1}$)	Rel. Error (%)	Act Conc ($Bq·g^{-1}$)	Rel. Error (%)	Act Conc ($Bq·g^{-1}$)	
Zirconium	1.79	-8	2.13	9	1.94	
Ilmenite	0.09		<MDA = 0.053		<MDA = 0.31	
Bauxite	<MDA = 0.05		0.25		<MDA = 0.58	
Fluorspar	0.08		0.19		<MDA = 0.40	

Table 2 summarizes the results of the same analyses for the U-238 radionuclide. According to the sample analysis results of the certified lab, only zirconium exceeds the minimum detectable activity. The activity concentration delivered by the automated spectrum analysis of the NaI(Tl) and LaBr(Ce) spectra are comparable: an underestimation of 8% is produced by the NaI(Tl) and an overestimation of 9% by the LaBr(Ce). The activity concentration exceeds the limit of 1 $Bq·g^{-1}$ for the U-238 series.

Table 3. Comparison of spectral analysis results of 900s measurements using a NaI(Tl) and LaBr(Ce) probe with results of a certified lab for the Ra-226 radionuclide.

Substance	NaI(Tl)		LaBr(Ce)		Certified lab SA	EC BSS
	Act Conc ($Bq \cdot g^{-1}$)	Rel. Error (%)	Act Conc ($Bq \cdot g^{-1}$)	Rel. Error (%)	Act Conc ($Bq \cdot g^{-1}$)	
Zirconium	1.8	-15	2.1	-2	2.14	
Ilmenite	<MDA = 0.04		<MDA = 0.053		0.04	
Bauxite	0.27	-8	0.27	-9	0.30	
Fluorspar	0.11	-37	0.19	7	0.18	

Finally table 3 presents the results of the analysis of the Ra-226 radionuclide. For the substances zirconium and fluorspar the LaBr(Ce) outperforms the NaI(Tl): a respective underestimation of 2% and overestimation of 7% versus an underestimation of 15% and 37% for the Ra-226 activity concentration. The results of the spectrum analysis for bauxite are comparable. Again, the only exceeding activity concentration in comparison to the basic safety standards requirements is detected for zirconium.

Discussion

Looking at the results presented in the previous section, a conclusion can be made that the LaBr(Ce) performs better than the NaI(Tl) when automated spectrum analysis is applied en builds assurance because the error is mostly an overestimation. The results are significantly better when Ra-226 has to be quantified. The comparison of the performance on U-238 is about the same, but only zirconium exceeded the minimum detectable activity. The results of the Th-232 analyses show distinct performances in comparison to the certified sample analysis.

An important issue in the automated spectral analysis seemed to be the detection and quantification of U-238. The certified method using sample analysis could not deliver a justifiable quantification of the activity concentration for three of the four substances. The automated spectral analysis method delivered an estimation of the activity concentration below the minimum detectable activity of the certified lab. Using the automated spectrum analysis the proposed method is able to quantify the activity concentration accurately enough to determine whether the activity concentration is below or above the threshold used in the new European basic safety standards. Further research is required to narrow down the limitations of this methodology to determine when a more accurate analysis is necessary, i.e. when the activity concentration approximates the basic safety standards' limits.

Conclusions

Automated spectrum analysis was applied on spectra recorded in an industrial setting. The main objective was to study whether automated spectrum analysis can be used in providing a fast tool to check the applicability of the new European basic safety standards with respect to NORM material. A methodology has been constructed consisting of a tablet-PC running a software that steers a measurement and interprets the spectrum accordingly to approximate the activity concentration of the measured substance.

Both machine learning techniques and traditional automated spectrum analysis were studied in order to determine and quantify NORM radionuclides. Spectra were recorded with two different probes (NaI(Tl) and LaBr(Ce)). Results showed a better performance of the analyses with a LaBr(Ce) probe. In this paper, we showed one can use an ANN to determine the presence of K-40, Ra-226, Th-232 and U-235 with an accuracy of 100% while the determination of the presence of U-238 is 87%. It is in our intention to use these figures to optimize the quantification algorithms used in the automatic spectral analysis.

Results of analyses of four investigated NORM materials were compared with the Council Directives (whether the measured values were in the safe zone, around the threshold, or above the threshold). The four substances which were the subject of this study were accurately classified according to the basic safety standards taking the relative error into account.

Further optimization of the tool will be an important objective of this project. The tool will be able to tell in a very short period if a company needs notification according to the new European basic safety standards.

Abstract

According to the council Directive 96/29 Euratom, handling or storage NORM or TENORM has to be considered from the radiological protection point of view. This directive has been implemented in French regulations by, in particular, the Ministerial order of May 25, 2005 related to activities operating NORM not used because of their radioactive properties. It imposes radiological characterization of any materials and assessments of the effective dose received by workers to be done. Since the publication of this text, ASN and IRSN have already received ninety studies which provide information about activities of materials and occupational exposure of nine different types of industrial facilities. These data show that activity concentrations strongly vary according to the type of material and industrial activity. Waste generally contain the highest activity concentration of natural radionuclides. Activities in raw materials and products sometimes exceed the exemption level recommended by IAEA for the use of NORM. Activity of ^{226}Ra and its daughters in waste or activity of ^{210}Pb and its daughters in ashes and dust related to heating processes are sometimes greater than the activities of the other radionuclides of ^{238}U series. Concerning occupational exposure, doses reported by operators range from less than 1 μSv.yr^{-1} to 82 mSv.yr^{-1}. Based on the French feedback, the following conclusions can be drawn. Assessments are still expected for some industries. About 10% of calculated doses are greater than the effective dose limit of 1 mSv.yr^{-1} for the public and need further examination. The highest doses correspond to the production of compounds with thorium. External and internal exposures are often of the same order of magnitude. Some types of industrial facilities currently not concerned by the French ministerial order, e.g. paper mills, are concerned by NORM and TENORM issue.

Introduction

Some industrial activities such as ceramic production or coal combustion in thermal power stations involve the use of materials, usually regarded as non-radioactive, but containing naturally occurring radionuclides (NORM). Handling or storage of these materials can lead to a significant increase of occupational exposure. According to the council Directive 96/29 Euratom (Council Directive, 1996), this matter has to be considered from the radiation protection point of view. French authorities implemented this directive to the French health and labour codes detailed in the Ministerial order of May 25, 2005 (Ministerial order, 2005). It sets out a list of ten types of industrial activities concerned by NORM and operators have to assess the effective doses received by workers on the bases of a radiological characterization of raw materials, by-products and waste involved in or produced by the technological processes. ASN asked IRSN to evaluate the methods adopted by some operators for assessing these doses and to draw the first conclusions in terms of radiological protection. Based on data presented by operators in the ninety studies received so far, a summary of the results of these studies in terms of activity concentrations and occupational exposure are presented hereafter.

Material and methods

Since the publication of the Ministerial order of May 25, 2005 (Ministerial order, 2005), ASN and IRSN have already received ninety studies which provide activities of materials and doses calculated for nine types of industrial activities (cf. table I). The majority of the studies deals with occupational exposure and about 91% of them report on effective doses received by workers.

Table 1. Breakdown of studies by different types of industrial activities.

Industrial activities sets by the French ministerial order of May 25, 2005	Part (%)
Production of refractory ceramics and smelting, metallurgy and glass industry using them	49%
Coal combustion in power plants	16%
Production of zircon and baddeleyite, and smelting or metallurgy plants using it	15%
Treatment of tin, aluminium, copper, titanium, niobium, bismuth and thorium ores	7%
Production of phosphated fertilizers and phosphoric acid	6%
Production or use of compounds with thorium	3%
Treatment of lanthanides series and production of pigments containing them	2%
Spas	1%
Underground water treatment by filtration	1%
Treatment of titanium dioxide	0%

Among the ninety studies, 43 present activity concentration measurements mainly carried out by gamma spectrometry for about 500 different samples. It represents more than 4200 results of measurements. Radionuclides of ^{238}U, ^{232}Th and ^{235}U series and ^{40}K represent respectively 47%, 29%, 15% and 9% of measurements and 69% of the measurements for ^{238}U series or ^{232}Th series are above the detection limit (LD), 32% for ^{235}U series and 59% for ^{40}K.

Uranium and thorium series activity concentrations

Measurements taken into account

Activity concentrations mainly measured by gamma spectrometry were analysed by IRSN. Uranium and thorium series have been divided into groups of radionuclides as recommended by the European Commission (Chen *et al*, 2003). For each chain segment, an activity was determined by the method whose principle is described hereafter (Maigret *et al*, 2008). For a given sample, if only one radionuclide activity of a group is measured, its activity stands for the group. If several radionuclide activities are measured and their measurements are consistent, the average of more reliable activities stands for the group. For example, regarding the chain segment of $^{226}Ra^{+}$[1], deconvolution of the ^{226}Ra gamma ray (186.2 keV) and the ^{235}U gamma ray (185.7 keV) cannot be done accurately by the classic HP-Ge detectors (detectors made of High Purity Germanium) mainly used in studies, whereas the activity of ^{214}Pb or ^{214}Bi is easy to measure with those detectors. So the average of activities of ^{214}Pb and ^{214}Bi stands for the group of $^{226}Ra^{+}$.

Activity levels and radioactive disequilibrium in NORM used in French industries

As a first step, all samples presented by operators were classified in four categories: raw materials, products, waste and environment. The category “Environment” represents a fifth of the samples and includes all the samples collected in the environment, e.g. soil, sediments, vegetables… These data have been excluded from our work. The category “Products” includes final products and by-products and the category “Waste” includes solid waste, effluents, sludge and dust. 26% of materials considered by operators are raw materials, 34% are products and 39% are waste.

In the second step, twelve industrial activities were identified: coal combustion, glass industry, production and use of zircon and baddeleyite, production of phosphated fertilizers, production of refractory ceramics, production or use of compounds with thorium, spas, treatment of aluminium ores, treatment of kaolin ores, treatment of lanthanides series, treatment of titanium ores and underground water treatment by filtration. All the samples were classified according to these categories.

Eventually, for each category of materials and for each chain segment, the minimum, the maximum and the median values, as well as the first and the third quartile values have been determined. Figure 1 presents activities of the most often measured chain segments: $^{226}Ra^{+}$ and $^{228}Ra^{+}$ groups.

[1] Symbol ‘+’ after a nuclide denotes a segment chain headed by that nuclide, e.g. $^{226}Ra^{+}$ corresponds to this segment chain: ^{226}Ra, ^{222}Rn, ^{218}Po, ^{218}At, ^{214}Pb, ^{214}Bi and ^{214}Po.

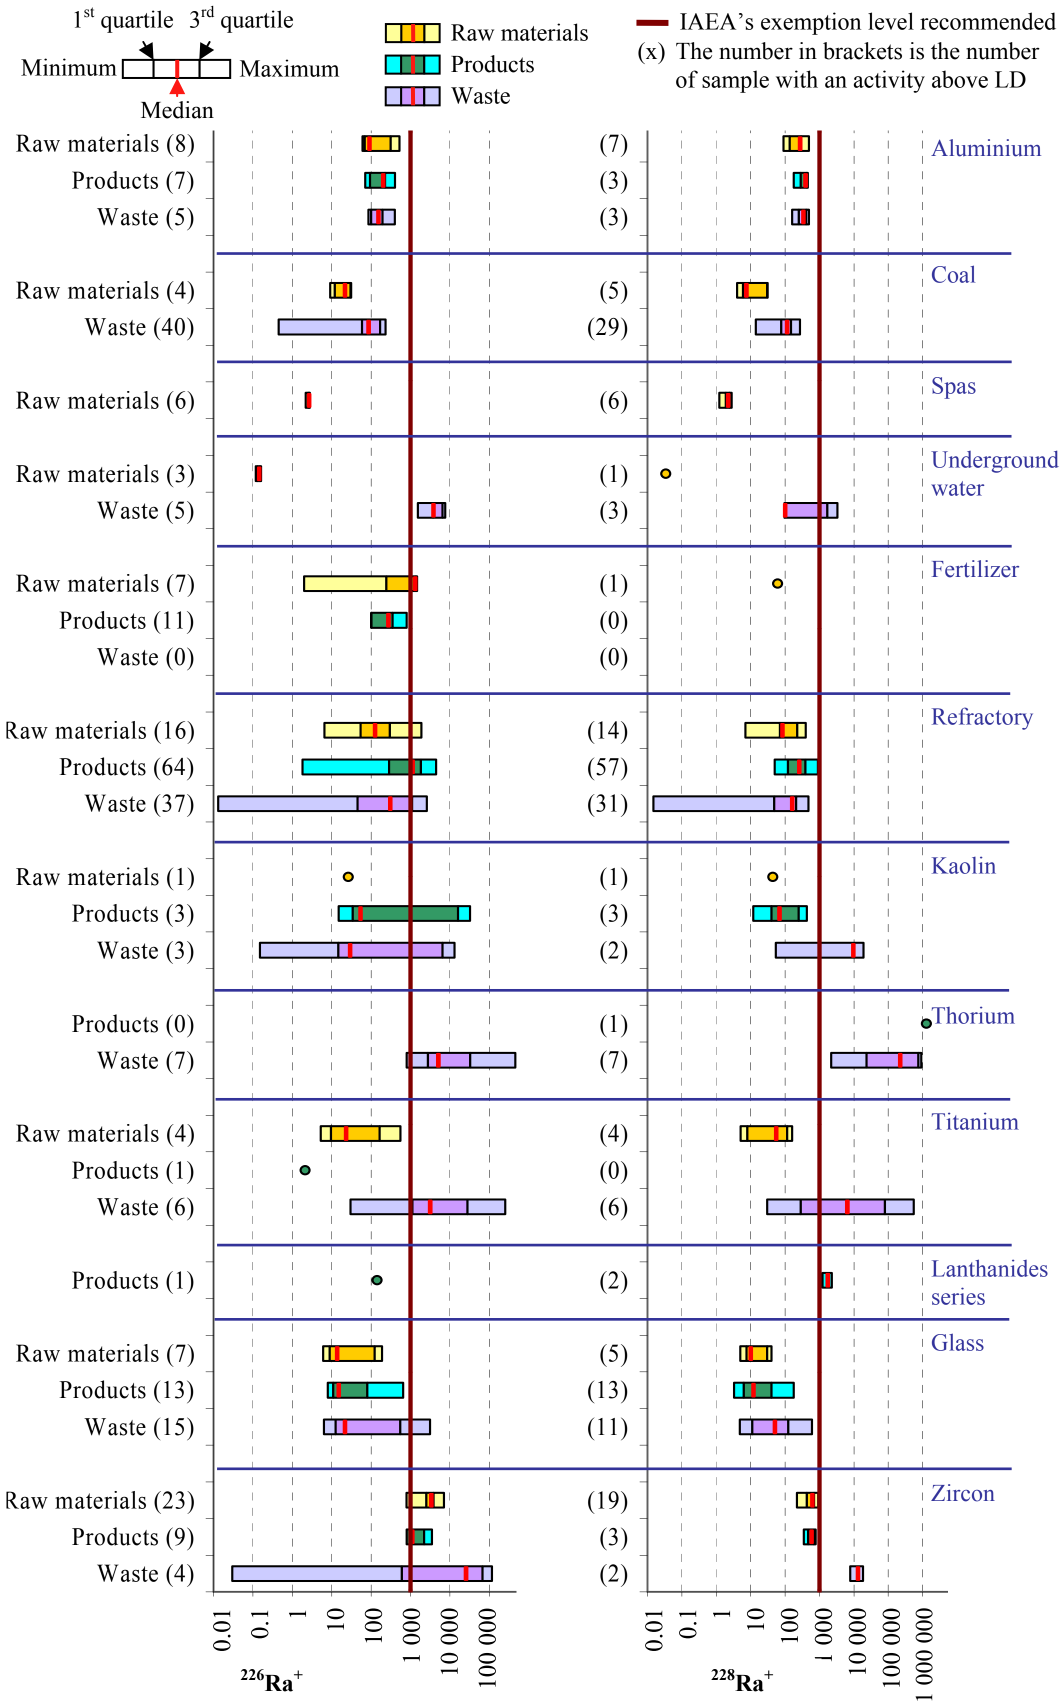

Fig. 1. Activities of $^{226}Ra^{+}$and $^{228}Ra^{+}$ (Bq.kg^{-1}).

Conclusions relative to activity levels

Based on French feedback, the following conclusions can be drawn:

- activity concentrations strongly vary according to the type of material and industrial activity;
- waste generally contain the highest activity concentration of natural radionuclides;
- 55% of materials with an activity higher than 1000 Bq.kg^{-1}, the IAEA's exemption level recommended for the use of NORM, are waste, 29% are products and only 16% are raw materials.
- the number of radionuclides measured and the accuracy of their activity determination are barely enough to assess the secular equilibrium or radioactive disequilibrium that occurs in NORM.
- imbalances have been identified: activity of ^{226}Ra^{+} group in waste (e.g. the category "underground water") or activity of ^{210}Pb^{+} group in ashes and dust related to heating processes is greater than the activities of the other groups of ^{238}U series. For example, figures 2 and 3 show two illustrations of excess of ^{210}Pb in dust from the refractory industries.

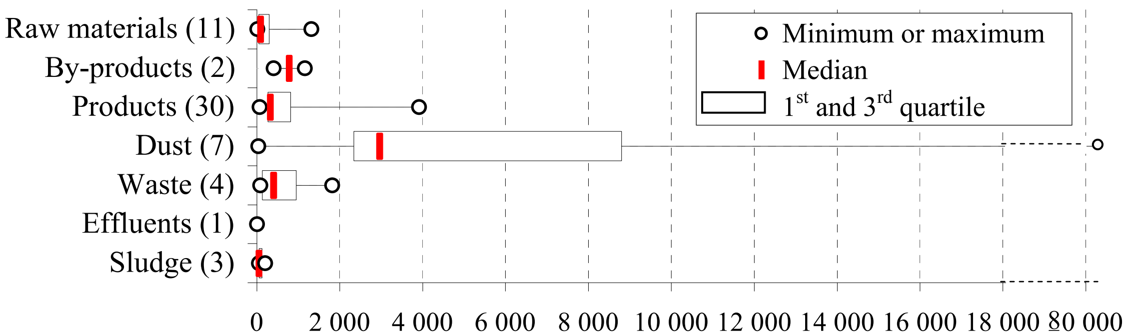

Fig. 2. Activities of ^{210}Pb^{+} in the refractory industries (Bq.kg^{-1}).

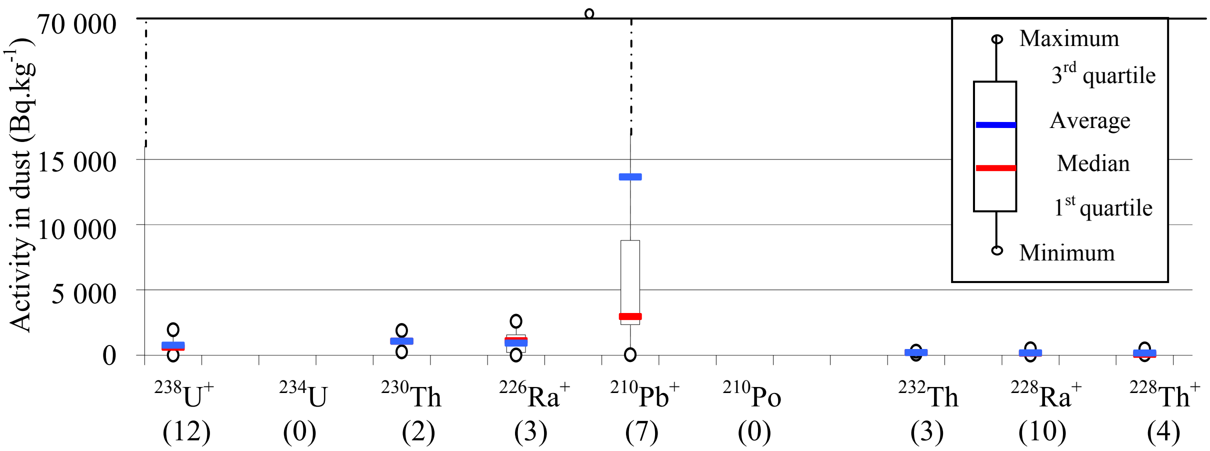

Fig. 3. Activities of ^{210}Pb^{+} in the refractory industries (Bq.kg^{-1}).

Occupational exposures

Data collected

The Ministerial order of May 25, 2005 imposes on operators to assess the occupational effective doses and to take into account external exposure, as well as internal exposure by dust inhalation and inhalation of radon progeny. Since the publication of this text, operators have assessed occupational exposure for more than 400 workplaces. A third of doses are less than 0.1 $mSv.yr^{-1}$, a half are less than 0.25 $mSv.yr^{-1}$ and 15% of doses are still greater than the effective dose limit of 1 mSv per year for the public in France (French Public Health Code, 2006) and so need further examination.

Firstly, some doses calculated by operators do not take into account external exposure or internal exposure by dust inhalation even if this route could be a significant pathway of exposure. Secondly, only some doses also consider exposure due to inhalation of radon progeny. Thirdly, only some operators take into account the exposure due to natural background in their assessment. Finally, the doses received by workers vary strongly according to the type of industrial facilities. Due to the different approach retained by operators, it is not possible to compare directly the doses reported. So, on the one hand, when data are available, exposure due to natural background was subtracted from the effective doses reported by operators. On the other hand, in order to compare the effective dose for each type of industrial activity and to identify the significant route of exposure, IRSN has analyzed the doses calculated for workers due to external and internal exposure for each type of industrial activity. Data relative to exposure to radon have been considered specifically.

Effective doses above the natural background

Production of refractory ceramics and smelting, metallurgy and glass industry using them

The production of refractory ceramics and smelting, metallurgy and glass industry using them is the most often assessed industrial activity: more than 100 workplaces have been assessed. Figure 4 shows the added effective dose. For two workplaces, doses are greater than 1 $mSv.yr^{-1}$ with a maximum of 1.5 $mSv.yr^{-1}$ but these doses are still consistent with literature (NORM V, 2008).

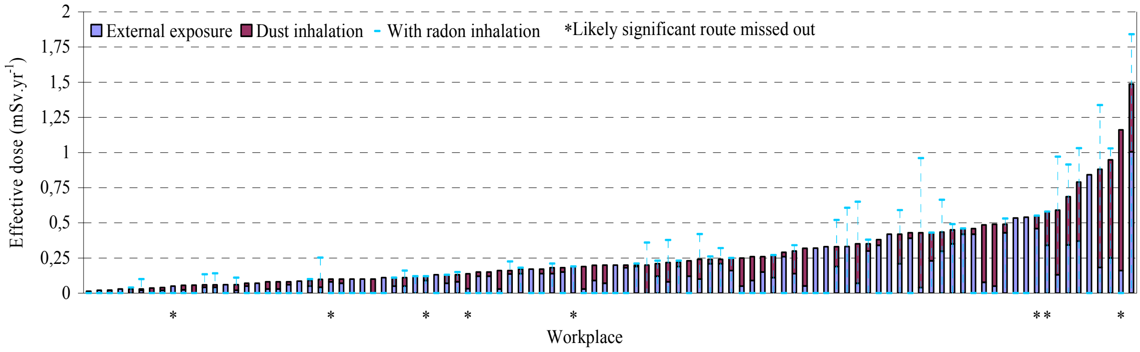

Fig. 4. Production of refractory ceramics - Added effective doses.

Production of zircon and baddeleyite, and smelting or metallurgy plants using it

The production of zircon and baddeleyite, and smelting or metallurgy plants using it is the second most often assessed industrial activity: more than 60 workplaces have been assessed. Figure 5 shows the added effective dose reported by operators. For eight workplaces, dose is greater than 1 $mSv.yr^{-1}$ with a maximum dose of 2.3 $mSv.yr^{-1}$. This dose is still consistent with results published in literature for zircone production by a thermic process (NORM V, 2008). Moreover, it is worth mentioning that the highest doses correspond to two studies in which a hypothetic and maximum time of exposure of 1600 $h.yr^{-1}$ have been considered.

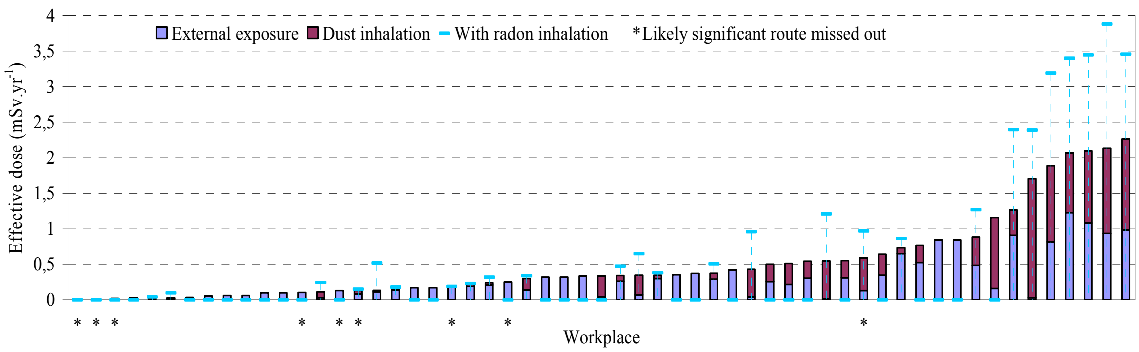

Fig. 5. Production of zircon and smelting or metallurgy plants using it - Added effective doses.

Treatment of tin, aluminium, titanium and niobium ores

The treatment of tin, aluminium, titanium and niobium ores is the third most often assessed industrial activity: more than 40 workplaces have been assessed. Figure 6 shows the added effective dose. For 13 workplaces, doses are greater than 1 $mSv.yr^{-1}$ with a maximum of 6 $mSv.yr^{-1}$ and are consistent with literature (NORM V, 2008), (UNSCEAR, 2000).

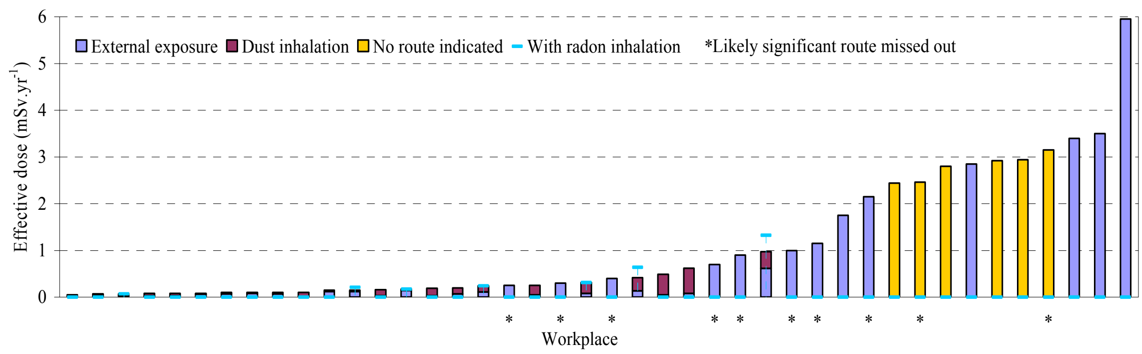

Fig. 6. Treatment of ores (Sn, Al, Ti, Nb) - Added effective doses.

It is worth mentionning that the highest doses correspond to only one study. New measurements in 2008 show an important reduction of dose rate: based on these new measurements, the maximum dose decreases to 3.2 $mSv.yr^{-1}$.

Coal combustion in power plants

30 workplaces for coal combustion in thermal power plants have been assessed. Figure 7 shows the added effective dose reported by operators. For any workplace, dose is less than 1 mSv.yr^{-1} with a maximum dose of 0.4 mSv.yr^{-1} which is consistent with literature (Smith *et al*, 2001).

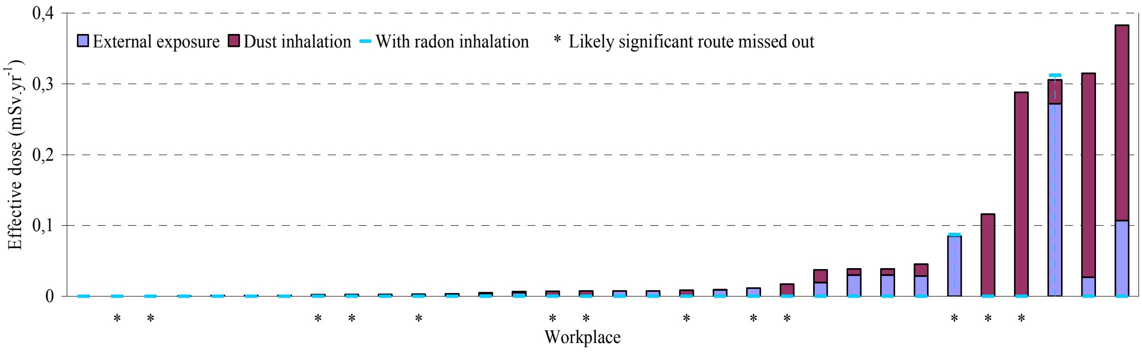

Fig. 7. Coal combustion - Added effective doses.

Other industrial activities

For the production or use of compounds with thorium, six workplaces have been assessed. For two workplaces, the doses are greater than 1 mSv.yr^{-1} with a maximum dose of 82 mSv.yr^{-1}. This dose is mainly due to dust inhalation. In order to reduce occupational exposure, the operator intended to equip workers with personal protective equipment and he should periodically clean the working planes and install a system of air filtration in his installations. These actions should significantly reduce the doses but IRSN and French authorities have not yet received the new study.

For the production of phosphated fertilizers, six workplaces have been assessed. Every doses are less than 1 mSv.yr^{-1} with a maximum dose of 0.5 mSv.yr^{-1} which is consistent with literature (NORM V, 2008), (AIEA, 2006).

For the treatment of lanthanides series, three workplaces have been assessed. Every doses are less than 1 mSv.yr^{-1} with a maximum dose of 0.3 mSv.yr^{-1} which is consistent with literature (AIEA, 2006).

Route of exposure

For only four types of industrial activities, workplaces have been sufficiently studied to allow to identify the significant route of exposure. Figure 8 shows the contributions of external and internal exposure for these four types of industrial activities.

– For coal combustion, data show clearly that external exposure is the significant route of exposure.
– For the production of refractory ceramics and smelting, metallurgy and glass industry using them and the production of zircon and baddeleyite, and smelting or metallurgy plants using it, data collected do not clearly show any significant route of exposure, though external exposure seems to be the most important pathway.
– For treatment of ores, no significant route of exposure could be identified.

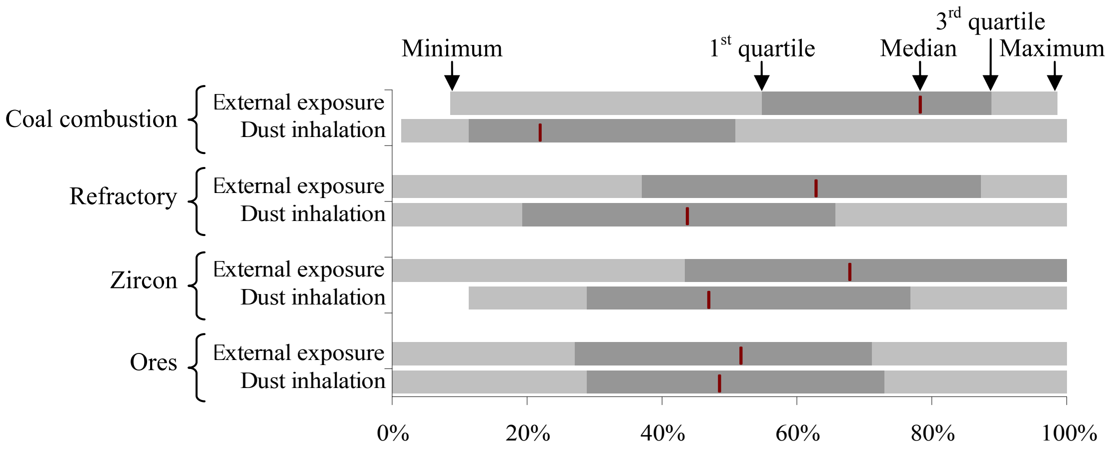

Fig. 8. Contributions of external exposure and dust inhalation.

Conclusions

Based on the feedback gained by IRSN and French authorities from the studies conducted by operators, the following conclusions can be drawn additionally to those presented in (Maigret *et al*, 2008):

– assessments are still expected for some industrial activities referred to in the Ministerial order of May 25, 2005 (Ministerial order, 2005). For example, in the next future, studies dealing with occupational exposure due to underground water treatment by filtration should be carried out;
– about 10% of added effective doses are greater than 1 mSv per year and need further examination;
– the highest doses were found in facilities which produce materials involving thorium (82 mSv.yr^{-1}) and which treat tin, aluminium, titanium and niobium ores (6 mSv.yr^{-1}). For the other types of industrial activities, the maximum dose remained below a few mSv per year;
– external and internal exposure are often of the same order of magnitude;
– some types of industrial facilities currently not referred to in the French ministerial order, e.g. paper mills, are concerned by NORM and TENORM issue and could be added to the list of industrial facilities set by the Ministerial order of May 25, 2005 (Ministerial order, 2005).

Abstract

Results of the radiological baseline study on the planned Sokli phosphate mine in Northern Finland are presented. From radiation protection point of view, the Sokli carbonatite massif contains considerable amounts of natural radioactive substances, i.e. thorium and uranium and their decay products. These substances are especially rich in the niobium ore. In connection with the Environmental Impact Assessment, the Radiation and Nuclear Safety Authority (STUK) carried out the radiological baseline study at the site of the planned Sokli phosphate mine and its surrounding environment. In the baseline study the activity concentrations were studied in ecosystems at the Sokli site, as well as in the immediate vicinity where the mine may have some radiological impact. The objective of the study was to obtain a detailed understanding of the radiation levels at and in the vicinity of the Sokli mining site before the commencement of mining and treatment of phosphate ore. The baseline study can be used in the future to assess possible impacts on the environment of the natural radionuclides released during the mining and milling process.

Introduction

The Sokli carbonatite massif is part the Kola alkaline province which covers an area of approximately 100,000 km^2, and is one of a few regions in the world where the paleozoic ultramafic-alkaline magmatism is well developed. A characteristic feature of the Kola carbonatites in many complexes is their close relation with phoscorites, rocks consisting essentially of apatite, magnetite and forsterite or diopside (Mi Jung Lee, et al. 2006).

Sokli is located in Savukoski municipality in the Finnish Lapland, close to the border with Russia (Fig. 1). The mineral deposit is associated with a carbonatite massif some 360 million years old, with a land surface diameter of 5–6 km. In addition to the phosphorus minerals, the carbonatite massif contains other ores, such as iron, niobium and vermiculite minerals. The Sokli carbonatite massif has been explored since 1967 and the pilot mining and milling of phosphorus minerals was performed in late 1970’s. However, in those days the commencement of phosphate ore concentrate and phosphate products in an industrial scale was not profitable. Today the plans for the Sokli mine project include opencast ore extraction and treatment, crushing and grinding of the ore, beneficiation, dewatering and storage of the products, tailings storage, water treatment and auxiliary activities. The planned production is 2.0 million tonnes of phosphorous concentrate per year. The amount of ore to be mined will be 4-10 million tonnes per year depending on the mining and milling strategy in the area. There are also plans to extract iron and other valuable minerals later. According the planned capacity, it has been estimated that the richest phosphorus ores will last for around 20 years of production. If the poorer parts of the deposit are exploited, it may be possible to extend the life time of the mine by twenty to thirty years, or even more.

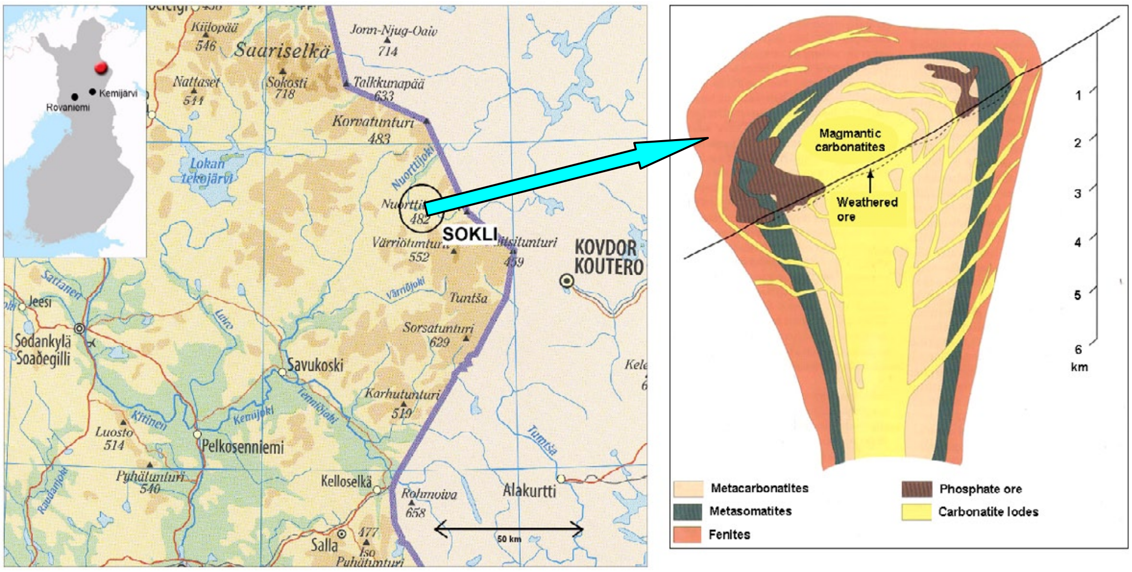

Fig. 1. Location and shape of the Sokli carbonatite massif. The magmatic carbonative ore continues tens of kilometers below the ground level.

Material and methods

The environmental samples were collected in 2008 and 2009. The samples were pre-treated and analysed at the STUK's Regional Laboratory in Northern Finland. In-situ gamma spectrometric measurements and radiochemical analyses of uranium in water samples were made by STUK's laboratories in Helsinki. Different environmental samples were collected: river water, river sediment, fishes, lichen, beard moss, water moss (*Fontinalis antipyretica*), mushrooms, berries, reindeer meat, ground water, soil, moose meat and pochard.

The environmental samples were analysed for gamma-emitting radionuclides with HPGe gamma spectrometers. The concentrations of ^{238}U, ^{235}U, ^{226}Ra, ^{228}Ra, ^{228}Th, ^{232}Th, ^{210}Pb and ^{40}K were analysed by using containers, which were inside the gas-tight aluminium bags in vacuum. The samples were kept in these bags at least three weeks before measurements so radium, radon and its short lived decay products were in equilibrium when measured. The ground water samples were also studied for ^{222}Rn.

In addition, radiochemical analyses were done to analyse activity concentrations for ^{210}Po and ^{210}Pb. All the solid samples were first dried at 105ºC and then homogenized. Suitable sample quantities were spiked with ^{209}Po tracer and digested by microwave. Polonium was deposited on silver plate and measured by alpha spectrometer (Vesterbacka and Ikäheimonen 2005). All samples were analysed before 6 months has gone from the sampling date. The solution remaining from the first deposition was stored about 6 months to allow the in-growth of ^{210}Po from ^{210}Pb. The second ^{210}Po deposition was then carried out by using ^{208}Po tracer and the ^{210}Po activity was measured by alpha spectrometer. The ^{210}Pb content of the samples was calculated and the first ^{210}Po determination was corrected for the radioactive decay between the time of sample collection and analysis and the in-growth of ^{210}Pb during sample storing before first ^{210}Po deposition was subtracted.

Results

The highest radioactivity concentrations were measured in the niobium ore and in the old mill tailings remaining at the site from the pilot enrichment in late 1970's. In the niobium ore the radioactivity concentrations were 8500 Bq/kg for ^{232}Th and 2200 Bq/kg for ^{238}U. In river sediments the activity concentrations of these radionuclides varied from few Bq/kg up to three hundred Bq/kg. In reindeer meat, game meat, berries, mushrooms and in river waters the activity concentrations remained in nearly all the samples below the detection limits of the used gamma spectrometric methods. More precise radiochemical analyses of uranium isotopes were performed for different water samples. The lowest concentrations were found in river water (0.001 - 0.024 Bq/L) and the highest concentration in spring water (0.01 - 0.02 Bq/L). The results are shown in Table 1.

^{210}Pb and ^{210}Po were found in all analysed samples. The lowest values were found in river waters and the highest values in water moss (*Fontinalis antipyretica*) which is a common aquatic plant in Lapland and known to be a good bio-indicator for heavy metals. High amounts of ^{210}Pb and ^{210}Po were found also in reindeer lichen (*Cladina rangiferina*) which is the main food plant of reindeers and in beard moss (*Bryoria*) growing on spruce and pine branches and in bolete. ^{210}Pb and ^{210}Po concentrations in different environmental media are presented in Table 2.

The activity concentrations of ^{222}Rn in ground water samples varied between 30-110 Bq/L. In river water samples radon concentrations were below detection limit 30 Bq/L.

Table 1. Concentrations of ^{234}U and ^{238}U in different water samples collected at the planned phosphate mine and its surroundings.

Water type	U-234, Bq/L		U-238, Bq/L	
	Year 2008	Year 2009	Year 2008	Year 2009
River water	0.0044 - 0.0241	0.0011 - 0.0099	0.0033 - 0.0199	0.0017 - 0.0088
Spring water	0.0189	0.0116	0.0203	0.0128
Ground water	0.0014 ja 0,0054	0.0011 ja 0.0045	0.0028 ja 0.0081	0.002 ja 0.0059

Table 2. Concentrations of ^{210}Po and ^{210}Pb in different environmental samples collected at the planned phosphate mine and its surroundings.

Sample	^{210}Po, Bq/kg	^{210}Pb, Bq/kg
Ground water	0.03 - 0.04	0.008 - 0.03
River water	0.003 - 0.01	0.0004 - 0.01
Bolete	129 - 832	1.9 - 3.4
Milk caps	15.6 - 42.9	9.9 - 21.7
Russule	6.4 - 18.3	4.1 - 6.7
Trout, grayling	2.0 - 19	1-3.6
Cloudberry	1 - 1.4	1.4 - 1.6
Lingonberry	4.6 - 4.9	2.5
Blueberry	4	2
River sediment	15 - 294	7 - 118
Water moss	182 - 1190	47 - 659
Reindeer lichen	167 - 186	89 - 96
Beard moss	302 - 472	166 - 251
Moose meat	4.3 - 4.7	0.7 - 1
Reindeer meat	8.0 - 83	0.8 - 2.5

Conclusions

The radiological baseline study in the area of the planned phosphate mine and concentration plant was performed in 2008-2009. It was considered important to investigate the natural radiological situation of the site and its environment before the commencement of mining and treatment of the phosphate ores to be able to assess possible radiological impact of these activities in the future. The Sokli carbonatite massif contains various ores and some of them contain elevated amounts of thorium and uranium. Radiological studies done before any industrial actions are the only way to verify the results of the Environmental Impact Assessment (EIA) because the studied radionuclides are occurring naturally in the environment. The local people have been worried about the radiological impact of the mining and enrichment activities to their health and the environment. It is important also to them to know the natural levels of radioactivity in different environmental media.

Preliminary results of the baseline study show that the amounts of natural radionuclides in mushrooms, berries, fish, lichens, beard moss, reindeer meat and moose meat samples were at the same level as in other environmental samples analysed from Finnish Lapland. The activity concentrations of ^{234}U, ^{238}U, ^{210}Pb and ^{210}Po in river water were close to the average concentration of Finnish tap water from waterworks 0.02. 0.015. 0.003 and 0.003 Bq/L, respectively. The highest ^{210}Pb and ^{210}Po concentrations were found in bolete, water moss, beard moss and lichen, which are good bio-indicators for radionuclides.

Radioecological investigations were performed at the Sokli area also in late 1970's when earlier plans to start phosphate production was current. The results obtained in 1970's were very similar compared with the results of this study. This indicates that the pilot production activities in 1970's had no significant radiological impact to the environment.

Naturally occurring radionuclides in drinking water – An overview of the problem in Sweden

Skeppström, Kirlna
Swedish Radiation Safety Authority, Radiation Protection, SWEDEN

Abstract

In Sweden, uranium rich soils and bedrocks can give rise to high concentrations of naturally occurring radionuclide (NORM) in groundwater. If the extracted water is then used as domestic water supply, an appreciable radiation dose can be received. Radionuclides that are of interest, originate principally from the decay series of uranium (^{238}U) and include radon (^{222}Rn), radium (^{226}Ra), polonium (^{210}Po), lead (^{210}Pb) and ^{238}U itself if the latter is present in high concentration (> 100 µg/l). A recent country wide mapping of about 700 drilled wells reveal that geological criterion cannot alone explain concentration variations of radionuclides in groundwater. 8% of the studied wells, located outside regions containing uranium rich bedrocks, had a radon concentration exceeding the recommended action level of 1000 Bq/l in water. A proper understanding of the factors guiding the mobilisation and transport of decay products of ^{238}U in the subsurface is a prerequisite to make accurate risk prediction. There are about 250 000 drilled wells that are used permanently in Sweden and between 5000 –10000 wells get constructed every year. The concentrations of radionuclides except for radon are seldom analysed. The National Board of Health and Welfare in Sweden recommends radon measurements in drinking water coming from private wells. Results of water analyses, if or when performed are not communicated to a centralised database that can be used by various national authorities but efforts are ongoing to build such a system. Knowledge regarding the extent to which private well owners check the quality of their water with regards to radionuclide and take appropriate remediation measures is poor. An ongoing survey regarding remediation measures is hoped to provide additional information on the issue.

NORM in the petroleum and geothermal industries: evolution of the French radioprotection legislation

Lafortune, Stéphane[1]; Pinte, Jean-Claude[1]; Sada, Martine[2]

[1] INERIS (French National Institute for Industrial Environment and Risks), Ground and Underground Risks Division, FRANCE

[2] French Ministry of Ecology, Energy, Sustainable Development and Sea, FRANCE

Abstract

Fluids produced from oil or gasfields and aquifers are naturally radioactive due to the presence of potassium-40 and isotopes from decay chains of uranium-238 and thorium-232 in these reservoirs. Thus, natural radionuclides can be carried away towards surface when petroleum or geothermal reservoirs are drilled and produced. These radionuclides can precipitate in deposits forming in process equipment, which can then be unusually radioactive, expose workers to hazardous materials and create waste disposal problems. Workers can also be exposed to high concentrations of radon. Due to their natural origin, these accumulations of radionuclides in equipment are called Naturally Occurring Radioactive Materials (NORM). They are also known as TENORM, because they are technologically enhanced.

In closed systems, exposition to gamma radiations penetrating equipment to the external surface can be reduced by restricting and controlling access to appropriate areas. But personnel may come into direct contact with NORM during maintenance and cleaning operations, when opening equipment and vessels.

In France, hygiene and safety rules concerning the protection of workers in the petroleum and geothermal industries are formulated in a specific legislation related to extraction and mining. Presently, both petroleum and geothermal industries are not included in the list of activities which have to follow radioprotection measures given by this legislation. French authorities are currently planning to update the list by including these two activities. There is a real need to realize a state-of-the art of the exposition level of French workers and to match the dose limits to those given by the Labor and Public Health Codes.

This paper will present the origin of NORM and radon contamination in the petroleum and geothermal industries and discuss the French legislation evolution for the radioprotection of personnel working in these two industries.

Ukrainian experience of monitoring of radiation exposure of population determined by building materials

Pavlenko, Tatyana[1]; German, Olga[2]; Serdyk, Andrey[1]; Los, Ivan[1]; Aksenov, Nikolay[1]
[1] Marzeev Institute of Hygiene and Medical Ecology,
Academy of Medical Sciences of Ukraine, UKRAINE
[2] Swedish Radiation Safety Authority, SWEDEN

Abstract
This article contains results of monitoring of the specific radioactivity of the natural radionuclides in the minerals used as construction raw materials. In total, 22 quarries (opencast mines) of crushed stone (gravel), 10 quarries of sand and 4 of clay were studied and around 800 samples of mineral raw materials used in construction were analyzed. Effective doses of external radiation exposure of the population determined by building raw materials were defined.

It was found that the raw materials produced at 12% of the quarries do not comply with the relevant requirements of the national regulations, thus, such materials can not be used for the residential construction. Based on the assessment of the study, it was found that the average weighted effective exposure dose of the population resulting from radioactivity of the construction materials in the structure of the overall country housing is 0.23 mSv per year.

Introduction
External exposure of population to radiation in the houses is determined by naturally occurring radioactive materials contained in building materials. Studies of this source of radiation are currently done in various countries of the world, however, there is less data for radiation exposure levels inside houses than that for the outside, at the open space. This is related to the fact that there are no relevant regulations restricting exposure of population in the houses to radiation in the majority of the countries of the world. The most profound review of the results of research of such a source of radiation is quoted in the report of the United Nations Scientific Committee on the Effects of Atomic Radiation [1]. Thus, based on the Committee data, the average weighted radiation exposure dose of the population of the planet is in the range between 20 nGy to 200 nGy per hour, with the average level of 84 nGy per hour.

Furthermore, according to the Report [1], the lowest levels of radiation exposure were registered in New Zealand, Iceland and the United States, where it was lower the 40 nGy per hour level, whereas the highest (95 to 115 nGy per hour) were registered in

Hungary, China, Portugal, Austria, Spain and Iran. As a rule, the high radiation population exposure levels exist due to the use of stone and concrete with higher content of naturally occurring radionuclides in construction of housing. [2,3]. For example in Sweden lots of dwellings were constructed of light concrete before 1975. The raw material used for the production of light concrete contains large volumes of alum shale, rich in Uranium. The average dose to the dwellers of the light concrete houses is 1,1 mSv/a.

First regulations restricting the content of the naturally occurring radioactive materials (NORM) in building materials in the USSR have had come into being in 1976 [4]. This regulatory standard was developed by the specialists of the Leningrad Scientific and Research Institute for Radiation Hygiene then headed by Ye. Krisyuk. His monograph manuscript provided the scientific rationale for the methodological specifics related to substantiation of the numerical values of Radium-226, Thorioum-332 and Potassium-40 content in construction materials. These standards [norms] remain the same to date and are applied according to Norms of Radiation Safety of Ukraine, thus, it is worthwhile to look at those in greater detail.

Here is the main idea behind such standard. The value of the standard [norm] is no more than 370 Bq/kg of the specific effective radioactivity (C_{eff}) of the naturally occurring radionuclides (Radium-226, Thorioum-332 and Potassium-40) contained in construction materials. This was 4 times more the relevant average value at the territory of the USSR (93 Bq/kg). Expected excess of the standard throughout the whole territory of the country was around 1%. Effective external radiation exposure dose in the houses built with the use of construction materials with NORM value of $C_{eff} = 370$ Bq/kg is 1.75 mSv per year for the period of being inside a house of 7000 hours per year [6].

Construction materials with the higher content of NORM are permitted to be used in road construction (up to 740 Bq/kg within the limits of towns and other settlements and between 740 Bq/kg and 1850 Bq/kg beyoned such limits) [7].

Monitoring of the NORM content of construction materials and mineral raw materials used in construction is mandatory in Ukraine throughout the whole territory. The article includes the analysis of the study results for 95% of all quarries in Ukraine where construction materials and mineral raw materials used in construction are produced. Based on data, resulting from the direct studies, effective radiation exposure doses assessment was made for the population of different regions of the country.

Material and methods

Measurement method

Spectrometry method involving the use of ORTEK (US) high resolution gamma spectrometry system with NaI (T1) scintillation detector and well was applied in the framework of this article in order to do the measurements of mineral construction raw materials samples.

Measured samples were put inside Marinelli container, that fill the space of the well with the detector crystal completely. With this placement of samples the geometrical effectiveness of registration is substantially higher than when cylinder form crystals are used.

Large volume well, 150 mm diameter, 150 mm height, was used to provide for sufficient sensitivity. AMERSHAM (Germany) standard source was used for calibration of the gamma spectrometer.

For geometry 'Marinelli 1 litre' the value of the lowest detectable radioactivity was 2 Bq/kg for Thorium-232, 3 Bq/kg for Radium-226 and 10 Bq/kg for Potassium-40.

Effective specific radioactivity of a sample (A_{eff}) was calculated based on the values of specific radioactivity of the NORM, Thorium-232, Radium-226 and Potassium-40.

$$A_{eff} = A_{Ra} + 1{,}31 \cdot A_{Th} + 0{,}085 \cdot A_K,$$

Where A_{Ra}, A_{Th}, A_K – values of specific radioactivity of Radium-226, Thorium-232 and Potassium-40, Bq/kg.

Method dose calculation

Transition coefficients from air-absorbed dose to effective dose and parameters for time of humans being enclosed inside house, quoted in attachments to the United Nations Scientific Committee on the Effects of Atomic Radiation report, were used to assess the average annual effective dose values [1]. Transition coefficient from air-absorbed dose to effective dose was set at the value equal to 0,7 Sv/Gy whereas factor for length of time of being inside housing was 0.8 [1].

The following data was used in relation to the country overall housing structure to do the assessment of the average weighted population effective radiation exposure doses (obtained from Radon measurement certificates from IHME (Institute of Hygiene and Medical Ecology) databases: buildings currently in operation (28 000 buildings) and building in process to be commissioned (34 000 premises). The certificate contains information about materials, used to construct a building, year of construction, number of residents in a building as well as that on the number of floors, coverings of the walls, type of dividers between floor and space under floor, availability of basements and ventilation system in buildings. Such information makes that possible to do adjustments when calculating values of the effective doses of radiation exposure of population considering specifics of architectural and layout solutions pertinent to individual regions in Ukraine.

For instance, housing structure of the rural areas of the Kiev Oblast comprises 60% of the building made of bricks, 33% are wooden buildings, 2% - adobe brick buildings and around 1% was build with the use of shell limestone and slag stone.

Effective exposure doses were calculated separately for residents of the brick-made and concrete-plate buildings in order to assess average annual radiation exposure doses of the urban population, and then the resultant value was weighted against the housing structure.

Results

Results of measurements of the NORM content in samples of mineral construction raw materials from 22 crushed stone, 10 sand and 4 clay quarries were analyzed to assess relevant effective exposure doses.

It was found in the analysis that the average weighted specific radioactivity $\bar{A}_{eff}$ for selected quarries (580 samples) was 238 Bq/kg with standard deviation of 128 Bq/kg.

Relevant value for 10 sand quarries (80 samples) was 127 Bq/kg with the standard deviation 309 Bq/kg, and for 4 clay quarries (120 samples) it was 79 Bq/kg and 14 Bq/kg accordingly. Frequency distribution of the effective specific radioactivity values of the NORM was of the lognormal character.

Average value A_{eff} for granite quarries usually does not exceed 370 Bq/kg and corresponds to Class I for mineral construction raw materials set out in NRBU-97 (Norms of Radiation Safety of Ukraine) (para 8.5.1.). Findings of the study have shown that A_{eff} for the two crushed stone quarries (9% of the total number of all measured samples) exceeds that value, in other words, the mineral materials from such quarries can not be used for the residential construction. At present, such mineral materials are used for industrial and road construction.

According to the study, mineral raw materials produced at only 12% of all quarries of the country can not be used for the purposes of residential construction.

Tables 1-3 indicate data on NORM content in the mineral construction raw materials produced in separate regions of Ukraine.

Table 1. Average Values of NORM Specific Radioactivity Samples of Crushed Stone from Quarries in Ukraine.

Oblast (Region)	Specific Activity, Bq/kg		
	Radium-226	Thorium-232	Potassium-40
Vinnitsya	32	120	917
Dnipropetrovsk	143	420	1032
Zhytomir	45	72	1250
Kiev	42	131	1351
Kirovohrad	55	120	1217
Rivne	44	45	840
Sumy	99	69	1246
Khmelnitsky	44	52	976

Table 2. Average Values of NOR Specific Radioactivity Samples of Sand from Quarries in Ukraine.

Oblast (Region)	Specific Radioactivity, Bq/kg		
	Radium-226	Thorium-232	Potassium-40
Zhytomir	16	34	270
Kiev	6	7	88
Volyn	22	13	157
Rivne	28	33	401
Chernihiv	13	24	495

Table 3. Average Values of NORM Specific Radioactivity Samples of Clay from Quarries in Ukraine.

Oblast (Region)	Specific Radioactivity, Bq/kg		
	Radium-226	Thorium-232	Potassium-40
Dnipropetrovsk	33	43	447
Zhytomir	13	27	255
Kiev	21	33	481

Radiation exposure doses

External radiation exposure doses of Ukraine's population are calculated based on results of the NORM specific radioactivity measurements of mineral construction materials samples, depending on the housing structure of regions and type of construction material. Table 4 contains results of effective radiation exposure doses calculation for population of Kiev Oblast as an example.

Table 4. External Radiation Exposure Doses of Population Determined by NORM Contained in Building Materials.

Raw Material	Raw material use Coeff.	Absorbed Dose for Weight Fractions for Raw Materials in Buiding Materials wm, nGy/hour				ED with wm = 0,5, mSv/a
		wm = 1	wm = 0,75	wm = 0,5	wm = 0,25	
Crushed stone	2,09	168	126	84	42	0,41
Clay	0,67	54	40	27	13	0,13
Sand	0,14	12	9	6	3	0,03

Table 5 illustrates main results of the assessment of external radiation exposure doses to population determined by construction materials. It was found that average annual radiation exposure dose for the urban population of Ukraine (around 70% of the total population of the country) is in the range of 0,28 – 0,33 mSv/a and that such doses are practically no different for residents of both brick-made and concrete-plate-made buildings. Only the mineral construction materials of the Class 1 were used to construct such buildings.

Table 5. Effective Radiation Exposure Doses of Population of Selected Oblasts of Ukraine Determined by Radioactivity of Construction Materials, mSv/a.

Oblast	Urban Population	Rural Population
Vinnitsya	0,31	0,10
Volyn	0,29	0,09
Dnipropetrovsk	0,29	0,30
Zhytomir	0,27	0,30
Zaporizhzhia	0,27	0,11
Kiev	0,33	0,20
Odesa	0,31	0,12
Poltava	0,31	0,09
Rivne	0,22	0,07
Kherson	0,28	0,09
Cherkassy	0,31	0,21

Effective radiation exposure doses may vary by several times for rural population depending on a specific region. For example, most of the dwellers in Volyn and Rivne Oblast live in buildings made of wood, thus, effective dose for the residents of the above Oblasts is less than 1 mSv per year. In Dnipropetrovsk, Kiev or Zhytomir Oblast houses are, as a rule, made of bricks, therefore, effective radiation exposure dose for population there is 2-3 times higher.

Thus, average weighted effective external radiation exposure dose for the population of Ukraine in the context of the country housing structure is 0.23 mSv/a.

It is still worthwhile to note out that in the separate instances, and, in particular, with regard to residents of the old concrete-panel type buildings, constructed back in 1950-1960 (prior to implementation of restrictions on the use of construction materials) individual effective radiation exposure doses may be much greater. According to our assessment, in such instances the maximum external radiation exposure dose is 1-1.5 mSv per year.

Such doses may be even higher than that in some separate cases in the rural areas. This is related to the use of the high NORM content waste produced by the local industrial facilities as additional material utilized to underlay foundation of a building. So, individual privately owned houses in Dniprodzerzhinsk is an example, in construction of which process waste of uranium milling was used. Individual radiation exposure doses of residents of such houses may be several times higher than average throughout the whole country.

Some outstanding cases have no impact on the assessment of the average radiation exposure doses, however give rise to serious concerns on the part of the local public when such cases are identified.

In summary of the results it can be stated that the existing mandatory radiological monitoring of the NOR in mineral construction materials and raw materials has made impossible the use [of non-compliant materials].

Conclusions

1. Effective specific radioactivity $\bar{A}_{eff}$ of crushed stone is 238 Bq/kg for 22 analyzed quarries. Relevant value for 10 sand quarries was 127 Bq/kg and for 4 clay quarries was 79 Bq/kg.
2. Construction raw materials produced at 12% of the studied quarries can not be used for residential construction as effective specific radioactivity of the naturally occurring radionuclides in the relevant samples exceeds 370 Bq/kg.
3. Average weighted effective radiation exposure dose determined by radioactivity of construction materials for Ukraine’s population with regard to the country’s overall housing structure is 0,23 mSv/year.
4. Contribution of that component in the average annual radiation exposure dose of the country’s population is 2% approximately.
5. Restrictions with regard to content of natural radionuclides in the mineral construction raw materials and materials used in residential construction have practically excluded that component from the category of sources that impact the value of radiation exposure risks for the population of the country.

The International Association of Oil & Gas Producers (OGP) naturally occurring radioactive material management (NORM) guidelines

Mously, Khalid[1]; Cowie, Michael[1]; Campbell, John[2]

[1] Saudi Aramco, Environmental Protection Department, SAUDI ARABIA

[2] International Association of Oil & Gas Producers (OGP), BRITISH INDIAN OCEAN TERRITORY

Abstract

It has been established that Naturally Occurring Radioactive Materials (NORM) may accumulate in the oil/gas production process. This can create a radiation hazard for workers, the general public and the environment if adequate controls are not established. Regulations and guidelines on radiation protection in general and NORM in particular have been issued by various National and International entities, however these are not specific to the Oil & Gas industry, and do not provide clear and concise guidance to enable NORM to be managed effectively. The International Association of Oil and Gas Producers (OGP) established a task force, headed by Saudi Aramco, to develop NORM Management Guidelines. This task was completed after research, review and thorough consideration of most available NORM regulations, and the industry's current best practices in NORM management. The OGP guidelines offer a simple and logical method of managing NORM impacted operations that are flexible enough to be implemented across the industry. This paper outlines major aspects of OGP NORM management guidelines and elaborates on key issues related to the management of NORM in the Oil & Gas Industry, in particular on NORM monitoring, control of NORM contaminated equipment, managing NORM waste handling and disposal, and worker protection, awareness and training.

Technologically enhanced NORM and heavy metals in iron and steel industry

Khater, Ashraf[1]; Bakr, Wafaa[2]
[1] King Saud University, SAUDI ARABIA
[2] Atomic energy Authority, EGYPT

Abstract

Iron and steel industry was ranked as the largest industrial source of toxic environmental contamination in USA. About 2 – 4 tones of various solid wastes (slag, sludge, dusts and scales) are generated per ton of steel produced. These wastes contain a notable concentration of Naturally Occurring Radioactive Materials – NORM and heavy elements that could be a source of environmental contamination and occupational exposure. Composite samples of different iron and steel industry's wastes were collected from four iron and steel factories. Natural radionuclides (^{238}U, ^{232}Th, ^{40}K, ^{210}Pb, ^{210}Po) and trace elements (e.g. Cd, Cu, Pb and Zn) were measured using gamma-ray spectrometry, alpha particle spectrometry and ICP-MS analytical techniques. There is a wide range of variation in the concentration of natural radionuclides and other elements that depends on their concentration in the process input materials and thermal treatment process. Occupational dose due to dusts inhalation was calculated. According to the assumed scenario, the occupational exposure is much lower than the reference dose limit. The environmental impact due to wastes storage and/or usage should be considered generally and case by case.

NORM and trace elements fractionation in phosphate rock beneficiation processes: potential hazards and useful applications

Khater, Ashraf
King Saud University, SAUDI ARABIA

Abstract

Beneficiation processes (mainly crushing, washing, magnetic separation and wet screening) of phosphate ore rock aims at increasing the phosphate content percentage. It starts with the ore rock and end with wet rock, and different rejects or processes by-products. By-products have potential hazards due to their content of Naturally Occurring Radioactive Materials – NORM especially uranium-238 series and heavy metals, e.g, Cd, Cu, Pb and Zn. They have also potential industrial and agricultural useful applications due its physical and chemical properties such as their relative high content of clay and iron. Representative samples of ore and wet phosphate rocks and beneficiation processes by-products (clay and dolomite rocks, wet screening, magnetic separation and slim) were collected. Natural radionuclides (^{238}U, ^{232}Th, ^{40}K, ^{210}Pb, ^{210}Po) and trace elements (e.g. Cd, Cu, Pb and Zn) were measured using gamma-ray spectrometry, alpha particle spectrometry and ICP-MS analytical techniques. Potential hazards due to beneficiation processes and their by-products were discussed from both the radiological and chemical point of views. Radiologically, internal hazards index, external hazard index, representative level index, gamma absorbed dose rate and occupational dose equivalent due to inhalation were calculated. Chemically, input of toxic heavy metals (radioactive or stable) to the environment due to by-products dump and/or usage were estimated and their hazardous aspects were discussed. Some of the by-products could have potential useful applications such as clay rock and slim for agricultural soil reclamation. The aspects of these useful applications were discussed.

NORM in clay deposits

Khater, Ashraf E. M.[1,2]; Al-Mobark, Layla H.[1]; Aly, Amany A.[1,3]; Al-Omran, A. M.[4]

[3] Biophysics Dept., Cairo University, Cairo, EGYPT

[4] Soil Science Dept., College of food sciences and agriculture, King Saud University, Riyadh, KINGDOM OF SAUDI ARABIA

Abstract

Clay minerals are among the most important minerals used by manufacturing and environmental industries. To reduce the occupational and environmental hazardous impacts of clays' mining, handling and applications, it is essential to investigate their radiological as well as physicochemical characteristics. Twenty one clay's deposit samples from three different regions (Al-Riyadh, Al-Kharge and Jeddah) were collected. Activity concentrations of naturally occurring radioactive materials (NORM), ^{226}Ra, ^{228}Ra and ^{40}K in Bq/kg dry weight were measured using a well-calibrated gamma-ray spectrometer. Radiation dose (e.g. absorbed dose rate- nGy/h and effective dose equivalent- µSv/y), radium equivalent (Raeq) value in Bq/kg and hazardous indices (e.g. external hazardous, internal hazardous and representative gamma level) due to natural radionuclides in clay samples were calculated. The variation of the average activity concentration of natural radionuclides (NOR) according to sampling region could be due to the origin of the geological formation and the geochemical behavior of the NOR. The average activity concentrations of NOR in Saudis' clay samples were much lower than their average concentrations in kaolin clays utilized in Egypt that imported from different countries. Based on calculated hazardous indices (external hazardous and internal hazardous), there are not hazardous effects of clay deposits utilization as a building material. This does not correct based on the average value of representative gamma level that was greater than unity. More detailed studies should be done to consider the occupational exposure due to clay mining and handling.

Introduction

Clay is a common name for a number of fine-grained, earthy materials. Chemically, clays are hydrous aluminium silicates, ordinarily containing impurities, e.g., potassium, sodium, calcium, magnesium, or iron, in small amounts. Clay deposits vary in the chemical and physical properties and mineral composition, especially in terms of the type of clay minerals dominant. Properties of clay minerals can be determined the field of the use in industry or agriculture. The most common minerals of clay are kaolinite, montmorillonite - smectite, illite, chlorite, attapulgite or palygroskite, feldspar and calcite. Clay deposits that contain high concentrations of smectite mineral are using for agriculture purposes, because they have desirable properties in agriculture such as a tendency to expand ,disperse, swelling - shrinking behavior as well as high cohesion, also they have a high cation exchange capacity (CEC). While clay deposits that contain kaolinite mineral are using for industrial purposes, because it has less plasticity, cohesion, CEC, and swelling than most other clay minerals [Sheta et al., 2006].

The application of natural clay deposits locally available in Saudi Arabia as soil amended material, soil conditioner, to improve the sandy soil physical condition such as relative swelling, cumulative infiltration, and water conservation were studied. It was concluded that using local abundance clay deposits could improve the predominantly sandy soils in the Middle Eastern countries [Sheta et al., 2006].

Radiation dose due to gamma emitter naturally occurring radionuclides represents the main external source of irradiation of the human body. More specifically, natural environmental radioactivity and the associated external exposure due to gamma radiation depend primarily on the geological and geographical conditions, and appear at different levels in each region in the world [UNSCEAR, 2000].

From the environmental point of view; it is essential to estimate the concentrations of the naturally occurring radioactive materials (NORM) in the clay deposits to ensure their radiological safety for their handling and applications. This study aims at measuring NOR activity concentration in clay samples from three different regions in Saudi Arabia, estimating the radiation doses and possible hazardous impacts of their applications.

Material and methods

Sampling and samples preparation:

Twenty one clay deposit samples were collected from, three Saudis' regions, Al-Riyadh, Al-Kharg and Jiddah. The selection of the sites was based on previous geological studies [Laurent, 1993]. Sampling was carried out by a scientific group from the soil sciences department, college of food sciences and agriculture, King Saud University. Samples were collected using the standard methods to get a composite sample that represents each site. Samples were dried in an open air of a dry place, mechanically crushed, and sieved through a 2 mm mesh sieve [Sheta et al., 2006].

Gamma-ray spectrometry:

The dried samples were transferred to polyethylene containers of 100 cm3 capacity and sealed at least for 4 weeks to reach secular equilibrium between radium and thorium, and their progenies. ^{226}Ra (^{238}U) series, ^{232}Th series, ^{40}K, 137Cs and 210Pb specific activities were measured using well-calibrated gamma spectrometry based on hyper-pure germanium (HpGe) detectors. The HpGe detector had a relative efficiency of ^{40}% and full width at half maximum (FWHM) of 1.95 keV for 60Co gamma energy line at 1332 keV. The gamma transmissions used for activity calculations are 352.9 (214Pb), 609.3, 1120.3 and 1764.5 keV (214Bi) for ^{226}Ra (^{238}U) series, 338.4, 911.1 and 968.9 keV (^{228}Ac) for ^{232}Th series, 1460.7 keV for ^{40}K, 661.6 keV for 137Cs and 46.5 keV for ^{210}Pb. The gamma spectrometers were calibrated using both ^{226}Ra point source and potassium chloride standard solutions in the same geometry as the samples (Khater, 2001).

Theoretical calculations:

Radium equivalent (Raeq) index in Bq/kg is a widely used radiological hazard index and a convenient index to compare the specific activities of samples containing different concentrations of ^{226}Ra, ^{232}Th (^{228}Ra) and ^{40}K. It is defined based on the assumption that 10 Bq/kg of ^{226}Ra, 7 Bq/kg of ^{232}Th and 130 Bq /kg of ^{40}K produce the same gamma dose rate. It is calculated using the following equation [Beretka and Mathew, 1985]:

$$Raeq = C_{Ra} + 1.43\ C_{Th} + 0.007\ C_K$$

Where; C_{Ra}, C_{Th} and C_k are the activity concentrations of ^{226}Ra, ^{232}Th and ^{40}K in Bq/kg, respectively.

The absorbed dose rates due to γ-ray the air at 1m above the ground surface for the uniform distribution of the naturally occurring radionuclides (^{226}Ra, ^{232}Th and ^{40}K) were calculated based on guidelines provided by UNSCEAR (1993, 2000). The conversion factors used to compute absorbed γ -dose rate (D) in air per unit activity concentration in Bq per kg (dry weight) corresponds to 0.462 nGy h−1 for ^{226}Ra (of U-series), 0.621 Gy h−1 for ^{232}Th and 0.0417 nGy h−1 for ^{40}K [UNSCEAR, 2000 & 1993].

$$D = 0.461\ C_{Ra} + 0.623\ C_{Th} + 0.0414\ C_K$$

To estimate the annual effective dose rates, the conversion coefficient from absorbed dose in the air to effective dose (0.7SvGy−1) and outdoor occupancy factor (0.2) proposed by UNSCEAR (2000) are used. Therefore, the effective dose rate in mSv.y−1 was calculated by the following formula [UNSCEAR, 2000]:

Effective dose rate ($\mu Sv.y^{-1}$) = Dose rate ($nGy.h^{-1}$) X 24 h X 365.25 d X 0.2 (occupancy factor) X 0.7 $Sv.Gy^{-1}$ (conversion coefficient) X 10^{-3}

According to ICRP (1977) the upper limit of radiation dose arising from building materials is 1.5 $mSv.y^{-1}$ [ICRP, 1977]. For limiting the radiation dose to this value, Krieger (1981) proposed the following conservative model based on infinitely thick walls without windows and doors to serve as a criterion for the calculation of external hazard index Hex - defined as [Krieger, 1981]:

$$H_{ex} = \frac{C_{Ra}}{740} + \frac{C_{Th}}{520} + \frac{C_K}{9620} \leq 1$$

Hewamanna et al. (2001) corrected this model after considering a finite thickness of walls and the existence of windows and doors. Taking these considerations into account, the equation used for the calculation of external hazard index becomes:

$$H_{ex} = \frac{C_{Ra}}{740} + \frac{C_{Th}}{520} + \frac{C_K}{9620} \leq 1$$

The value of this index must be less than unity for the radiation hazard to be negligible, i.e. the radiation exposure due to radioactivity in construction materials must be limited to 1.5 $mSv.y^{-1}$.

In addition to the external irradiation, radon and its short-lived products are also hazardous to the respiratory organs. The internal hazard index (Hin) is used to control the internal exposure to 222Rn and its radioactive progeny. The internal exposure to radon and its daughter products is quantified by the internal hazard index (Hin) which is given by the following equation [Krieger, 1981];

$$H_{in} = \frac{C_{Ra}}{185} + \frac{C_{Th}}{259} + \frac{C_K}{4810} \leq 1$$

For the safe use of a material in the construction of dwellings Hin should be less than unity.

Another radiation hazard index called the representative level index, Iγ, is defined from the following formula [NEA-OECD, 1979; Alam et al., 1999];

$$\mathrm{I}\gamma = \frac{C_{Ra}}{150} + \frac{C_{Th}}{100} + \frac{C_K}{1500} \leq 1$$

The safety value for this index is ≤ 1.

Results and discussion

The statistical summary of activity concentration of naturally occurring radionuclides (NOR), i.e, ^{226}Ra, ^{228}Ra and ^{40}K, and radium equivalent value (Raeq) in Bq/kg dry weight of clay deposit samples was given in table 1,and shown in figures 1 and 2.
There are a noticeable differences in the average activity concentration of ^{226}Ra, ^{228}Ra and ^{40}K, in clay samples from different regions (I:Al-Riyadh, II: Al-Kharg and III: Jeddah). The lowest average activity concentration of both ^{226}Ra and ^{40}K, and the highest average activity concentration of ^{228}Ra were found for Jeddah region samples. Average Raeq values for the three regions samples were comparable and less than 370 Bq/kg. That is equivalent to the maximum permissible limit for indwelling radiation dose due to NOR in building materials.

Table 1. statistical summary of activity concentration of ^{226}Ra, ^{228}Ra and ^{40}K, and radium equivalent value (Ra-Eq) in Bq/kg dry weight of clay deposit samples

Reg.	^{226}Ra	^{228}Ra	^{40}K	Ra -Eq
I	50 ± 3, 7 (45-59),6	28 ± 3 , 8 (16-35), 6	823 ± 143, 350 (298^{-1}181), 6	151 ± 17, ^{40} (92-200)
II	54 ± 11, 31 (11^{-1}08),8	39 ± 5.17, 15 (26-69),8	781 ± 143, ^{40}5 (262^{-1}387),8	169 ± 17, 48 (72-200)
III	29 ± 7, 14 (10-42),4	62 ± 13, 26 (34-85),4	583 ± 104, 209 (356- 768),4	162 ± 33, 66 (86-222)
ALL	47 ± 6, 23 (10^{-1}08),18	^{40} ± 5, 20 (16- 85), 18	751 ± 82, 347 (262- 1387),18	162 ± 11, 48 (72- 222)

*Average ± standard error, Standard deviation (range), No. of measured samples. I:Al-Riyadh, II: Al-Kharg and III: Jeddah

Average activity concentrations of ^{226}Ra, ^{228}Ra and ^{40}K, and Raeq value for clay samples were 47, ^{40} and 751, and 162 Bq/kg, respectively. These values were within the world activity concentration range of ^{226}Ra, ^{228}Ra and ^{40}K in soil; 10-50, 10-50, 100-700 Bq/kg, respectively [UNSCEAR 1988]. There is a trend for the NOR activity concentrations in the different regions where the maximum activity concentration of ^{228}Ra was found in region III while the minimum average activity concentration of both ^{226}Ra and ^{40}K were in region III. This trend is not clear for Raeq value because it is dependent on the activity concentration of the three radionuclides with weighting factor of 1, 1.43 and 0.07 for Ra, Ra and K, respectively.

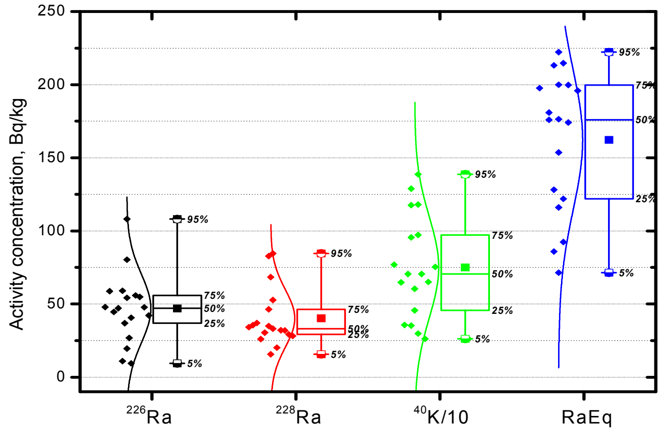

Fig. 1. Box chart of activity concentration of ^{226}Ra, ^{228}Ra and ^{40}K, and radium equivalent value (Ra-Eq) in Bq/kg dry weight of clay deposit samples.

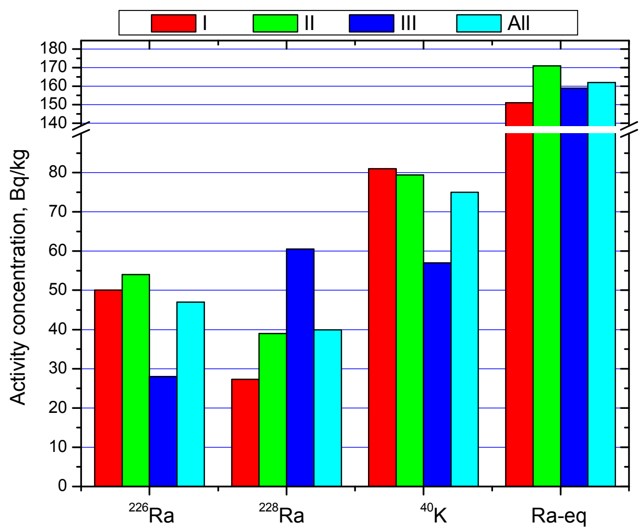

Fig. 2. activity concentration of ^{226}Ra, ^{228}Ra and ^{40}K, and radium equivalent value (Ra-Eq) in Bq/kg dry weight of clay deposit samples according to sampling region (I:Al-Riyadh, II: Al-Kharg and III: Jeddah).

Walley El-Dine et al., 2004, studied the activity concentration of NOR in local and imported kaolin (china clay) types used in Egypt. Kaolin is widely used in paper industry, ceramics, refractory bricks, white cement, textiles, rubber, medical industries, and special types of plastics. Their results show an obvious wide range of variation in ^{226}Ra, ^{228}Ra and ^{40}K activity concentrations, and radium equivalent values (Ra-Eq) that had mean values (ranges) of 965 (48-8633), 252 (96-1079), 59 (8-270) and 1329 (188-10185) Bq/kg, respectively [Walley El-Dine et al., 2004].

Clay is a widely distributed, abundant mineral resource of major industrial importance for an enormous variety of uses. Table 2 shows the average activity concentrations of ^{226}Ra, ^{228}Ra, ^{40}K and Raeq in clay bricks as building materials from

12 different countries [Hewamannaa et al., 2001]. The results of Saudi's clay samples are less than the average activity concentrations for ^{226}Ra, ^{228}Ra and Raeq, and slightly higher than the average activity concentration for ^{40}K.

According to IAEA (international Atomic Energy Agency) activity concentration values for exclusion, exemption and clearance (1000 Bq/kg for ^{40}K and 1000 Bq/kg for any other NOR), it is not recommended that the exposure dose be investigated for the studied clay deposits. Due to the limited number of studied samples and the possible variation in NOR activity concentration, it is recommended to measurement of NOR activity concentrations for more clay deposit samples from the same and other geological formation[IAEA, 2004].

Table 2. Comparison of activity concentrations and radium equivalents- Raeq (Bq.kg^{-1}) in clay bricks in different areas of the world [Hewamannaa et al.; 2001]

Country	No. of samples	^{226}Ra	^{232}Th (^{228}Ra)	^{40}K	Raeq
Australia	25	41	89	681	220
China	n.m.[a]	41	52	717	171

& Mean ± Stand. Error (range)

Clays and clay minerals occur under a fairly limited range of geologic conditions. The environments of formation include soil horizons, continental and marine sediments, geothermal fields, volcanic deposits, and weathering rock formations. Most clay minerals were formed where rocks are in contact with water, air, or steam. Examples of these situations include weathering boulders on a hillside, sediments on sea or lake bottoms, deeply buried sediments containing pore water, and rocks in contact with water heated by magma (molten rock). All of these environments may cause the formation of clay minerals from preexisting minerals. Extensive alteration of rocks to clay minerals can produce relatively pure clay deposits that are of economic interest (for example, bentonite, primarily montmorillonite, used for drilling mud and clays used in ceramics) [USGS, 1999]. The activity concentration and the environmental behavior of natural occurring radionuclides (NOR) in the geosphere depend on many parameters such as their geochemical properties. Radium (Ra) is an alkaline earth element, and can exist in nature only in the +2 oxidation state. In the pH range of 3 to 10, the uncomplexed ion Ra2+ is the dominant aqueous species for dissolved radium in natural waters. In sulfate- containing waters, precipitation and redissolution of calcium (Ca), strontium (Sr), and barium (Ba) sulfates, rather than adsorption/desorption, could control the concentrations of dissolved radium in the soil. Precipitation of radium is readily possible as the solid-solution solids (Ba, Ra)SO4 and (metal, Ra)CO3 in water where the concentration of dissolved sulfate and carbonate, respectively, are sufficient high. The adsorption behavior of radium will be very similar to that of strontium. Relative to other alkaline earth elements, radium is the most strongly sorbed by ion exchange on clay minerals. The adsorption of radium is strongly dependent on ionic strength and concentrations of other competing ions that adsorption of radium decrease with increasing ionic strength. Radium is also strongly adsorbed in mineral oxides present in soil, especially at near neutral and alkaline pH conditions. The results of some studies also suggest that radium may be strongly adsorbed by organic material in soils. [EPA, 2004].

The physical characteristics of clay deposits, as one type of sedimentary rock, are governed by many factors of which some include parent rock material, mode of formation of the minerals, the means and distance of transport, and the depositional environment. These characteristics together with uranium, thorium and radium content of the parent rock, and recent physical and chemical events (i.e. chemical leaching, transport with water, and precipitation/adsorption) can affect the final distribution of radium [Edsfeldt, 2001].

Neither radium itself, radium salts, radium carbonates, nor radium oxides are very soluble. However, radium solubility is enhanced by alpha recoil. During the decay of a radionuclide by alpha emission, alpha particles are rejected from the nucleus, carrying off most of the excess energy. The created progeny recoils in the opposite direction. Thus, uranium deposits can kick radium compounds into interstitial pore water due to alpha recoil process [Cothern and Rebers, 1991].

To evaluate the radiation hazardous due to the natural radionuclides in different clay deposits and their various applications, absorbed dose (D) in $nGy.h^{-1}$, effective dose rate (E) in $\mu Sv.y^{-1}$, radioactivity level index ($I\gamma$), external hazard index (H_{ex}) and internal hazard index (H_{in}) were calculated, Table 3. Calculations of both D and E were considered to estimate the radiation dose due to gamma ray emitter in clay samples. Calculated values are much lower than their value due to natural background (2.4 mSv/y) [UNSCEAR 1993].

Table 3. statistical* summary of calculated radium equivalent in Bq/kg dry weight of clay deposits sample, absorbed dose (D) in $nGy.h^{-1}$, radioactivity level index ($I\gamma$), external hazard index (H_{ex}), internal hazard index(H_{in}) and effective dose rate (E) in $\mu Sv.y^{-1}$

Average ± standard error, Standard deviation (range

Other calculated indices considered when clay deposits use as a building material where their values should be less than unity. Both internal and external hazardous indices were less than unity that indicates their safe utilization as building material. While, the representative level index values in about 65% of the studied samples and the average value were higher than unity that indicates their unsafe utilization as building material.

Conclusions

- Average concentration of natural radionuclides (NOR) in clay deposit samples from different regions were varied. That could be due to the different of the geological formation origin and the geochemical behavior of the NOR. Variation of both Ra and K average concentrations were similar (I> II> III) while that of Ra was reversed (III> II> I). Radium equivalent values were comparable in the three regions.
- The activity concentrations of natural radionuclides (NOR) in the studies clay deposit samples are higher than the world average of soil.
- The average activity concentrations of NOR in clay samples were much lower than the NOR concentrations in kaolin clays that imported from different countries and industrially used in Egypt.
- The average activity concentrations of NOR in clay samples were fall in the low range of NOR concentration in clays blocks from different countries that were used as a building material.
- Based on calculated external and internal radiation hazardous indices, the studied clay samples could be utilized safely as a building material.

Distribution pattern of NORM on Red Sea shore sediments in relation to non-nuclear industries

Khater, Ashraf
King Saud University, SAUDI ARABIA

Abstract

The Red Sea is a deep semi-enclosed and narrow basin that has an intensive non-industrial activities on and near its shore. Oil exploration, phosphate mining and trading, navigation activities and intensive touristic activities are consider as non-nuclear pollution sources that could impose a serious radiological and ecological impacts on the Red Sea marine environment. Both oil and phosphate related activities could increase the concentration of Naturally Occurring Radioactive Materials – NORM such as uranium-238 series, thorium-232 series and potassium-40. Forty representative shore sediment samples were collected from the Egyptian Red Sea shore, from Shuqeir to Marsa Alam City region. Activity concentration of ^{238}U, ^{232}Th, ^{40}K, ^{210}Pb and ^{210}Po were measured using gamma-ray spectrometry, alpha particle spectrometry and ICP-MS analytical techniques. Previous study showed the possible impact of industrial activities on the activity concentration of NORM in shore sediment. This study will investigate such relation and the distribution pattern of NORM in more details.

NORM and heavy metals partitioning during water treatment processes

Khater, Ashraf
King Saud University, Physics, SAUDI ARABIA

Abstract

Water samples were collected from underground water purification plant to study the variation in Naturally Occurring Radioactive Material (NORM) e.g., U, Th and K, and heavy metals e.g., Cd, Pb, Hg, Cu, and Zn concentration through the treatment processes and its relation to physical and chemical properties of water. Samples represent the different treatment processes (input, output, after filtration, sludge tank, reverse osmosis permit and reject, and waste water ponds). NORM and heavy metals concentration in the collected samples were measured using ICP-MS. Their concentrations in water samples show a wide range of variation that depend mainly the water treatment processes and the chemical properties of water samples. Water physical and chemical properties, i.e. pH, EC, major cations (Ca, Mg and K) and major anions (CO_3, HCO_3, Cl and SO_4) were determined. The effect of water treatment processes on NORM concentration; dose assessment due to water drinking (before and after treatment) and the radio-ecological risk assessment were discussed.

Soil-to-plant transfer factors of ^{210}Pb and ^{210}Po in boreal forests

Vaaramaa, Kaisa[1]; Aro, Lasse[2]; Solatie, Dina[3]

[2] Finnish Forest Research Institute (METLA), Parkano Research Unit, FINLAND

[3] STUK – Radiation and Nuclear Safety Authority, Regional Laboratory in Northern Finland, Rovaniemi, FINLAND

Abstract

The general goal in this project was to obtain overview on ^{210}Po and ^{210}Pb behaviour and mobility in the environment. Binding and mobility of ^{210}Po and ^{210}Pb in forest soil and transfer of polonium and lead from soil to plants were considered. The main study areas were located in Scots pine forests in southern Finland (62º9'N, 22º52'E) and in northern Finland (66º21'N, 26º44'E). The soil samples were collected and separated into different soil horizons (litter, organic and mineral soil layers). Vertical distribution and concentrations of ^{210}Pb and ^{210}Po in soils were determined. Wild berry samples and edible mushrooms were collected at the sampling sites. Activity concentrations of ^{210}Po and ^{210}Pb were analysed from roots and rhizomes of the berry samples as well as from berries (i.e. fruits), leaves and stems separately. Mushrooms were divided into caps and stipes and each part was analysed separately. The mean ^{210}Po/^{210}Pb ratio was 0.9 in the organic soil layer in the southern and the northern Finland sites. The activity ratios of ^{210}Po/^{210}Pb in the wild berry and mushroom samples were mainly higher than one, indicating elevated concentrations of polonium in the samples. In mushrooms the concentrations of ^{210}Pb and ^{210}Po were higher than in fruits of the wild berries. Soil-to-plant transfer factors for lead and polonium will be discussed. The research results gained in this project will enable an assessment of the mobility of ^{210}Po and ^{210}Pb in the environment and in the food chains and estimation of ensuing radiation doses to humans.

Radiological assay techniques associated with TENORM industry

Dulama, Cristian; Dobrin, Relu; Toma, Alexandru; Ciurduc Todoran, Germizara Anca
RAAN-SCN, Radioprotection, ROMANIA

Abstract

In recent years there has been an increasing awareness of the radiological impact of non-nuclear industries that extract and/or process ores and minerals containing naturally occurring radioactive materials (NORM). Actions were undertaken to find and characterize the main industrial activities involving NORM and to assess the impact of these activities on the nearby public. The main concern was on past activities in phosphate fertilizers industry and the associated by-products disposal as well as the activities in oil and gas production and processing industry. Phosphogypsum is the main by-product generated during the phosphoric acid production process (wet process), and phosphate slag is the principal by-product generated from the production of elemental phosphorus (thermal process). During the wet process, a selective separation and concentration occurs for radionuclides which are naturally associated with the phosphate ores. In oil and gas production and processing equipment some elevated TENORM contamination might occur due to the physical processes to which the extraction fluids are exposed. Some radium and radium daughter compounds are slightly soluble in water and may become mobilized when this production water is brought to the surface. The paper presents the methodology used in some particular cases to deal with NORM characterization as a regulatory requirement for non-nuclear practitioners to improve their radiological safety and to achieve an adequate level of knowledge as concerns the risks associated with NORM industry.

NORM management in the oil & gas industry – Saudi Aramco experience

Mously, Khalid; Cowie, Michael
Saudi Aramco, Environmental Protection Department, SAUDI ARABIA

Abstract

It has been established that Naturally Occurring Radioactive Materials (NORM) may accumulate at various locations along the oil/gas production process. Components such as wellheads, separation vessels, pumps, and other processing equipment can become NORM contaminated, and NORM can accumulate in the form of sludge, scale, scrapings and other waste media. This can create a potential radiation hazard to workers, general public and the environment if certain controls are not established. Saudi Aramco has developed NORM management guidelines and is implementing a comprehensive strategy to address all aspects of NORM management which aim towards enhancing: NORM monitoring, Control of NORM contaminated equipment, Control of NORM waste and disposal, Workers protection, awareness, and training The benefits of shared knowledge, best practice and, experience across the oil & gas industry are seen as key to the establishment of common guidance. This paper presentation outlines Saudi Aramco's experience in the development of a NORM management strategy and its goals of establishing common guidance throughout the oil and gas industry.

The needs and feasibility of land reclamation of areas affected by enhanced natural radioactivity

Michalik, Boguslaw
Laboratory of Radiometry, Central Mining Institute (GIG), POLAND

Abstract

The major efforts devoted to disposal of radioactive materials are focused on those originating from nuclear industry. Far less attention has been paid to environmental burden of waste with natural radioactivity enhanced by non-nuclear industry. Such waste differs significantly from classical nuclear ones and the radiation risk is often associated with risk caused by other pollutants. Contrary to the nuclear waste that's strictly controlled, it has been a common practice to put TENORM *(Technologically Enhanced Naturally Occurring Radioactive Material)* into heaps, where they can reach thousands of cube meters or tonnes, without any protection. Exposure to meteorological conditions sets some chemical or physical processes in motion, leading to the selective transfer and accumulation of radionuclides and disequilibrium in decay series.

As a result of the inconclusive European law, that left the decision where risk caused by TENORM is significant under each member state's competences, non-nuclear industry is hardly ever aware of environmental problems caused by natural radioactivity or expect negative consequences in case of implementing radiation protection measures. This results in the substantial underestimation of the detrimental effects to the environment originating from TENORM. EU member states apart each other try to regulate this problem case by case when but the risk caused by TENORM is rarely taken into account when the treatment of such waste is planned.

The feasibility of different methods of land reclamation was discussed including hard land reclamation, bioremediation and phytotechnology. An approach based on dilution of TENORM with inert materials was considered. Contrary to the nuclear waste, where dilution is totally forbidden, natural radioactivity, which is present in small amounts elsewhere, is a case where such approach to decrease risk sounds rationally. In extraction industry where huge amount of gangue is present, such approach is well-founded also from economic point of view.

Introduction

Natural radioactivity is ubiquitous in human environment. According to the state-of-the-art radioprotection, radiation emitted by primordial radionuclides in their natural state that has not been altered due to human activity is not considered to be a source of harmful effects neither for human beings nor environment. There are many areas in the world having elevated so called "natural background" caused either by the geological and geochemical structure of the rocks, or by the radioactive content of water flowing from underground springs. Whether or not it can cause a negative or positive effect on human beings is a matter of opinion. But if concentrations of natural radionuclides have been changed as deliberate or accidental action carried out by human being it is quite another matter. The classical case where radiation risk caused by natural radioactivity is not negligible is uranium mining and milling. It is abundantly clear that such processes must be carried out at the region where reach uranium ore occurs. But such activity is considered to be an immanent part of nuclear industry to be enclosed in radiation protection domain at the very beginning. After the enhanced natural radioactivity had been thoroughly studied in other industries it became clear that such phenomena are very frequently present in the anthropogenic environment. Many processes beyond nuclear industry lead to a situation where the activity concentration of naturally occurring radionuclides is enhanced. Such alteration of natural state can result in increased radiation risk to the people as well as to environment and non-human biota. Hence, the monitoring and prevention of occupational radiation risks caused by enhanced natural radioactivity has become obligatory in many cases of industry of concern.

Enhanced natural radioactivity is usually associated with industrial processes where a significant mass reduction of raw materials occurs. As a matter of fact, these processes are not aimed at production of natural radionuclides or the deliberate use of radiation. Therefore, radioactive nuclides are often accumulated in useless industrial residues. From the point of view of the general principles of radiation protection, the activity concentration of natural radionuclides in such materials is sometimes high enough to rank them as radioactive waste. Their amount collected in one site frequently riches hundreds of thousands of cubic meters or tonnes. For instance, in coal mining industry radium activity deposited in single tailing ponds may reach as high as 300 GBq (Michalik et al. 2005). Probably, the biggest "producer" of waste with enhanced concentration of natural radionuclides are phosphate processing plants where radionuclides remain associated with the phosphogypsum particles, being subsequently stored in a disposal sites located in the vicinity of the factories with surface dose rate reaching 350 MBq/h (Bolivar et al. 2009). In spite of that TENORM-type waste (TTW) is often deposited directly into the environment, what is strictly forbidden in case of "real" radioactive waste. Contrary to the occupational risk, which is more or less controlled, by far, less attention has been paid to the environmental burden emerging due to TENORM-type waste (TTW). This results in sites where such waste have been dumped not to undergone adequate land reclamation and often even monitoring of radioactive pollution is not carried out. There are only few examples where TENORM type waste are treated in correct way (Welbergen and Wiegers 2008). There are significant number of cases where only non-radiological parameters are effectively taken into account during presumptive land reclamation, mainly due to the lack of proper regulation.

Environmental burden of TENORM residues

There is a lot of data dealing with the behaviour of natural radionuclides being in the natural state on the border of abiotic and biotic matter. Frequently, the processes of metabolism lead to concentration of some long-lived natural radionuclides in particular tissues of fungi, plants as well as animals (McDonald et al. 1996). Derived committed dose can be higher than doses resulted from artificial radionuclides accumulated simultaneously (Aarkrog et al. 1997). There are some examples of societies based on limited trophic chain where the related committed dose to individuals caused by biologically accumulated natural radionuclides such as polonium and lead ingestion is significant. J. Van Oostdam et al. (2005) indicated ^{210}Po derived doses as high as 10 mSv per year for some aboriginal northern communities consuming large amounts of caribou. Either, annual doses reaching 3 mSv were reported for population of fisherman just living on seafood (Alonso-Hernandez et al. 2002), (Camplin et all. 1996). If such processes are going on in unchanged environment, one can easily image what is going to happen in the vicinity waste dump where residues containing enhanced concentration of natural radionuclides had been collected.

Each particular occurrence of TTW presents a unique scenario of exposure – usually different from those caused by artificial radionuclides present in radioactive waste or spent nuclear fuel. As a result of the direct contact with environment, some transformation processes such as mobilisation of radionuclide species from solid phases or interactions of mobile and reactive radionuclide species with components in soils and sediments may be set in motion (Vandenhove and Van Hees 2007). Also considerable transfer of radionuclides to biota can be observed (Soudek et al. 2007). All these result in that the original distribution of radionuclides deposited in environment can change over time. Moreover, natural radionuclides are often associated with other pollutants as heavy metals or hydrocarbons that can escalate negative impact on environment if dumped out of plants. That's why, to plan the land reclamation of a site affected by TTW, information on radionuclide species deposited, interactions within affected site either local ecosystems or environment compartment and the varying in time distribution of radionuclide species influencing mobility and biological uptake is essential (Tamponnet et al. 2008).

TENORM-type waste characterization

TTW produced by non-nuclear industrial activities such as mineral production, mining activities or coal fired power plants contain a number of long-lived natural occurring radionuclides from the uranium and thorium decay series. The main, from radiation protection point of view, properties of TTW which make them significantly different from "classical" radioactive waste are (Michalik 2007);

- the occurrence in bulk quantities deposited directly in the environment,
- the wide variety of radionuclides speciation and different minerals content,
- the possible coexistence of other pollutants as heavy metals, sulphates, hydrocarbons

Taking into consideration the radionuclides that occur in TTW and either their activity concentration or total activity, some part of them should be classified as radioactive waste containing alpha emitters, (i.e. the limit of activity concentration for radium isotopes is 10 kBq/kg). Actually, the decision to rate TTW among the radioactive waste at all, not only as alpha emitters is rarely taken. It results in technical problems and economical consequences that would follow such decision (to remind, such waste must be sealed and deposited in a repository, in case of alpha emitters in deep underground repository). After they are classified as radioactive waste TTW would generate enormous cost- related implications and fill available repository very quickly. There is no possibility to treat them as such with regard to existing regulation, which had been prepared when thinking about nuclear waste. Finally, there are gaps, no special regulation and no correct way of deposition. Moreover, from environmental point of view, very interesting is, what one should do with waste that contain slightly lower than limit radioactivity content, in case of radium, for example, 9 kBq/kg. Expected effects on environment caused by waste with 10 and 9 kBq/kg of radium should not be significantly different. Actually, the proposed clearance level for natural radionuclides from uranium and thorium decay series have been set at the level of 1 kBq/kg. So, even if one wants to follow the existing regulation quickly will meet the big gap between 1 and 10 kBq/kg.

After deposition TTW in environment, enhanced concentration of natural radionuclides first of all, results in enhanced exposure of biota to external gamma radiation. So, accurate measure of the total radionuclides concentration in these waste materials is crucial to asses the potential radiological risk at a dump site. However, if one managed to gather data about physical presence of each particular radionuclide, this information would give only a part of the knowledge necessary to evaluate its harmful potential. The radiological hazards can be increased by migration process of mobile fraction of these radionuclides to the vicinity of a depository (Sheppard et al. 2005). Being released into an ecosystem, they can enhance the gamma radiation doses to biota. That is the reason why it is crucial to know the mobility of radionuclides (Martinez-Aguirre et al. 1995). The mobility and environmental behaviour of every element depend on their speciation in certain waste material (Zhongwen et al. 2002). The speciation of a radionuclide is generally related to its physical and chemical forms existing, that is, simple and complex ions in interstitial solution, exchangeable ions associated with waste material organic fractions occluded or co-precipitated with metal oxides, carbonates, sulphates and other secondary minerals.

But the exposure to external gamma radiation is only a tip of an iceberg. One should remember that in thorium and uranium decay series there are 7 and 12 alpha particles respectively (additional 12 are in actinium series). Even when one consider decay series starting from radium (^{226}Ra or ^{228}Ra) what is very common in TTW waste the number of alphas decreases only to 7 and 9, respectively. It is hardly ever taken into consideration but in environment, in case of plants, especially plant roots, the exposure to external alpha radiation is as important as exposure to alpha radiation emitted by incorporated emitters. Also one should remember about betas emitted by natural radionuclides. Actually the weighting factors for alpha and beta radiation established for human being can not be directly applied for plants but there are no rational reasons why they should be significantly lower. Direct measurements showed that absorbed dose resulted from alpha radiation can reach the same level as doses from gamma radiation (Michalik 2008).

Besides the problems caused by activity concentration, radionuclides speciation and migration, the evolution of the related risk must be taken into consideration. Namely, the most common radionuclides responsible for risk creation are radium isotopes. In case where source of TTW are formation waters (oil and gas industry, underground mining) radium isotopes, both from uranium and thorium series, ^{226}Ra and ^{228}Ra are dominant. It means that, significant disequilibrium in natural decay series exists. At the beginning, just after deposition, there are almost pure radium as the only contaminant (besides possible other, non radioactive ones, of course). Radium isotopes are usually weakly mobile and not bio-available in environment. As it was proven radium creates not soluble radium-barium sulphate or its atoms are strongly bonded with fine clay minerals. The bio-available part usually does not exceed 1 % of total activity (Leopold et al. 2007). So, the environmental risk is limited only to the exposure to external gamma radiation, or as it was shown above, alpha radiation and finally could be partially limited by a cover from an inert material. Moreover, the part of exposure derived from radium ^{228}Ra will relatively quickly decreases (the half live of ^{228}Ra is 5.7 years, so not supported by long-lived parent radionuclides ^{228}Ra will quickly disappear). The only difficult situation is that, in the decay series started with not-supported radium ^{228}Ra, the activity concentration of decay products i.e. ^{224}Ra can exceed the activity concentration of radium after few years. It can cause troubles during measurements and appropriate actual dose assessment.

Quite different situation exists in case of radium ^{226}Ra. It decays slowly. Not only from the point of view of a human being but also form point of view of the environment it lasts eternally. 1600 years is long enough to be eye witness of changes going on in an ecosystem.

As it was already mentioned, the bio-availability of radium is very weak, but such comfortable situation with immobilised radium does not last long. Taking into consideration the relationships inside the uranium decay chain one should expect not so quickly, but permanent growth of long lived radium daughters as lead ^{210}Pb and polonium ^{210}Po. Both these radionuclides are very well known as easy migrating nuclides in environment and available to biota. After decay, the nuclide of radium is released from the barium-sulphate or clay mineral cage. Moreover, between radium and lead and polonium, there is radon (or thoron respectively) occurring in gaseous form. So, after one hundred years one should expect in the site where TTW with radium had been dumped exactly the same activity of easy migrating and easy bio-available lead and polonium isotopes. Besides specific chemical properties, they are beta and alpha emitters respectively and both of them are chemiotoxic elements.

In summary, the proper land reclamation of sites affected by TTW is an interesting challenge.

Remediation trials

Among noticed approaches to the reclamation of land affected by TTW, the simplest one, compliant with radiation protection rules, is to treat such waste literally as radioactive ones and apply all required restrictions. But for many reasons, it is applicable in limited cases (Michalik 2008,2). Usually, only parts of dewatering systems from crude oil and natural gas industry (Varskog 2007) or gangue from mineral sand processing (Hutchinson and Toussaint 1998) are disposed to especially prepared repositories. Sediments had been created in surface tailings sometimes are treated in special way (Al-Masri and Suman 2003) but usually, they are left without any action. Some promising efforts to wash out radium from oil sludge were made in Egypt (Afifi et al. 2009). Also applications of biotechnology, in order to make radium more mobile from uranium milling waste were noticed (Muñoz et al. 1995). But any of them have been applied in technical scale. In uranium mining and milling industry, where implementation of strict rules of radiation protection has long history, usually a kind of hard remediation is applied. Land-filing and covering with an inert matter is sufficient to limit the exposure to external radiation as well as further radon exhalation (Krizman 1995), (Juhász et al. 2001). But this approach is not sufficient enough to stop radium and further polonium migration.

The possibilities of application of different methods of land reclamation have been considered towards the sites contaminated by radium rich sediments originating from underground coal mining (Chałupnik et al. 2001), (Michalik 2004). The first based on application of phytotechnology was tested on an abandoned mining settling pond. Six-year-lasting observation of contaminated area let one noticed that the process of natural plants transgression was so effective and, even without any support, good enough to stop the physical propagation of contamination. The plants overgrowing the pond created a tight cover able to stop water and air land erosion. It supposes that, in case of controlled and supported propagation of selected plant species, it would be actually an effective and cheap method for immediate land reclamation of contaminated with radium sites.

The possibility of phytoextraction at this area was evaluated for two plant species *Cirsium vulgare* and *Calamagrostis epigejos*. The balance of radium ^{226}Ra in plant and sediment at the tested areas showed that one can expect only less than 0.01% of total amount of radium will be extracted during one vegetation season (Michalik et al. 2009). So it is by far too small for effective application of this method. Moreover, the experiment was done based on sediments in which radium was mainly adsorbed at clay minerals. Other experiments, done on sediments with radium-barium sulphate, a hardly soluble mineral, let one to expect even lower results. So, such approach does not solve the problem at all.

The recommended and usually followed approach to utilisation of sediments that had been gathered in underground workings is to put them into old galleries considered never been used again. From the radiation protection point of view such approach is optimal for safe disposal of sediments from surface settling ponds too. However, from technical point of view a lot of obstacles exist as limited capacity of empty underground spaces or distance from settling pond to the nearest shaft in use.

Finally, an approach based on dilution of radium waste was taken into consideration. In general, dilution of radioactive waste is totally forbidden. But in case of natural radioactivity, which is present in small amounts elsewhere, such approach to decrease derived risk sounds rationally. Especially in case of hard coal mining, where technological process creates fovorable circumstances to do it in economic way. During coal exploitation process, at least, half of mine spoil is waste rock and gangue. The radium activity concentration in thse waste do not differ significantly from average value taken as background for earth crust. So that it would be a good "solvent" for radioactive sediment. Actually, mechanical mixing of huge amount of mineral waste is complicated and expensive but again, coal exploitation process provides an opportunity to do it as a "by the way". Namely, all excavated matter must pass through a coal treatment plant in order to clean coal from gangue and prepare expected fraction of coal by flotation. The total amount of flotation and coal cleaning waste is big enough to turn back radium activity concentration in sediments to background level after homogenous mixing.

The possibility to apply such approach was tested in a mine. The total amount of mine spoil: coal and all types of created waste were balanced against total amount of radioactive sediments gathered in water galleries at all mine levels. It have been done year-by-year since 2005 (table 1). Codes were given based on rules of European waste catalogue (Michalik 2009).

Table 1. The balance of the excavation process.

year	Mine productivity (t):					
	total	coal	Waste from coal cleaning process code: 010102	Waste from flotation code: 010481	Sediment from water galleries code: 190899	Sum of : 010202 and 010481
2005	6895262	3674000	3050585	170677	1740	3221262
2006	6760336	3703900	2894547	161889	1620	3056436
2007	7056571	3737600	3163933	155038	3668	3318971

The current and archive data concerning radium activity concentration in every kind of considered materials were used (table 2). Because there are no data about behaviour of such sediment during coal enrichment process, all possibilities were taken into account, it means: total amount of radium accumulated in particular kind of waste have been considered separately (table 3).

Table 2. Basic statistics of radioactivity in sediments and gangue.

	code: 190899		code: 010202 & 010481	
	Ra-226	Ra-228	Ra-226	Ra-228
	Bq/kg			
average	705,6	364,4	79,7	73,1
median	409,0	246,0	73,0	79,0
Minimum	21,2	19,0	24	10
Maximum	8272,0	2880,0	189	112
Number of samples	39		15	

Table 3. Radium activity concentration in mixed waste.

nuclide	year	190899 + 010202 + 010481		190899 + 010102		190899 + 010481	
		maximum	*average*	*maximum*	*average*	*maximum*	*average*
Ra-226 [Bq/kg]	2005	193,36	80,07	193,61	80,09	270,57	86,05
	2006	193,28	80,06	193,52	80,08	269,08	85,93
	2007	197,92	80,42	198,36	80,45	375,81	94,19
Ra-228 [Bq/kg]	2005	113,49	73,22	113,58	73,23	139,93	76,01
	2006	113,47	73,22	113,55	73,23	139,42	75,95
	2007	115,06	73,39	115,21	73,40	175,97	79,80

Obtained results seem promising. The average activity concentrations in all end-products of the process are slightly increased in comparison to their original value. Moreover, considering the worst case scenario, it means the total amount of radium remains in the flotation waste, the smallest contributor to the total mass of concern, the activity concentration does not differ significantly from other ones and there are no limitations in their disposal at surface mine spoil bank and further use as i.e. aggregate.

Conclusion

In the light of different approaches to remediation of areas affected by waste with enhanced concentration of natural radionuclides, the dilution method with inert material or waste originating from industry of concern seems to be well justified from technical and economical point of view. The example from coal mining industry shows, based on the balance of waste rock and gangue produced by every mine, that there are enough capabilities to use this technology for safe disposals of radium-rich sediments that had been gathered in surface settling pond due to either former or current mining activity. However, such approach needs to be approved by appropriate regulation.

Uranium and heavy metals in narghile (shisha, hookah) moassel

Khater, Ashraf[1]; **Amr, Mohamed**[2]; **Chaouachi, Kamal**[3]

[1] King Saud University, Physics, SAUDI ARABIA

[2] Atomic energy Authority, Physics, EGYPT

[3] University of Paris XI-XII, DIU Tobaccology, FRANCE

Abstract

Cigarette smoke is a source of some trace and heavy metals but also the smoking mixtures used in narghile. Some cigarette filters retain significant quantities of cadmium, lead, magnesium, iron, and other metals. However, data on narghile (hookah, shisha, water-pipe) are scarce. So, the objective of the present study was to investigate the contents of the main and widely used smoking product: moassel. Ten representative samples of 3 different moassel brands were collected from the local market of Cairo city-Egypt and Riyadh City- Saudi Arabia. Uranium and heavy metals (e.g., Cd, Cu, Pb and Zn) were assessed using ICP-MS. Among the 10 representative samples of the 3 different moassel brands, The results indicate the existence of a wide range of variations in uranium and other element concentrations that could be because of non standard manufacture processes. The concentration levels were compared to the results of other studies and that of cigarette tobacco. Our study shows that, as far as trace elements are concerned, harm can be reduced. Public health officials could include in the national prevention plans the use of smokeless tobacco, particularly when addressing heavy narghile smokers. However, it must be clear that there are important differences between smokeless products. On one hand, some of them, like the Sudanese "tumbak", contain high levels of carcinogenic nitrosamines and we fear that Arabian shamma might be of a similar nature. On the other hand, a moist snuff like the Swedish SNUS, is, in the view of prominent international experts, highly recommendable all the more that it is also very low in carcinogenic substances. We therefore encourage its use all the more that this harm reduction product is culturally adapted to the Arab world context and other similarly sanitary and socio-cultural ones.

External gamma radiation produced by materials: proposal of an evaluation model. Application case study NORM

Alitto, Gabriele
Environmental Regional Protection Agency of Calabria, Provincial Department, 87100 Cosenza (CS), ITALY

Abstract
External gamma exposure to natural radiations is due to a series of isotopes gamma emitting, contained in all building materials. Beginning from the set up of a calculation model to estimate the emission in a closed environment, it was possible to derive the effective dose in the environment. The case of materials generally rich of natural radioisotopes was investigated.

From an inverse process, starting from the examination of the radiation field it is possible to estimate the extension of an activated surface. A case of contamination and activation surface in a general context as the inner part of nuclear plant or a radioactive facilities was evaluated. This method, moreover, is also applicable to NORM.

Introduction
The emission of total gamma radiation of simple or variegated structural configurations does not represent a simple modeling phenomenon, since the factors associated with emission, absorption and reflection, principally due to radiation-material interaction, generate a series of secondary events, the precise estimation of which inevitably risks complicating the problem.

Emitted radiation comes into being, due to various processes, involved in a series of intermediary interaction, then to be definitively absorbed. A global balance can be created considering the equation.

$$\text{Incident Radiation Energy} \rightarrow \text{Converted} + \text{Absorbed Radiation Energy} \qquad (1)$$

At this stage, it becomes inevitable to refer to the “medium”, or rather to the space-material reference in which the radiation is to be found.
Introducing a medium in which radiation is propagated, has the substantial aim, not just of identifying parameters such as propagation speed or refraction index in the medium, but of verifying if such a medium is of influence in terms of radiation intensity reduction, and therefore of absorption - bremsstrahlung of the same.

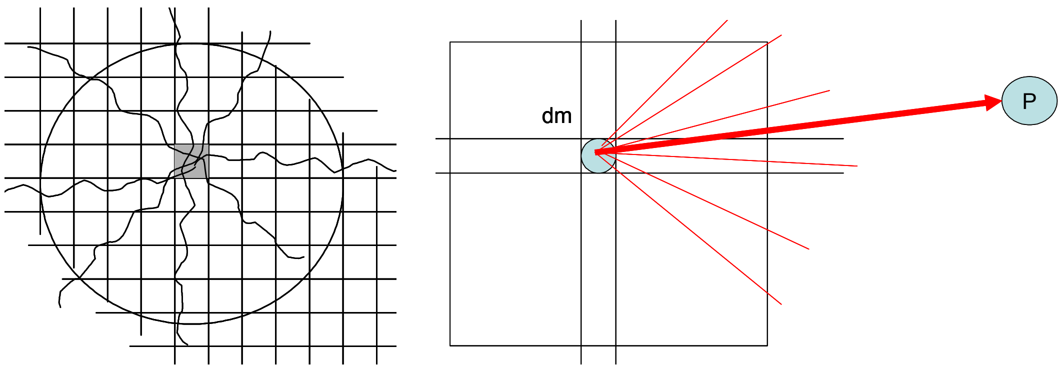

Fig. 1. Finite radiant element in the material matrix (left), and activity produced by a finite element on a P external point.

The study conductible on the emission of a finite source will start from a global approach, considering the attenuation properties of the finite elements and the data inherent to the absorption properties[1] of the interested medium being available. In the treatment of the subject, which will be carried out, the material presents prevalent gamma emissions (radionuclides greatly present), uniformly distributed and unequivocally determined by spectral lines. It is possible to hypothesise in order to reduce a sample in finite elements, considered as precise sources for simpler treatment, yet it is computationally suitable at the same time.

In the majority of cases, the level of activity of a source varies by varying the distance of the P observation point from the source, and from the properties of the medium crossed by ionised radiation.

$$A(P)=A(Ao, \underline{S}, \rho) \tag{2}$$

where:
Ao = activity in correspondence with the emission point;
P= observation point or radiation exposure target;
$\underline{S}$ = vectorial coordinate of point P compared to source origin;
ρ = specific density of material seen in relation to its mass attenuation;

Theory

The final objective of this study of materials is to determine the dosimetrical units associated with exposure to emitted radiation. The knowledge of the dose values descends directly from the values of the field typical parameters. In such a paragraph Laws are presented in order to determine the flow density for definite sources in space, in the hypothesis that the interplaced medium is air and that the point-source distance is such that it is able to disregard the effects of secondary absorption.

It is known that an isotropic point source is for the simplest case of emission. Photons are uniformly emitted in all the 4π solid angle, and in the absence of absorption, the φ flow density results as being thus defined (Pelliccioni, 1993):

$$\varphi = \frac{S}{4\pi r^2} \tag{3}$$

[1] Each medium considered has known properties such as density and degree of radiation absorption. Moreover the spectrometric analysis add information relative to the emissive properties of the material. The latter data can be evaluate according to an approach which takes into account each single radionuclide and of its own emission frequency, or rather, its total radiation contribution given by the finite material block.

At this point, also the attenuation produced by auto-absorption of the same materials comes into play, as well as the air. It is necessary to introduce a further complication (Salinas et al., 2006). Returning to the formula for photon attenuation, the pass-ratio results as being:

$$f = 1 - \frac{N}{N_0} = 1 - e^{-(\eta/\rho)\ \rho l} \tag{4}$$

For mono-energetic radiation the mass attenuation coefficient is known, as is the density of the material crossed. The term "l" represents the distance in the material with which the equi-balanced source sees the target[2]. The latter being dependant on the spatial coordinates of the integration dominion (Alitto, 2005), even the f function will depend on them.

$$\varphi = \iiint_V \frac{S_v \cdot f(x,y,z)}{4\pi r^2}\, dx\, dy\, dz \tag{5}$$

The study of an almost standard indoor environment with six walls, is conducted by the study of each individual wall. For exposure symmetry the maximum emission plane is situated along the axis of each wall. Radioactive emission of a wall presents a bell trend with the maximum situated in correspondence with the centre axis of the wall. Since gamma radiation covers a certain distance in the air ($1.2 \cdot 10^4$cm) it is a reasonable hypothesis to consider that the emissions of each wall are overlapped and culminate in the central area of the environment where people are more likely to be residing.

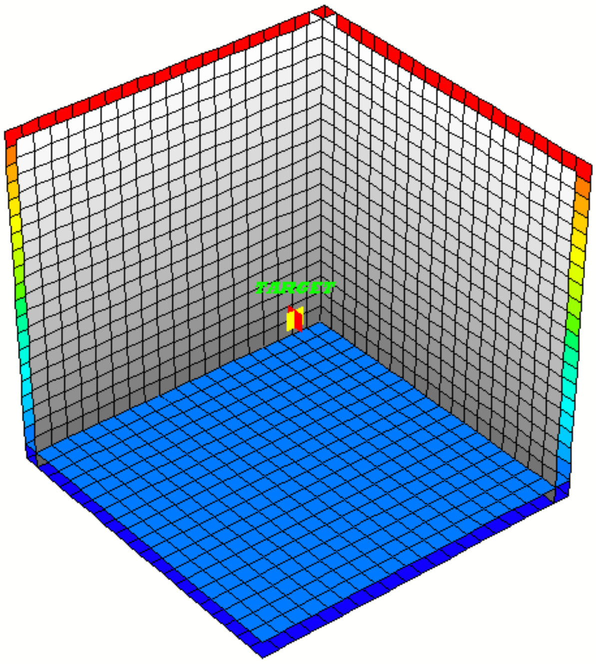

Fig. 2. Identification of the calculation target of a hemi – environment.

[2] Supposing that the wall is on an xy plane, that the target has P(x0,y0,z0) coordinates, that the distance of P from the wall is d, r the distance of a generic radiant point dV of the wall from P, then the distance $l = r(1 - d/|z - z_0|)$.

Furthermore, considering the absorption power of the air is translated into the introduction of a multiplicative factor similar to f(x,y,z), considered with the parameters of standard air composition.

$$\varphi = \iiint_V \frac{S_v \cdot f(x,y,z)\ f_a(x,y,z)}{4\pi r^2}\, dx\, dy\, dz \tag{6}$$

Such a further contribution leads to the natural extension of the formula to the case in which, in the virtual path of radiation, from the source to the target, a series of different mediums and materials, components such as mixed-layer thicknesses with different attenuation properties (Stranden, 1979), is in existence.

$$\varphi = \iiint_V \frac{S_v \prod_i f_i(x,y,z)}{4\pi r^2}\, dx\, dy\, dz \tag{7}$$

Nevertheless, the lack of "good geometry" conditions leads to the necessity of taking into account the build-up effect (Brar et al., 1999), on the basis of the components which characterize the materials. A corrective factor will be correlated to the formula (7) which is equal to

$$B(E,r) = 1 + \frac{(b-1)(K^x - 1)}{K - 1} \tag{8}$$

The formula to undergo simulation will be the result of the following mix (Alitto,2005):

$$\varphi_{sim} = \frac{S_v}{4\pi} \iiint_V B(E, r(x,y,x)) \frac{\prod_i f_i(r_{(x,y,z)})}{r^2}\, dx\, dy\, dz \tag{9}$$

Validation of the simulations was carried out using a comparison of the results with scenarios that have already been experimented and calibrated (R.P. 112). By means of the data provided by it, it was possible to carry out the direct identification of the external gamma dose, due to the presence of walls, floors, surfaces, thicknesses etc., by means of the conversion formula:

$$D^i_{\gamma\text{ - ext}} = \varphi \frac{c_i}{Sv} \tag{10}$$

Since the valuation of the external dose in mSv/year is through the knowledge of the fluence rate φ, obtained from the simulation, from the typical mass photon flow of the material and from c_i[3] which is a characteristic function of the i single radionuclide considered, in the case of mono-energetic radiation. The extension of poly-energetic radiation (Higgy et al.,2000), therefore a classical distribution of nuclides in the material matrix, is obtainable simply as a summary of the contributions of the single nuclide dose.

[3] The term Ci depends on the concentration of activity of the natural gamma-emitter element at a given frequency, and by a equal scale factor characteristic of the considered standard environment in R.P. 112 for 4x5x2,8 m³ , with wall thickness equal to 0,2 m and radiant material uniformity conditions.

Materials and methods

The field of radiation produced by a single finite wall, in which a certain concentration of natural radionuclides results as being uniformly distributed, can be inferred through the use of the equations seen previously, with the use of an appropriate calculator, through the use of volumetric numerical resolution, through libraries which are, in part, present in the software used (Matlab 7.0).

Such graphic representations of the emitting wall allow for the hypothesis that, in a preliminary and evidently superficial way, the previously formulated theory is correct, or rather that the field produced in a standard indoor environment (6 walls, of which two floors and four horizontals) is at its greatest in the central point.

The incorrectness of this assumption was verified proceeding with a volumetric analysis of the volume considered tridimensionally.

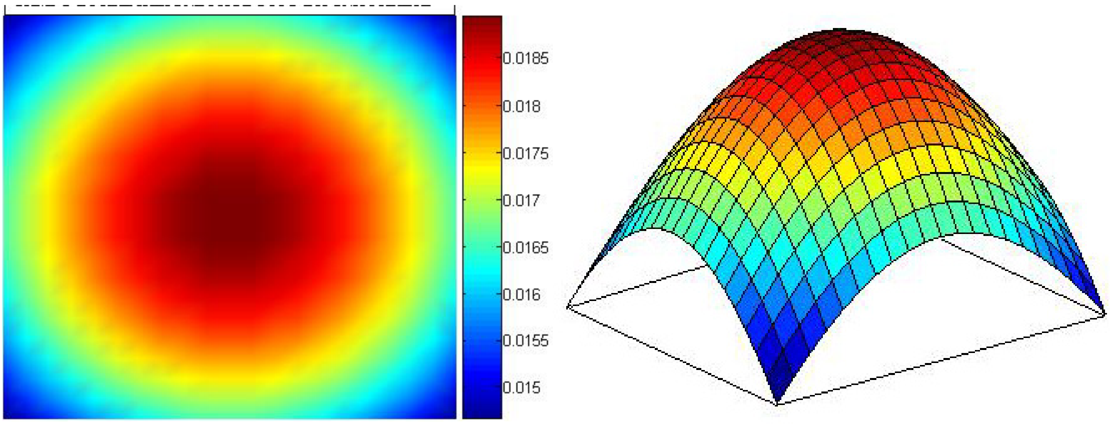

Fig. 3. Radiation field produced by a single wall by materials containing natural gamma emitters per unit of mass photon flow (left) and graphic visualization of the field produced by a wall as 3D surface (right).

In the first phase, the distribution of a reference mono-energetic source (K-40), uniform in all the material forming the 6 walls of a standard indoor environment, having cubic dimensions (4 x 4 x 4 m³), and equal thickness for each wall (0,2 m) was considered (Alitto, 2005).

A tridimensional calculation model was created which considered, for the evaluation of the field of radiation, volumetric elements of the room that were sufficiently small to be able to consider, the reasonably constant field of radiation within them.

The centres of each of these volume elements, aligned according to the three spatial directions, form the calculation plane of the field of radiation, or rather the planar portions of the environment space, to evaluate the variability of the field of radiation.

Results and discussion

The simulation was carried out, taking into consideration the aforementioned parameters, for the determination of the fluence rate of gamma radiation in each point-packet of the volume delimited by the walls according to the schematisation highlighted in the following image.

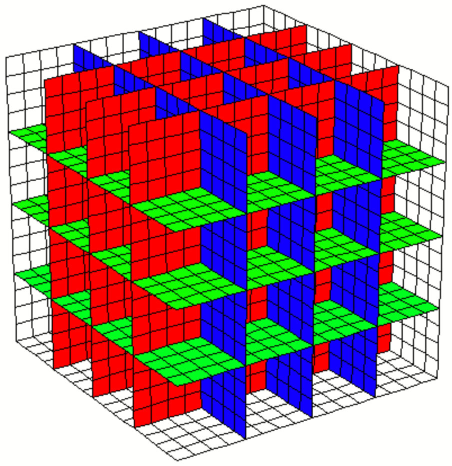

Fig. 4. The hemi-environment delimited by the walls (white grid), and the calculation planes (coloured) along the three directions. Some of them are shown as examples.

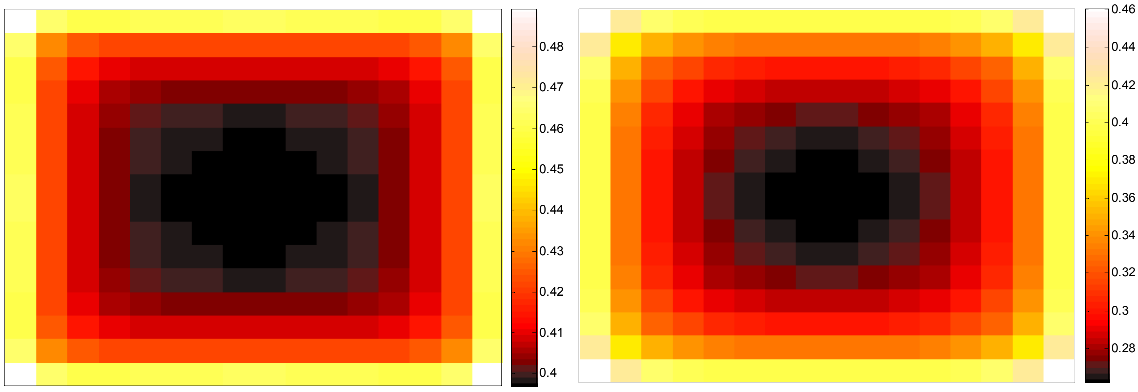

Fig. 5. Colorimetric evaluation of the field of gamma radiation induced by a source distributed per unit of photon volume flow, in proximity to one of the radiant walls (left) and for a central section (right).

The symmetry intentionally chosen for the case, which does not preclude the possibility of extending the model to scalene dimensional parameters, allows for the carrying out of an exhaustive evaluation of the calculation planes once for all components, taking one of them as a starting point.

From the compared images it is possible to note how, in reality, the hypothesis carried out previously is not correct. The most intense points of the field of radiation are represented by the areas contiguous to the walls. In substance, the greater effect of the field is in the vicinities of the corners. Instead, the centre of the environment must be considered as that having the lesser radioactive impact.

The example was executed in the maximum symmetry conditions: in this case, the reference environment was cubic, with uniformity also in the material considered. It is necessary to bear in mind that, in the reality of the cases, the environments are of scalene dimensions and that the materials used are composites and mixed-layers (Jalali et al., 2008).In order to render the example more realistic a simulation was carried out considering the case of an environment with unequal dimensions on three sides (4 x 5 x 3 m^3), with different horizontal wall compositions (masonry- full and perforated ricks) and lower and upper floors (granitic flooring, standard slab).

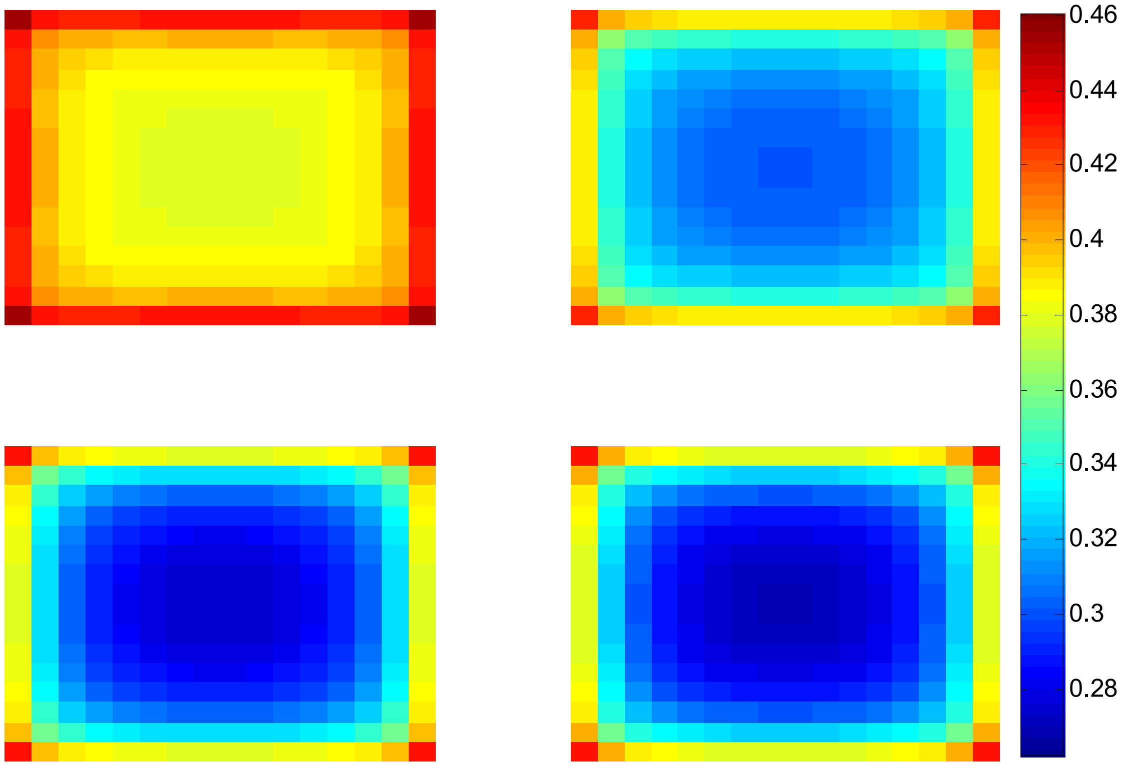

Fig. 6. Comparative evaluation of the field of radiation in the calculation planes which start from the area adjacent to the wall to the central one of the indoor environment.

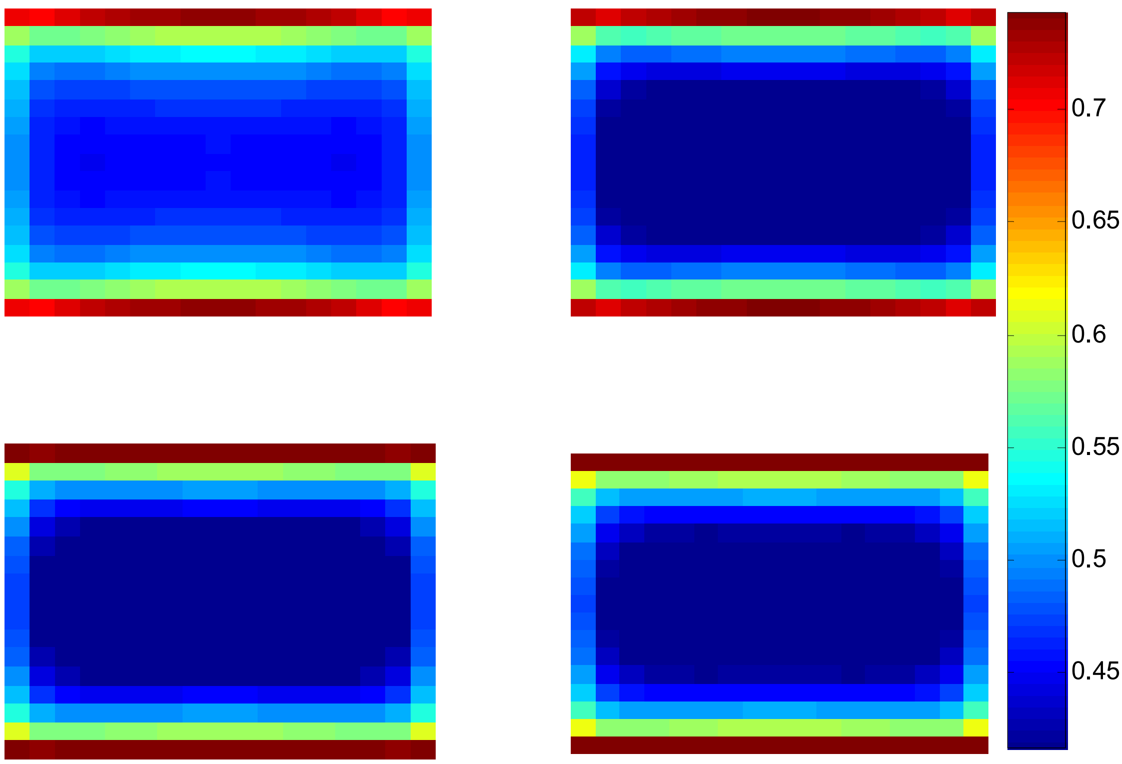

Fig. 7. Comparative evaluation of the field of radiation for an environment with scalene dimensions with a diversity of materials forming the walls (granite, masonry-bricks).

Such complications only introduce new weighting factors for the radiation field attenuation, modifying the geometry and symmetry of the field already seen in the previous case.

This new example cannot be exhaustive of the real conditions of use, and therefore of exposure that, obviously, depend on the typical occupation times but also furnishings, the presence of obstacles which more or less influence the trend of radiation.

The following values of concentration of activity referring to the single components of the simulation were inserted:

Table 2. Activity for materials used for the simulation.

Data in literature on commonly used materials (R.P.112)	Average activity (Bq/kg)			Conventional dose values (R.P.112	
	^{226}Ra	^{232}Th	^{40}K	I	E (mSv/a)
Cement	40	30	400	0,42	0,22
Pink Granite	150	120	1600	1,63	2,46
Perforated bricks	125	85	1220	1,25	1,50
Stucco – plaster	10	30	200	0,25	0,10
Wall paint	5	5	15	0,05	0,01

The value of the fluence rate per unit of mass photon flow, in the environment considered in figure 7, has an average value equal to about 0,5. The effective annual dose that results by applying the simulation, results as being equal to E[4] = 1.53 mSv. Such a value corresponds to the corresponding gamma radiation produced by the excess materials as well as the natural dose. This value can be significant of an uncontrolled situation since it concerns the values of indoor exposure to only gamma radiation. The limit introduced by National legislation, which regards exposed workers, imposed an annual limit value equal to 1 mSv. According to epidemiological studies (UNSCEAR 2006), this value corresponds to a probable mortality rate of 0.01%. This value risks further complication due to the coexistence of radon.

The evaluation was made taking in account conversion coefficient in UNSCEAR 1993, 2006 and conversion coefficient from the dose in the air to the effective dose received by an adult individual, 0.8 for the indoor occupation factor, and 0.2 for outdoor (Mulligan et al., 2004). From these values some dose evaluation samples follow, evidently starting from dosimetrical valuations:

Indoors: 84 nGy h^{-1} 8,760 h × 0.8 × 0.7 Sv Gy^{-1} = 0.41 mSv
Outdoors: 59 nGy h^{-1} × 8,760 h × 0.2 × 0.7 Sv Gy^{-1} = 0.07 mSv

The global average resultant for the effective dose is 0.48 mSv, with oscillating values from country to country ranging from 0.3 to 0.6 mSv. For children and infants, the values result as being from 10% to 30% higher, in direct proportion to the increase in the air dose conversion coefficient to the effective dose.

[4] In the dose value nuclides that are more significant to gamma emission, such as ^{40}K, ^{232}Th, ^{226}Ra are taken into consideration.

Application case study and conclusion

In this last part the possibility of identifying known radioactive sources in structures to be demolished in an indirect way will be shown, examining the model predisposed in the second paragraph.

In the case in which a nuclear plant is being dealt with, for which the principal radionuclides deriving from processes are known, the evaluation carried out previously is not applicable in a direct manner. In fact, considering a uniform distribution of the contaminant agent would not be correct. However, theoretically the considered parameter, Sv, should be substituted with a function that quantifies more or less realistically the contamination situation. In that case it could be possible to adopt a concentration distribution of nuclides equal to an expression such as:

$$Sv = Sv_0\, e^{-k\left((x-x_o)^2+(y-y_o)^2+(z-z_o)^2\right)} \qquad (11)$$

Where the mass photon flow is defined with Sv_0 per volume unit which then is configured in the central contamination position (x_0, y_0, z_0), k represents a scale factor.

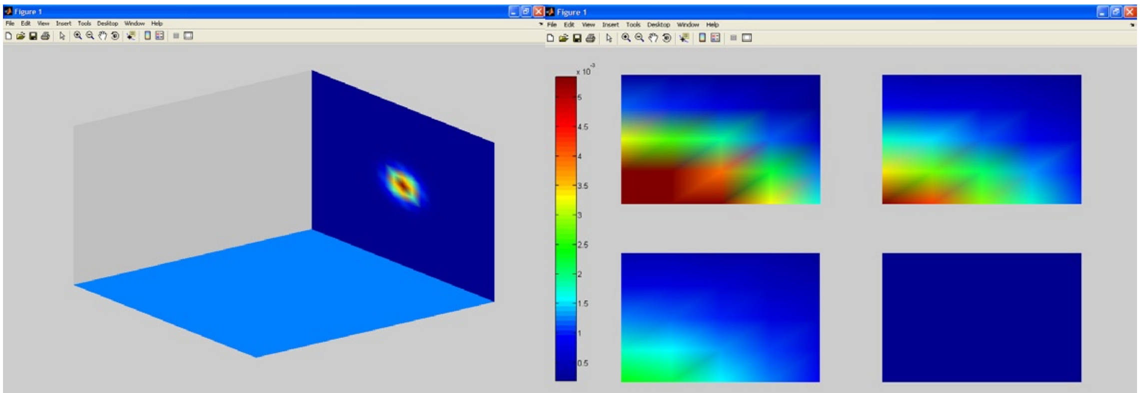

Fig. 8. Widespread Distribution hypothesis of a contaminated source or NORM (left) and distribution of the field of radiation of a source, concentrated in the corner of a standard room, starting from the wall adjacent to the radiation.

Within contaminated environments, there are automatic devices which capture the actual activity level (gamma-environment systems, dosimeters, instantaneous detectors, etc.). For practical reasons, such instruments are placed in correspondence of one of the delimiting walls of the environment.

Considering the case of a source that is concentrated in one point of the environment (e.g. in the corner) the distribution of the field of radiation, starting from the calculation plane corresponding to the wall adjacent to the contamination, to the one corresponding to the most distant one (hypothesising a regular environment), is described in figure 8.

Prior to resolving the problem it is first necessary to attempt to formulate it, the problem consists of the evaluation of the entity of a contaminating component, starting from the information provided by in-situ spectrometric data.

As already stated, there is in existence a diversified typology of portable or fixed instruments, even remotely connected, which acquire data providing the instantaneous value of parameters which can be the dose, the activity of a source, the fluence rate etc. Such instruments provide data which is more or less precise of the parameters considered.

Case histories require that the involved radionuclide are known, and with well known emission properties. It all rests upon the determination of the most suitable calculation positions for the evaluation of the actual contamination of the environments: an object of fundamental importance for the entire decontamination process.

The limit of decontamination at the desired clearance level consists, inevitably, of the computation and separation of the natural radiation component, which, as we have already seen, is not negligible and, often, complicates the foreseen removal process.

The Safety Culture as a part of radiation protection in medical imaging

Henner, Anja[1]; Servomaa, Antti[2]
[1] Oulu University of Applied Sciences, FINLAND
[2] Oulu University, FINLAND

Abstract
The safety culture means individual awareness of the importance of safety, competence, commitment, motivation, supervision and responsibility, concerning also attitudes of the staff at all levels. The enhancement of patient safety involves a wide range of actions in the recruitment, training and retention of health care professionals, performance improvement, environmental safety and risk management, equipment safety, safe clinical practice and safe environment of care. To find out some features of the radiation safety culture, several studies in different areas concerning radiation safety officers in diagnostic departments and patient doses were analyzed. The main factors affecting to the safety culture in medical use of radiation were regulatory and organizational environment, management styles, workers and their attitudes, patients' dose optimization as well as technological characteristics. Optimization of image quality and patient dose allows the patient dose to be decreased by more than 50 % in many patient groups. Digital imaging gives possibility to degree dose and still has image quality good enough. The attitudes and fear of change are the biggest barriers to reach the good safety culture. The next step is the establishment of safety culture, which takes into account the attitudes, behavior and other human factors, which have effect on safety.

Introduction
In industry the concept of "safety culture" has been known and in use for long time (Cooper 2000). To the area of radiation it has become from the OECD Nuclear Agency report (INSAG 1988) on the Chernobyl disaster. The safety culture means individual awareness of the importance of safety, competence, commitment, motivation, supervision and responsibility, concerning also attitudes of the staff at all levels. It describes the corporate atmosphere or culture in which safety in understood to be and is accepted as, the number one priority. (Cullen 1990.) International Atomic Energy Authority (IAEA 1991) defined safety culture as "assembly of characteristics and attitudes in organizations and individuals which establishes that, as an overriding priority, nuclear plant safety issues receive the attention warranted by their significance".

A British advisory committee on human factors in nuclear safety identified senior management commitment, management style, management visibility, communication, pressure for production, training, housekeeping, job satisfaction and workforce composition as key indicators of the safety culture. (Flin et al 2000.) Also the concept "safety climate" has been analyzed.

Safety culture does not operate in a vacuum by it self along and without any reflections. It affects to other organizations and is affected by other organizations. In the same hospital all users of medical radiation should have a common and together agreed goal how to apply the safety culture in clinical use and what it includes. The enhancement of patient safety involves a wide range of actions in the recruitment, training and retention of health care professionals, performance improvement, environmental safety and risk management, equipment safety, safe clinical practice and safe environment of care. (Flin 2000, Holopainen 2004, Niemi 2007)

The main trends in safety culture of radiation protection in medical radiology in Finland can be described as shown in Table 1. The Radiation and Nuclear Safety Authority in Finland (STUK) made in 1950's radiation safety measurements in hospitals, because hospitals were not able to do these measurements by themselves. The weight was in the radiation safety of the staff. Later the measurements developed from protection measurements to quality assurance, performance of the unit and patient dose measurements. The radiation safety of the patient was emphasized. Gradually the responsibility from measurements transferred to hospitals and the authority only control these measurements. In the 2000's new activities such as optimization of image quality and patient dose, clinical audit and continuous education and training in radiation protection were started. (Kettunen et al 2007, Holopainen 2004.)

Table 1. The rough schedule of activities in medical radiation protection in Finland. (Kettunen et al 2007)

(Action in Medical Radiation Protection	Year
Safety license and inspections	-1960
Occupational dose measurement	-1960
Radiation safety of the diagnostic units	-1965
Performance of the units	-1970
Quality assurance	-1980
Radiation dose to patients	-1990
Optimization of examination technique	-1990
Clinical audit	-2002
Education and training in radiation protection	-2003
Safety culture	-2004

Trend in radiation protection of medical radiology shows that the clinical audit is the new step to promote good practice because in audits the current clinical written practices are compared to so called 'good practice'. Clinical audit covers the whole imaging chain from writing the referral to imaging examination up to the report of imagines. The hospital is responsible for that action. (European Commission 2009.)

Follow up of the dose reference levels (DRL) can be also seen as a part of good practice (Säteilyturvakeskus 2008). The background of these guidelines and orders is very complex and several steps and organizations are needed (Figure 1).

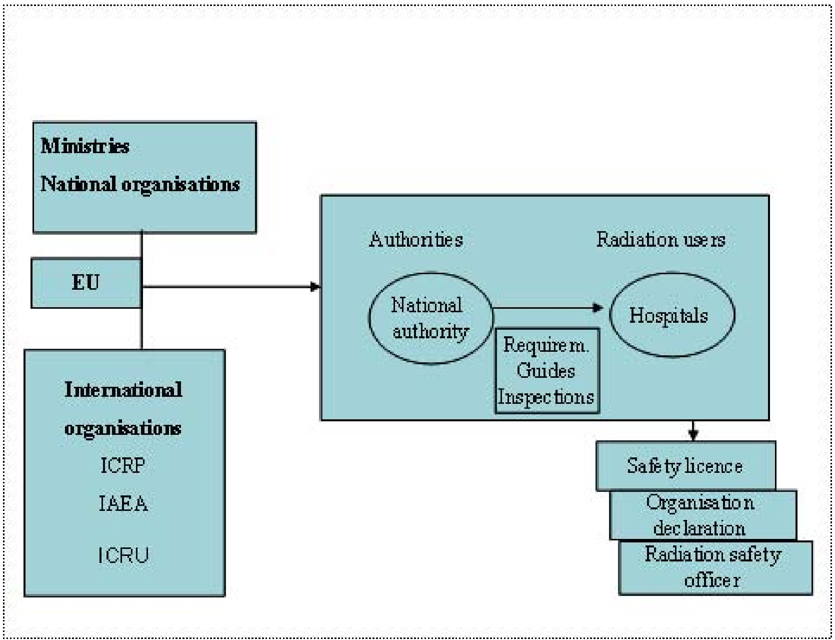

Figure 1. Factors affecting to the safety culture in medical use of radiation. (According to Holopainen 2004).

The latest, very fast development in the area of imagining modalities demands a lot of work in dose and image quality optimization and management. Deterministic harms have been reported both in interventional (e.g. Siromäki 2004) and diagnostic radiology (Yoshimasa 2005).

The next step could be the establishment of safety culture, which takes into account the attitudes, behavior etc human factors, of the staff. This has been already established in nuclear power plants where the consequences of the accident may be remarkable. The errors of the diagnoses reported in literature show high frequencies so the follow up and reporting system should be established. The safety culture may cover all those factors. One model for the assessment of safety culture has been made by IAEA 1998 (Figure 2).

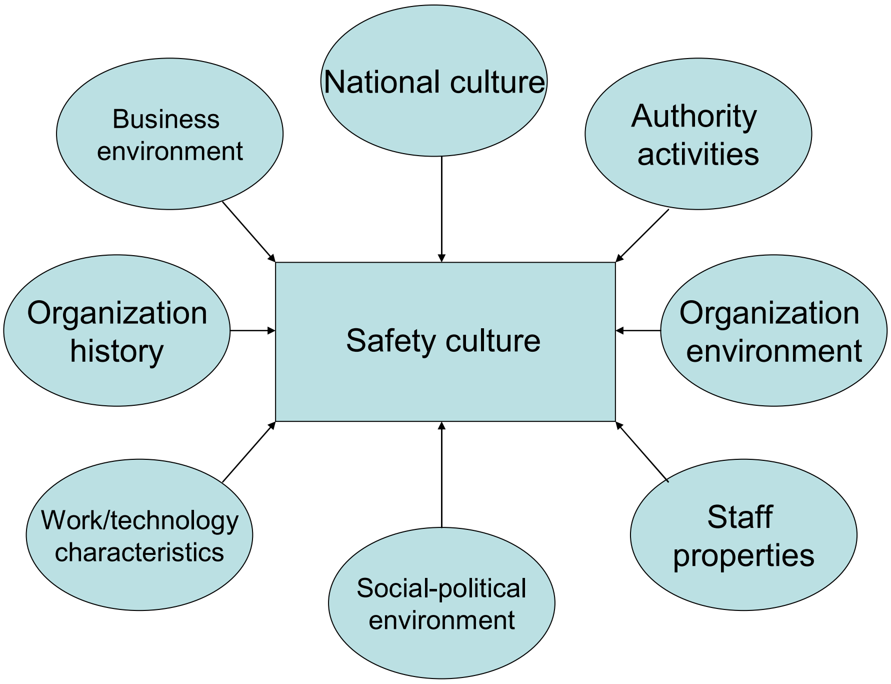

Fig. 2. A model for the assessment of safety culture. (IAEA 1998)

Material and methods

To find out some features of the radiation safety culture in Finland, several studies, reports and articles in different areas were analyzed concerning radiation safety officers in diagnostic departments and patient doses in medical imaging.

The volume of medical radiation activities of medical radiology in Finland has been quite the same level during last ten years. There are about 650 Safety licenses and 1500 x-ray units. Number of radiologists in dose monitoring in 2007 was 543 and number of radiographers in dose monitoring in 2007 was 2583.All personnel in health care in dose monitoring in 2007 was about 4900 including nurses, bioanalytics, dental personal, surgeries, orthopedics etc. (Rantanen 2009, Lehtinen 2008)

Radiation and Nuclear Safety Authority has given reference levels for adult patient in common projection examination, in computed tomography examinations and cardiac angiograms. There are also DRLs for nuclear medicine examinations as well DRLs for children in projection examinations. The adult's DRLs have been updated in 2009. (Säteilyturvakeskus 2008.) The Regulatory Guides on radiation safety (ST Guides) are updated approximately once in five years.

Two studies concerning radiographers' work and one concerning radiation safety officers work and attitudes where analysed as well a group of papers about the doses to patients or to patients groups. Examples of dose and image optimisation are given based on results of small optimisations in clinical practice made by the staff and radiographer students.

Results

The safety culture is divided here in two parts. First the group of people and their role in safety culture and second the dose management as a part of safety culture.

Regulatory and organizational environment, management styles, workers and attitudes as well as technology characteristics were the main factors affecting the safety culture. Niemi (2006) found four shared meanings in radiographer's safety culture in the medical use of radiation. The meanings were challenges of knowledge and skills structuring safety culture, dimensions of cooperation enabling safety culture, disorientation conditioning safety culture and multidimensional professionalism as the foundation of safety culture. The significance of radiation protection was emphasized but the radiographers were confused by the different directions and practices in implementing it.

Paalimäki-Paakki (2009) described ethical dilemmas in radiographer's work in diagnostics. Most important ethical dilemmas were found to consider the use of radiation, patient care, and radiographer's work community. In the use of radiation, implementation of justification and optimisation principles were found to be lacking. Dilemmas in work community consisted of problems among employees and insufficient practice. The radiographers noticed some times that the colleagues did not work as said in quality handbook (written good practice). Dose and image quality optimisations and the use of lead shields were not good enough. According to Paalimäki-Paakki is due the lack of safety culture.

Radiation safety officers are the key persons in the radiation safety culture of medical radiology. The study concerning radiation safety officers show that organizational aspects are the main factors in the safety culture of radiation protection in medical radiology. The most remarkable developing targets were stated the clarification of field of activity of radiation safety officer, possibility to affect decisions, increase of education and increase of cooperation with other radiation safety officers in various hospitals. New active partners in this field have appeared (quality assurance, education and training, occupational dose measurements, accreditation, clinical audit etc) secure the sufficient status and empowerment in the organization. Regulatory and organizational environment, management styles, worker as well as work/technology characteristics were the main factors affecting the safety culture of safety officers. (Holopainen 2004, Servomaa, Holopainen 2005.)

In the study of newborn premature babies 118 chest x-ray examinations to 43 newborns (gestational age from 26 to 42 weeks) were estimated. The effective dose from one chest radiograph varied from 7.5μSv to 54.8μSv. Retrospectively, the total number of radiation examinations to these newborns totalled 399 during the study; the mean was 9.3 (range 1-40). 98% of the examinations were produced during the first treatment period after birth. The total effective dose per child varied from 0.31 mGy to 3.7 mGy. (Kettunen 2004.) The smaller the baby is the more x-rays are usually needed for the follow-up during the first living months (Siironen 1994)

The study of pregnant woman' examinations showed that there was no common practice on how to exclude the possibility of pregnancy and the dose to a foetus was not estimated either before or after the pelvic x-ray examination. (Kettunen 2004.)

The dose study of pediatric reflux patients showed that about 6. 9 examinations / patient were made up to the age of 16 years. Average effective dose was 4.3 mSv and maximum dose about 11 mSv (Table 2). (Kettunen et al 2003.)

Table 2. Numer of examinations and effective dose, average and range to 12 patients under 16 years due to examinations of vesico-uretal reflux. (Kettunen et al 2003)

	MCU	MCU TC99m	Urography	Kidney with Tc99m	Total Number of examinations
Total Number	40	15	20	2	77
Average (range)/ one patient	3.8 (1-7)	1.3 (0-3)	1.7 (0-7)	0.2 (0-1)	6.9 (1-15)
Effective dose /patient annos(mSv)	1.7 (0.6-3.5)	0.25(0.15-0.6)	2.0(1.3-8.1)	0.3(1.9)	4.3(0.7-11)

The study of radiological examinations made for young accident patients showed that average number of examinations varied between 9-59 and effective dose varied between 5.3-33.9 mSv. (Huusko, Räsänen 2002, Servomaa & Kettunen 2005.)

These studies show some special groups of patients which need a lot of attention and especially tight indications for x-ray examinations. Next results will show how dose and image quality optimization can be applied with small steps in everyday clinical work.

The new full field mammography equipment had Dose- and Standard (STD) programs. The vendor recommended to use the STD program. The radiographers wanted to evaluate the difference in the dose and image quality between these programs. From ten females in mammography were exposed randomly either left or right breast with STD-program and other with Dose-program. Three experienced radiologists (used to read screening mammograms) evaluated them "blind" without knowing which are taken by which technique. All mammograms were good enough for diagnostic. There were no difference find between images taken by STD- or Dose-programs and now all mammograms are taken by Dose-program and lower dose. The dose reduction was about 30 %. The AEC (Automatic exposure Control) was tested in order to reach lower dose level. In Lumber spine lateral examination -16 % decrease and in hip joint -27 % dose decrease was achieved very easily image quality was still good enough. The PACS (Picture Archiving and Communication System) offered opportunity to analyse the quality of images afterwards. The use of air grid is not very common in Finland. In hip axio-lateral project the use of air gap (30 cm) instead of a grid decreased skin dose two thirds (Figure 2). (Henner et al 2009.)

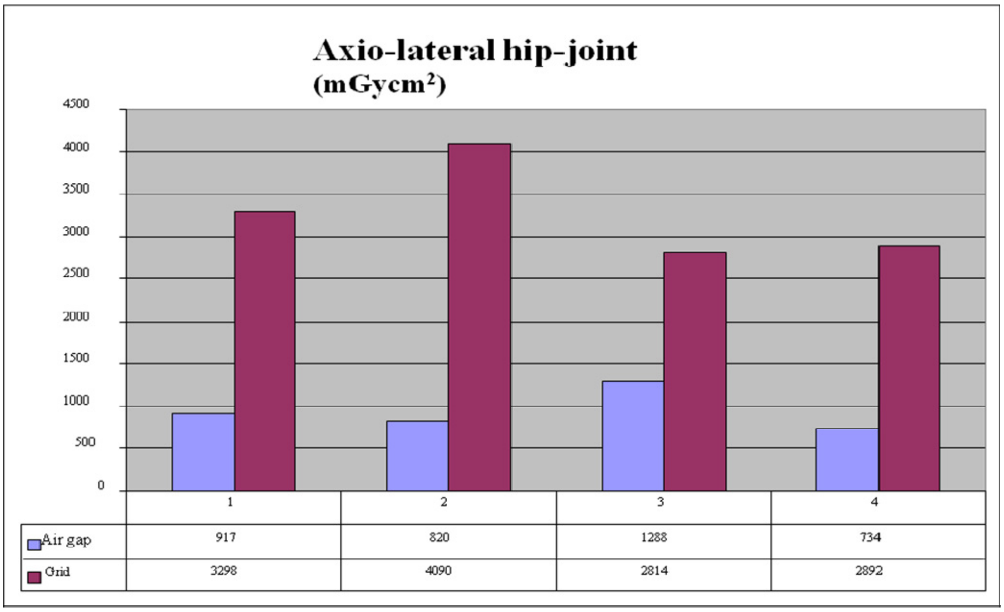

Figure 2. DAP in Axio-lateral hip joint with Grid and Air Gap. (Henner et al 2009)

Because in the lower extremity mechanical axis the required image quality for a diagnosis is not high, the results showed that the patient radiation dose could be lower when additional filtration and higher voltage were used. The results also showed that by using different AEC classes the patient dose could be affected and thus should be used. According to these results it is not necessary to use a grid while imaging a normal size patient, because the quality of the image does not need to be as high as for example when diagnosing a fracture. While imaging the hip predetermined exposure charts should also be considered. (Hilli, Hirvelä 2010.)

Discussion

The concept of safety culture and safety climate is not yet well-known and they are quite difficult to find out in every day clinical practice. Problems in healthcare all over the world are common: less money, more seriously ill patients, expensive equipments and medication, lack in education, more work and less staff. The role of Radiographer is expanding to new areas partly because of higher education and partly because lack in radiologists and physicists. Better equipment means better image quality with higher dose. Does this mean also more harms due to radiation? Who is responsible for the dose optimisation? As seen from the results of Niemi (2006) and Paalimäki-Paakki (2009) stress, hurry, new demands and more complicated situations are parts of radiographers work, every day. They are barriers to work as well as they want. They also purchase the further development of work conditions and dose and image optimization.

Radiation and Nuclear Safety Authority has given reference levels for adult patient in common projection examination, in computed tomography examinations and cardiac angiograms. There are also DRLs for nuclear medicine examinations as well DRLs for children in projection examinations. The doses have to be monitored at least every third year. (Säteilyturvakeskus 2008.) This part of safety culture has been applyid very well since 1996. The Regulatory Guides on radiation safety (ST Guides) are updated approximately once in five years and the guidelines are applied in all radiological departments. Second round of clinical audits is running (Faulkner et al 2009).

There are special patient groups which are exposed quite often (children with scoliosis or vesico-uretal reflux, premature babies). The new technical solutions offer a lot of possibilities for dose reduction, if we want. (e.g. Al Khalifah., Brindhaban 2004, Arreola, Rill 2004, Bush 2004, Hamer et al 2005 Uffman 2008, Geijer 2009, Lanca et al 2009).

One model for the assessment of safety culture has been made by IAEA 1998 is too large for this kind of work. It should be divided to smaller parts in research. Other vise there are a lot of very congregate and everyday ways to develop the safety culture. The management and legislation offer the basics but the work must be done among those who are working in radiological departments.

Conclusions

Optimization of image quality and patient dose allows the patient dose to be decreased by more than 50 % in many patient groups. Digital imaging gives possibility to degree dose and still has image quality good enough. The attitudes and fear of change are the biggest barriers to reach the good safety culture. The next step is the establishment of safety culture, which takes into account the attitudes, behaviour and other human factors, which have effect on safety.

Abstract

In the European Member States, the use of ionising radiation in the healthcare environment is regulated by the transposition into national legislation of Directive 97/43/Euratom of 30 June 1997 on health protection of individuals against the dangers of ionising radiation in relation to medical exposures.

EFOMP noted the definition of the Medical Physics Expert and the involvement of this expert in radiotherapeutic, diagnostic nuclear medicine and other radiological practices in this Directive. EFOMP has for many years sought to harmonise and promote the best practice of medical physics in Europe and has in this respect issued Policy Statement No. 9 in response to the above directive.

The EFOMP strategy is directed towards the recognition of the European Medical Physicist and for this purpose the Federation's approach has been to encourage registration schemes (on a voluntary basis) where no regulated scheme (as imposed by law) exists. EFOMP recognised that the most appropriate way to achieve harmonisation of standards across the whole of Europe was to express the duties and competencies

expected of the Medical Physics Expert (MPE), as set out in the 1997 Directive, in very practical terms.

A framework of five levels of competency that covers the whole career structure of the medical physicist was developed including the duties of the MPE. A system for recognised Continuing Professional Development is recommended by EFOMP and has been described in a Policy Statement.

This paper aims to present EFOMP's efforts to harmonise the education, training and competences of the Medical Physicist in Europe and thus to meet the role and responsibilities of the MPE as specified in the above directive.

Introduction

In the European Member States, the use of ionising radiation in the healthcare environment is regulated by the transposition into national legislation of Directive 97/43/Euratom of 30 June 1997 (EC, 1997) on health protection of individuals against the dangers of ionising radiation in relation to medical exposures. This directive supplements Directive 96/29/Euratom (EC, 1996) laying down basic safety standards for the protection of the health of workers and the general public against the dangers arising form ionising radiation.

In these directives, the definitions of the professionals involved are subject to various interpretations. For example under article 2 of directive 97/43/Euratom, the definition of the Medical Physics Expert is given as:

"Medical Physics Expert: an expert in radiation physics or radiation technology applied to exposure, within the scope of this Directive, whose training and competence to act is recognized by the competent authorities; and who, as appropriate, acts or gives advice on patient dosimetry, on the development and use of complex techniques and equipment, on optimization, on quality assurance, including quality control, and on other matters relating to radiation protection, concerning exposure within the scope of this Directive."

In the above directive extract, the recognition of the MPE is left to the national competent authorities and this has been recognised at different levels of competence in most of the European Union Member States, as evident from the latest EFOMP survey (Eudaldo, 2008). Furthermore Article 6 clause 3 of the same directive states:

"In radiotherapeutic practices, a medical physics expert shall be closely involved. In standardized therapeutical nuclear medicine practices and in diagnostic nuclear medicine practices, a medical physics expert shall be available. For other radiological practices, a medical physics expert shall be involved, as appropriate, for consultation on optimization including patient dosimetry and quality assurance including quality control, and also to give advice on matters relating to radiation protection concerning medical exposure, as required".

The phrases "closely involved", "shall be available" and "shall be involved, as appropriate" take a different interpretation in each and every setting. It is again left to the local competent authorities to interpret these phrases. The EFOMP survey (Eudaldo, 2008) has in fact shown that there is a large variation between the European Union Member States.

In a similar fashion Directive 96/29/Euratom defines Qualified Experts as:

"Qualified Experts: Persons having the knowledge and training needed to carry out physical, technical or radiochemical tests enabling doses to be assessed, and to give advice in order to ensure effective protection of individuals and the correct operation of protective equipment, whose capacity to act as a qualified expert is recognized by the competent authorities. A qualified expert may be assigned the technical responsibility for the tasks of radiation protection of workers and members of the public".

The term "Qualified Expert" is mentioned in a number of places in this directive implying a different professional such as Medical Physicist Expert, Radiation Protection Expert, Radiological Practitioner, etc. Again the competence of the Qualified Expert is recognised by the national competent authorities (which may in fact be different from those deciding the competencies of the MPE). Furthermore the role and responsibilities of the various Qualified Experts are not clearly stated in this Directive but are left to the National Competent Authorities and others to specify.

Therefore within the European Union, we have two directives relevant to radiation exposures in the Healthcare Environment and 27 national sets of legislations and regulations. This is due to the interpretation being understood differently, taking into account the culture, language and other political influences present in each national setting. This is hindering the harmonisation of the education, training, competences, roles, responsibilities and effectively the mobility of the professionals responsible for implementing the various functions covered by these directives.

With respect to the MPE, EFOMP noted its definition and the involvement of this expert in radiotherapeutic, diagnostic nuclear medicine and other radiological practices in this Directive. EFOMP has for many years sought to harmonise and promote the best practice of medical physics in Europe and has issued Policy Statement No. 9 (EFOMP, 1999) in response to the above directive.

In this Policy Statement, EFOMP lists in general terms the involvement of the MPE as follows:

"• *to carry out the physical measurements related to evaluation of the dose to the patient and to take responsibility for dosimetry;*
- *to improve any conditions that will lead to a reduction in unnecessary patient dose;*
- *to lay down tests in the field of quality assurance of the equipment;*
- *to assure the surveillance of the installations with regards to radiological protection;*
- *to choose equipment required to perform radiation protection measurements and to give advice on medical equipment;*
- *to take part in the training of medical practitioners and other staff in relevant aspects of radiation protection;*
- *to provide skills and responsibilities that complement those of medical practitioners."*

This Policy statement gives further guidance with respect to the education, training and continuous professional development of the MPE. These will be discussed in this paper.

Recently the Commission has undertaken a simplification of Community legislation in the area of radiation protection and has proposed the consolidation into a single text of the following Directives:

- Council Directive 96/29/ Euratom of 13 May 1996, laying down basic safety standards for the protection of the health of workers and the general public against the dangers arising from ionising radiation,
- Council Directive 97/43/Euratom of 30 June 1997 on health protection of individuals against the dangers of ionizing radiation in relation to medical exposure,
- Council Directive 89/618/Euratom of 27 November 1989 on informing the general public about health protection measures to be applied and steps to be taken in the event of a radiological emergency,
- Council Directive 90/641/Euratom of 4 December 1990 on the operational protection of outside workers exposed to the risk of ionizing radiation during their activities in controlled areas,
- Council Directive 2003/122/Euratom of 22 December 2003 on the control of high-activity sealed radioactive sources and orphan sources.

The latter four Directives cover different specific aspects complementary to the overall Basic Safety Standards (the first Directive).

The task of consolidation was given to the Euratom Treaty Article 31 Group of Experts. Their task was finalised in February 2010 and their "Draft Euratom Basic Safety Standards Directive" (This document is not yet publicly available) has been submitted to the European Commission for its approval and further submission to the European Council and Parliament for the necessary political scrutiny.

Definitions have evolved over time and have been adjusted to specific scopes. While many requirements may fit in the original context they could not be extended to act as a general application of the Standards, so the consolidation proceeded through a recast rather than a simple codification of the original texts.

From the latest publicly available summary reports of the Group of Experts (GoE) referred to in Article 31 of the Euratom Treaty meeting (EC, 2009a, 2009b), the new European Basic Safety Standards (BSS) Directive appears that will be defining the roles and responsibilities of services and experts who should be involved in ensuring that technical and practical aspects of radiation protection are managed with a high level of competence. It further appears that will be defining the role, responsibilities and competences of the Radiation Protection Expert (RPE) and the MPE and appears to be introducing the function of the Radiation Protection Officer (RPO).

It also appears to be strengthening the requirement for information, training and education addressing these in a specific title in order to highlight the importance of education and training in radiation protection. In the medical area, education and training should also raise the awareness of the medical profession, in particular with a view to risk communication with patients.

Changes may, however, be made before the Directive is approved and finally published in the Official Journal of the European Union.

Discussion

From what is known at the moment about the recast version of the European Basic Safety Standards Directive, it would seem that an overall improvement to the existing directives is being made. It is acknowledged that the role, responsibilities and competence of the RPE and RPO in facilities outside the healthcare environment are essential for the radiation protection of the workers and the public at large. There could, however, be considerable ambiguity with the roles, responsibilities and competence of the MPE within the healthcare environment. It is therefore necessary that clear guidance is produced to clarify the different roles and responsibilities of the RPE, RPO and the MPE, as well as the need for collaboration between them.

An attempt is made here to assist in the interpretation of these functions (MPE, RPE and RPO) from the EFOMP point of view.

Firstly ionising radiation is used in a large range of different healthcare facilities, from the dentist's office with a simple dental radiographic unit to the large university hospitals with highly sophisticated devices such as Multi-Detector Computed Tomography (MDCT) systems and Positron Emission Tomography (PET) and in their radiotherapy departments systems such as Linear Accelerators (LINACS) using highly complicated treatment procedures such as Image Modulated Radiation Treatments (IMRT) and Image Guided Radiation Treatments (IGRT), not to mention Tomotherapy and Cyberknife systems.

Secondly it is very important to accept that the definitions, roles, responsibilities and competence of the RPE, MPE and RPO are functions that are required to be fulfilled and are not necessarily separate professions or even individuals.

The unique feature of healthcare is that it is the only application of ionising radiation where there is a need for optimisation. Radiation Protection can never be seen in isolation for image quality (in diagnostic radiology) and tumour control (in radiotherapy). This is one of the reasons that radiation protection is part and parcel of the education process of medical physicist.

The continuous application of the radiation protection principles and the routine implementation of any daily quality assurance programme to assure the correct performance of the equipment would be the role of the RPO. The number of RPOs will depend on the number of modalities and sophistication of the healthcare facility. The function of the RPO may be undertaken by any individual with the appropriate training and competence (for example an appropriately trained technologist). The RPO must be a permanent staff of each facility. It is not acceptable to outsource the function of the RPO.

The function of the MPE is an inherent role of the Qualified Medical Physicist (QMP) and in more sophisticated facilities this function may need to be the role of a Specialist Medical Physicist (SMP) (Eudaldo and Olsen, 2010). It can be outsourced for small healthcare facilities, or it can be assigned to in house medical physics services, again taking into consideration the sophistication of the modalities and the workload of the healthcare facility.

Within the healthcare environment the function of the RPE can be undertaken by a QMP or in more sophisticated facilities by a SMP, since the role and responsibilities of the RPE within the healthcare environment are part of the education, training and competence of the QMP and SMP (Dendy, 1997), (EFOMP, 1997 and 1999). The function of the RPE can be outsourced for small healthcare facilities, or it can be assigned to in house medical physics services, again taking into consideration the sophistication of the modalities and the workload of the healthcare facility.

The EFOMP strategy is directed towards the recognition of the European Medical Physicist and for this purpose the Federation's approach has been to encourage registration schemes (on a voluntary basis) where no regulated scheme (as imposed by law) exists (EFOMP, 1995, 1998 and 2001). EFOMP recognised that the most appropriate way to achieve harmonisation of standards across the whole of Europe was to express the duties and competencies expected of the MPE, as set out in the 1997 Directive, in very practical terms.

As far back as 1997, a framework of five levels of competency, covering the whole career structure of the medical physicist was developed including the functions of the MPE (Dendy 1997):

"Level 1 - relevant first degree or equivalent
Level 2 – completion of specialist expertise
Level 3 – completion of practical experience
Level 4 – advance practical experience
Level 5 – mature overview and greater responsibility."

Over the years these were further refined with the latest version given in Policy Statement 12 (Eudaldo and Olsen, 2010). This framework now also includes an extensive requirement of Continuous Professional Development. Also other initiatives have taken place, which are briefly discussed here.

European School of Medical Physics

This is an annual event in collaboration with the European Scientific Institute - ESI and takes place in Archamps, France. The first school was held in 1998. Originally it consisted of five weeks of intensive training in Medical Physics (EFOMP, 1998b). One week is spent on covering each of Medical Imaging with Non-ionising Radiation, Medical Imaging with Ionising Radiation, Medical Computing, Physics of Modern Radiotherapy, Brachytherapy. As from 2008 a sixth week was added on Radiation Protection.

EFOMP Sponsoring Programmes

The sponsorship of meetings and congresses is instrumental in disseminating and encouraging the adoption of the policy statements. EFOMP organises, co-organises, supports and recognises meetings, congresses and courses together with its National Member Organisations (NMOs). Guidelines that explain the above terms and the requirements for interested NMOs to collaborate in such events can be found on EFOMP's website.

The purpose of these Guidelines is to help NMOs to obtain EFOMP sponsorship for their events by setting out the steps that they need to take and the conditions that must be fulfilled.

The biggest event is the biennial European Congress on Medical Physics. Note that there are detailed guidelines on the requirements for this event.

Furthermore, EFOMP collaborates with other European and International Organisations (ESR, EANM, ESTRO, ESMRMB, IOMP, IFMBE, IRPA) by having joint sessions at their conferences, with the objective of promoting its activities, mainly on Education, Training and Professional matters of the Medical Physics Profession (Caruana et al, 2009), (Christofides et al, 2008, 2009a, 2009b, 2009c).

Lifelong Learning

On the 23rd of April 2008, the European Parliament and the Council issued recommendations on the establishment of the European Qualifications Framework (EQF) for lifelong learning (EC, 2008). With these recommendations the European Union is encouraging its Member States to compare and align their education and training qualifications with the eight (8) levels of learning outcomes described in these recommendations.

The purpose of EFOMP's work in education and training is to position the various stages of the Education, Training and CPD of the Medical Physicist in Europe, as stated in the various EFOMP Policy Statements, within the eight levels of the EQF) for lifelong learning and identify any gaps that need to be addressed.

Figure 1 shows the preliminary results of the various stages of the education and training of the Medical Physicist in Europe according to EFOMP Policy Statement No.12 using the eight levels of the EQF for lifelong learning.

The level of graduation (Master's level) of the Medical Physicist corresponds to level 5 of the EQF for lifelong learning and the level of the QMP correspond to level 6. The level of the SMP corresponds to level 7.

Level 8 of the EQF for lifelong learning goes beyond the EFOMP Policy Statement No.12 and it corresponds to the Medical Physicist holding a Doctoral Degree (PhD) or higher, working in a research environment (University or Research institution).

EFOMP needs to develop a Policy Statement to bridge the gap between level 7 and level 8 of the EQF.

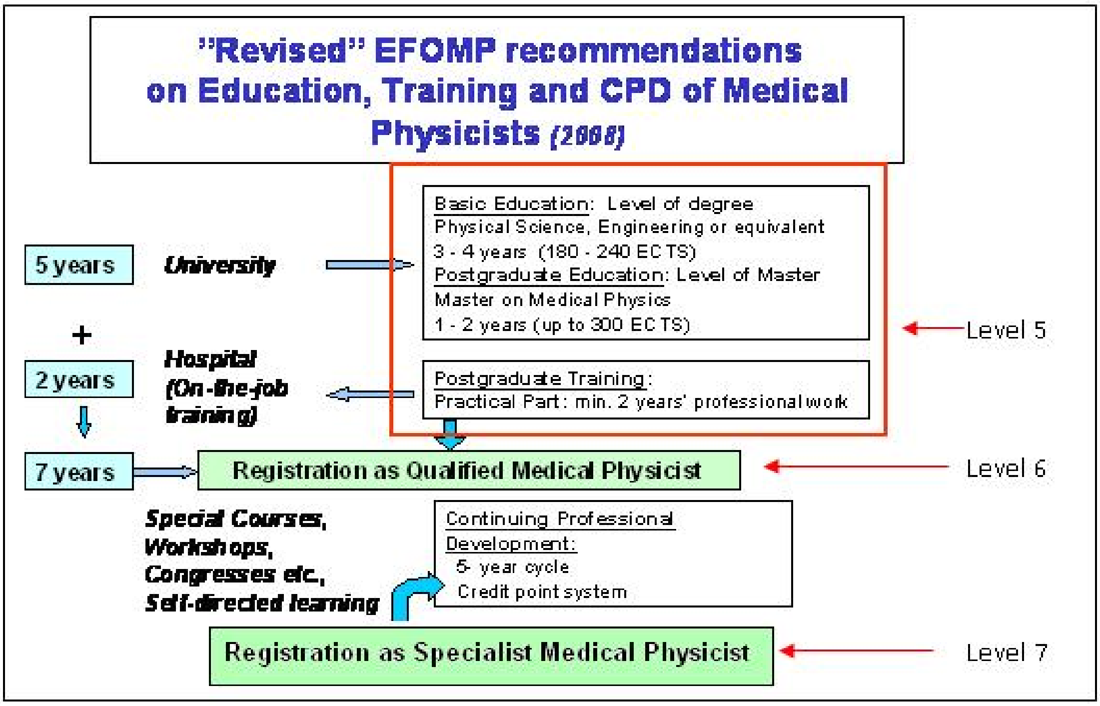

Fig. 1. The various stages of Education and Training of the Medical Physicist in Europe according to EFOMP Policy Statement No.12 using the 8 levels of the EQF for lifelong learning.

Medical Physics as a Profession

In due consideration of the following facts, EFOMP believes that Medical Physics should be recognised by the European Union as a regulated Health Profession in accordance with the EU Directive on the recognition of professional qualifications (EC, 2005):

a) Medical Physicists have a formal education and training in Anatomy, Physiology and Radiation Protection as applied to medical activities.
b) Medical Physicists have the necessary skills to manage the quality of the performance of the equipment used in hospitals.
c) Medical Physicists have a relatively long practical training in Hospitals.
d) Clinical professionals regard medical physicists as invaluable specialists who facilitate the safe use of radiation in hospitals.
e) Quality Assurance and Quality Control in Radiotherapy, Nuclear Medicine and X-Ray diagnosis is, normally, done by medical physicists. The results of these activities have clear implications on patient diagnosis, treatment and safety.
f) Medical Physicists have the experience to perform basic and applied physics research in medicine.
g) In a number of European Countries Medical Physics is a profession regulated by law.

There is more than enough evidence to prove all the above statements apart from two very important issues:

a) The education and training of the medical physicist is not harmonised across Europe according to the EFOMP Policy Statement No. 12.
b) The Medical Physics Profession is not regulated in all European Member States.

These two issues can only be resolved by the individual Member States by applying the EFOMP recommendations.

EFOMP participation in European Projects

The importance of medical physics in the area of radiation protection in medicine and the lack of uniformity in training and education has led the European Commission to commission research projects with aim the ultimate definition of the MPE with the required education, training and competencies. To this end, the Commission has tendered two research contracts in both of which EFOMP is a partner. These are:

- the European Medical ALARA Network –EMAN (Contract No: TREN/09/NUCL/SI2.542127), and
- the European Guidelines for the Medical Physics Expert (Contract No: TREN/09/NUCL/SI2.549828).

The contribution of EFOMP to these projects was considered essential by the European Commission and it was a condition that EFOMP should be represented in all of their work packages.

Conclusions

By accepting the fact that the role, responsibilities and competences of the MPE, RPE and RPO are functions to be undertaken by recognised professionals and that this recognition will be according to the complexity of the modalities of any given healthcare facility, then the new European Basic Safety Standards Directive can be implemented by the European Member States in a more harmonised way so facilitating the mobility of these professionals within the European Union. Additional guidance will be required to assist in the implementation and interpretation of the provisions of this directive.

Some of the activities of EFOMP in the area of Education, Training and Professional Development of the European Medical Physicist, with emphasis on Radiation Protection have been discussed.

These activities can only materialise through the collaboration of all the Medical Physicists of EFOMP's National Member Organisations (NMOs). The NMOs must actively adopt and implement the guidelines of the policy statements as well as participate in the various events organised by EFOMP in collaboration with its NMOs.

The contributions of all interested parties are more than welcome in order to further develop the harmonisation of the education, training and professional status of the Medical Physicist in Europe.

Acknowledgments

EFOMP acknowledges all those that have contributed to the development of its policy statements as well as all those involved in the organisation of educational and training events under its auspices.

EFOMP also would like to express its sincere thanks to all those that through the years have contributed actively in promoting the Profession of Medical Physics.

Computer based radiation protection course for workers in the health care sector

Busoni, Simone[1]; **Fulcheri, Christian**[2]; **Gori, Cesare**[1]

[1] Azienda Ospedaliero-Universitaria Careggi, Health Physics Department, ITALY

[2] Università degli Studi di Firenze, Health Physics Specialization School, ITALY

Abstract

Radiation protection aspects in the health care sector are a primary concern due to the very different kind of occupational activities and to the large number of people involved with ionising radiation (I.R.), for instance in a large hospital.

The Government of the Tuscany Region (Italy) has promoted the realisation of a computer based radiation protection training course for all I.R. workers of the National Health Service within the Tuscany region.

The challenging goal of this project is to provide the basic safety information in such a complex field, where people with very different education levels and duties do work together, with the aim of fulfilling the specific educational requirements of Directive 96/29/EURATOM as introduced in the Italian legislation.

The course is devoted to provide radiation protection education to all health workers, with special attention to those without high level of education in the I.R. field (i.e. physicians outside the radiology area, surgery room staff, nurses in nuclear medicine or radiotherapy and laboratory staff).

The course is composed of five sections dealing with the general aspects of radiation protection (basic I.R. physics, biological effects, regulatory system, dosimetry and radiation protection principles) while four other sections deal with sector specific radiation protection aspects: radiology, nuclear medicine, radiotherapy and laboratory. A further special chapter, summarising all aspects treated in the course, is devoted to workers with poor educational level or no-background in the field of physics, radiation protection and current legislation. Each section includes a multiple choice test with hint function, numerical examples, a glossary and bibliographical references.

First feedback outcomes and multiple choice tests results from hospital workers are also reported.

Introduction

According to EC regulation, all persons whose work may be associated with ionising radiation risk must be adequately educated to ensure that they are informed about the potential health risks which could result from radiation exposure, the basic principles of radiation protection and the relevant radiation protection regulations as well as safe working methods and techniques in radiation zones.

Radiation protection (RP) aspects in the health care sector are a primary concern due to the very different radiation sources, kind of occupational activities and large number of people involved with ionising radiation (I.R.), for instance in a large hospital.

The Government of the Tuscany Region in Italy has promoted the realisation of a computer based training RP course for all I.R. exposed workers of the National Health Service (N.H.S.) within the Tuscany region. The project was developed by the Health Physics Department of the Florence University Hospital (Azienda Ospedaliero-Universitaria Careggi) as leading institute, in collaboration with the other Health Physics Departments of the Tuscany N.H.S. The course is also open to contractors' personnel as complementary information in addition to the RP training they must receive from their own employers.

The main challenge of the project is to provide the basic safety information in such a complex field as the health care sector, where people with very different education levels and duties do work together (e.g. in a radiological interventional room).

In Fig. 1, the distribution of Tuscany region health care workers exposed to I.R. is shown. In the "Others" group are included, biological lab staff, logistics and cleaning staff and medical physicists A total amount of roughly 6000 I.R. exposed people work in the NHS of the Tuscany region, servicing a population of about 3.7 million inhabitants. In Fig. 2, the Tuscan NHS exposed workers distribution between health care activity sectors is reported.

The goal of the project is to fulfil the specific educational requirements of Directive 96/29/EURATOM as introduced in the Italian law.

In this paper we present a description of the course as well as an evaluation of the course effectiveness as resulting from the outcomes of the multiple choice tests.

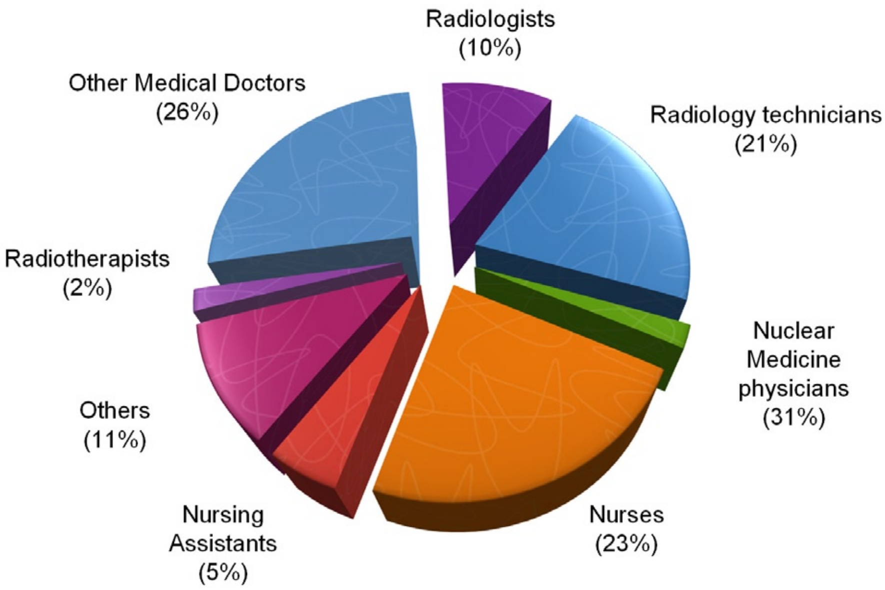

Fig. 1. Distribution of exposed workers, according to their professional role, in Tuscany region health care sector.

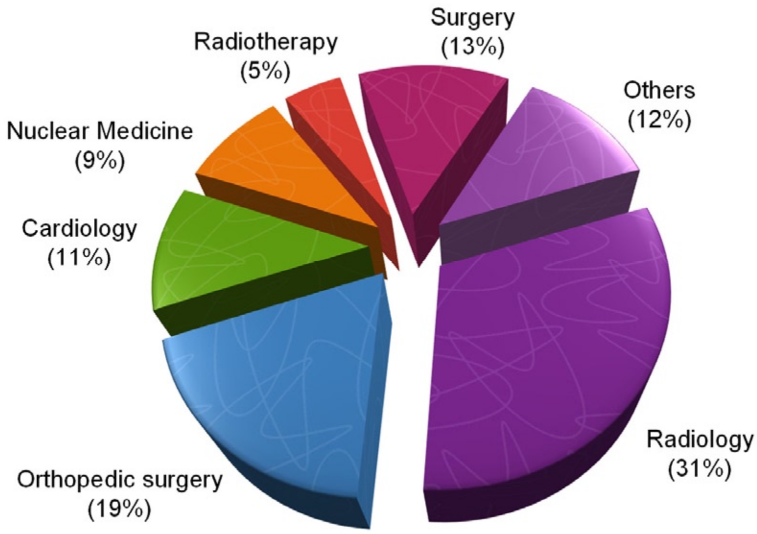

Fig. 2. Distribution of exposed workers according to medical specialties in the Tuscany region.

Material and methods

The course is addressed to all people working in the health care sector, with special attention to workers without high level education in the I.R. field (medical doctors outside the radiology area, surgery room staff, nurses in nuclear medicine or radiotherapy departments, laboratory staff, etc.)

Course description

The main course is composed of a few sections dealing with general aspects, covering the main topics of radiation physics, biological effects of I.R., national regulatory system, dosimetry and RP principles. The other sections deal with the specific aspects of RP in radiology, nuclear medicine, radiotherapy and laboratory. A special section, summarising all the fundamental notions of the course, is devoted to workers with poor educational level or no-background in the field of physics, radiation protection and related legislation, that is: hospital auxiliary staff, workers belonging to external service providers (i.e. cleaning services) and non-health (i.e. logistics) workers. In this section, each sub-section contains detailed information on how to act (things to do/ not to do) and a list of Frequently Asked Questions (FAQs) with related answers.

The main aspects of safety procedures, definitions and health hazards are stressed through a series of numerical examples, pictures and warning text boxes spread out in each chapter. Moreover, besides those data coming from international/national literature and reference publications (e.g. ICRP, IAEA Publications), lots of the data reported in tables and/or used in examples come from direct measurements carried out in several hospitals within Tuscany region in the typical operating conditions.

A summary of the course content, divided in chapters and sections, is reported in Table 1.

Table 1. Radiation protection course content.

Section	Sub-sections
1. Ionizing radiation (I.R.) principles	1.1. Atomic structure 1.2. Ionizing radiation 1.3. Sources of I.R. 1.4. Radioisotopes 1.5. Artificial radiation sources 1.6. Basic physical quantities and units
2. Biological effects of I.R. and epidemiological information	2.1. Radiation Interaction with cells and tissues (deterministic and stochastic effects) 2.2.Epidemiological information and radiation protection
3. Radiation dose and its measurement	3.1. Radiation dosimetry 3.2. Basic dosimetric quantities 3.3. Dose measurement 3.4. Personal dosimetry service
4. Introduction to radiation protection	4.1. The radiation protection principles 4.2. Types of radiation exposure, radiation hazard warning signs 4.3. Dose reduction principles 4.4. Protection devices
5. Radiation protection regulations	5.1. Introduction 5.2. The basis of radiation protection regulation 5.3. Italian national regulation 5.4. Classification of workplaces 5.5. Classification of workers 5.6. Limitation of doses 5.7. Employer's duties 5.8. Workers' duties 5.9. Special protection during pregnancy and breastfeeding
6. Radiation protection in diagnostic and interventional radiology	6.1. Radiation sources and risk sources 6.2. Hazard Assessment 6.3. Radiation safety measures 6.4. Local rules and operational procedures
7. Radiation protection in Nuclear Medicine	7.1. Radionuclides for diagnostic uses 7.2. Radionuclides for therapeutic uses 7.3. Hazard Assessment (External exposure, Contamination and internal exposure) 7.4. Radiation safety measures 7.5. Local rules and operational procedures 7.6. Decontamination procedures 7.7. Handling of radioactive wastes
8. Radiation protection in Radiotherapy	8.1. Radiation Sources (External beam radiotherapy, Brachitherapy) 8.2. Hazard Assessment (External Beam Radiotherapy, Brachitherapy) 8.3. Radiation safety measures 8.4. Local rules and operational procedures 8.5. Biological irradiators
9. Radiation Protection in clinical analysis and biomedical research laboratories	9.1. Radiation Sources 9.2. Hazard Assessment (External exposure, Contamination and internal exposure) 9.3. Radiation safety measures 9.4. Local rules and operational procedures 9.5. Decontamination procedures 9.6. Handling of radioactive waste
10. Radiation protection for non experts	10.1. Ionizing radiation 10.2. Sources of ionizing radiation 10.3. Biological effects of ionizing radiation 10.4. Dose measurement 10.5. Introduction to radiation protection (Classification of workers, Classification of workplaces, Radiation hazard warning signs, Dose reduction principles, How to prevent contamination) 10.6. Radiation protection regulations (Incl. Workers' duties) 10.7. Radiation protection in diagnostic and interventional radiology 10.8. Radiation protection in nuclear medicine 10.9. Radiation protection in Radiotherapy 10.10. Radiation protection in laboratories

Each section includes a multiple choice test, a glossary, a reference list and a "Focus on" sub-section for further information on specific topics.

The entire radiation protection course counts about 150 web pages, and about 6 hours of study are estimated being necessary in order to proficiently acquire the basic knowledge and to become able to correctly answer the test questions. A learning time of 3 hours is estimated for not experts workers, as they are supposed to read the section "Radiation protection for non experts" only.

A web based user interface was chosen to take advantage of the flexibility, in terms of information search and retrieving, hyper text features, document storage capability and eventual future upgrading. Other advantages are inexpensive distribution, reduced technical support and cross platform delivery.

The course provides additional learning tools, such as:

- interactive glossary: in order to make learning easier. When passing the pointer over a term defined in the glossary, a "mouse over" function interactively opens a box with that term definition
- hint function for the multiple choice tests: in case of wrong answer a pop up window linked to the web page containing the right information is opened
- PDF documentation of main national (i.e. Italian) regulations concerning exposure to ionising radiation
- links to external web sites of prominent international radiation protection committees and agencies
- bibliographic notes and links
- links to complementary material and curiosities related to radiation exposure.

In a first stage the course is distributed cost free as an interactive CD-ROM to all radiation workers in Tuscany.

In Fig.3 and Fig.4 the screenshots of two pages are shown as example.

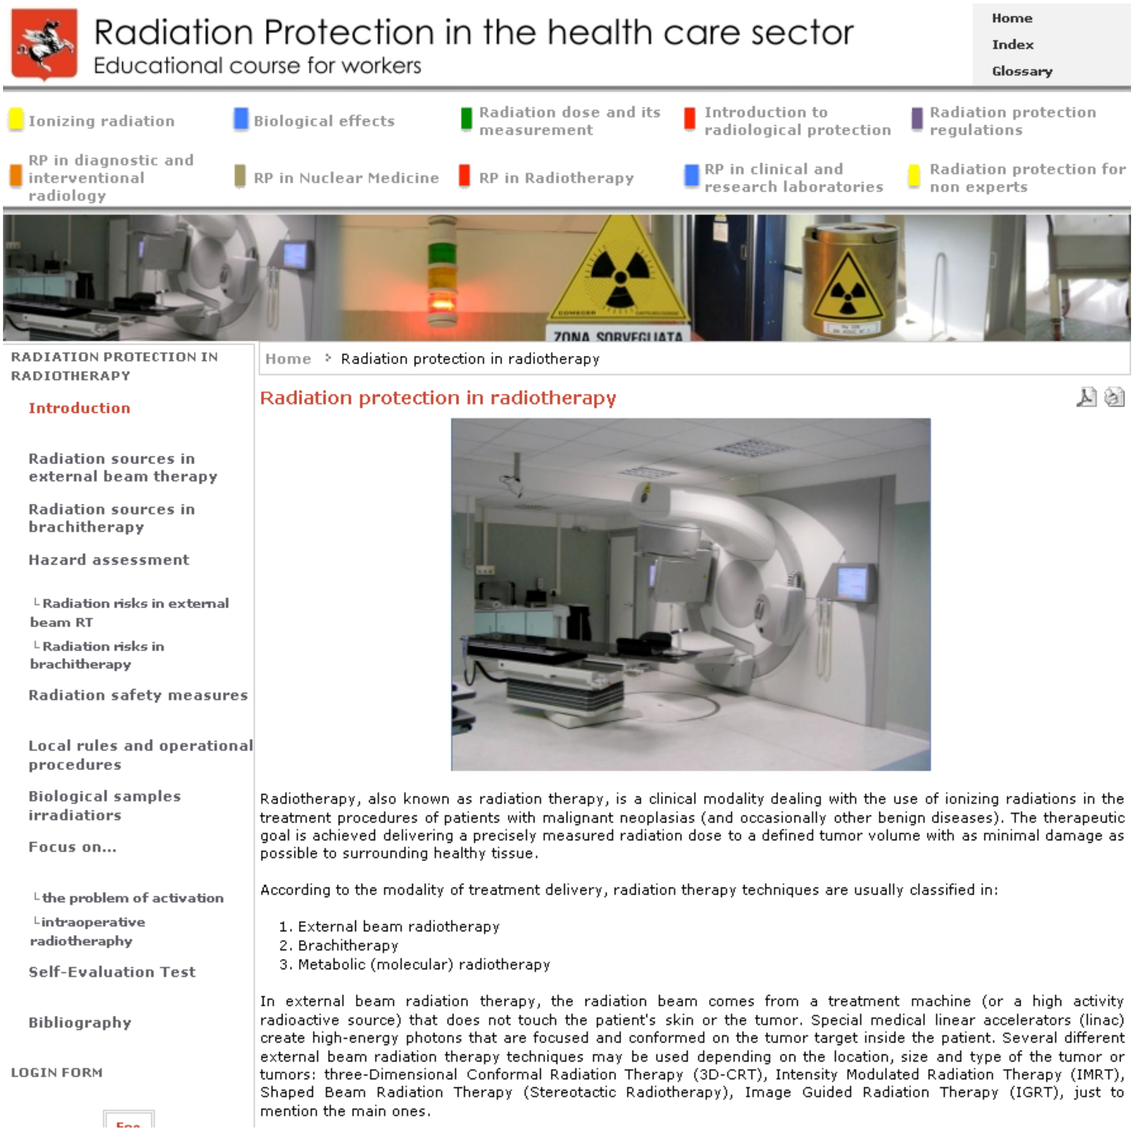

Fig. 3. Screenshot of a course page, showing the web user interface.

Course evalutation

A release candidate version of the course has been made available in February 2010 either on CD-ROM and online to a testing group of 49 workers for evaluation. The workers engaged in the testing group have been selected according to their competence profile. The testing group composition is the following:

- 12 radiological technicians
- 14 professional nurses in a radiological area
- 5 physician specialized in a radiological area
- 12 physician not specialized in a radiological area
- 6 non experts (2 cleaning staff and 4 auxiliary staff)

Each tester was asked to read only the group of chapters appropriate for its job. A test with multiple choice questions concerning RP topics was given before and after the reading of the content. The course has been submitted to the testers along with an assessment and satisfaction questionnaire concerning the relevance of the subject treated, the quality and usefulness of the information presented, the clearness of the explanations and in general the usability of the course and of the learning tools available (more details in the *Results* section).

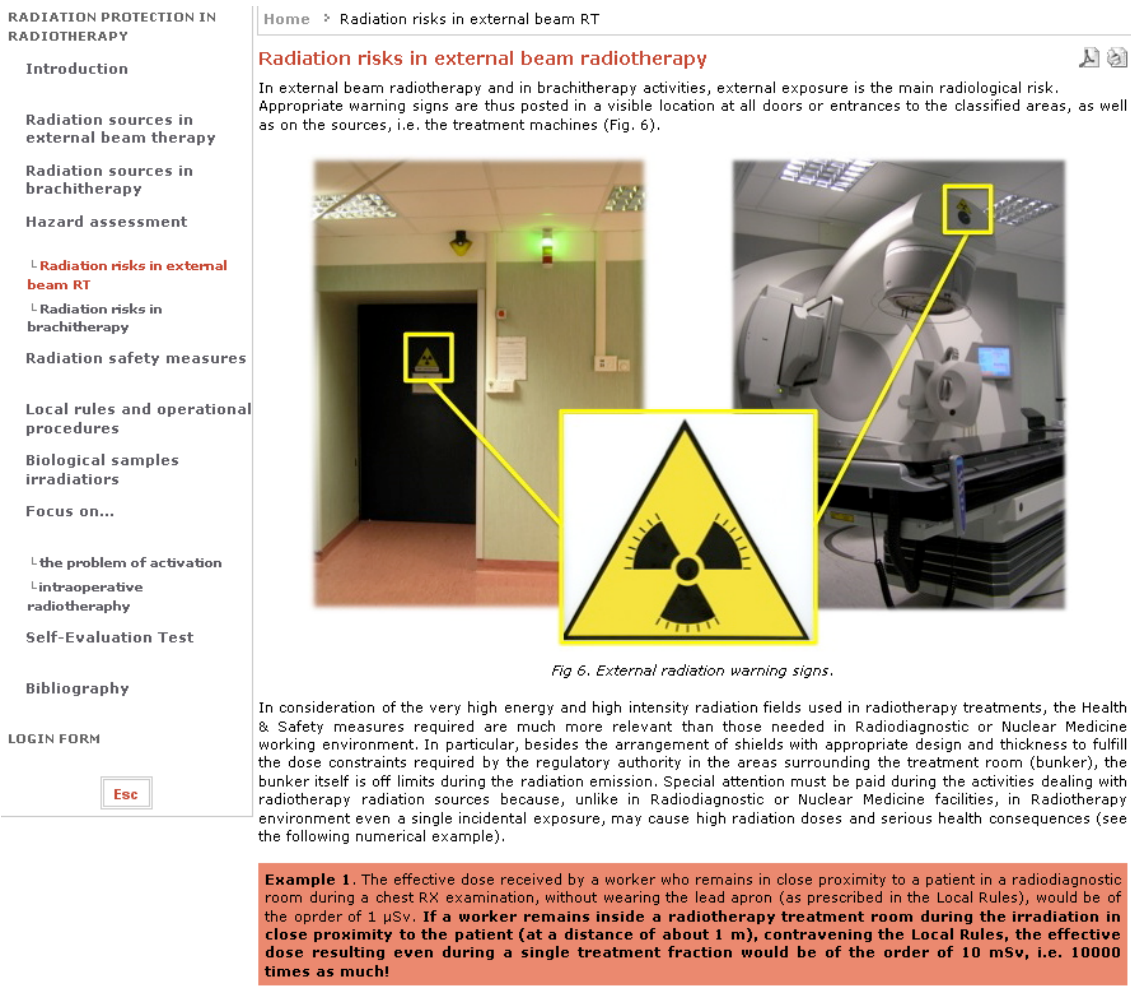

Fig. 4. Screenshot of a course page containing a numerical example.

The effectiveness of the course has been evaluated by comparing the results from the tests performed before and after the course delivering.

Results

The overall results of the satisfaction questionnaire is reported in Fig.5, together with the investigated aspects. Users were asked to express a four steps judgement (from “Insufficient” to “Very Good”) to rate the course educational features.

The multiple choice test results, expressed as wrong answer percentage, are shown in Fig. 6 for the tests performed before and after the course delivering. The educational effectiveness is reported for the different professionals groups and as average.

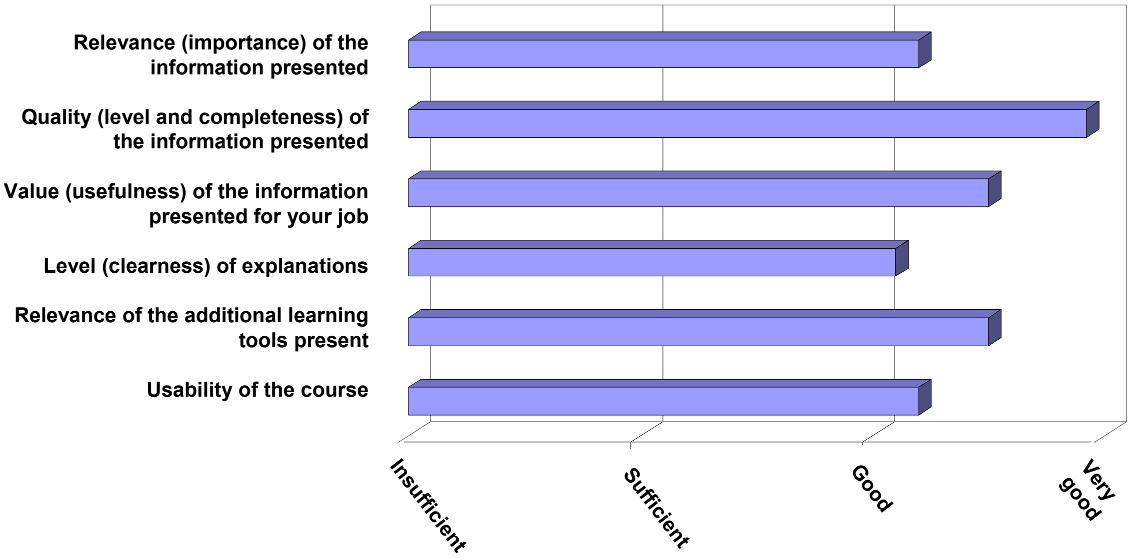

Fig. 5. Synthetic outcome of the assessment questionnaire returned by the workers of the testing group.

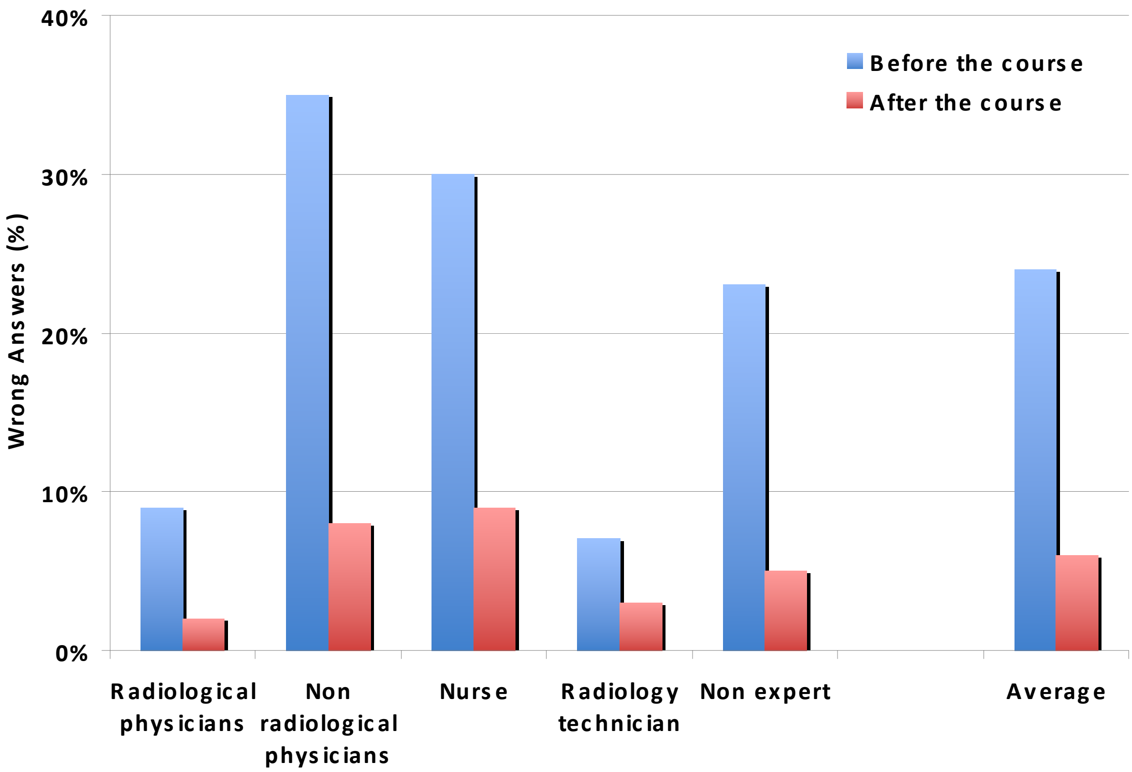

Fig. 6 Multiple choice tests results (expressed as wrong answers percentage) for the different professional groups.

Conclusions

A computer based radiation protection course for all radiation exposed workers of the National Health Service within the Tuscany region, Italy, has been developed. The main challenge of the project is to provide the basic safety information in such a complex field as health care sector, where people with very different education levels and duties work together. The course is addressed to all people working in the health care sector, with special attention to workers without high level education in the I.R. field (medical doctors outside the radiology area, surgery room staff, nurses in nuclear medicine or radiotherapy departments, laboratory technologists, etc.) The main course is composed of a few sections dealing with the general aspects, including basic radiation physics, biological effects of I.R., national regulatory system, dosimetry. Other sections deal with the specific aspects of RP in radiology, nuclear medicine, radiotherapy and laboratory. A special section, summarising all aspects treated in the course, is devoted to workers with poor educational level or no-background in the field of physics, radiation protection and current legislation concerning the exposure to ionising radiation.

First feedback outcomes and multiple choice test results from hospital workers are also reported. The response of first users resulted quite positive according to the questionnaire and the educational content proved to be well suited for the intended target user.

In a close future the course is going to be implemented as a Web Based Course to make it accessible to a larger number of workers, possibly outside the Tuscany region, on an e-learning platform. In the latter case the course could become part of the institutional CPD programme in any hospital.

e-Learning in DAP-measuring

Varonen, Heidi[1]; Kurtti, Juha[1]; Parviainen, Teuvo[2]; Halonen, Noora[1]; SR08S1, Radiography students[1]; Grönroos, Eija[1]

[2] STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

According to studies lower limits for radiation dose setting can be established for computed radiography (CR) systems to produce diagnostic quality images than the standard values used for film/screen systems. This is especially important in examinations performed for the children. Flat panel Detectors (so called direct radiography, DR) gives even more possibilities for dose reduction and still having at least as good image quality as with CR. One of the most important quality assurance procedures is to evaluate the doses delivered to patients who undergo x-ray examination. The DAP-meter is a real-time patient dose monitoring system for auditing patient doses. Technical data from each exposure and for every examination type can be collected. Radiography students and lecturers of Metropolia University of Applied Sciences produced an e-based learning module about DAP-measuring in co-operation with Metropolia degree programme in multimedia technology and Finnish Radiation Protection Authority. In this presentation the contents and pedagogical solutions of this module are presented. Also the development process of this learning module is depicted. The educational module consist of articles to be read, different kinds of tasks to be solved e.g crossword about central concepts of dose-area product-meter (DAP). The group also made a film that shows how to measure patient doses with DAP when using digital radiography (DR) technology.

e-Learning philosophy and structure for a Nordic education project in evidence based radiography

Voima Hellebring, Tiina[1]; Grönroos, Eija[2]; Varonen, Heidi[2]; Ween, Borgny[3]; Waaler, Dag[3]; Henner, Anja[4]; Ahonen, Sanna-Mari[5]; Kurtti, Juha[2]; Saloheimo, Tuomo[2]; Fridell, Kent[1]

[5] University of Oulu, FINLAND

Abstract

Helsinki Metropolia University of Applied Sciences has initiated a Nordic project to increase competence of radiographers by evidence-based training in quality in radiographic imaging. The members of this project are radiography lecturers, principal lecturers and physicists from universities in Finland, Norway and Sweden. The goals of the project are to produce curricula and learning materials using internet solutions for ground-, master and PhD-level web-based education and finally to implement the education and evaluate the training program and the materials produced. The main contents will be evidence-based digital imaging, dose optimization and quality assurance of digital imaging systems. The main principle for the education project is that the way of training as well as the contents will be evidence-based. In according to this the members of the project group apply evidence-based way of working in planning the education and in the contents. To give the students understanding, knowledge and tools for working evidence-based, the training program will start with an introduction to evidence based knowledge and its use in radiography, which is elementary in the whole education. The training program applies various web-based methods depending on the subject and the expected learning outcomes. In some cases the method used will be group activities like lectures by videoconference, face to face meetings on the web and discussions in groups synchronously or asynchronously via Wiki-based IT-solutions. Some subjects will be suitable for individual studies by self-paced e-learning online e.g. when searching articles or offline e.g. in learning dose area product measuring or other procedures. Students from the participating universities are even involved in the project from the very beginning e.g. by writing thesis for the needs of the project.

Developing a radiation protection culture at school

Abstract

Since September 2007, actions to develop a radiation protection culture have been undertaken in several schools in cooperation with experts from the Institute of Radiation Protection and Nuclear Safety (IRSN), the Nuclear Protection Evaluation Centre (CEPN) and the centre for scientific culture (Pavillon des Sciences – Franche Comte). The aims are to provide school-students with scientific and social bases on radiation protection in order to be better prepared for dealing with societal issues, to promote a scientific and technical culture, and to allow the students to better understand the "world" of radiation protection.

Each year, this approach includes two steps:

One part is dedicated to training during the school-year; each school works on different topics chosen according to local concerns (e.g. radon in dwelling, medical radiation protection, radioactivity in the environment, radiobiology…). In order to facilitate the development of this culture, practical aspects are favoured, notably with experiences and visits to laboratories, hospitals, … Special attention is given to multi-disciplinary approach including physics, chemistry, biology, philosophy, geography, economy… This task is lead by school teachers in cooperation with experts.

The other part consists in participating to a "student workshop" allowing them to present their work and to exchange with other students and experts. In 2008, the first workshop was held in Montbeliard (France), the second one, involving French as well as German, Ukrainian and Belarussian schools, was held in Poitiers (France) in 2009 and the third one was held in Paris in March 2010, involving more than 200 participants from French and foreign schools (Belgium, Belarus, Germany, Italy and Ukraine).

This paper details the actions developed during the last years and discusses the lessons drawn on the way to address radiation protection with young people combining scientific issues and social concerns.

Introduction

There is an increasing trend to involve stakeholders in radiation protection management. Some issues will be of particular importance in next years: radioactive waste management remains a sensitive issue, new development of nuclear energy is anticipated, medical exposure increases drastically, management of radon exposure needs to be improved… However, members of civil society need basic knowledge in radiation protection together with practical experimentation to be able to improve their level of protection regarding radiation exposures, to express their concerns and expectations on these issues and to play a role in the related decision making processes.

Therefore, Institute of Radiation Protection and Nuclear Safety (IRSN), Nuclear Protection Evaluation Centre (CEPN) and the "Pavillon des Sciences de Franche-Comte" (a centre for scientific and technical culture) decided in 2007 to initiate a pilot programme with some high schools (lycee) in France.

Material and methods

The programme is based on cooperation between school professors and radiation protection experts either from IRSN, CEPN, universities or environmental NGO.

In order to develop multidisciplinary approach, professors teaching biology, physics, philosophy, arts … are involved. School students, from 15 to about 19 years old, participate, on voluntary basis, in small group(s) up to 20 students in each high school.

Each school year, the programme includes two parts: the first one concerns practical experiments performed by school students with their teachers and the second one consists in the organisation of a workshop, involving all the schools, held in Spring.

The following topics are proposed: biological effects of radiation, cancer epidemiology in exposed population, radiation detection, radon exposure, radioactivity in the environment, medical use of radiation, ethics…

Each high school chooses topics, according to regional or personal interest.

For each topic, a radiation protection expert is identified on voluntary basis to accompany professor and students.

Experiments are designed for the students to cope with radiation protection bases through practice and to identify the issues at stake for the management of radiation protection in specific situations (mining residues areas, environmental surveillance around nuclear installations, radon management in dwelling, radiation protection at hospital,…). Protocols for experiment are defined in order to avoid risks for participants.

Figure 1 summarizes the approach adopted for developing a radiation protection culture at school.

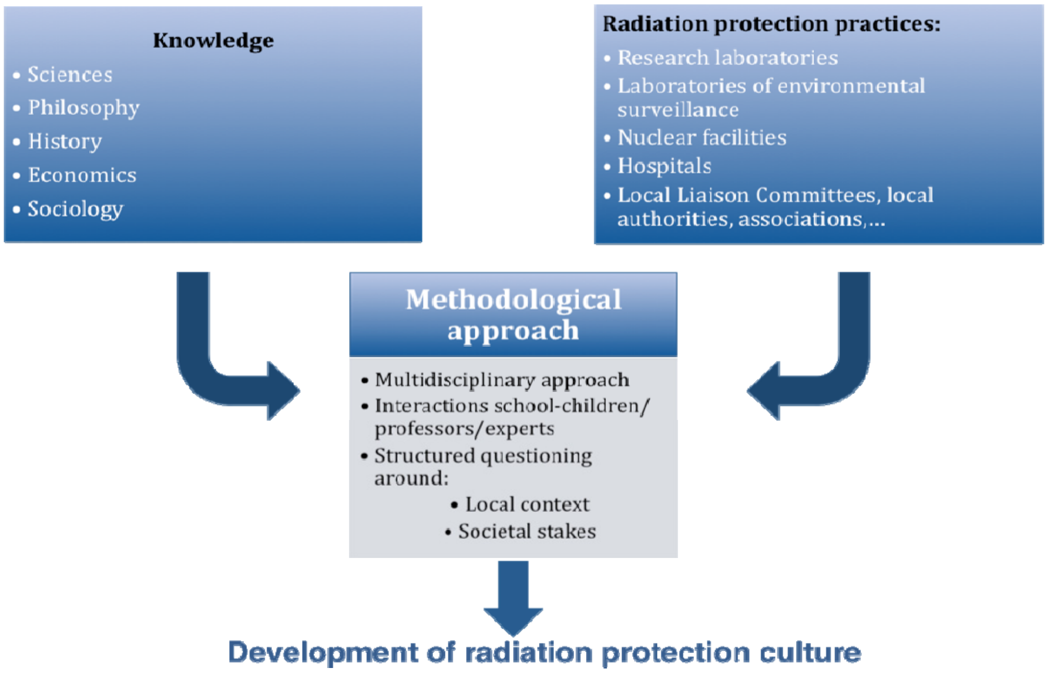

Fig. 1. Approach adopted with schools.

Besides, instruments needed must be either simple ones used in high school (colorimeter, computer, microscopes…) or tools which could be lent by experts (portable dosimeters…).

In most cases, first step is a meeting between professor(s) and expert to define experimental protocol. As second step, expert makes a short presentation of the topic to the students. Then, the experiment is performed by students with their professor, the expert remaining as support if necessary. Often, this step is followed by a technical visit of a unit specialized in the corresponding field; it allows students to discuss their results and work performed in the unit. Visits and discussions are also organised with practitioners form nuclear installations, surveillance laboratories, elected people, local liaison committee members around nuclear installations, …

The Workshop is an opportunity for students to present their work and exchange with the other students, but also with experts. It includes thematic sessions with oral presentations by students, as well as some lectures by experts on special topics. The Workshop programme also includes technical visits and entertainments.

Results

The programme has now been operated for three years. Except for special circumstances (retirement of school professor…), high schools remained involved through the years.

The programme was initiated with French high schools. From second year, schools form Belarus, Ukraine and Germany were involved, and during the third year schools from Italy and Belgium joined the programme, although the language used was French to facilitate exchanges.

For the year 2009-2010, 14 schools and about 230 persons participated to this action. Figure 2 presents the evolution of the participation to this action.

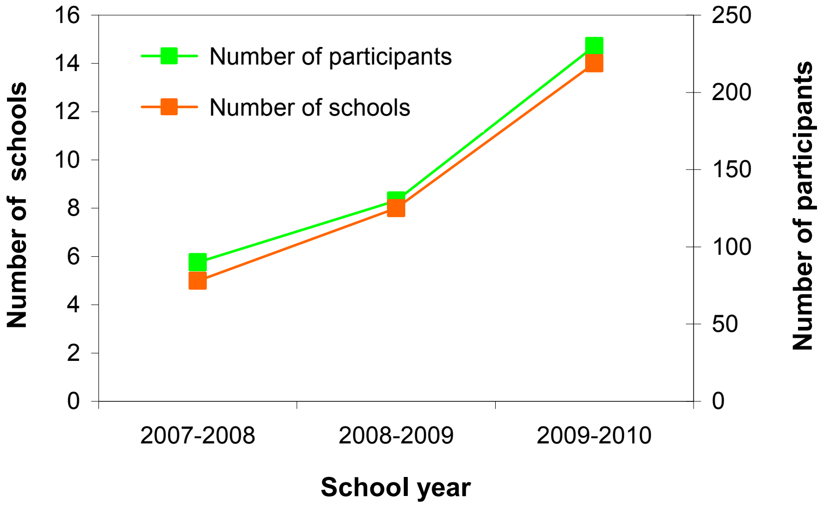

Fig. 2. Evolution with time of the numbers of schools and participants.

Each year, over 20 experts, who are technicians, engineers or researchers, participated to this action, with a large participation from IRSN.

From practical experiments, students learned about physical, biological, regulatory… bases in radiation protection. For instance, biological dosimetry experiment was organised to study effects of radiation. Students had to identify and count chromosome aberrations (dicentrics) on metaphase spreads from blood samples irradiated at various doses; after defining calibration curve, they had to evaluate dose on an unknown sample. From chromosomal aberrations, students learned about radiation induced DNA damages, cell death… Search of hidden sources with different dosemeters or analysis of tissue proportional counter spectra gave them an opportunity to study, for different radiations, interactions of radiation with matter, radiation detection, energy deposition at micrometer level... Students exposed radon dosimeters in various conditions: basement, living rooms, caves…; analysis of results gave them the opportunity to learn about radon exposure. To understand radionuclide release in the environment, students took samples in environment surrounding a nuclear facility, these samples were then analysed in laboratories.

In addition, the multidisciplinary approach together with the interaction with different experts and stakeholders give the opportunity to engage a reflection on the societal issues associated with different radiation protection practices. Inquiries have been performed by students around nuclear installations for example on the type of information available for the population. A measurement campaign has been organised with an environmental NGO in addition to the visit performed in a nuclear installation. Students living in territories contaminated by the Chernobyl accident in Belarus and Ukraine worked on the memory of the accident and the current consequences in the day-to-day life.

Fig. 3. Schools students searching for hidden sources.

The Workshop is an opportunity for the students to present their work, share the knowledge they had acquired, express their view on the societal issues at stake, exchange about their experience and discuss with experts.

In addition, few experts gave lectures on topics such as recent discoveries in radiobiology, SOCATRI accident in France, sources of exposure to ionizing radiations of French population, management of post-accident situations…

Fig. 4. Student lecture and presentation during workshop.

Discussion

Each year very different topics were selected, but interestingly radon, which is not generally considered as a sensitive issue by population, was over selected every year.

Since each group cannot work on all topics, part of the bases are not acquired directly, but though exchanges with other students. It would be interesting to check how far they are able to understanding the technical and scientific aspects of radiation protection issues as well as their capability to address societal issues at stake with different radiation protection practices.

So far, experts who participated to this programme are enthusiastic about sharing their knowledge and experience, but they are almost exclusively issued from institutions. It would be interesting to widen the spectra by involving more members of civil society.

One important condition is to work on voluntary basis to involve highly motivated professors, students and experts.

It is interesting to underline that this approach could contribute to favour the participation of citizen to the debate on radiation protection issues. Besides radiation protection purpose, this programme could also promote scientific careers at a time when interest for this field is sharply decreasing in France.

Conclusions

This pilot programme has been rather successful, in demonstrating that scientific and technical bases of radiation protection, which are known as complicated, can be rather easily acquired by school students. It has also demonstrated the interest of addressing the radiation protection issues with practical experiments and within local contexts. The challenges are now to adapt the programme to cope with anticipated increase of participants, to define a charter to precise conditions of participation, to involve a wider panel of experts and to further investigate the best approach for the diffusion of the radiation protection culture for school students.

How to share with children the basic knowledge about radioactivity and nuclear Risks?

Baumont, Genevieve[1]; **Allain, Evelyne**[2]
[1] IRSN, FRANCE
[2] IFFO RME FRANCE

Abstract

This paper presents the strategy of IRSN to increase the basic Knowledge of young of children about radioactivity and nuclear risks in partnership with associations. 58 reactors are built on the French territory but a review performed by M Vroussos in 2004 highlighted that French people have a very poor knowledge about radioactivity and nuclear risk. This was confirmed by the Eurobarometer surveys. The consequences of such a low background knowledge should be, first, that the public cannot reduce the doses due to natural, medical exposition. Second, in case of nuclear event (example Tricastin 2008) or nuclear accident, the behaviours of concerned people and French consumers could create strong social and economical effects due to inadequate representations of the accident impacts. Third, in a more general way, citizens have few knowledge to discuss the nuclear renewal.

In order to diffuse a better knowledge IRSN and IFFO RME decided to have a partnership to develop tools for teachers and children. The Gafforisk fan was the first tool, with the objective to give fundamental knowledge about natural radioactivity, nuclear reaction, accident fallout, crisis management with a special emphasis on behaviour recommendation in case of nuclear crisis.

The tool was developed in a mobile exhibition which can be used by local information commission (CLI), for example during crisis exercise. The paper will present in detailed the strategy, the partnerships the different tools and their use.

Introduction

In 2004, after a large review to reinforce radioprotection in France, in his report asked by the French Nuclear Safety Authority (ASN), Pr Vroussos concluded that French people have a very poor knowledge about radioactivity and nuclear risk and he suggested main ways to improve Radioprotection. One of them is “to invent, or at least to experiment, new modes of information and dialogue with the population to share the knowledge and try to establish a dialogue between the citizen and the services in charge of the control, and to allow each one to form its opinion, in particular on the question of the risks connected to the use of the nuclear energy”.

To make it in a pragmatic way, he recommended "a strong action with the Ministry for Education so that the programs of the secondary education integrate the physical and biological bases of the effects of ionizing radiations, their diverse applications and the radioprotection within the citizen-centred approach to the environment topics and to the sustainable development".

In its strategic plan for 2010-2012, the ASN makes a commitment to associate more widely the public with the process of decision-making and to explain its decisions. For it, it would be necessary to increase the level of information of the public. According to the Eurobarometer about nuclear Waste (2005) [1], 22% of French people declared not to be informed on nuclear waste, and the knowledge on this topic was tested by 5 questions. As a result, France is eighth (60% of good answers), three first ones are Slovenia (72%), Finland (68%), Sweden (68%), countries where the number of nuclear installations is less than in France. This can be explained by the very long period (until 2006) during which many documents and recommendations on safety issues were not available to the public, thus without debates with the society.

The consequences of such a low background knowledge should be (1) in a more general way, citizens have few knowledge to discuss the nuclear renewal. (2) the public is not able to reduce the doses due to natural, medical radioactive risks to which they expose themselves and, (3), in case of nuclear event (example Tricastin 2008) or nuclear accident, the behaviours of concerned people and French consumers create strong social and economical effects due to inadequate representations of the accident impacts. Because, as said by M Covello in the conference in Bethesda in March 8, 2010 about risk perception, "when people are stressed and upset, the gap between perceptions and reality often becomes wider.", "perception equals reality", "that which is perceived as real is real in its consequences.".

For these reasons, the French Institut de Radioprotection et de Surete Nucleaire (IRSN) wondered about the best way for developing a knowledge on the nuclear power and the radioactivity in particular towards the school pupils, the citizens of tomorrow. Recognizing that the pedagogy was not its field of expertise, IRSN decided to have a partnership with the French Institute of Trainers at the Major Risks and Environment (IFFO RME) [2]. In this association, half of the 800 adherents are voluntary teachers to educate their pupils at the major risks (natural and industrial risks also too little handled in course of study), other are coming from French public services involved in risk management or risk specialists.

The most challenging aspects for education

The first step of the partnership was to well identify the most important challenges of the common work.

Nuclear accident seems to be the topic where the knowledge is the lowest and with the most important consequences on society if it occurs. IRSN risk barometer 2009 [3] shows that French people consider the accident in nuclear plant as the most important potential risk (fig 1). But they have little knowledge on it and on the risk management in such a crisis. They don't know who give information. In this area, authorities have a poor credibility [4] (fig 2), these verbatim are very frequent: «they lied to us. The cloud of Chernobyl stopped on the border", "they do not say to us everything ","If we do not die at once, we shall die from cancers ", "they speak about nuclear safety but not about risks". This shows that in the representations of the population on the nuclear risk, Chernobyl consequence and its management in France takes an important place and contributes nevertheless to a certain consciousness of the risk..

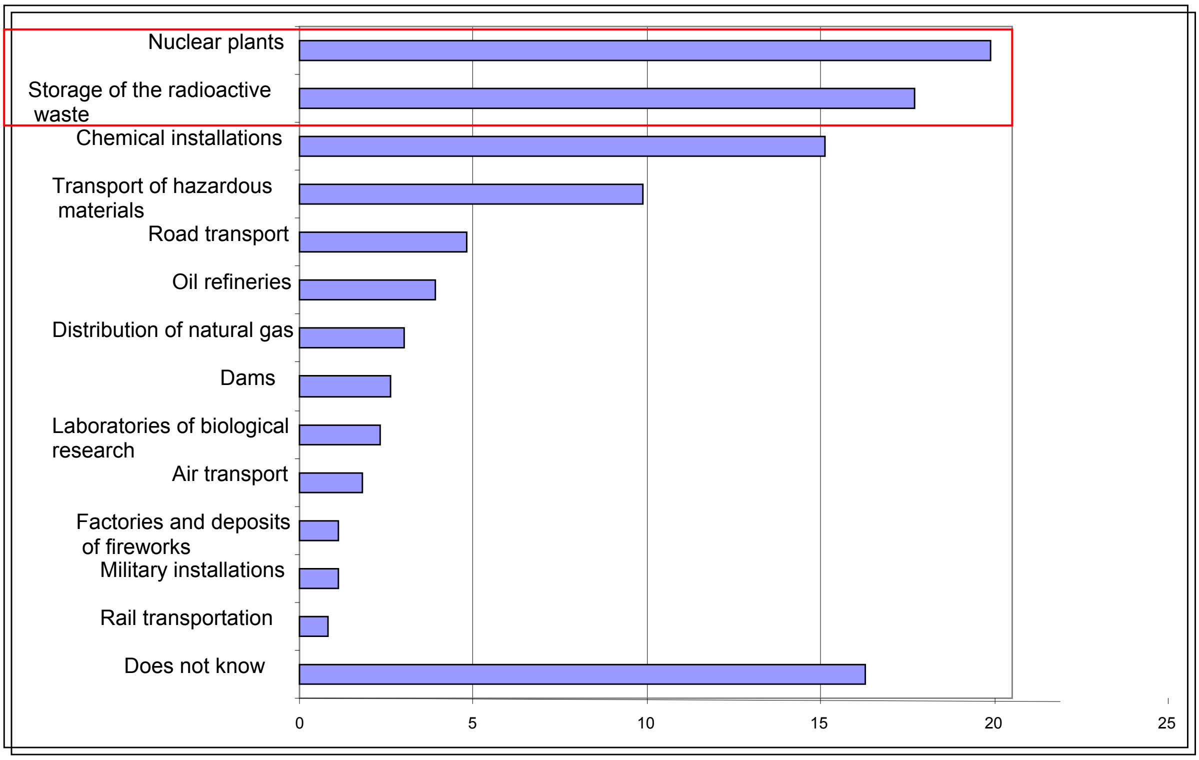

Fig. 1. IRSN risk barometer 2009 : Percentage of answers to this question " Among the diverse industrial or technological activities following ones, which are the ones which risk most to provoke a grave accident or a disaster in France? " (3 possible answers)

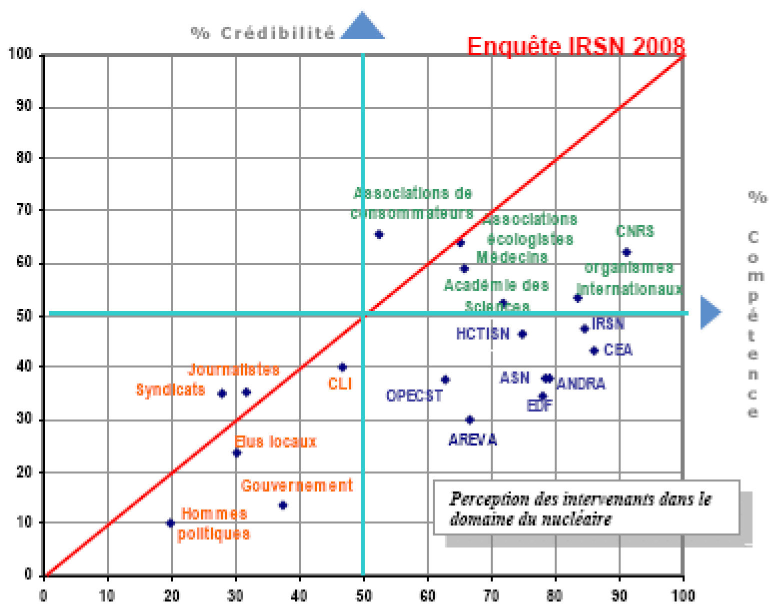

Fig. 2. " This picture give the rate of credibility and the rate for competence given to different actors. This shows that the credibility of ASN (nuclear safety authority) and IRSN is less than the average and the greater credibility is given to scientist and ecologist associations. "
From the IRSN barometer 2008

More, the population knows rather little the major risks which could occur as well as measures of prevention and protection they have to use in a crisis. Besides, the partners recognize that without a minimum of knowledge about a topic, it is impossible to ask questions and participate as a citizen in a nuclear debate. So, two major difficulties were identified to change the tendency: it is needed to popularize a scientific and technical domain (viewed as an elitist topic) and to take the heat out of the debate, without which we cannot build of information and educational.

So, for that, other partners join the working group such as Commission locale d'information (CLI), Association nationale des Commissions locales d'information (ANCLI), ACRO (Association pour le Contrôle de la Radioactivité de l'Ouest), Versailles Academy. The concerns of all the partners were to lock the cursor for the center and not to overturn into the debate "for" or "against". The approach was guided by Dr V. Covello principes in [5] on Risk Communication recommendations: the risk Communication is an interactive process of exchanges of information and opinion among individuals, groups, and institutions. It involves multiple messages about the nature of risk, not strictly about risk, but also legal and institutional arrangements for risk management.

The past experience of IFFO RME on risk education

Since 1990, the IFFO RME association worked about education on risk. But some recent laws reinforce their actions. Some events occured in France have drastically changed the policies on natural and industrial risk management and crisis organisation, to reinforce the regulations in prevention and in preventive information of the populations. The Ministry in charge of Environment prepared the Law N 2003-699 of 30/07/03 relative to the prevention of technological and natural risks and to the repair of the damages, the Interior Ministry, the Law n°2004-811 of August 13th, 2004 of modernization of the civil protection, and the government promulgated the Law N 2006-686 of June 13th, 2006 relative to the transparency and to the safety in nuclear domain.

This information will be perceived all the better than it will take support on an early educational approach instead of waiting the treatment of event only by the media. To train the future citizen in responsible behavior, the education in the prevention of major risks joins in an education the environment, the safety and the health, in other words in the sustainable development education. In this perspective, speak about nuclear risks need to consider the overall nuclear activities from the mine extraction to the energetic and medical uses. This education calls to the notions of country planning, scales of time (management with more or less long terms for wastes or spoilt soil contamination and radioprotection measures) and spaces (solidarity / responsibility international). This education to the complexity develops the critical thinking and the education in the choice. It puts the thought of accepting a certain level of risk towards our needs.

One of the last tool developped by the IFFO RME association was "the major risk and me", an exercise book. Its various exercises are proposed based on, first, the observation of local risks (it can be a nuclear plant or installation) in its immediate environment and, second, on personal research. The booklet also identifies the major risk players and offers thinking on collectively and individually safety. In this progressive educational approach, the knowledge is build step by step. Pupils can work on this book in class or independently. In this case, the tool takes part of education.

The experience shows that it is very important that teachers participate to the design of the tool and to give their feeling about the pedagogical approach. They have to be stakeholders in the educational development. They must find anchors in the syllabus of geography, of life sciences and earth, of history, of languages, of sports in link with civics education. The major risk education is fostered by interdisciplinary work In parallel to the work done to create the manual, web pages have been designed to support teacher. They specify the general approach of the support, the level of targeted instruction, the anchoring discipline, the knowledge and skills which have to be developed from the teaching notes and always the basic knowledge for the own use of teachers.

More, schools have to organize the pupil's safety inside their buildings, in case of major risk crisis, waiting for emergency assistance teams. In France the specific plan for safety, named PPMS, is recommended by the Education Ministry. To prepare such a plan, the entire school community (adults, students, parents) need to be mobilized and to trigger appropriate behaviour and solidarity. For being well understood and applied, this organisation have to be based on pedagogical approach: in order to know why this plan, what for, what to do, in which case, against which danger.

To conclude, two essential objectives are pursued by IFFO-RME. First, the cultural one: the construction of a risk culture which enlighten citizen and make him the actor of the public debate. Second, the operational aspects, which permit the comprehension of the procedures of crisis and its management. The stake is double and of equal importance because, if somebody does not understand source data, he cannot subscribe to the message of the authorities in a crisis.

An overall strategy

From this 15 years experience of IFFO-RME, 3 complementary levers can be activating to build a nuclear risk education or modestly hope to build a conscience of nuclear risk for young people (and indirectly for parents):

1. Partnership between scientists, teachers and administrations: The exercise was difficult, it is necessary to find the consensus between the rigor, the detail of the scientist and the popularization which does not infer false representations (ex: the cooling tower never produces radioactive fallout). A common understanding of partners and the conception of a common speech takes time. The partnership between IFFO-RME and IRSN permits to share knowledge without which the population could not understand and adopt the adequate behaviour in a nuclear crisis based on the knowledge of a nuclear institution but with the wording of the users.
2. Tools: In a society which is ceaselessly called, sought by the visual communication, the visual appearance's tools "funny", "attractive", "coloured" is a key to catch the attention and interest of young people on a difficult subject. It is not a question of using the competences of the communication "to sell yoghurts", but to put these in the service of the education. The tools are always developed with an additional document for the teachers use where more detailed information is given.
3. Adults trainings: special training are organized for teachers and trainers (with various background) to let them able to ask questions and to have a deeper knowledge.

The final decision of partners was to center the purpose of tools on the nuclear risk (and not nuclear energy), in a perspective of radio-protection aspects of accident, crisis and post-accident issues.

This overall strategy includes a diffusion plan for schools (duplication of tools, the manpower-ressources, downloading on internet) where key people coming from National Education are involved. Without them the project can be unsuccessful…
However, education is not the exclusivity of schools but it is built all the life. So, the planning of itinerant exhibition includes cities and public services.

The development of tools and events

The first tool was the fan "Gafforisk", developed for fourteen year old children even if nothing in their school programme is in link with the information. Ten pages (recto verso) the first ones gives information about major risks, then one page for general knowledge about atoms and material, radioactivity and radiations. An other one for the origins of the radiations received by the population in France and their percentage in the exposure doses.

One page about the use of fission reaction giving energy in nuclear plant, and the fission product problem in case of accident, another page summarized the Chernobyl catastrophe. The various radiation uses and the different layers for protection are illustrated in other pages,. The units to measure radioactivity and its impact on the body are explained. Differences between Irradiation and contamination are illustrated. Four pages are used to explain the crisis management: alert signal, seclusion and stake under cover. Some exercises are proposed to make active children.

To build this tool, partners discussed a lot to find the last word. The selected words were not the most scientific ones but the most understandable ones for a 14 years old children.

IRSN and the French Ministry in charge of environment and Sustainable Development bought more than 35 000 copies of this fan to be broadcasted in schools with the help of the IFFO RME net.

One itinerant exhibition was created : 14 panels pulled by the fan Gafforisk were published to be posted in the schools and places where an in deep discussion was wanted. A trainer or an IRSN specialist accompanied the exhibition. Taking care of the remarks of trainers, education experts and users, 2 panels were added on the specific topic of the Chernobyl consequences. Due to the French context, these panels are very important for allowing each one to get it of his chest on the management of this accident in France and to hear the information coming from the posterior studies on this subject At the national level, three copies of the exhibition can be borrowed for various events..

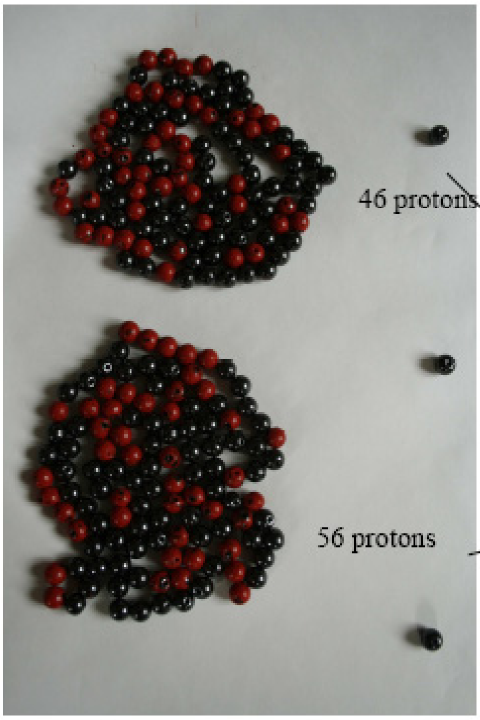
For example, it can be used when a crisis exercice is organised near a nuclear plant and when school participate to it, using the PPMS (the pupils confine themselves to the school), or when the mayor wishes to give an information to the city hall during the distribution of pastille of iodine to the inhabitants. Because in case of crisis, the key to risk management success is anticipation, preparation, and practice.

An other way to use it is during French education events such as the Week of sustainable development, or the days of Science Festival.

The lessons learnt is that that is exhibition is easy to used as well with the adults without any knowledge on radioactivity and nuclear that with the children (the youngest were 10 years old). The speaker has to adapt his language to the public.

Additional kits were developed to be used in front people to explain fission and fission products (235 +1 magnetic hematite pearls, 92 painted in red) in order to produce the feeling to be able to understand this elitist topic and to understand what is the iodine problem…They can feel what is a scientific approach and go very far in their understanding.

Fig 3 What are the fission products produced in this fission?



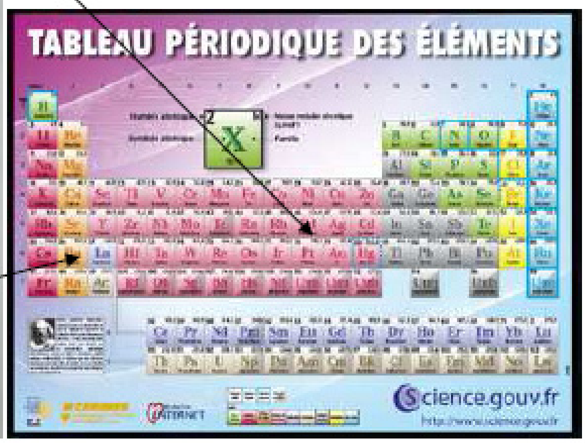


Fig 4 The answers found by people themselves by counting red pearls spread over the table and using Mendeleev table.

A local guide of exhibition

This document, composed with the partner "Local commission of information of the nuclear research center of Saclay" (CLI de Saclay) based on the fan Gafforisk. It was developed to be given to the public, alone in the exhibition when no speaker is present.

The booklet presents the exhibition in 5 parts and gives local informations. The five parts :

1. What's the radioactivity?
2. For what to do?
3. Minor incident or major accident?
4. What to do in case of crisis?
5. How to inform myself?

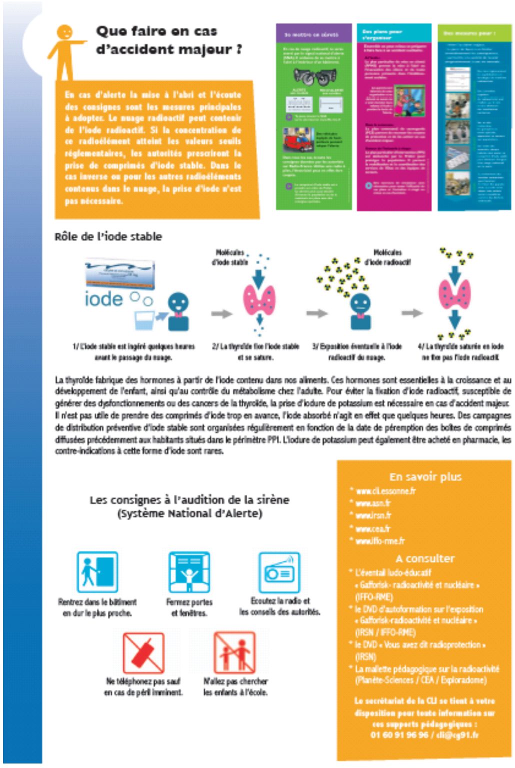

Fig 5 In this last part of the booklet, the behaviours recommended during crisis situation and protection against iodine radioactive contamination by distribution of iode tablets are explained.

Proposal of teachers training and trainer's tools

Because it is not easy to trust in ourself when we are not a specialist of the domain, trainings or tools for self-training must be developed for the attention of the voluntary persons. The academy of Versailles had organized in partnership with IRSN and IFFO-RME a session of 3 days about "radio-activity and nuclear". The training was opened to every voluntary professor to form on this subject. Professors of physics and natural sciences were present but also professors in industrial techniques as well as professors of geography, history, civic instruction, French. This unit of training will be renewed next year and suggested to others French academy.

DVD for trainers

Otherwise, IRSN and IFFO RME are preparing a DVD for auto-training based mostly on videos, free on internet, because new tools and media can be efficient vehicles for our purpose. Because, most of the concerns and questions of upset or concerned people can be predicted and prepared for in advance. It was considered as possible to anticipate them and to develop answers which will remind the aims developed in the panels of exhibition. The commentaries will be given by teachers and specialist of crisis management. There will be additional topics to about diseases, international responsibilities.

It will contain some practical experimentation about the atoms, the fission, the produce of fission, the dispersal of radioactive cloud…

Conclusion

In the context of sustainable development, the nuclear issues arise in terms of society choice: what are the risks/benefits of this choice.

To build an education on nuclear energy and especially on nuclear risk, we have to imagine various systems (paper, video, kits) with multiple sources of education messages. The messengers of education have to be diverse to multiply the meets between the citizen and rational representations of risks. So the citizen could access to information, understand it and take a better part to his security.

In the framework of the nuclear renewal, several questions arise.

– How different States can combine their efforts in the field of education in nuclear risk and radioprotection ?
– What international working group on teaching practices would allow the construction of white book of best practices and adapting existing tools in the countries concerned
– What evaluations of educational strategies in nuclear risk would measure its effectiveness in the long term.

These actions contribute to a better society resilience.

Abstract
The new ICRP recommendations (ICRP 103), and in particular the detailed treatment of optimisation in the ICRP Publication 101, define optimisation of protection as a source-related process aimed at keeping the likelihood of incurred exposures, the number of people exposed and the magnitude of their individual doses as low as reasonably achievable, also below constraints, taking into account economic and societal factors. The implementation of the optimisation of protection into practice is supported by the ALARA principle. The term ALARA is an acronym for "As Low As Reasonably Achievable". In essence, the ALARA principle requires that radiation exposure of man and environment be kept as low as reasonably achievable (also below constraints) when using ionising radiation. Practical implementation and further development of the ALARA principle has been achieved for many years now by the successful cooperation of experts from different European organisations; first as pioneers by establishing the European ALARA Network and then by enthusiastically supporting the activities of the network itself. This contribution presents the evolution, operation and key activities of the European ALARA Network (EAN) in the last years; the successful cooperation of experts from different professional backgrounds, advocating the ALARA principle in a range of radiation protection areas, and contributing to its further development by trading experience and networking. The interaction between the EAN and international organisations, which support the ALARA principle by including relevant activities in their work programmes, is described, as well as the cooperation between EAN and other networks to identify the role of ALARA in the process of improving radiation protection culture.

ENETRAP-II: development of European training schemes for RPE's and RPO's

Abstract

ENETRAP II, aims at developing reference standards and good practices for education and training programmes for radiation protection experts and officers, reflecting the needs of these professionals in all sectors where ionising radiation is applied. The introduction of a radiation protection training passport as a mean to facilitate efficient and transparent European mutual recognition of these professionals is another ultimate deliverable of this project. It is envisaged that the outcome of ENETRAP II will be instrumental for the cooperation between regulators, training providers and customers (nuclear industry, research, non-nuclear industry, etc.) in reaching harmonisation of the requirements for, and the education and training of, radiation protection experts and officers within Europe, and will stimulate building competence and career development in radiation protection to meet the demands of the future.

Introduction

Radiation protection (RP) is a major challenge in the industrial applications of ionising radiation, both nuclear and non-nuclear, as well as in other areas such as the medical and research area. As is the case with all nuclear expertise, there is a trend of a decreasing number of experts in radiation protection due to various reasons. On the other hand, current activities in the nuclear domain are expanding: the nuclear industry faces a so-called "renaissance", high-tech medical examinations based on ionising radiation are increasingly used, and research and non-nuclear industry also make use of a vast number of applications of radioactivity.

Within this perspective, maintaining a high level of competency in RP is crucial to ensure future safe use of ionising radiation and the development of new technologies in a safe way. Moreover, the perceived growth in the different application fields requires a high-level of understanding of radiation protection in order to protect workers, the public and the environment of the potential risks. A sustainable education and training (E&T) infrastructure for RP is an essential component to combat the decline in expertise and to ensure the availability of a high level of radiation protection knowledge which can meet the future demands.

Today's challenge involves measures to make the work in radiation protection more attractive for young people and to provide attractive career opportunities, and the support of young students and professionals in their need to gain and maintain high level RP knowledge. This can be reached by the development and implementation of a high-quality European standard for initial education and continuous professional development for radiation protection experts (RPEs) and radiation protection officers (RPOs), and a methodology for mutual recognition of these professionals on the basis of available EU instruments, such as the European qualification framework (EQF) and/or the directive 2005/36/EC.

Within the framework of this project, the RPE and RPO should be interpreted as:
Radiation protection expert (RPE): *an individual having the knowledge, training and experience needed to give radiation protection advice in order to ensure effective protection of individuals, whose capacity to act is recognized by the competent authorities.*
Radiation protection officer (RPO): *an individual technically competent in radiation protection matters relevant for a given type of practice who is designated by the undertaking to oversee the implementation of the radiation protection arrangements of the undertaking*.

These are the definitions proposed by ENETRAP 6FP (www.sckcen.be/enetrap) and EUTERP (www.euterp.eu) to the EC DG TREN and Article 31 group, who is working on the revision of the Basic Safety Standards.

Project details

Determined to build further on the achievements of 6 FP ENETRAP, most ENETRAP partners participate in 7FP ENETRAP II (www.sckcen.be/enetrap2). The overall objective of this project is to develop and implement European high-quality "reference standards" and good practices for E&T in RP, specifically with respect to the RPE and the RPO. These "standards" will reflect the needs of the RPE and the RPO in all sectors where ionising radiation is applied (nuclear industry, medical sector, research, non-nuclear industry). The introduction of a radiation protection training passport as a mean to facilitate efficient and transparent European mutual recognition is another ultimate deliverable of this project.

With respect to the RPE the overall objective is to be achieved by addressing both education and training requirements.

In the field of education this project deals with high-level initial programmes, mainly followed by students and/or young professionals. It is foreseen to analyse the European Master in Radiation Protection course, which started in September 2008. Broadening of the consortium and quality analysis of the providers and the content of the modules can be performed according to, primarily, the standards and guidelines for quality assurance in the European higher education area (ENQA) and, secondly, to the ENEN standards.

In the field of RPE training the ultimate goal is the development of a European mutual recognition system for RPEs. Hereto, the ENETRAP training scheme initiated as part of the ENETRAP 6FP will be used as a basis for the development of a European radiation protection training scheme (ERPTS), which includes all the necessary requirements for a competent RPE. In addition, mechanisms will be established for the evaluation of training courses and training providers.

With respect to the RPO role the desired end-point is an agreed standard for radiation protection training that is recognised across Europe. Data and information obtained from the ENETRAP 6FP will be used to develop the reference standard for radiation protection training necessary to support the effective and competent undertaking of the role.

Furthermore, attention is given to encouragement of young, early-stage researchers. In order to meet future needs, it is necessary to attract more young people by awaking their interest in radiation applications and radiation protection already during their schooldays and later on during their out-of-school education (university or vocational education and training). Radiation protection experts and officers work more and more on a European level. It is therefore important bringing together all the national initiatives at a European level: tomorrow's leaders must have an international perspective and must know their colleagues in other countries.

It is envisaged that the outcome of ENETRAP II will be instrumental for the cooperation between regulators, training providers and customers (nuclear industry, medical sector, research and non-nuclear industry) in reaching harmonisation of the requirements for, and the education and training of RPEs and RPOs within Europe, and will stimulate building competence and career development in radiation protection to meet the demands of the future.

Specific objectives of the ENETRAP II project are to:

- develop the European radiation protection training scheme (ERPTS) for RPE training;
- develop a European reference standard for RPO training;
- develop and apply a mechanism for the evaluation of training material, courses and providers;
- establish a recognised and sustainable ERPTS "quality label" for training events;
- create a database of training events and training providers (including OJT) conforming to the agreed ERPTS;
- bring together national initiatives to attract early-stage radiation protection researchers on a European level;

- develop some course material examples, including modern tools such as e-learning;
- develop a system for monitoring the effectiveness of the ERPTS;
- organise pilot sessions of specific modules of the ERPTS and monitor the effectiveness according to the developed system;
- development of a European passport for CPD in RP.

The objectives of ENETRAP II 7FP will be reached by several activities dealing with
- the analysis of job requirements (RPE and RPO);
- the design and implementation of appropriate training standards and schemes to support these requirements;
- development and application of a quality assurance mechanism for the evaluation of the training events, used material and training providers;
- setting up a database of training events and providers conforming to the agreed standards;
- the development of training material (traditional texts, as well as the introduction of more modern tools such as e-learning modules) that can be used as example training material;
- monitoring the effectiveness of the proposed training schemes.

The final goal is the development of a European mutual recognition system for RPEs and the introduction of a training passport.

The different work packages (WP) defined in this project are:

WP1	Co-ordination of the project
WP2	Define requirements and methodology for recognition of RPEs
WP3	Define requirements for RPO competencies and establish guidance for appropriate RPO training
WP4	Establish the reference standard for RPE training
WP5	Development and apply mechanisms for the evaluation of training material, events and providers
WP6	Create a database of training events and training providers (including OJT) conforming to the agreed standard
WP7	Develop of some course material examples (text book, e-learning modules, …)
WP8	Organise pilot sessions, test proposed methodologies and monitor the training scheme effectiveness
WP9	Introduction of the training passport and mutual recognition system of RPEs
WP10	Collaboration for building new innovative generations of specialists in radiation protection

ENETRAP II 7FP is realised by 12 partners, each having relevant experience in policy support regarding E&T projects on radiation protection. It concerns SCK•CEN (Belgium), CEA-INSTN (France), Karlsruhe Institute of Technology, Centre for

Advanced Technological and Environmental Training KIT-FTU (Germany), Federal Office for Radiation Protection BfS (Germany), the Italian National Agency for New Technology, Energy and Environment ENEA (Italy), NRG (The Netherlands), CIEMAT (Spain), Health Protection Agency HPA (UK), the ENEN Association (France), the Nuclear and Technological Institute ITN (Portugal), the Budapest University of Technology and Economics BME (Hungary), and University Politehnica of Bucharest (Romania). Staff members of the different partners who play a key role in this project, have also proven to be highly involved with E&T matters, on national and international levels, and are member of several E&T networks. Most of them also have an advisory role towards the national regulatory authority.

ENETRAP II (grant agreement number 232620) is a coordination action that runs under the theme "Euratom Fission Training Schemes (EFTS) in all areas of Nuclear Fission and Radiation Protection" (Fission-2008-5.1.1). The project will run over 36 months.

Results

Although this project is still in its first phase, some work packages have already reached intermediate results. In the following paragraphs a summary is given of the work carried out in the different WPs, and the first achievements are highlighted.

Requirements and methodology for recognition of RPEs

WP2 deals with the requirements for recognition of RPEs and the development of a methodology for the recognition of RPEs. Although the execution of any recognition process is the responsibility of the national regulatory authority, ENETRAP II will put forward a harmonised methodology, in line with the national approaches. The existence of this European methodology will facilitate the ultimate goal: a European mutual recognition process for RPEs. Qualification, competence, and continuous professional development will be discussed and elements for these three requirements will be defined. An outline of the proposals for key elements of a national scheme for RPE recognition was put forward at the most recent ETRAP conference (Lisbon, November 2009 (http://www.euronuclear.org/events/etrap/index.htm). Here, also a questionnaire was presented which was sent out to all participants, EUTERP contact points and other relevant stakeholders. The results of the questionnaire are currently being analysed and will be used to provide guidance with respect to national schemes for recognition of RPEs. From there, a mechanism will be developed for the mutual recognition of RPEs between Member States.

Requirements for RPO competencies and establishment of guidance for appropriate RPO training

WP3 deals with requirements for RPO competencies and the establishment of guidance for appropriate RPO training. Employees, appointed to act as RPOs in hospitals, industrial companies or teaching and research institutions should have an adequate level of understanding of concepts related to radiation protection and understand the radiation protection issues pertinent to their radiation application. Therefore the level and format of training required by an RPO is dependant on the complexity of that application. It is therefore essential, on the EU level, (i) to define requirements for the competencies of

RPOs according to their area of work and specific radiation protection tasks, and (ii) to establish European reference standards for RPO training. The first intermediate report on this topic is submitted.

Establishment of the reference standard for RPE training

WP4 continues on the achievements of WP2. Here, it is the aim to develop appropriate European radiation protection training schemes (ERPTS), with objectives, target audience(s), audience prerequisites, required topics, suggested durations and evaluation methods for both initial and refresher training of RPEs, taking into account the nature and requirements of the RPE role. The starting point is the ENETRAP 6FP training scheme. Furthermore internationally recognised training material such as the material developed by the IAEA will be incorporated. The ERPTS should meet the requirements of the revised definitions of the RPE and should eventually replace Communication 98/C133/03, as a guide for the Member States to develop, or evaluate, their national strategies for RPE qualification and recognition.

Development and application of mechanisms for the evaluation of training material, events and providers

In the EU, a vast number of training events, material and providers exist. Given that formal recognition is required for RPEs, it would be prudent for training providers involved in the RPE training process to also be formally recognised. The aim of this WP5 is to develop a mechanism for the comparison, through a transparent and objective methodology, of training materials, courses and training providers, which can be used by regulatory authorities to evaluate their national radiation protection training programme for compliance with the ERPTS. First results are presented at this conference.

Database of training events and training providers

It is foreseen in WP6 to create a database of training event and providers conform to the agreed standards. The database will be made public through the ENETRAP II website and will thus be available for all interested parties. It is the aim that such a move would add credibility to the recognition process and would help to provide reassurance to RPE candidates and to employers that the training obtained satisfies an agreed European standard. It is foreseen that this database will also incorporate an overview of institutes hosting on-the-job-training possibilities. First announcements are foreseen by the end of 2010.

Development of course material

In order to provide examples of standardised training material, meeting the requirements of the ERPTS, WP7 foresees a European textbook for several modules of the ERPTS. It is suggested to launch a "cyber book", using the MOODLE platform that was introduced in ENETRAP 6FP. The modules that will be treated in this book are to be decided from the 66 entries WP7 received to their survey amongst the partners regarding the available course material. An additional suggestion is to create a sonorized (video + audio) PowerPoint presentation.

Pilot sessions

In the framework of ENETRAP II, pilot sessions of the European reference training scheme will be organised. The date put forward for the first pilot session, containing the basic RP modules and a specialized module on radiation protection issues in nuclear power plants, is spring 2011. This will be organised at KIT-FTU, Germany. Another specialized module on NORM issues will be organised at HPA, UK. At this conference the pilot sessions are presented in a poster presentation.

Introduction of a training passport and mutual recognition system

The ultimate goal of the ENETRAP II project is the introduction of an EU mutual recognition system for RPEs. In WP9 coordinating actions will be undertaken to establish such a system. Furthermore, the European training passport will be introduced as a tool for facilitating an efficient and transparent mutual recognition system.

Whenever possible, a collaboration will be established with the "training" working groups of the three EU "platforms" that were launched in 2007 (in particular, to discuss the added value of a "European training / skills passport" and the balance between theoretical and practical training that is desired to improve both the quality and the mobility of nuclear experts in public as well as private sector). The results of this WP are expected in the last phase of the project.

Building new innovative generations of specialists in radiation protection

Those people who developed concepts in radiation protection and held leadership positions at universities and research institutions to further develop radiation research and educate and train the next generation in the EU are retired or starting to retire. We are facing the same situation for numerous radiation protection experts and officers who devoted their knowledge and experience to build up a high level of radiation safety in all radiation applications in industry, medicine and research in the EU. In order to maintain this high level and to further develop a European safety culture, it is necessary to attract more young people by awaking their interest in radiation applications and radiation protection. More young people must be inspired to take an interest in radiation research and prepared to take leadership positions at universities and radiation applications in industry, medicine and research in the EU. Because high-level RP professionals often work in a European context, tomorrow's leaders will benefit from having an international perspective and knowing their colleagues in other countries.

Summary and conclusions

Based on the outcome of the ENETRAP 6FP, ENETRAP II 7 FP aims at contributing further to the EU harmonisation of E&T of radiation protection professionals. With the introduction of a modular European reference training scheme and European recognition methodologies, key issues will be delivered for the development and implementation of mutual recognition system of RPEs. In this way ENETRAP II meets the EC requirements to rely on the principles of modularity of courses and common qualification criteria, a common mutual recognition system, and the facilitation of teacher, student and worker mobility across the EU. ENETRAP II will structure research on radiation protection training capacity in all sectors where ionising radiation is applied. End users and specifically regulatory authorities are represented through foreseen participation in the advisory board which will advise about the best balance between supply and needs, thereby ensuring stable feed back mechanisms. The tasks defined in this project maximise the transfer of high-level radiation protection knowledge and technology, addressing young as well as experienced radiation protection workers. In this context, the proposed project will thus contribute to meeting the objectives of the EURATOM research and training work programme.

A Training Programme for Regulatory Inspectors under ISO 17020

Fennell, Stephen; Cunningham, Noeleen; Howett, Dermot;
Kenny, Tanya; Ryan, Tom; Synnott, Hugh
Radiological Protection Institute of Ireland, 3 Clonskeagh Square, Dublin 14, IRELAND

Abstract

The Radiological Protection Institute of Ireland (RPII) is the competent authority for all matters pertaining to ionising radiation in Ireland. In fulfilment of its statutory responsibilities it oversees a regulatory programme (licensing, inspection, enforcement and the provision of technical guidance and advice) for all users of sources of ionising radiation.

In December 2008 the RPII was awarded accreditation to ISO 17020: General Criteria for the Operation of Various Types of Bodies Performing Inspection by the Irish National Accreditation Board (INAB). In achieving this award the RPII became the first regulatory authority in Europe engaged in radiation protection inspections to be accredited for its inspection services under this standard. The RPII's quality manual and quality procedures describe in detail how its inspection programmes are planned, carried out and reviewed as well as setting out training requirements for inspectors.

This presentation will describe the formal training programme that was developed for a new inspector who joined the RPII's Regulatory Services Division in October 2007. The programme was developed in accordance with the requirements of the ISO standard and audited by technical assessors from INAB. The programme clearly identifies all aspects of training, both technical and non-technical, that a new member of staff has to undertake in order to be warranted as an inspector/authorised officer.

In addition to the development of a formal training programme for new inspectors the ISO standard also required the RPII to develop a formal programme for assessing the on-going competency of existing inspectors. This is achieved through a programme of inspection witnessing of individual inspectors by their technical managers. Inspectors are deemed competent provided their technical manager is satisfied with their knowledge and performance as witnessed during inspections.

Introduction

In 2005 the RPII commenced work on developing a quality management system for all of its work activities associated with the inspection of licensees holding sources of ionising radiation. The primary motivation for this work was the desire to ensure that the RPII performed all activities associated with inspections, such as planning and carrying out inspections, issuing of inspection reports, follow-up actions and inspector training, to the highest international standards. Through the development of an externally audited quality management system, containing elements such as documented work procedures, programmes of continual review and formalised inspector training programmes the RPII could ensure that all inspections are carried out in a professional and competent manner ensuring consistency of inspections and the approach taken by inspectors.

The RPII originally commenced work on developing a quality management system under ISO 9000 for all of its licensing and inspection activities. However, following meetings with the Irish National Accreditation Board (INAB), the national body with responsibility for accreditation in Ireland, a more appropriate standard for the RPII was identified, namely *ISO 17020: General Criteria for the Operation of Various Types of Bodies Performing Inspection* (ISO, 1998). This standard is typically sought by inspection bodies whose functions include the examination of materials, products, installations etc. and the determination of their conformity with requirements, including the subsequent reporting of the results of these activities. As the RPII has a statutory responsibility to license all holders/users of sources of ionising radiation, and to carry out inspections, it determined that to seek accreditation to the ISO 17020 standard would be the most appropriate standard for it.

Over the course of two years the RPII developed a quality manual which described in detail the systems and processes it had in place to address the requirements of the ISO 17020 standard. The quality manual was further supported by a comprehensive set of quality procedures that documented all the work activities that support its inspection programmes. A list of the quality procedures is given in Table 1.

Table 1. RPII Inspection Quality Procedures.

Procedure No	Title
QP01	Corrective/Preventative Action Procedure
QP02	Document Control Procedure
QP03	Management Review Procedure
QP04	Audit Procedure
QP05	Annual Inspection Programme
QP06	Pre-Inspection Procedure
QP07	Inspection Procedure
QP08	Post-Inspection Procedure
QP09	Inspectors Meetings
QP10	Training Programme Procedure
QP11	Equipment Procedure

In relation to the training of new inspectors the RPII's quality manual identifies a number of criteria which must be met:

- Staff responsible for inspections shall have appropriate qualifications, training, experience and a satisfactory knowledge of the requirements of the inspections to be carried out;
- The RPII shall establish a documented training system to ensure that the training of inspectors is kept up-to-date;

- The training shall depend upon the qualifications and experience of persons involved, and shall include an induction period, a supervised working period with experienced inspectors and continuation training to keep pace with developing technology;
- The RPII shall provide guidance on the expected conduct of inspectors.

The quality system went "live" in September 2007 and was operated for a full year before INAB carried out a pre-registration assessment visit over two days in September 2008. As well as reviewing the quality manual and all the documented procedures the INAB auditors witnessed RPII inspectors carrying out an inspection of a nuclear medicine department in a major teaching hospital as well as an inspection of a licensee carrying out non-destructive testing work. The INAB auditors were satisfied that the RPII had met the requirements of both the ISO standard and the IAF/ILAC guidance document (IAF/ILAC, 2004) and subsequently awarded it accreditation to ISO 17020 in December 2008.

Inspector Training pre accreditation

Prior to the introduction of a formal training programme under ISO 17020, the RPII had informal procedures for training new inspectors. Due to the limited usage of ionising radiation in Ireland, it is difficult to recruit inspectors with several years experience of working with sources of ionising radiation and, in practice, most new inspectors are employed straight out of university, the majority of them having studied physics.

Newly recruited inspectors would undergo an induction period during which they would be provided with on-the-job training in relation to the licensing and inspection processes and are provided with a full set of relevant legislation and guidance documents. The emphasis during this training focused on the hard skills such as knowledge of the applications of ionising radiation, inspection procedures, use of radiation monitors, report writing etc. rather than on the softer skills such as interviewing techniques and communication skills.

Over the course of their first couple of months a newly recruited inspector would accompany experienced inspectors to observe how inspections were conducted across all sectors. Prior to 2005, inspectors did not specialise in particular areas and were trained to be able to undertake inspections across all sectors such as medical, veterinary, industrial, education research etc. In 2005 it was decided that two distinct categories of inspectors would be created: those who would specialise in carrying out inspections in the medical, dental and veterinary sectors and those would conduct inspections in the industrial, educational and research sectors. This specialisation meant that inspectors could focus on relevant sectors and attendance at appropriate conferences, meetings and training courses could be arranged.

New inspectors would continue to observe inspections across a wide range of activities until such time as the experienced inspectors felt that the new inspector could lead an inspection with their assistance, and under their supervision. Once the inspector was deemed competent by their technical manager, the Board of the RPII would be asked to issue a warrant to the new inspector.

While this approach had worked very well over the years it was acknowledged within the RPII that its inspector training programme should be formalised to ensure consistency in how its inspectors were trained. The programme would include milestones indicating when new inspectors could be deemed competent to undertake inspections on their own and accordingly be issued a warrant. It was also acknowledged that the focus to date had been on teaching a new inspector how to plan and undertake inspections and that softer skills, such as interviewing techniques, assertiveness training and chairing meetings, all of which are necessary when carrying out inspections, were not given as high a priority.

In practice, during the period 2004 – 2007 there were only two new inspectors appointed. One inspector returned from working as a medical physicist in a large hospital to the RPII, having previously worked as an inspector in the 1990s, and required relatively little training to bring her up to date. When a member of staff transferred from a different department within the RPII into the Regulatory Services Division (RSD) it provided an opportunity to trial the new inspector training programme that was in the process of being developed.

Inspector Training under ISO 17020

Shortly after switching on its new quality management system in September 2007, the RPII recruited a new inspector to the Medical, Dental & Veterinary Section within the RSD. The new inspector joined the team responsible for licensing, inspection and enforcement activities in these sectors and was the first inspector to go through the formal inspector training programme developed under the quality management system.

The specification drawn up for the post required candidates to hold an honours degree in physics or in electrical, electronic, mechanical or clinical engineering. Additionally candidates were advised that experience working as a medical physicist was desirable.

The new inspector commenced work in October 2007 as a Scientific Officer. Holding a diploma in applied physics and a BSc in physics and physics technology she had previously worked as a research assistant in a third level college and as a field service engineer for a major semiconductor company. In the year prior to joining the RPII she completed an MSc in medical physics.

Training Programme

The RPII's quality management system allows for some flexibility when drawing up a training programme for a new inspector, as he or she will have different skills and experience. For the newly recruited inspector a formal training programme was drawn up and mutually agreed though discussions during her first week. As well as focusing on the skills required to carry out inspections the training also looked at wider training requirements, particular as this person was coming from the private sector into the public sector. The training programme was broken into 13 modules, which are summarised below:

- Introduction to the RPII: internal structures; relationship with/to government departments;
- Introduction to regulatory responsibilities: licensing; inspection; enforcement; provision of guidance and advice;
- Inspector behaviour: RPII staff handbook; code of business conduct; inspector's code of conduct;
- Health and Safety: RPII health & safety management system; manual handling; construction site safety (Safe Pass); fire safety;

- ISO 17020 Quality Management System: quality manual; quality procedures;
- Legislation: primary & secondary legislation; legal workshop; courtroom skills;
- Information technology: licensing & inspection database; IT usage policy;
- Equipment: personal protective equipment; types and use of radiation monitors; personal dosimetry;
- Inspection procedures: planning; reporting; follow-up;
- Inspections: observation phase; supervisory phase; competency assessment;
- Incident investigation: accidents; personal dosimetry investigations;
- RPII business planning: strategic planning; annual business planning, Performance Management Development System (PMDS);
- Training: on-the-job training; formal courses; technical meetings; conferences.

Based upon discussions between the new inspector and her technical manager it was agreed that she would accompany experienced inspectors on a total of 20 inspections as part of the observation phase of her training programme. These 20 inspections would cover diagnostic and therapeutic applications across the medical, dental and veterinary sectors. Over the course of these inspections the new inspector would gain experience of how inspections are planned and arranged, witness firsthand how an inspector interacts with the licensee during all stages of the inspection and how the findings of inspections are reported and followed up.

This would then be followed by a supervisory phase where the new inspector would lead five inspections supported by one of the experienced inspectors. She would be responsible for arranging and conducting the inspection as well as issuing the final report and dealing with follow-up actions. Finally, her technical manager would assesses her competence by witnessing her carrying out an inspection in each of the modalities of diagnostic radiology, nuclear medicine and radiotherapy in the medical, dental and veterinary sectors as appropriate. This graded approach to the competency assessment means that the inspector can be signed off for simple inspection types e.g. dental radiology, DXA etc. working up to more complex inspection types such as nuclear medicine and radiotherapy as she gains more experience.

As each phase of the training was completed both the trainee (new inspector) and trainer would formally sign off her training record.

On-the-job training

The RPII has developed inspection audit forms, which are part of the quality system, for all sectors which inspectors complete during inspections. Specific audit forms have been developed for modalities within individual sectors, such as diagnostic radiology, nuclear medicine and radiotherapy within the medical sector. As well as being an *aide-memoir* for inspectors the forms also ensure that different inspectors cover the same areas during inspections i.e., there is consistency among different inspectors on the issues examined during inspections.

At the outset of the training programme for the new inspector it was agreed that she would witness a total of 20 inspections by accompanying experienced inspectors. By the end of this phase of her training she had in fact witnessed 27 inspections. Table 2 summaries the inspection types observed during the period October 2007 – July 2008.

Table 2. Inspections observed during observation phase of training programme.

Inspection Type	Number of inspections observed
Diagnostic Radiology (Medical)	14
Nuclear Medicine (Medical)	1
Radiotherapy (Medical)	4
Diagnostic Radiology (Dental)	4
Diagnostic Radiology (Veterinary)	2
Equine Nuclear Medicine (Veterinary)	1
Distributor of Radioactive sources	1
Total	27

Following this period of observation the experienced inspectors deemed her competent to lead an inspection under their supervision. In practice this meant that she was the lead inspector but was assisted by one of the experienced inspectors. However, in order for her to be able to lead an inspection she had to be formally appointed an inspector by the Board of the RPII, in accordance with the provisions of the Radiological Protection Act 1991 (RPA, 1991). In July 2008, the Board of the RPII was advised that the inspector had reached a stage in her training where she had been deemed competent to lead an inspection, under the supervision and with the support of an experienced inspector. In order to complete her training she would be required to be appointed as a warranted inspector so that she could lead inspections. Accordingly, nine months after joining the RPII she was appointed as an inspector and issued with a warrant.

As part of the supervisory phase of her training programme she ended up leading six inspections, four in diagnostic radiology facilities within hospitals and two dental practices, assisted by an experienced inspector. She also participated on the inspection team for two radiotherapy and one diagnostic radiology inspections during this phase of her training.

In January 2009, for the final phase of her inspector training her technical manager assessed her competency as an inspector. It is important to note that as her technical manager had to assess her and sign off on her training he could not be involved directly in her training as this would present a conflict of interest i.e., he couldn’t both train her and be the person responsible for determining that she had been fully trained. Over the course of two days she was witnessed carrying out inspections of diagnostic radiology facilities in two hospitals, a dental practice and a veterinary practice. After each inspection her technical manager reviewed her performance during the inspection, posing a series of hypothetical scenarios in order to further assess her technical competence. Later that month, after all the inspection reports had been issued and follow-up issues closed out, the new inspector was formally deemed to have completed her initial inspector training and could undertake diagnostic radiology inspection on her own. To lead radiotherapy or nuclear medicine inspection teams she would have to be further assessed by her technical manager.

Formal Courses

While on-the-job training is very effective for developing hard skills, such as knowledge of legislation, using radiation monitors there are many soft skills that a new inspector needs to acquire. These soft skills include interviewing techniques, conflict management, negotiating skills, communication and presentation techniques, chairing meetings etc., all of which are put into practice each time an inspector carries out an inspection. As part of her training programme suitable training courses and opportunities were identified which cover both hard and soft skills. While it was possible to identify some of these at the outset of the programme, others only came to light as the training programme progressed. In addition to her initial training programme the new inspector continues to attend relevant training courses as part of her personal development. The courses attended by the new inspector since joining the RPII in October 2007 are listed below:

- "How to inspect" – a foundation course in non-technical aspects of inspection, Irish Medicines Board (Dublin) – October 2007;
- Quality customer services training, RPII (Dublin) – October 2007;
- A Course in Radiotherapy Physics, Royal Marsden Hospital & The Institute of Cancer Research (London) – March 2008;
- WHO Co-ordination Meeting - Radiation Safety in Healthcare Settings, WHO (Geneva) – June 2008;
- ICRP Seminar, ICRP (Dublin Castle) – September 2008;
- Presentation skills course, Irish Times Training (Dublin) – October 2008;
- "Radiation Protection in Nuclear Medicine", IPEM meeting, IPEM (London) – November 2008;
- Radiation Physics for Nuclear Medicine - Madiera Course, EC funded (Milan) – November 2008;
- Auditor training, RPII (Dublin) – May 2009;
- ADR basic training, (Dublin) – May 2009;
- ADR Class 7 specialisation course, One Photon Consultancy (Louth) – May 2009;
- Three week technical placement in Medical Physics Department, Royal Surrey County Hospital, Guildford, UK - June 2009;
- Radiological Protection Summer School 2009, IBC Global Academy (Cambridge) – July 2009;
- Court room skills: *The Expert Witness*, La Touch Legal Training (Dublin) – August 2009;
- Workshop on Incident Management, Health Protection Agency (Dublin) – October 2009;
- Legal training workshop, Harry Mooney & Co Solicitors (Dublin) – November 2009;
- Assertiveness Skills, Irish Times Training (Dublin) – February 2010;
- Safe Pass: Health and Safety Awareness Training Programme for the construction industry (Dublin) – April 2010.

Inspection witnessing

One of the requirements of the ISO 17020 standard is that the inspection body must have procedures in place to be able to assess the on-going competence of all its inspectors. To address this requirement the RPII has developed a programme of inspection witnessing whereby each inspector is witnessed by his or her technical manager carrying out a series of inspections.

In the medical sector inspections are divided into four broad categories: diagnostic radiology (including medical and dental), nuclear medicine, radiotherapy and the activities associated with the distribution of X-ray equipment and radioactive sources. Each inspector must be witnessed carrying out an inspection at least once each year and in each of the four categories at least once every three years. The technical manager for the Medical, Dental & Veterinary Section is in turn witnessed by the technical manager for the Industrial Section, and vice versa. A set of inspection witnessing audit forms have been developed which the technical manager completes as he witnesses the inspection. The competency assessment covers the entire range of activities associated with inspections, from the planning stages, though the actual inspection itself and finally the inspection reporting. In particular, the following issues are audited:

- Did the inspector plan and document all pre-inspection arrangements?
- Did the inspector bring photographic identification, his/her inspector's warrant, relevant legislation and appropriate personal protective equipment on the inspection?
- Did the inspector follow all leads in an objective and resolute manner?
- Did the inspector use an open/probing questioning style?
- Did the inspector use test or inspection equipment correctly and was it fit for purpose?
- Did the inspector investigate all areas pertaining to the scope of the inspection?
- Could the inspector answer all questions raised by the licensee?

Following each witnessed inspection the technical manager meets the inspector to discuss how the inspection went, posing a series of challenging scenarios to the inspector. Provided that the technical manager is satisfied with the inspector's performance the inspector is deemed competent to continue to inspect within that category.

This system of formal inspection witnessing ensures that all inspectors carry out inspections in a manner that is both consistent with their fellow inspectors and with the objectives of the RPII quality management system.

Conclusions

The RPII has successfully developed and implemented a formal training programme for new inspectors under its ISO quality management system. As well as providing a structured approach to training, it also provides both new staff and their technical managers a clearly defined set of training modules which are mutually agreed at the outset of the programme. The programme is flexible and can be tailored to suit the training needs of trainee inspectors, taking account of the expertise they bring to the organisation.

In addition to the development of a training programme for new inspectors, the RPII has also introduced measures to assess the on-going competency of all inspectors through its inspection witnessing programme. This programme provides a formal mechanism where the technical competence and ability of all inspectors are assessed on an annual basis. As well as providing reassurance to the RPII it also provides reassurance to licensees that the RPII has procedures to ensure that its inspectors are performing their duties to the highest standards.

Abstract

Nuclear Safety Culture is a topic of paramount importance for nuclear operators as well as those working with radiology and radiotherapy. Safety culture is a combination of individual and group beliefs, values, attitudes, perceptions, competencies and patterns of behaviour that determine the commitment and the proficiency of an organization's safety management. Implementation of safety culture requires continuous and multilateral efforts involving not only technical but also human and social aspects. Many principles of safety culture are generally applicable , and could be disseminated through seminars on best practices, case studies, feedback studies, pilot sessions, etc. Such dissemination would contribute to harmonisation according to high standards, and it would promote the mutual recognition of training throughout Europe.

A consortium of 19 partners working together in a 4 year project, TRASNUSAFE, will develop and test relevant training schemes on Nuclear Safety Culture, based on an evaluation of the training needs in a European context. Special attention will be given to the links between the ALARA principle currently used in the radiation protection community and the safety culture of the nuclear industry. Two user groups, involved throughout the entire development process, will contribute to the training schedule by providing their input and feedback and by participating in the training modules.

Training needs will be assessed throughout Europe using a questionnaire to be separately developed and validated prior to the assessment. The actual assessment of training needs will make use of web based surveys, e-mails and regular mails, telephone conversations with correspondents, as well as seminars and site visits.

This paper will focus on the training needs analysis. It will explain the methodology and will give a report of the first results.

Managing medical exposure through education

Avadanei, Camelia; Florescu, Maria Gabriela
”Horia Hulubei” National Institute of Physics & Nuclear Engineering, ROMANIA

Abstract
Nuclear physics is providing medicine investigation and treatment methods of a priceless value. During over one hundred years, radiological equipment become more and more performing from the point of view of easy handling and rapid answer, quality of radiation beams and, not the last, radiation protection of operators and patients.
Physicians' enthusiasm due to these possibilities and society concern for individual health risk to transform these achievements from friends to enemies of health due to their excessive utilization.

It is important to estimate supplementary cancers expected by un-relevant computer tomography examinations but it should be more adequate to develop measures and methods for preventing transformation of these potential figures into real ones.

In this context, education could be used as a mean to present both sides of these special applications involving individuals, on one hand by public information and on the other hand by improving physicians' education.

Public education could begin even from elementary school by graduate introduction of the necessary notions to understand the specific aspects of radiation biologic effects. It could continue through mass media communication and by physicians at their surgeries.

This paper proposes to represent guidance for patients' education in order to involve them in the medical act. Being aware of radiological examinations specific aspects, people would participate more active to the implementation of individual monitoring systems.

As a result of the international actions already initiated, it is presumed that prescribes would become more restrictive when recommending radiological examinations and radiologists and non-radiologists physicians would become more aware to comply with the regulatory requirements on justification of each examination.

Introduction
Taking into account that each science progress depends of its efforts to integrate the results of other sciences, it could be noticed that medicine took an impressive advantage in the 20^{th} century, as a result of cooperation with other sciences, such as physics, chemistry, biology, materials science, information technology.

This multidisciplinary approach determined the development of new branches, such as radiology, bio-chemistry, cell biology, etc., (attached to medicine) or medical physics, radio-biology, bio-materials, drugs production (attached to other sciences).

Medical radiation exposure

For Nuclear Physics, cooperation with Medical Sciences started in 1895, after X Rays discovery. X Rays applications for diagnosis rapidly extended (in one to three years) in all Europe and out of it and since then they have been continuously developed.
Three major directions could be identified in this expansion:

1. extension of applications in medicine by
   - using of radioactive sources (sealed and unsealed) beside Roentgen generators and electrons accelerators (in the last decades)
   - adding to radiological examination for diagnosis densitometry and interventional radiology
   - extending use of ionising radiations in radiotherapy and stereo tactic surgery.
2. technical development and improvement of equipment and data systems by developing more versatile equipment with fluorescent screen or film, image amplifier or image digitalization (with different handling and storage possibilities) and from 2D imagines to 3D (CT) or 4D. It is estimated that it was obtained a reduction of dose per examination by a factor of a few tens between the first and the last generations of radiological equipment.
3. development of regulations in compliance with the development of the extension of applications in medicine and technological development to reduce the biological risk for medical personnel and patients. Looking behind, it could be noticed that regulations implemented after the development of applications. Over 30 years of X Rays utilization in diagnosis were necessary to establish the International Commission on Radiological Protection (1928) – nongovernmental organization which suggests rules for ionising radiations utilization for protecting users against their adverse effects. Radiation protection concept appears as a definition of assembly of measures/rules for health protection and limitation of risks in radiation sources utilization after 1928. Radiation protection requirements addressed exclusively to operators of radiological facilities because they were the first persons who developed symptoms of over exposure and could be monitored during their activity.

Increase of radiological examinations procedures and extension of applications in other medical fields determined an important increase of population exposure. Medical exposure is the most important artificial source of exposure for population and it has an increasing tendency.

Consequently, the IAEA in cooperation with other international organizations introduced, in 1996, through the International Basic Safety Standards, the first requirements on patient protection that involved the importance of justifying and optimizing radiation doses.

Recent UNSCEAR estimations shows that medium dose per patient is about 200 times higher than that of medical personnel. Analyses of radiological practices in many states underlined an overuse of radiological examinations due, mainly, to medical system: lack of education in radiation protection of physicians (especially non radiologists), poor communication between different departments/hospitals and even technical mistakes.

These evaluations determined an international action plan for radiological protection of patient, involving a number of international organizations, such as UNSCEAR, ICRP, WHO, PAHO, European Commission, International Electro-technical Commission, International Organization for Standardization, medical physics (IOMP). All these actions dedicated to reducing medical public exposure take into account solutions such as:

– new requirements of training in radiation protection of medical personnel, including prescribes
– monitoring of each exposure and recording of all examinations per patient
– implementation of a national electronic health recording system which could also be accessed by EU countries

These initiatives should be easier performed if they are completed with educational and informing programmes for patients. Educated patients should cooperate with medical staff and other involved bodies to control their own exposures, being directly interested in results.

Programmes dedicated to education of patients should be developed in cooperation with the national education system and nongovernmental organizations for social assistance. If for physicians doctors it was considered worthy to issue a”guide on the utilization of radiological examinations and imagistic procedures”, an adapted guide for patients on such applications would be useful, too.

In some states these kinds of initiatives coming from medical side are already in place, consisting in dedicated websites. They could be completed by oral presentations in schools, universities and clinics. Oral presentations have the advantage of adjusting the information to auditors’ level of knowledge and interest for the subject and permit dialogue with participants. They could be completed by printed documents including images and graphics, attractive and easy to understand. For some countries the websites’ communications are quite restrictive and utilisation of direct communication is very suitable.

No matter how we address to the (potential) patients and their interest, we have always to answer to the same questions:

What are X-rays?
How do X-rays tests work?
What is the difference between X-rays tests?
What is the amount of radiation we receive from each of them?
How the organism responds to that amount of radiation?
What is the risk of developing cancer or other diseases from having X-rays tests?
What is the number of x-ray examinations that are advisable in one year?
What is the minimum period between two examinations?

To respond to these questions, accessible and friendly means and methods should be used, based on similitude with well known notions, such as: comparison of X rays with radio waves, light or ultraviolet rays, comparison of doses administrated in each examination with natural exposure expressed in days or months of exposure, graphics or images to compare different X ray tests.

Special attention should be given to the possibilities of minimizing risks of exposure in case of:

- repeating in short time some higher-dose X-ray tests (for example a CT scan or a barium meal or enema)
- being pregnant, or thinking you may be (your doctor and radiographer may look for other ways to make their diagnosis (If an X-ray is required in this situations, the test will either be delayed or supplementary preventive measures will be used to protect the unborn child).

Asking for a pregnancy test before having an X-ray procedure is, surely, the safest method to avoid an undesired exposure for young women.

One must know that if he/she needs to have an X-ray test soon after another one he/she would tell doctor about that. One of these examinations should be sufficient and another one would not be necessary. Patients should be educated to keep their own record on X-ray history to help medical decision.

To avoid a successively exposure due to patients movement during examination, they have to know before being tested that most X-rays and scans are entirely painless. Although a mammogram for example can be uncomfortable and for a number of scans an injection of dye into the arm is necessary, there is usually no other discomfort.

For children and their parents or accompanying persons it is necessary to be informed on special means used during the exposure if it is case, taking into account their possible reactions in unknown situations.

If a child is undergoing an X-ray test and their parents have been asked to hold him or her during examination, they have also to be protected with a lead apron.

Conclusions

- Radiology is an important method of investigation.
- Justification is necessary for each test.
- Medical stuff has to appreciate the importance of the test for establishing the diagnostic and decide when it is necessary and patients would make an option. Both medical staff and patients need information for a right decision.
- Basic education is important for both categories. If information may be required from the medical system, educational support should be provided by society.

Improving radiation protection culture: Social representations, attitudes towards risks and stakeholders involvement

Cantone, Marie Claire[1]; Sturloni, Giancarlo[2]

[1] Università degli Studi di Milano, Dipartimento di Fisica and INFN, ITALY

[2] Innovations in the Communication of Science, SISSA, Trieste, ITALY

Abstract

The culture in RP is an integral part of the safety and prevention culture and it includes the complex of all those risk-based approaches chosen to set the standards and the philosophy governing those standards. The level of ambition against risk has evolved during the time on the basis of new information about the effects of radiation and considering changes of attitude towards risk. The concern on environmental protection is an emblematic example. Often it has been asked if really RP has been and continues to be a model with the capability to also influence the protection against risks of different nature than radiation, as regards to the proposed approaches in risk assessment and evaluation. In this paper the authors are proposing a multidimensional approach to the study of the RP culture by carrying out: 1) a comparative analysis of the various and different approaches which, during the past years, have been adopted in managing the technological risk both in the RP area and in other areas of technological and scientific knowledge; 2) the historical reconstruction of the evolution of the collective imagination about the possible risks connected with nuclear radiations. In the context of the modern societies, in fact, a wide range of factors of socio-cultural, ethic and political nature contribute to determine the social representations on which the attitudes to accept or to reject the technological innovation and its related risks are founded. We are convinced that by deepening the nature of the close connections of the co-evolution between the collective imagination about radiations and the different approaches to the governance of the technological risk, starting from the inclusion of different stakeholders, by also taking into consideration the lessons learned from experiences in other fields of activities, it will be possible to define useful cognitive tools aimed to strength the RP culture.

The EUTERP Platform: Towards a European approach for harmonisation in education and training for radiation protection professionals

Draaisma, Folkert[1]; van Elsacker-Degenaar, Heleen[2]
[1] Nuclear Research and consultancy Group, Quality, Safety and Environment, NETHERLANDS
[2] Nuclear Research and consultancy Group, Radiation and Environment, NETHERLANDS

Abstract

In Europe, a common vision for maintaining competences in radiation protection is emerging, focussing on a common denominator for qualification of radiation protection experts (RPEs) and radiation protection officers (RPOs), and for mutual recognition and mobility of these professionals across the European Union and related countries. Started as an initiative of the European Commission the European Platform on Training and Education in Radiation Protection (EUTERP Platform) has been transformed into a legal entity under Dutch law. The Platform facilitates a permanent dialogue between all involved parties by the use of its website (*www.euterp.eu*), by issuing newsletters and by organising workshops. From the workshops several recommendations based on common agreement among the participants - were given to the EC, IAEA, IRPA and national authorities including proposals for definitions of the RPE and the RPO. Currently, the possible consequences for national legislation and E&T activities and guidance needed in relation to this proposed definitions of RPE and RPO that will be implemented in the Euratom BSS are the main focus of the EUTERP Platform. The role of EUTERP concentrates on the objectives to strengthen and harmonise education and training, and to facilitate the development of mechanisms of mutual recognition, based on a common approach. EUTERP will be provided with input from the ENETRAP II project. With these results it will: develop guidance on a methodology to compare the quality of training courses and training material; develop guidance on a standardized methodology of assessing the recognition of RP professionals as a basis for future mutual recognition, based on a description of roles and duties, education, training and work experience; develop guidance for a formal recognition process of the competences of RPEs and RPOs. EUTERP aims for being a European body on harmonisation of criteria and qualifications for and mutual recognition of RP professionals.

Abstract

To maintain a high level of competency in Europe regarding radiation protection and to facilitate harmonisation and (mutual) recognition of Radiation Protection Experts (RPEs) and Officers (RPOs) quality assurance and quality control might play an important role. The ENETRAPII project (FP7-EURATOM) aims at developing European high-quality 'reference standards' and good practices for education and training in radiation protection. In Work Package 5 (WP5) the quality issue is addressed. Therefore, WP5 deals with the development and application of mechanisms for the evaluation of training material, training events and training providers by means of a transparent and objective methodology. The results can be used by regulatory authorities to benchmark their national radiation protection training programme and will be communicated to other networks, e.g. EUTERP. This paper addresses the first results of WP5: the comparison of training material. Training material is defined within WP5 as books and duplicated lecture notes.

The reference table that is developed for the comparison of training material is used to compare two Dutch text books for RPE/RPO training, and showed that the demanded content of this training is covered by both books on most of the subjects. For the remaining subjects additional material has to be used.

Introduction

The FP7 European Network for Education and Training in Radiation Protection II (ENETRAPII) project is a specific tool for EURATOM policy for E&T implementation in the radiation protection field and towards a mutual recognition of professional qualifications. The project will last three years.

Today's challenge in the field of radiation protection involves measures to make the work in radiation protection more attractive for young people and to provide attractive career opportunities, and the support of young students and professionals in their need to gain and maintain high level knowledge in radiation protection. These objectives can be reached by the development and implementation of a high-quality European standard for initial education and continuous professional development for Radiation Protection Experts (RPEs) and Radiation Protection Officers (RPOs).

For the purposes of this project the Radiation Protection Expert is defined as :

“An individual having the knowledge, training and experience needed to give radiation protection advice in order to ensure effective protection of individuals, whose capacity to act is recognized by the competent authorities.”

and the Radiation Protection Officer as:

“An individual technically competent in radiation protection matters relevant for a given type of practice who is designated by the registrant or licensee to oversee the application of the requirement of the Standards.”.

These are the definitions as proposed by the second EUTERP workshop in 2008 in Lithuania and submitted to the Euratom Article 31 Group of Experts.

To reach high-quality European standards for initial education and continuous professional development, there has to be agreement between the European countries concerning the duties and responsibilities of both RPEs and the RPOs. These standards are developed in Work Packages 3 and 4 (WP3 and WP4) of the ENETRAPII project.

When these standards are known, each country will be able to access and benchmark its own education and training against the European standards. It will also be possible for a country to benchmark an RPE or RPO, educated and trained in another country, to their own national standard. Shortcomings in education and training materials, events and providers become clear, when it is possible to compare education levels and national standards to the European standard. Therefore, one of the cornerstone work packages in ENETRAPII is Work Package 5 (WP5), entitled: *Develop and apply mechanisms for the evaluation of training material, events and providers*.

WP5 has started with an inventory of topics, items and subjects that need to be addressed in the education and training of the RPE and RPOs. These main subjects are subdivided in a reference table to come to a methodology of comparison. With this reference table each country can compare its own training and education methods with that of the European Standard (WP3 and WP4).

Material

The inventory has started with the subjects addressed in the syllabus EG133 (EC, 1998), the IAEA syllabus (IAEA, 2002), the European Master's degree in Radiation Protection syllabus – EMRP - (result of WP8 ENETRAP, www.sckcen.be/enetrap), the existing tables of subjects for education and training in radiation protection and similar tables used in different countries. This has to lead to a common reference table, which can be used to compare training material. Training material in WP5 is defined to be a text book or duplicated lecture notes.

IAEA Basic Syllabus PGEC

The IAEA basic syllabus (IAEA, 2002) can be used for post graduate students to become a qualified expert. The basic syllabus is split up in 11 modules, which cover the whole basic radiation protection. The duration of the course is 18 weeks.

Each module is divided in main subjects and these are subdivided in more detailed subjects. Only for the modules the number of hours spent is clear. For each main subject lecture notes and practical exercises are given.

EG Basic Syllabus 98/C133/03

In its communication 98/C133/03 (EC, 1998) the European Council guides the European countries in how to implement the basic safety standards 96/29/EURATOM in their own legislation. In this document the basic syllabus for the qualified expert in radiation protection is published as a list of subjects to be addressed in radiation protection training. Most of the subjects mentioned in the basic syllabus are not subdivided in detail. No information can be found about the hours spent on the different subjects, except for the statement: "the depth to which topics of the syllabus should be covered should depend on the level of advice/input required from the qualified expert". The listed subjects cover the basic radiation protection training and additional training in five different fields: nuclear installations, general industries, research and training, medical applications, and accelerators.

ENETRAP training scheme

The ENETRAP training scheme of the ENETRAP 6th FP project is based on the IAEA syllabus, the European basic syllabus, the EUTERP recommendations and other ENETRAP output. The scheme consists of different modules. The first three modules are the basic modules. Afterwards at least one additional module has to be followed, concerning the area of interest. This area can be Nuclear power plants or research reactors, waste management and decommissioning, non-nuclear research or oil and gas, medical, or NORM.

The ENETRAP training scheme modules are divided in main subjects, with the numbers of hours spent on all the main subjects. The main subjects are subdivided in more detail. It is not clear which level of education is required to enter the ENETRAP training scheme. The duration of the whole course is 42 days.

Tables of issues in radiation protection training

In the Netherlands a reference table – The first and the two last columns in Table 2 - is used since the 1980's for different levels of training in radiation protection. This table is divided in main subjects and subdivided in more detail. There are no numbers of spent hours in this table, but only a characterisation of the level of detail at which the detailed subjects are covered during the training, together with its training goal (Table 1). The advantage of using grades above hours spent on the different subjects is that the entrance level of students doesn't have to be set. Theoretical people with different levels can enter all courses.

Table 1. Grades at which subjects are covered in training material.

grade	Covered	goal
0	not covered	–
1	global, qualitative	aware of the subject
2	important subjects covered, quantitative	understanding of the subject
3	Detailed, quantitative	detailed understanding of the subject and able to work with it

Results

Since the main subjects of the different syllabi and reference tables are more or less the same, it does not matter which table to use. The reference table of the Netherlands is used, because it was ready to use.

As explained before, in this table no hours or pages spent on different subjects can be found, but only grades, corresponding to the grades in Table 1. The advantage is that the entrance level of students does not matter, just like the number of pages spent on a topic.

This reference table will be used for the comparison of training material and for the comparison of training courses. If the reference table is filled with the demands for the RPE, RPO and radiation worker (RW), it can be used to see which material can be used for which course and when other, additional material is needed.

The reference table is applied in a comparison of training material, i.e. two text books, to determine whether this table is suitable for this purpose. The first part of the comparison table can be seen in Table 2. In the first column the main subjects and more detailed subjects can be found. In the second and third column the grade of the different subject can be found for respectively book A and book B. Both books are written to educate student in radiation protection to the same end level. In the fourth and fifth column the demands for RPE are displayed for respectively small and large 'users' in the Netherlands.

The table shows that the books cover most of the items as asked for by the government. There are some minor deviations between the books, caused by the interest of the authors.

An exception is the mathematics which is not covered by either book. Therefore, an additional book has to be used during the training course.

In reality however, there is a difference between the levels of the books. This results in the usage of book A as study material for basic level RPE in small companies or institutions while book B is used for a more advanced level for small and basic level for large companies or institutions. This is not obvious in the reference table, since this is caused by the more detailed description of the topics covered in book B.

Table 2. The first part of the comparison table of training material. Book A and book B are compared to each other and to the demands in knowledge of the different RPE functions in the Netherlands.

grade	Subjects of basic radiation protection training covered	Goal
0	not covered	–
1	global, qualitative	aware of the subject
2	important subjects covered, quantitative	understanding of the subject
3	Detailed, quantitative	detailed understanding of the subject and able to work with it

	level of competence			
	book A	book B	3 (RPE of small institutes)	2 (RPE of large institutes)
Math				
- Differentiate, integrate, differential equations	0	0	2	2
- Exponential function	0	0	2	2
- Graphs (linear and logarithmic axis)	0	0	3	3
- Statistics (distribution, standard deviation)	2	2	2	2

Discussion and conclusions

The reference table can be used for the comparison of training material. All main subjects of the different syllabi can be put in this reference table and can be compared in detail with regard to these main subjects. Also, the different additional modules can be put in this table. For the competencies that need to be covered in the study material a similar table can be made.

When the table is filled out with the detailed grades of subject that have to be known by RPEs, RPOs and RW, the table can be used to show which book can be used by which part of the training modules for RPE, RPO and RW.

The reference table is probably too extensive to be used for a lot of comparisons. For this purpose the table can be made more condensed by taking some subjects together.

A further study will be carried out towards the usefulness of this reference table in the comparison of training modules and towards the usefulness of a competencies reference table in the comparison of training material and training courses.

Abstract
The Council Directives require that each Member State shall take the necessary measures with regard to teaching, education and vocational in radiation protection. Moreover, it is foreseen that each Member State shall fulfill the requirements on establishment of an appropriate curricula and recognition system of competences in radiation protection and the undertaking is obliged to provide appropriate radiation protection training and information programmes for their personnel. In order to establish a harmonized framework and to avoid overlapping with national regulation, EU strategy on establishment of a common infrastructure for education and training in radiation protection throughout the European Union should be built. It should be defined the European agreement on the qualifications for training and education and requirements for mutual recognition of the competencies. Following the EU directions, each Member State should revise the national strategy in order to establish the national training needs, the system for credentialing radiation protection programs, national policy on the selection and training of trainers and to comply with the EU mutual recognition system. Participation in EUTERP and ENETRAP meetings on this subject represents a good opportunity for sustaining these proposals.

European Medical ALARA Network (EMAN): Supporting the ALARA principle in the medical field

Abstract

The main objective of this project is to establish a sustainable European Medical ALARA Network (EMAN) where different stakeholders within the medical sector will have the opportunity to discuss and to exchange information on different topics relating to the implementation of the ALARA principle in the medical field. This network will also support the European Commission (EC) in its activities in this field. In addition, EMAN will aim to:

- Disseminate up-to-date information about literature, studies, research and good practices relating to the ALARA principle in the medical sector,
- Identify and communicate to the EC needs for development and update of European Union guidance,
- In particular cover the areas of education and training as well as continuous quality improvement as requested in the Directive 97/43 EURATOM
- Formulate proposals to the EC on harmonization issues,
- Propose to the EC solutions of identified issues at the European level,
- Establish co-operation with appropriate international organizations and associations.

To fulfil these objectives, EMAN will especially rely on:

- Three Working Groups, where three specific topics, all deserving special attention, will be widely discussed by professionals of the medical area:

on optimisation of patient and occupational exposures in CT procedures,
on optimization of patient and occupational exposure in interventional radiology,
on radiological safety for patients and personnel in activities using X-ray equipment outside the X-ray departments,

- A website to widely diffuse the information gathered and the work done by the network and to facilitate the exchange of information within the members of the network,
- A final workshop to present and discuss the work performed in the scope of the network and of the three working groups and to propose recommendations to the EC for improving the optimisation of radiation protection in the medical sector.

EMAN – the project

On the 23 October 2009 the European ALARA network project started. The project's main objective is to create a network supporting optimisation of medical and occupational exposures in the medical sector. Methodology of networking will be studied and efforts will be spent on setting up the network to create conditions favourable for its long term survival.

Three working groups will work with the optimisation process in different areas of medical applications, for computed tomography examinations, cardiac and non-cardiac interventional radiology procedures and x-ray examinations performed outside the radiology department, respectively. Much effort has been spent on recruiting highly experienced experts to the different working groups.

The project management consists of seven organisations with different perspectives and experiences of the field. The consortium consists:

- **Strålsäkerhetsmyndigheten (The Swedish Radiation Safety Authority), SSM, Sweden**
- **Bundesamt für Strahlenschutz (Federal Office of Radiation Protection), BfS, Germany**
- **Centre d'étude sur l'Evaluation de la Protection dans le domaine Nucléaire, (Nuclear Protection Evaluation Center), CEPN, France**
- **European Federation of Organisations for Medical Physics (EFOMP)**
- **European Federation of Radiographer Societies (EFRS)**
- **European Radiation Dosimetry Group (EURADOS)**
- **European Society of Radiology (ESR)**

In the consortium key professions are represented such as, radiographers, radiologists, medical physicists. It is planned during the project to broaden the medical competences involved, for example with prescribers, cardiologists and surgeons. Other stakeholders having an impact or interest in the optimisation process, such as manufacturers, hospital managers or the general public, will also be involved in the project. When the project ends in 2012 the objective is to have created an independent functioning European Medical ALARA network with a large potential to expand to the various fields involving medical exposures.

EMAN – the network

There exist many types of constellations called networks. Some networks are rather unstructured driven by common interests, others with a formal structure and management. Some are sponsored by organisations and some rely on voluntary work only. In the project we will investigate and make use of experiences from other networks in order to find the success factors and an optimised structure for EMAN.

Networking relies on communication and transparency, both internally and externally. Different communications tools, e.g. on information technology, has to be used efficiently. The opportunities for exchanging information are endless today. The project must develop a strategy for what tools to use and be flexible to use new tools.

Networks, both professional and personal, exist for different topics in the medical sector, and also in the radiation protection community. The future network will collaborate with other networks and organisations. Therefore it is necessary that the network, its mission and its vision is know by the other networks. Work has to be allocated to informing about the network.

EMAN – the working groups

During the project work of specified topics is going to be performed in 3 working groups.

- WG 1 on optimisation of patient and occupational exposures in CT procedures,
- WG 2 on optimization of patient and occupational exposure in interventional radiology,
- WG 3 on radiological safety for patients and personnel in activities using X-ray equipment outside the X-ray departments.

Each working group, in its special field of medical activity will:

- Collect up-to-date literature, on-going clinical studies and current reports concerning good practises on optimisation of radiation protection for patients and workers.
- Identify needs for development and update of guidance on optimisation of RP for patients and workers.
- Identifying needs and collect proposals to improve the European legislation on radiation protection in these medical fields.
- Contribute to the elaboration of the final workshop.

These working groups are also functioning to experience how collaboration and work can be performed in the future.

EMAN – the website

The EMAN website has been created at the beginning of the project with two main objectives:

- Facilitate the effective and efficient information exchange between the members of the network.
- Provide information to concerned stakeholders on the life of the network and on topics linked with ALARA in the medical field.

The web portal is organized into different sections. First of all, a specific section describes the objectives and the organisation of the network, and makes available a list of the network's members. Each of the Working Groups created in the scope of the network has a dedicated web page, where information on the work of the Working Groups will be found. Links to appropriate websites and to international organisations and associations cooperating with EMAN are also provided. After the final workshop of the project, the abstracts and slides of the oral presentations as well as the conclusions and recommendations will be made available.

The website will be regularly updated with news concerning the work undertaken by the network, publications, regulations, etc. related with ALARA in the medical field.

In order to collect information on the potential interested members of the future network, it is possible for any interested persons to register on the web site to the project newsletter which will be published regularly, as well as to register to a specific directory giving the names and contact of other interested persons.

EMAN – the workshop

In spring 2012 a European workshop is going to be arranged with the aim to widely diffuse the information gathered and the work done by the working groups and by the network in general and to facilitate the exchange of information within the members of the network. This workshop will also be an opportunity to draw and disseminate conclusions and recommendations from the network as well as to elaborate and discuss further actions to be made by the network.

EMAN – the future

The rapid change introducing new equipment and examinations is a huge challenge for all involved in the medical sector. A consequence of the increasing demand on productivity is that the optimisation process needs to be efficient. To have an efficient optimisation process will be very important but very demanding. More than ever it will be important to exchange experience and to share information in this field.

We believe that EMAN will contribute positively in this field; we have to work further on the methodology and gather experience from others and also listen to colleagues and interested parties in order to create an attractive network.

EMAN – contact information

All information can be found on the web site: **www.eman-network.eu**

Acknowledgements

The EMAN project is financially supported by the European Commission. Contract number: FP6/036455. At present many persons other than the author of this paper are involved in the project in the working groups or supporting the project in other ways This is very much appreciated.

Thinking about stakeholders and safety culture in the ionizing radiation medical field

Tellez de Cepeda, Marina[1]; Huerga, Carlos[1]; Ordoñez, Jorge[1]; Sende, Jose Antonio[1]; Huertas, Conchi[1]; Serrada, Antonio[1]; Corredoira, Eva[1]; Plaza, Rafael[1]; Vidal, Jesús[1]
Hospital Universitario La Paz Madrid, SPAIN. Email: mtellez.hulp@salud.madrid.org

Abstract
This works treats about:
1. The need to have a well built radiation protection frame not only from de scientific and technical point of view but from that of the organization and the stakeholder perception.
2. The importance of knowing how to relate and communicate to:
   Regulators
   Organization Directors
   Exposed and not exposed workers
   Patients
   People; media; judges and lawyers.
3. The need to improve and maintain the safety culture.

Conclusions:
- A deep built radiation protection organization system maintained and actualized is needed.
- The radiation protection experts must have a continuous training related to technical radiation protection aspects and how to communicate to stakeholders.
- The safety culture must be a part of the quality assurance program with a systematic incidents' review and the spread of the measures taken to minimize the appearance of errors.

Introduction
In relation to the majority of other risk agents presents in our actual society the ionizing radiations (IR) are one of the most studied and known ones. The justification, optimization and limits system is logic and a well built system.

Though many things should be susceptible of harmonization, the expert's language is understandable and common between them. Magnitudes, calculation units and so on, are well defined and there are plenty of reference organism publications and guides to support that. But, when we go into the social field the issue gets complicated and we go into other world with more and not so well defined variables. So we can say that if we are good experts but we do not control the play rules in every case, we are not doing our work well enough.

Nowadays, and after great efforts, the IR Medical Physics and the related RP , is included into the Health Sciences field specialities like that of medical doctors under the name of "Radiofísica Hospitalaria" (RFH) and his activity is developed in: Radiotherapy. Radiology, Nuclear Medicine and laboratories that use IR, including in, all these areas: The patient, workers and public RP.

The RFH title is obtained passing an exam similar to that of medical doctors, but referred to physics, and three years (we are asking for four actually) working at one hospital with a Health Ministry Accredited Teaching Unit.

The RI Spanish legislation that applies to heath field, is numerous and systematically updated [1, 2, 3, 4, 5]. The quality is contemplated in three laws, divers national quality protocols related to: Radiotherapy, Radiology and Nuclear Medicine and a dynamic Health Forum with participants of the: Two reference Spanish societies; Medical Physics (SEFM) and RP (SEPR) and so of the CSN (Regulator Organism). Looking at this we can say that the frame to support and develop the system is solid.

Material and methods

Our "Radiofísica y Radioproteccion" Service is integrated by seven RFH, five technicians and a secretary, but we have to work also at centres outside the hospital with Nuclear Medicine in two of them and plenty of RX units.

The actual philosophy of our hospital, concerning to RI field, is to get the ISO 9001/2008 certification. Our service and the Nuclear Medicine one have already gotten their certificate. Radiotherapy and Radiology Services are in process to achieve it this year. Besides that way, the hospital got, last year the 14001 Certification for environment.

Our certification is referred to:

- Patients, exposed workers and public RP.
- Physical and clinical dosimetry.
- Equipment quality control
- Radioactive installations management.
- RFH Teaching Unit.

Our "Radiofísica & Radioproteccion" Service is integrated by: Seven RFH , five technicians and a secretary, but we have to work also at centres outside the hospital with Nuclear Medicine in two of them y plenty of RX units.

The Service Head has, also, the RP Responsible title according to CSN requirement.

Results and discussion

Thinking about, a good ISO Organization, we must have efficient and practical procedures for:

- Making appropriate technical reports within the legal framework and to enable its compliance.
  Giving a rapid and scientific response in "special" situations, incidents and accidents.

Radiophysics and RP procedures should be indicated as a reference for medical services mentioned above; and a good management of the whole system must have an active role in the development and implementation of quality programs.

With respect to RP training programs for all workers exposed to ionizing radiation, there is a national program for physicians who are doing their specialty. This training is based on a 6-hours course that is organized by the RFH and RP services in each hospital. The course is mandatory for most medical specialties and it carried on during the early days after their incorporation to the hospital. In addition, for those who are more concerned with IR, there is 4-6 hours more of training. Those who are working in: Radiology, Nuclear Medicine and Radiotherapy have a 50 or more training hours which includes a course approved by the CSN. Technicians and some nurses of these services also have an accreditation or license granted by the CSN.

We believe that in order to have an effective system, day by day, there is a need for continuing education in open, practical, and enabling participation sessions and seminars without forgot interdisciplinary meetings in critical situations.

To organize and actively participate in all this is a very important job in the role of the RFH and RP Services.

The information of unexposed workers, patients and people who contribute to his comfort and the information associated with critical situations has to be translated from a technical language into something understandable and that built up confidence in the auditorium.

It is very important to disable the unfounded and unreasonable fear for radiation and prevent, in some cases, the use of this fear to obtain unjustified “collateral benefits”, but, at the same time, we must properly listen to the stakeholders in every circumstance and know their problems and perceptions. We must answer to them in an understandable language but without losing the technical foundation. It must seem truthful.

We must avoid the use of RP for other purposes. For instance, the porters, who transfer patients to RX services for radiological probes, said that they wanted personal dosimeters like the ones the technicians have. We organized briefing session for them and we realize, they felt something pejorative when we said they are classified as common public. We had to make clear all about the limits for the public and so on.

Information to patients and caregivers also has its own characteristics. It is important that the information shall be contained in clear and brief notes adapted to each set of circumstances but, at the same time, there should be an open communication line to resolve particular questions (this often occurs in the case of patients receiving radiopharmaceuticals, pregnant women etc).

Excessive exposed and unexposed workers IR fair may create situations of improper alarm or confusion. For instance, in a hospital, the Patient Care Service received a complaint letter from a father who accompanied his young son in a big common room in the Intensive Care environment area because he observed that when the RX technician went into the room to make a radiography to another baby he shouted ¡¡ RAYS!! And then all the staff leaved the place running. It is necessary that, in such situations, both, the technician that manage the RX equipment and the rest of the professionals act properly and inform the family that at a certain distance of that RX equipment, a person does not receive any measurable radiation.

It is obligatory to have visible written rules, but the process requires something more: To keep an open contact with the workers periodically; to collect impressions and feed back and to take into account the different perceptions, mainly for new workers.

Concerning Media issues related to external events, the SPR must have appropriate minimum information but the issue can be channeled to reference scientific societies experts well prepared for that.

With respect of internal issues, we have to act quickly but with the security that technical data provides.

There are two kinds of media: The scientific and documental and the "daily" one. In the first case we have time and possibility to use a logical and technical treatment of the problem. The real challenge is to manage the second one. It is frequent to listen something that "good news are not news" and " the bleeding news are more engaging for the auditorium". Then the RP experts should prepare themselves for that, because another kind of response and attitude is required.

In relation to lawsuits, the "linear not threshold hypothesis" can generate problems, if the judge finds that any microsievert can be carcinogenic, even if the RP system is correct and according to the norm.

If a negligible amount of radiation can have this consideration, the system ALARA would not support itself, and workers and those present in the radiation facility would have an excessive weighting factor and unjustifiable risk considerations. We must give an appropriate weight to radiation and not create unfairness to other agents.

We must add that the Radiation Protection Service should work together with the Occupational Risk Prevention and the hospital Health and Safety Commission in which there are trade union representatives who must be informed.

National and international organizations (ICRP, IAEA etc) have a great concern for the safety of radioactive sources. It is necessary to efficiently organize the safety of equipment and radiation sources in RT and MN. The safety of patients in RT is based on a good quality program that affects to equipment, facilities and treatments. All interdisciplinary team: Medical doctors, RFH and technicians must know their work very well, case by case, and they must interact appropriately between them in each patient.

Open communication, progressive incorporation of well informed new workers, regular sessions and good incidents follow up is essential.

This approach can be adapted to nuclear medicine and radiologic therapeutic interventional procedures.

Conclusions

- A deep built radiation protection organization system maintained and actualized is needed.
- Radiation protection experts must have a continuous training.
- The Clinical Medical Physicist; Qualified Expert in Radiological Protection, should include, into his skills, the relation with a broad stakeholders field.
- Each stakeholder group has to be listened and well considered but each special problem must be, always, managed under the suitable technical framework.
- The ionizing radiation workers need to be well informed and protected but shouldn't be treated better than other workers with similar level of risk

- The safety culture must be a part of the quality assurance program with a systematic incidents review and the spread of the measures taken to minimize the appearance of errors.
- A well informed media could be one of the best paths to spread the radiation protection
- Adequate Conduct Code (IRPA, IAEA, Montbeliard[6] … should be incorporated to the practice.

Abstract

The change from film-screen radiographic imaging systems to digital imaging systems has brought vast challenges in medical imaging services. Firstly, new general guidelines and working models optimising the radiation dose and image quality are needed.. Secondly, the challenge derived from the first one is to update the competence of the staff working with imaging units and to train the new health care personnel so that their competence could match the needs of the new technique.

The project's purpose is to increase the competence of staff working in imaging units by evidence based education in digital imaging, and dose optimisation according to the principles of the ICRP and DIMOND3 in the three Scandinavian countries: Finland, Sweden and Norway. The specific objectives of the project are to:

1) Plan and implement Scandinavian evidence-based course in digital imaging and dose optimisation, and the materials needed on the basis of national and international regulations about the subject in 1st, 2nd and 3rd cycle education degree and life long education,
2) Produce the materials for the education and
3) Evaluate the evidence-based course plan in quality of digital imaging and the materials produced.

The project management group consists of radiography lecturers, principal lecturers and physicists of College University of Gjøvik - Norway, Karolinska Institutet - Sweden, University of Oulu –Finland, Oulu University of Applied Sciences – Finland and Helsinki Metropolia University of Applied Sciences – Finland. Also students of these organizations are involved in the project from very beginning.

The project is realized between autumn 2008 and spring 2011. In the presentation the main results of the project tills summer 2010 are presented.

Introduction

The change from the film-screen (conventional) radiographic imaging systems to digital imaging has brought great challenges in medical imaging services. Firstly, general new guidelines and working models optimising the radiation dose and image quality of radiographs. Secondly, the obvious challenges derived from the first one are to update the competence of the staff working with imaging units and educate the new health care personnel who are in the middle of their studies to match the needs of the new technique.

According to the studies (e.g. Al Khalifah & Brindhaban 2004), lower levels of radiation dose setting can be established for computed radiography (CR) systems than the standard values used for film-screen systems to produce diagnostic images of equal quality. This is especially important in the examinations performed for children (Livingstone et al. 2008). Flat panel detectors (so called direct radiography, DR) gives even more possibilities for dose reduction and still gives at least as good image quality as with CR (e.g. Willis & Slovis 2004; McEntee M et al 2006; ICRP 93 2004) At the European level, European Councils Directives about radiation protection define at least the minimum criteriafor quality of imaging services (Directive 84/466/, 96/29/ and 97/43/Euratom). The Council Directive 97/43 Euratom defines Quality assurance as ‘’all those planned and systematic actions necessary to provide adequate confidence that a structure, system, component of procedure will perform satisfactory complying with agreed standards.’ The latter part of the Directive describes more specifically the general principles of radiation protection. At the moment Radiation Safety Authorities in all the Scandinavian countries are working on to make national guidelines for digital imaging taking account both the quality assurance and dose and image optimisation. They do this in co-operation with universities and Universities of Applied Sciences that are educating health care personnel who use radiation in their work.

Guidelines and working practices in radiography must be done systematically by using research findings and best available evidence as the basis. Evidence based medicine (EBM) has been defined as ‘the conscientious, judicious and explicit use of current best evidence’ in clinical decision making (Sackett et al. 1996). In studies in the radiography area, in addition to the concept *evidence-based radiography* (Keenan et al. 2001; Ebrahim 2005), also terms such as *evidence-based medical imaging* (e.g Smith 2008), *evidence-based practice* (e.g. Pitt 2004; Pickersgill 2007), *evidence-based clinical practice* (Bonnetti et al. 2006) and *evidence-based medical practice* (e.g. Omorphos & Kontos 2003; Banerjee & Van Dam 2006) are generally used.

In this project, our purpose is to increase the competence of staff working in imaging units by evidence-based education in digital imaging and dose optimisation according to the principles of the ICRP and DIMOND III in the three Scandinavian countries: Finland, Sweden and Norway. Targeted objectives are to: 1) plan and implement Scandinavian evidence-based course plan in digital imaging and dose optimisation and the materials needed on the basis of national and international regulations about the subject in 1st, 2nd and 3rd cycle education degree and life long education. 2) produce materials for the education and 3) evaluate the evidence-based course plan in quality of digital imaging and the materials produced.

The project unifies the Scandinavian knowhow in the radiography field in different levels of professional and adult education. It also fosters the professional status of the radiography education and radiography science. The competence of imaging units staff working in hospitals, health centres and clinics will be developed in a area of digital imaging and dose optimisation. As a result of this, quality of digital imaging will be developed and radiation doses of the patients will be lowered.

Material and methods

Organization of the project

The project group consists lecturers (radiography and physicists) and principal lecturers in higher education institutions. They give first cycle Bachelors level (juvenile and adult) and second cycle Masters level education in radiography and radiotherapy in three Scandinavian countries. From Finland the network includes two Universities of Applied Sciences, from Sweden one University and from Norway one University College.

The steering group of the project consists of the members of Radiation protection Authority in Finland (STUK), Oulu University, Finnish dentists association Apollonia and member of Finnish Research Society of Radiography.

The projects' working principles and ee-learning philosophy

The project group meets approximately once a month in a web conference via Adobe Connect Pro (ACP) videoconferencing system, and twice a year face to face. Mean while the project group members work in the Moodle-platform in the web. The project group uses evidence-based way of working: seeking consensus of peers, experts and member of radiation protection authority, making literature surveys, taking into account national and international guidelines about digital imaging quality assurance and radiographers competency and consulting the radiography departments' staff. Also radiography students take part the project. They prepare some contents and learning material for the e-based course, comment and test it. They work in a co-operation with the multimedia technology students preparing technical solutions for the course.

The learning philosophy of the course was chosen in the beginning of the project on the basis of the basic idea of the project, which is to learn evidence-based radiography. At first the core competencies of the course module were formed on the basis of literature survey (e.g. Medina & Blackmore 2006; Cronin 2009 a and b; Kelly 2009 a and b), national (STUK 2004) and international recommendations (e.g. DIMOND III 2003; ICRP 2004), critical views of project group members and experts. On the basis of core competencies, the core contents of the learning modules were derived. On the basis of core competencies and core contents, learning technological solutions were chosen. This means that the mode of learning is mainly chosen according to the substance to be learned.

Timetable of the project

The project started in autumn 2008, and it operates for two years, untill autumn 2011. During the autumn 2008 and spring 2009 the project organisation and common principles of action were formed. The Scandinavian project group had its first meeting in Helsinki in December 2008. It started planning the core competencies of the evidence-based course plan for the juvenile level. During autumn 2009 the core competencies and some of the learning material became ready. Also the first part of the course module was tested in Helsinki University of Applied Sciences. During spring 2010 the curriculum and learning materials for the Bachelor level was finished and tested. Experiences of those were collected and used for revision of the course. The group also started planning the core contents and learning materials for the Masters level course.

During autumn 2010, the project group will finish the Masters level educational package and test it in Oulu University and Metropolia University of Applied Sciences (Masters Programme in Clinical Expertise). During the spring 2011, the project aims to make PhD level course ready, and if possible, also to test it at least by some radiographers having their PhD studies in the Scandinavian Universities. Also the final evaluation of the learning materials and evidence-based course plan in quality of digital imaging will be performed. In the summative evaluation the aims of the project are compared to the achievements of the project. Also unintended results of the project are evaluated. The value of the educational program for the needs of the working life is asked (theme interviews for key persons at the imaging units) and evaluated. (see e.g. Frechtling et al. 2002)

Results

Evidence-based radiography is a learning philosophy as well as learning contents of the project. This is to say, evidence-based radiography is learned by evidence-based method. In evidence-based learning philosophy, the research evidence and other best knowledge (e.g. national and international guidelines and recommendations) combines with the technical and clinical experience of the student, his/her peers and experts. E-based learning fits to this kind of learning philosophy very well. That is why the project group started to call it ee-learning.

As a result of the project groups' evidence-based way of working described in Materials and Methods section of this article, ten core contents and respective themes of the learning module were formed for 1st cycle Bachelors level education. These were: 1) The basic concepts, methods and process of evidence-based radiography, 2) Decision making in radiography, 3) Technical Quality Features of Digital Images, 4) Visualizing the important information of the image in an optimal way, 5) Applying demands for positioning and collimation for digital radiography, 6) Managing digital radiographic equipment, 7) Applying diagnostic requirements in projection radiography, 8) Applying post processing techniques to improve diagnostic image quality, 9) Assuring and optimizing image quality, and 10) Motivating multiprofessional way of working and documentation. When defining core competencies and core contents of the learning module, it was taken into account that they apply European Qualifications Framework level six adopted by the European Council on 23 April 2008. The EQF is a common European reference framework, which links countries' qualifications systems together, acting as a translation device to make qualifications more readable and understandable across different countries and systems in Europe. (European Council 2008)

It was also defined core contents for each theme based learning module. As an example core contents for the theme 'The basic concepts, methods and process of evidence-based radiography' were defined as follows: The student knows concepts, principles and purpose of evidence-based health care, recognizes the phases of evidence-based radiography, is able to differentiate between sources of evidence, knows what are the most central health care databases, knows how to use scientific databases correctly, knows how evidence-based knowledge is applied to the decision making and development of radiographic practice, is able to make narrative reviews, is able to read and understand systematic reviews and recognizes the connection between radiography science and evidence-based radiography.

Core contents for learning module ' Technical Quality Features of Digital Images' were defined as: The student applies Fryback´s and Thornbury´s model of the efficacy of diagnostic imaging, understands the dilemma technical vs. diagnostic image quality, applies basic properties of a digital image: features relating to (technical) image quality (contrast, noise, geometric distortions, artefacts), and effect of exposure settings (kV, mAs, filtration, grid use….) and object positioning on image quality.

From the viewpoint of e-learning, the project applies mixed mode setting. Individualized self-paced e-learning is used online e.g. when the students search for evidence-based knowledge about the quality assurance (QA), and offline e.g. in learning dose area product measuring (DAP-meter). Also the modes of group-based e-learning synchronously (e.g. videoconference lectures and face-to-face meetings on the web) and asynchronously (e.g. in discussing about problem cases in QA via Wiki-based IT technical solution) are used.

Discussion

Working in a multinational and multiprofessional project group has been very interesting and challenging. It took for half a year for the project group to form a common view about what is quality assurance in digital imaging and how it should be defined in this project. This difficulty came up because radiographers responsibilities in quality assurance differ in Finland, Sweden and Norway. We had to find out what are the central competencies radiographer in all these countries should possess. A great help in this work was achieved through literature reviews and discussions with peers, experts and radiation protection authority. We also had to define the basic level presupposed when the students enter the course. It was defined what the students should know about evidence-based radiography and digital imaging quality assurance before starting this course. Although half a year in a two years project is quite a lot, as an experience we would say that it was a right thing to do. After having a clear view about what to do, the rest of the project is just to do it.

Project group works mostly at the web by using the Moodle platform and Adobe Connect Pro (ACP) videoconferencing system. At first, using the Moodle was a bit difficult at least for those who were not familiar with it. We had not clear user's instructions in English language, which caused that the learning method was consulting each other and trial and error. After some difficulties in the beginning, the Moodle proved to be quite a handy platform of working in this kind of project. The ACP videoconferencing system suited also very well for the work. Seeing each othe's faces and hearing the speech is quite different from just communicating via text. It gives a sense of belongingness to the project group and this can and was in our project been seen straight as a productivity of the project group.

Radiography students of the higher education institutes taking part of the project were involved in it at the early phase. The project was integrated to their studies. The students reported that they liked a lot studying in this kind of 'real' project, although it was sometimes very challenging. They learned many kind of things while doing the project: evidence-based way of working, English language, digital imaging quality assurance, problem solving skills, team work and project management. The students wrote articles about their working at the project and took part project groups'work in face to face and ACP meetings.

As the parts of the learning module were tested with the radiography students, it was reported that most of the students had difficulties in understanding the English vocabulary. However they felt that the content of the course was mostly easy. There were some difficult concepts, which needed clarification. A large part of the students hoped that the course would be in Finnish or at least have an English-Finnish dictionary for the difficult words. The course will continuously be tested by radiography students as well as by radiographers working at the hospitals. It will be revised according to feedback received between the testings.

The project group will translate the course to national languages after the project will be finished. The course has been built up to the Moodle in a way that it can be transferred to other web based platforms. This is necessary because higher education institutions use different platforms in their e-based teaching and there is no point bothering the students to learn the use of new platform for one course. Instead of it they can concentrate on learning the contents of the course.

So far the project has proceeded approximately in its timetable and reached its' objectives. The project produces common Scandinavian understanding about what is evidence-based radiography and digital imaging quality assurance. As unintended outcome of the project, R&D networking on the area of radiography among Scandinavian countries has got some impetus, which we hope, will continue.

Conclusions

As a result of the project, a learning module consisting of ten core contents and respective themes for evidence based digital imaging quality assurance was formed for 1st cycle Bachelors level education. The learning module also comprises learning material and learning tasks. In the multinational and multiprofessional quality assurance project one of the most challenging things is differing responsibilities of radiation using staff. This will become easier in the future as the national guidelines for digital imaging will be developed. According to the experience of this project evidence and e-based way of working is very useful to develop new applications in the field of radiation use quality assurance. Ee-learning has also proved to be a useful learning philosophy in radiography.

Monte Carlo based PCXMC-program as a tool of learning dose optimisation in plain (project) radiography

Henner, Anja
Oulu University of Applied Sciences, FINLAND

Abstract
Effective dose can be defined for X-rays as the sum of the weighted average absorbed doses in all the tissues and organs of the body. International Commission on Radiological Protection (ICRP) has produced a list of tissue weighting factors for a number of organs and tissues. The calculation of effective dose is based on the Monte Carlo technique or direct organ dose measurements. PCXMC is a widespread and well tested Monte Carlo program for calculating patients' organ doses and the effective dose in medical X-ray examinations. The anatomical data is based on the mathematical hermaphrodite phantom models of Cristy (1980). The program computes doses in freely adjustable x-ray projections and other examination conditions. The program describes patients of six different ages: newborn, 1, 5, 10, 15 -year-old and adult patients. Radiographer students calculated effective doses to patients of different age and changed technical parameters one by one. They analysed the results and compared their own result to those found in literature. With PCXMC it is also possible to evaluate the risk to the patient due the x-ray examination and compare the difference in organ doses calculated based on the data of the ICRP publications 60 and 103. The students have found out the benefits of PCXMC in dose optimisation. It is easy to point out, what kind of changes have to be done and how much the changes help to decrease the dose.

Introduction
It is well known that ionising radiation may course harms. From stochastic point of view, there is no evidence at present of a threshold to the radiation dose below which there is no risk. The probability - but not the severity - of stochastic harm increases along with increased dose. In addition, the latest studies have indicated that there may also be effects on the lower levels and consequently the optimisation of an individual dose is important. (Hall et al 2004, International Commission on Radiological Protection 103 2007.)

The effective dose was developed by ICRP to reflect the fact that some organs are more sensitive than other organs. They have a higher risk of producing a cancer or another deleterious effect. The effective dose also helps in evaluating the biological effects of radiation (International Commission on Radiological Protection 103 2007).

The effective dose is the sum of the effective doses for exposed organs. The calculation of these doses requires knowledge of the size and configuration of the individual, the geometrical projection of the beam, size and location of the primary and scatter beams, Entrance Surface Dose and x-ray beam energy spectrum. The radiation quality factor is needed because of the different biological effects when interacting with tissue. For x-rays, the quality factor is unity (Lampinen 2000), which according to International Commission on Radiological Protection 74 (1997) and Marttila (2002) means that the effective dose can be defined for x-rays as the sum of the weighted average absorbed doses in all the tissues and organs of the body. The unit is Sv (Sievert). International Commission on Radiological Protection has produced a list of tissue weighting factors for a number of organs and tissues and they are mean values for the whole population. The factors were published first time in Publication 16 (1970), re-evaluated in Publication 60 (1991) and once again in Publication 103 (2007).

. The calculation of effective dose is based on the Monte Carlo technique described in NRPB-R186 (Jones, Wall 1985) or direct organ dose measurements by TLD (McCollough, Schueler 2000). The anatomical data in PCXMC is based on the mathematical hermaphrodite phantom models of Cristy (1980), which describe patients of six different ages: newborn, 1, 5, 10, 15 -year-old and adult patients. PCXMC is a widespread and well tested Monte Carlo program for calculating a patient's organ doses and the effective dose in medical x-ray examinations (e.g. Tapiovaara et al. 2000, Geijer et al. 2001, Tort et al. 2001,Dimov, Vassilieva 2002, 2002, Hansen et al. 2003, Uffam et al 2005). The height and weight of the patient can be set from a real patient. All organ doses calculated by PCXMC relate to the patient entrance air kerma (free-in air, without backscatter) at the point where the central axis of the x-ray beam enters the patient. The datum can be obtained by combining data on the examination techniques and the radiation output of the x-ray source or by using the surface dose or Dose-Area Product measurements of actual patient examinations. (Tapiovaara et al. 1997, Tapiovaara et al 1999, Tapiovaara, Siiskonen 2008.) This enables the calculation of the effective dose related to the x-ray field size and provides a technique for monitoring the collimation of the x-ray field.

Material and methods

The concepts like absorbed dose, entrance surface dose, Dose Area Product, organ dose and equivalent and effective dose are first discussed and clarified. The PCXMC program is introduced to students by two hours lesson and demonstration. After that the students practice by them selves to calculate the doses according the given examples in small groups for two hours supervised by the lecturer. They calculate first dose to an adult person and then the perceptions are discussed with the whole group. The aims of this part are at first to make the program familiar with the students so that they understand the concepts used in PCXMC program and secondly that they can use the program independently in a correct way.

After that the students get the written tasks. First they calculate doses for five patients in some examination. This data has been collected earlier in clinical practice for the ESD (Entrance surface dose) calculation. Next they pick up one patient and calculate doses changing parameters one by one. The changed parameters are: Tube potential (kV), added filtration, height of exposed field, width of exposed field, projection (ap /pa), age and focus to skin distance and finally both kV and mAs (e.g. kV from 70 kV to 80 kV and from 20 mAs to 10 mAs to keep to dose on the same level). Students evaluate the effect of changes to the whole body effective dose and organ doses organ by organ. They also have to calculate effective doses to a new born, 1, 5, 10 and 15 years old child in one examination e.g. chest ap. The risk analyses are made based on some of those calculated effective doses. The PCXMC program calculates the whole body effective dose according to tissue weighting factors from ICRP 60 (1991) and ICRP 103 (2007). It is easy to find e.g. the differences in effective dose between female and male with the same dose as well as the correlation between the risk and age.

The students write also a report in pairs about what they have done and found. The results and observations must be compared to those from literature at least with ten scientific articles. They also have to evaluate and reflect their own experiences and learning outcomes as well as how to use the program later in clinical practice.

Some examples of these reports are shown and the students own learning outcomes has been analysed by content analysis method.

Results

The students understood the basic concepts of the PCXMC program during the two hours lesson and demonstration. The two hours training in small groups clarified the concepts and the students could after that session use the program correctly in order to calculate doses. In small groups the students had different examination (chest, pelvis and lumbar spine ap (anterior-posterior) and pa (posterior-anterior). the results were discussed and there was a lot of discussion about the differences and how to transfer them to clinical practice. The next tables will demonstrate one student's calculations in adult patient's chest examination (Table 1).

Table 1. Five patients in chest examination used in calculations.

	Length	Weight	kV	mAs	BMI	ESD (mGy)
Female	170	55	125	1,26	19.03	0.07
Female	178	80	125	1,73	25.24	0.11
Male	175	86	125	1,79	28.08	0.11
Male	166	60	125	1,08	21.77	0.07
Female	164	77,6	125	1,65	28.85	0.1

All patients are adult. BMI is body mass index calculated from the patient's height and weight. The ages varied from 23 to 55 years.

Table 2. Organ doses and effective doses according to ICRP 60 (1991) and ICRP103 (2007) for five patients introduced in table 1 calculated with PCXMC program in chest examination.

	Dose (mGy)				
Organ	Female 179/55	Female 178/80	Male 175/86	Male 166/60	Female 164/78
Bone marrow	0.009411	0.010732	0.010377	0.007748	0.010495
Breasts	0.008188	0.008722	0.008362	0.006013	0.007866
Colon	0.000241	0.000271	0.000354	0.000287	0.000506
Lungs	0.025360	0.031904	0.030964	0.021119	0.029790
Heart	0.012914	0.014500	0.013495	0.009985	0.013336
Thyroid	0.003530	0.004531	0.003427	0.003492	0.003874
Effective dose ICRP60 (mSv)	0.007070	0.008187	0.008047	0.006305	0.008884
Effective dose ICRP103 (mSv)	0.007849	0.009013	0.008939	0.006516	0.009112

The results in Table 2 show that effective dose is dependent of the patient's size and there is difference in doses calculated according to the ICRP 60 and ICRP103.

Table 3 shows differences in doses with same patient with different technical settings. In chest ap / pa it is easy to find the benefit in pa projection both in organ doses and in effective doses. Most important difference is in the dose of breasts and active bone marrow. Also the thyroid dose decreases in pa projection although it was not in the primary beam. The effective dose in chest ap is increasing more with the ICRP 103 weighting factors due the change in breasts factor. Added filtration decrease all doses and Cu more than aluminium. Higher tube potential and lower mAs decreases also all doses.

Change in the size of exposed area decrease patient dose also: two centimetres smaller area in height gives 18 % decrease in effective dose. Distance is also one parameter influencing to patient dose. With 30 cm longer distance from the x.ray tube focus to patient's skin, the dose to patient is lower and in digital imaging the mAs and kV can be on the same level, the image quality is still equal.

Table 3. Doses to one adult female patient in chest examination calculated with PCXMC program with different parameter settings (on the first row the basic dose with 125Kv, 3mmAl, FID 200cm, 125kV, 2,4 mAs, in others only documented parameter has been changes from the basic settings**)**

Parameters	Average dose in total body	Effective dose mSv (ICRP 60)	Effective dose mSv (ICRP103)	Breasts mSv	Lungs mSv	Active bone marrow	Thyroid	Oesophagus
Pa	**0.014488**	**0,016581**	**0,018372**	**0.017273**	**0.065154**	**0.021996**	**0,005304**	**0.037316**
Ap	0.014182	0.023271	0.029565	0.107345	0.055809	0.012905	0.008714	0.028139
Filtration +2mmAl	0.011650	0.013596	0.01506	0.014530	0.052790	0.017851	0.004491	0.031598
Filtration +1mmAl+0,1Cu	0.010305	0.012232	0.013608	0.013378	0.046896	0.015943	0.004156	0.029293
kV135, mAs1.2	0.008726	0.010116	0.011221	0.010731	0.039393	0.013369	0.003296	0.023265

The students also make risk assessment with the program. Figures 1 and 2 show the difference in risk with same dose and age between male and female. The risk is very small due one chest pa projection but, as seen, female has higher risk. Due to one chest x-ray a female has loss of life expectancy is 0,3 hours and and male 0,1 hours. In other risks the male has higher rate.

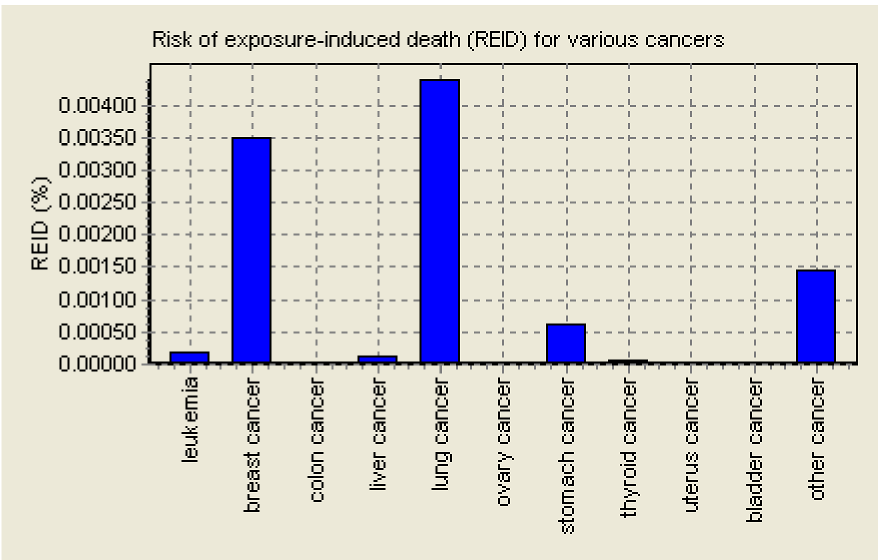

Figure 1. Radiation risk assessment: Stochastic radiation risks (Finnish mortality data). 20.0 year-old female, Expected length of remaining life 59.5 years, Risk of exposure-induced cancer death (REID): 0.000176 %, Cancer mortality for other causes; not related to this exposure 17.1 % , Loss of life expectancy (LLE): 0.3 hours.

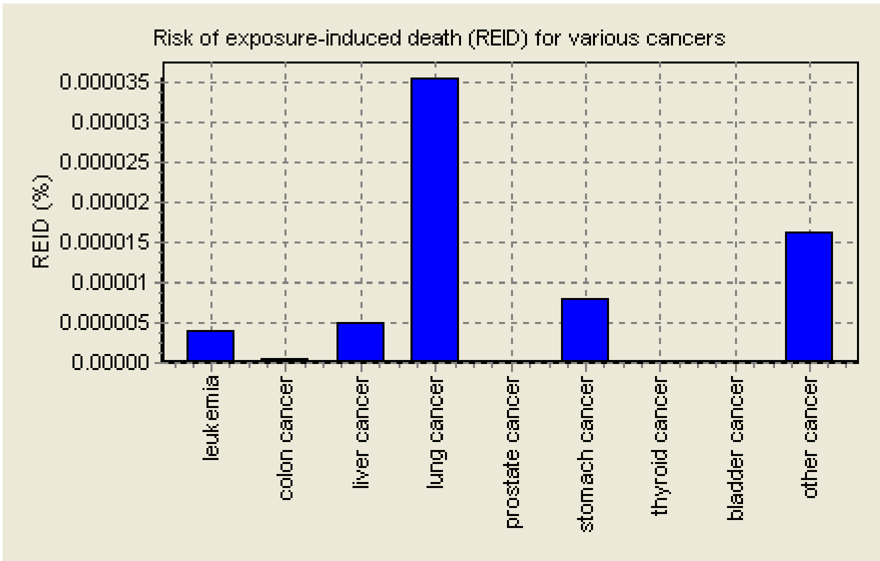

Figure 2. Radiation risk assessment: Stochastic radiation risks: Finnish mortality data, 20.0 year-old male, Expected length of remaining life 52.9 years, Risk of exposure-induced cancer death (REID): 6.95E-5 %, Cancer mortality for other causes; not related to this exposure: 20.1 %, Loss of life expectancy (LLE) 0.1 hours

The younger the child is the higher is the risk. It is also possible calculate cumulative risk due to many x-ray examinations.

Discussion

The PCXMC program can be used as a new tool to evidence the effects of the technical parameters and projection view to the patient dose. There are several examinations which can be taken either as an ap or pa projection. In dose optimisation it is easy to calculate both organ doses and effective dose and compare the difference between them and make the decision based on the evidence based results. It is also possible to calculate the dose to a foetus, if needed, especially during the first half of pregnancy (Perisinakis 1999, Kettunen 2004).

Tube potential (kV) affects to the contrast of the image. With higher kV the radiation beam is more penetrative and may for that reason cause loss in image quality especially in soft tissues and ribs (Uffman et al 2005). They used the PCXMC program to evaluate the effective dose and image quality with different kV levels (90, 121 and 150 kV) and as a conclusion they recommend lower kV at a constant effective patient dose.

Most x-ray equipment has possibility to use different added filtration in x-ray tubes. The effect of added filtration has been evaluated by Hamer et al (2005) and they pointed out about 31% reduction in ESD with 0,3 mmAl Cu-filtration. Decrease in effective dose can be found also in effective dose with PCXMC program.

PCXMC evaluates also the risk to the patient due the x-ray examination. As well known the children are more sensitive to radiation than adults (Paile 2002, ICRP 2000). There are also some special groups among small children and young people, which are frequently x-rayed, e.g. a child with scoliosis, heart problems, vesico-uretal reflux etc. Also premature babies might be exposed tens or even hundred times during the first living months. The risk assessment may give more evidence for the dose optimisation. (Kettunen et al 2003, Kettunen 2004., Servomaa, Kettunen 2005.) The program reports the risk as a loss of life expectancy or as a cancer mortality. The program shows also the cancer mortality due to other risks and that gives perspective to risk assessment.

The new detectors offer a good possibility for dose reduction. It is still quite difficult in clinical practice, because the more radiation is used; the better is the image quality. (Correa et al 2008,Geijer et al 2009.) The staff get more motivation to dose and image quality optimisation when they notice the effect of the change to the patient's dose. The students reported a lot of possibilities to use PCXMC program to demonstrate how to optimise dose and what is the effect of each technical parameter or direction of the projection. It is amazing to find out how small changes can effect so much to the patient's dose.

Conclusions

The students have found out the benefits of PCXMC program in dose optimisation. It is easy to point out, what kind of changes have to be done and how much the changes decrease the dose. Also the meaning of critical organs clarifies. The age –dependence in risks due to ionising radiation can be demonstrated as Students analyse their findings and compare them to the results of scientific articles published during the last years.

Radiation protection of the staff in operating theatres

Henner, Anja
Oulu University of Applied Sciences, FINLAND

Abstract

Purpose: The universal features of the safety culture are individual awareness of the importance of safety, knowledge of competence, commitment, motivation, supervision and responsibility. In Finland nurses and medical doctors are allowed to use the c-arm in operating theatres and emergency rooms. The purpose of this study is to point the key factors affecting to the radiation protection and safe use of mobile c-arm in operating theatres and emergency.

Methods and materials: About 40 courses (1,5 ects) concerning the safe use of mobile c-arms have been given to nursing staff all over Finland. The course consist of 5 areas given in EU legislation: Fundamentals of Radiation Physics and Radiation Biology, Radiation Protection Provisions, Radiation Safety Measures at the Workplace and Procedures Involving Exposure to radiation. In demonstration all features of that c-arm are shown step by step. In the end of the course there is a written exam and more than 1300 answers have been analysed for this research.

Results: About 80% of the participants passed the test in first exam and only 1% needed third exam. Mostly participants are nurses but also some medical doctors and other staff. According to this study the most difficult areas are the basic concepts: radiation and it's features, effects of radiation at the molecular, cellular and tissue levels, deterministic and stochastic effects of radiation and their identification, radiation user's organization, dose motoring and categories A and B and what they mean in everyday work, controlled and supervised areas and monitoring of radiation exposure of workers. The operational radiation protection is quite well known.

Conclusion: During the courses there has been discussion about factors influencing the interpretation of fluoroscopic images procedures exposing children and pregnant women to radiation. The nursing staff is very willing to involve to good safety culture. More hands on training is needed to the nursing staff.

Radiation protection training in the Joint Research Centre of Ispra

Giuffrida, Daniele[1]; Vanetti, Silvia[1]; Osimani, Celso[2]
[1] Joint Research Centre, Ispra, European Commission, Radiation Protection Sector, ITALY
[2] Joint Research Centre, Ispra, European Commission, Nuclear Decommissioning Unit, ITALY

Abstract

The Joint Research Centre of Ispra, one of the research Sites belonging to the European Commission, Directorate General JRC, was created in the late '50s, in order to steer European research on nuclear industry. It hosts numerous nuclear facilities, some of which are maintained in operation, while others were shutdown in past years, namely: two research nuclear reactors, hot cells facilities, radiochemical laboratories, one Cyclotron (still in operation), facilities for studies on fissile material (in operation), and some facilities for the treatment and storage of liquid and solid waste (in operation). The JRC accounts for 21 nuclear licences, 14 Controlled Zones and 12 main Surveilled Zones, on its Ispra Site. The Radiation Protection Sector has developed, during the last years, a new approach for training in Radiation Protection: this includes an improvement and extension of the traditional classroom-based training to Exposed Workers, and:

1. the generation of new training modules on radiation and radiation risks, specifically addressed to non-exposed Personnel;
2. on-the-job training to newcomers and Radiation Protection Officers;
3. development and operation of mock-up facilities for specialized training (glove boxes, high contamination areas, etc.).

Evaluation of training effectiveness has also been modified and enhanced. Moreover, the need for a more comprehensive set of "education and training" actions in the field of Radiation Protection is becoming a priority, in Italy, due to the reduced availability of competent Technicians in the Radiation Protection market. The JRC-Ispra is currently studying the possibility to re-evaluate its training offer to the market, in order to further improve, according to its mission, the dissemination of technical and scientific knowledge in this field.

Radiation protection related teaching in Estonia and using of web-tools

Lust, Merle[1]; Isakar, Kadri[2]; Realo, Enn[2]
[1] Eesti Energia AS, Laki 24, Tallinn, ESTONIA
[2] University of Tartu, Institute of Physics, Riia 142, Tartu, ESTONIA

Abstract
This paper will provide a time-line overview of the progress on teaching of radiation protection in Estonia following the 1991 declaration of independence. We will address several important factors and the means which promoted the teaching, and give the overview of different tools used for that. Also it is our intention to share the experience in order to facilitate the learning process.

Introduction
The Republic of Estonia (area of 45 227 km², population of 1.34 million) is situated in North-East of Europe, on the eastern coast of Baltic Sea. Estonia regained its independence in 1991, which created a need for changes in many areas, including radiation protection. During the Soviet period there was research in the field of nuclear physics and nuclear-related courses were taught at the universities. However there were no courses in Estonian universities about radiation protection or nuclear safety.

After regaining the independence a sudden need appeared to build up the radiation protection system in the country. Also taking into account the heritage sites – nuclear submarine training centre and uranium mining and milling facility, there was need for educated people. The first radiation protection courses were taught at the University of Tartu. These courses were addressed mostly to the students of environmental physics and were based almost entirely on the environmental radiation. Soon the courses concerning the use of ionizing radiation in the medicine followed. During the last decade the scope of the courses taught at several universities has been widening, so that currently the topics covered are wider and the courses are addressed for the several specialities.

From late nineties the radiation protection course is taught also in the Türi College of University of Tartu, where most of the environmental specialists of Estonia are educated. Türi College is a relatively small institution, which actually has only one curriculum – Environmental Regulation and Planning. Taking also into account that Türi is a small town (population of about 6000) situated in the middle of Estonia, without any research facilities, national environmental institutions or big universities, qualified lecturers usually will be available only during the lecturing course for three to four days. However the college has good technical facilities, including the special web-teaching rooms for students with good internet connection. Considering this, and also the lack of teaching materials available in Estonian language, the main radiation protection lecturers at the Türi College decided after almost 10 years of teaching to develop the web-based teaching tool.

Material and methods

Developed web-based teaching course is basic radiation protection course, which is part of the required curriculum for Türi College students. However the same course is available also for other students of Tartu University on optional basis, if they care to travel to Türi. There are no special requirements to students in order to enroll, however some knowledge about mathematics is useful. The course aims to provide the knowledge of basic principles of radiation protection, and to give the ability to assess some easier cases including activity estimation or simple shielding calculations for radioactive sources. At the end the student should also have understanding about the sources of ionizing radiation, biological effects caused by ionizing radiation and principles of the nuclear energy. The course covers also terminology and units used in radiation protection.

The Blackboard Learning System (Blackboard Inc, 2010) was used in preparation of the web-based course. The Blackboard Learning System is a web-based server software platform, which features include course management, a customizable open architecture, and a scalable design that allows for integration with student information systems and authentication protocols. Its main purposes are to add online elements to courses traditionally delivered face-to-face and to develop completely online courses with few or no face-to-face meetings. The options available in the system include for example announcements, discussions, mail, calendar, learning modules, assessments, assignments, media library, etc (Fig. 1). Regarding the quite specific terminology used in radiation protection, that students may not be familiar with, one of the most useful application in Blackboard system is the Glossary. Course developer can insert new terminology into the Glossary and particular word in the teaching material will become a hyperlink, clicking on which results a new window opening with the particular explanation from the Glossary (Fig. 2 and 3).

Fig 1. Student view of a learning material about III generation nuclear reactors. On the left side is visible the list of Blackboard capabilities used in this course.

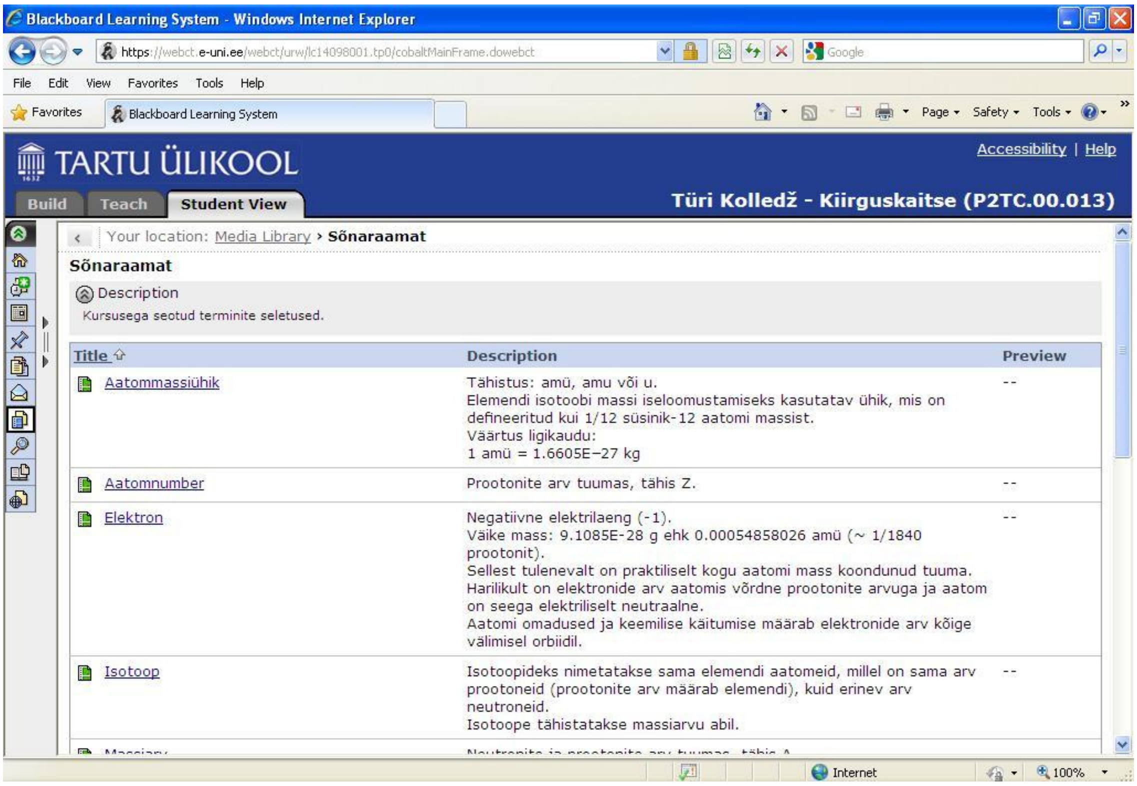

Fig 2. Example of a Glossary application.

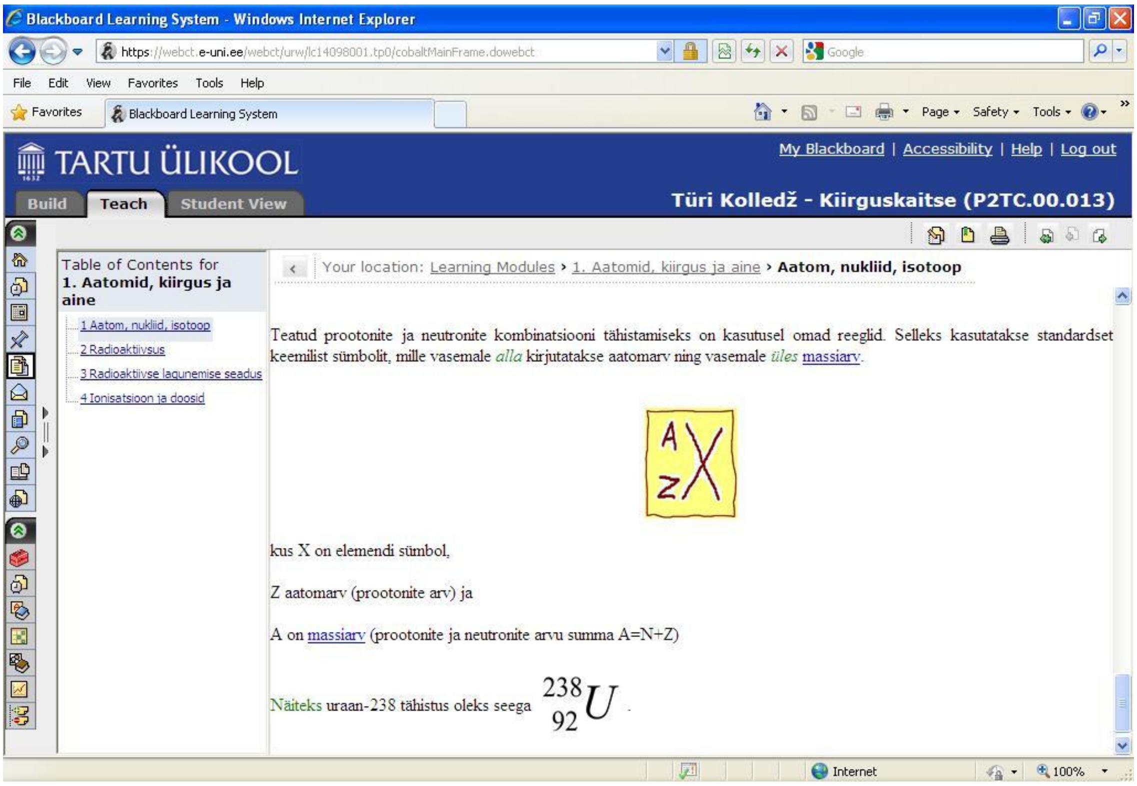

Fig 3. Example of teaching material. As you may see the word "*massiarv*" is automatically formated as a hyperlink, because it is defined in a Glossary seen on Fig. 2. On the left side of the screenshot is visible the Table of Contents for the first chapter of the course.

Results

The web-based teaching tool helps to facilitate better interaction between the lecturer and students while residing in different regions of Estonia, and also provide them learning environment with additional information. The preparation of current web-based course was started in spring 2009, it was finished and tested first time in autumn 2009. The prepared web-based basic radiation protection teaching course consisted of 6 learning modules:

1. Atoms, ionizing radiation and dosimetry

   Giving an overview of topics like: atom, nuclide, isotope, radioactivity, radioactive decay law, ionization and dosimetry.

2. Natural and man-made radiation sources

   Consisting of: environmental radioactivity, decay chains, radon, internal radiation, uses of radiation sources, medical radiation, industrial applications of ionizing radiation, results of nuclear weapons testing, accidents.

3. Biological effects caused by ionizing radiation

   Which includes: biological effects of ionizing radiation, four stages of the interaction between ionizing radiation and human cells, DNA and direct and indirect effects of ionizing radiation, deterministic and stochastic health effects, cancer development, hereditary effects, acute radiation syndrome.

4. Nuclear Energy

   Giving an overview of: nuclear energy and radioactive waste management, pressurised water reactors, boiling water reactors, III generation reactors, fuel cycle and waste, radioactive waste jurisdiction, releasing radioactive waste into the environment, liquid, solid and gaseous radioactive waste, used nuclear fuel, decommissioning.

5. System of Radiation Protection

   Covering the topics of: history of radiation protection, organizations, main principles of radiation protection, justification, optimization, limitation, national radiation protection system.

Different materials and experiences gathered were used in preparation of the course. One of the main supporting materials was booklet "Radiation, People and the Environment" (Lust *et al* 2006*,* Wrixon *et al* 2004). The book, which was produced by the IAEA in close co-operation with the UK National Radiological Protection Board, provides a broad overview on the subject of ionizing radiation, its effects and uses, as well as the measures in place to ensure it can be used safely. It also discusses the benefits and risks of practices that use such radiation in medicine, industry and energy production and considers some topical concerns about environmental pollution, waste management, emergencies and transportation safety. The book was translated and published in Estonia in 2006.

The course is usually held in the autumn semester. The course calendar will provide the exact dates for the assessments, assignments, lectures and exams. The teaching will be held as mix of the auditorial work and self-based work online, the course will start with introductory lecture. Each learning module provides explanation of the topic with a lot of illustrative material – photos and schemes. Considering that basic radiation protection course consists mostly of new information to read, different colours for text were used to make it easier for the student. Additionally each learning module has assessment and assignments. The assessments (Fig. 4 and Fig.5) were usually organized in self-testing form and consist of questions or calculation exercises. In order to pass the course the student has to do all the assessments. Most of the supporting materials were provided online. The final step will be passing the exam, which can be done online as well. This has been also quite an important feature in order to provide the security for the results. After collecting the information from the learning modules provided in the course, the result was booklet consisting of 111 pages.

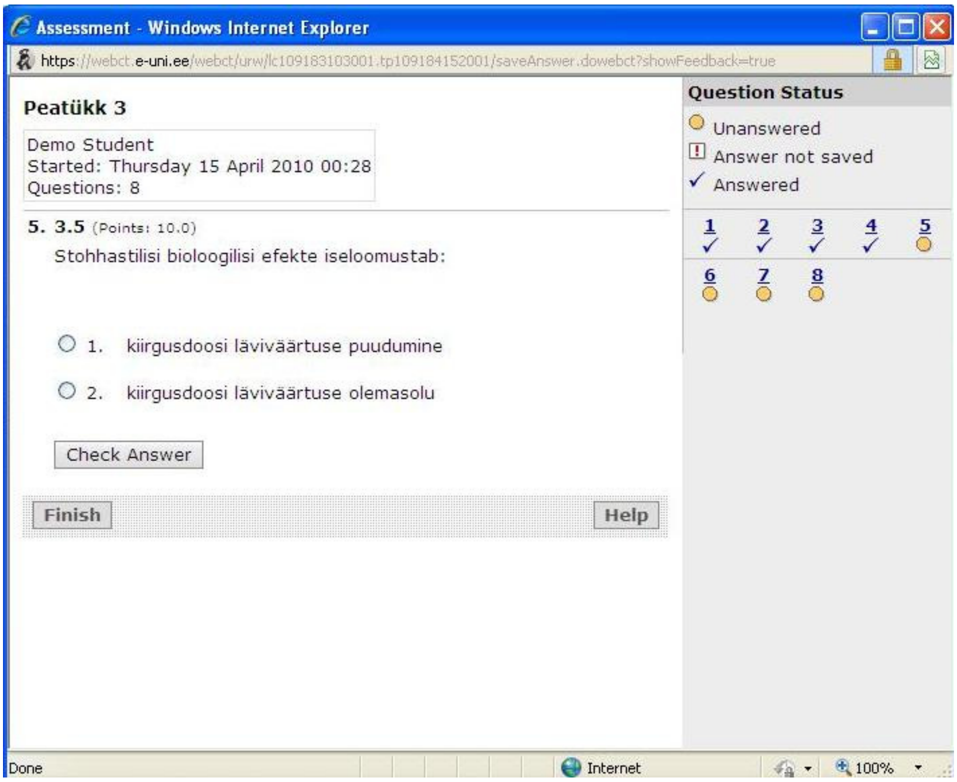

Fig 4. Example of a multiple-choice type self-assessment test. Questions are taken randomly from the question-bank filled by the teacher.

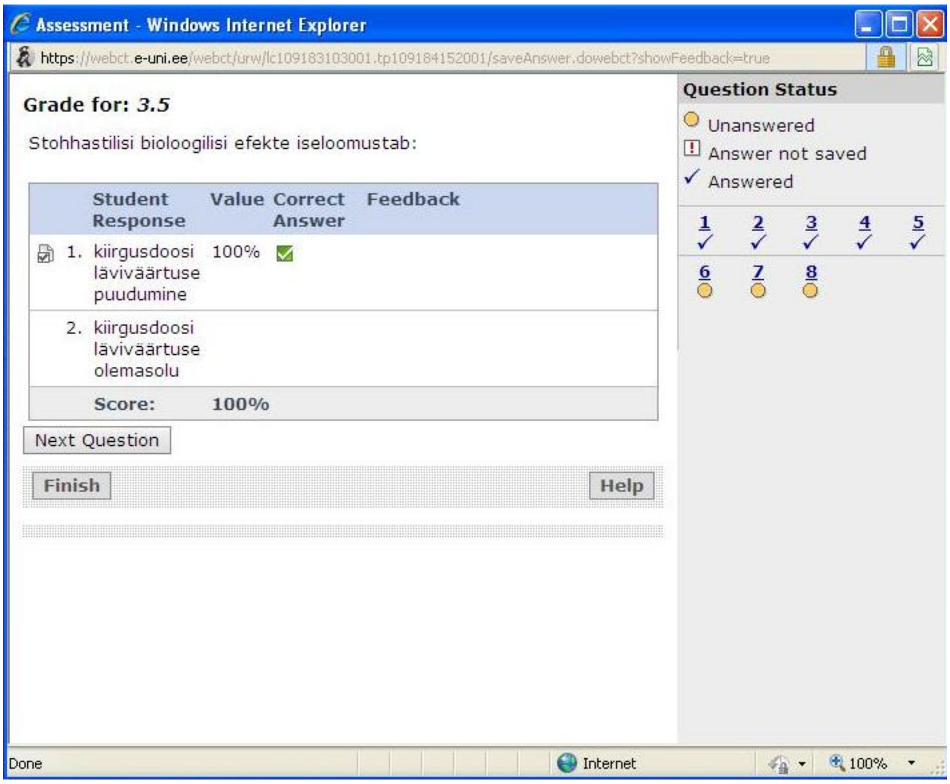

Fig 5. Instant feedback for the student that the answer to the 5th question on the self-assessment test was correct.

Discussion

Around year 2000 started the first courses for the users of radiation sources. Most of the first courses were organized through international co-operation projects, but during the years there has been teaching of the local trainers. This has lead to the situation, where basic radiation protection education for the operators can be provided by local experts. Estonian Radiation Protection Centre (since February 2010 known as Radiation Safety Department of Environmental Board) has facilitated translation and publication of several radiation protection related publications and has used its web-pages as a tool for providing the information. Now additionally the information gathered through preparation of the course can be used and published for wider public as well.

Other future applications and expansions of such a course may also relate more closely to nuclear energy. Taking into account the vision approved by the Parliament in June 2009, which lists the nuclear development as one of the possible future scenarios, there is a great need for education in nuclear safety. University of Tartu and Tallinn Technical University have started the preparation of nuclear safety and nuclear energy master course. The first students are supposed to be admitted in the autumn of 2011. The prepared course can be used in the curriculum of these master courses as well.

Conclusions

Estonia started building up the radiation protection infrastructure a bit more than 10 years ago. There was no clear governmental mandate and no accompanying support training system to start with. During the last decade the remarkable steps have been made in providing the information related to radiation protection to the public and also in preparation of the specialists at the universities. There is still much work to do, however using the technical tools available, the current human resources can be used much more wisely. The web-based course prepared last year passed the first test successfully and it also provides a good platform, which can be used in several occasions.

Acknowledgement

The authors are grateful for the support provided through European Social Fund „BeSt“ program in preparation of web-teaching tool.

Radiation protection education and training activities at the Belgian Nuclear Research Centre SCK•CEN

Coeck, Michèle
Belgian Nuclear Research Centre SCK•CEN, BELGIUM

Abstract
The scientific world of radiological protection (RP) is in constant motion, triggered by new research as well as by developments and events in the daily industrial and medical sectors. In addition, national and international regulatory policies try to streamline and guide daily practice along procedures that guarantee the protection of workers and public, and that at the same time also ensure optimization of all peaceful uses of applications of radioactivity. Harmonization and coordination are in this sense of the utmost importance, not only 'on the work floor', but also with regard to education and training (E&T). Within this spirit, the international school for Radiological Protection (isRP) of the Belgian Nuclear Research Centre SCK•CEN participates to several E&T activities: SCK•CEN experts lecture several courses within existing academic programs, and give guidance to Master and PhD students in the framework of their thesis. We also organize courses on a wide variety of RP topics for professionals of the nuclear and medical sector and - in parallel - we aim to play a role in national and international policy through active participation in several European networks.

Introduction
The Belgian Nuclear Research Centre SCK•CEN was created in 1952 in order to give the Belgian academic and industrial world access to the worldwide development of nuclear energy. It is a Foundation of Public Utility, with a legal status according to private law, under the tutorial of the Belgian Federal Minister in charge of energy. Since 1991, the statutory mission gives priority to research on issues of societal concern such as safety of nuclear installations, radiation protection, safe treatment and disposal of radioactive waste, fight against uncontrolled proliferation of fissile materials and fight against terrorism. The Centre also develops, gathers and disseminates the necessary knowledge through education and communication, and provides all services asked for in the nuclear domain (by the medical sector, the nuclear industry and the government). Today, about 630 employees advance the peaceful industrial and medical applications of nuclear energy, and realize a turn-over of about 85 M EURO.

Thanks to its thorough experience in the field of peaceful applications of nuclear science and technology, the Belgian Nuclear Research Centre SCK•CEN has garnered a reputation as an outstanding centre of not only research, but also education and training. SCK•CEN is an important partner for training projects in Belgium (to the nuclear sector, the medical and non-nuclear sector), as well as at the international level (IAEA, EC, …). The Centre's know-how and infrastructure are available for education and training purposes. One of the research topics that is strongly developed at SCK•CEN's Institute for Environment, Health and Safety, is radiation protection. From years of experience and recent knowledge that results from the latest innovative research, an extensive range of course modules has grown. Our courses are directed to the nuclear industry, the medical and the non-nuclear industry, national and international policy organizations, the academic world and the general public.

Academic collaborations

SCK•CEN experts are involved as lecturer in several academic programs, at Belgian and foreign universities and technical universities. They also deliver contributions to courses set up on specific occasions such as the courses given in the framework of ENEN, CHERNE, WNU, etc.

Radiation Protection Expert

Together with XIOS Hogeschool Limburg, ISIB and IRE, SCK•CEN organizes the Radiation Protection Expert course, given in Dutch and in French. This course broadens the scientific and technological basic knowledge of radiological and nuclear techniques with special attention for practical radiation protection. It is aimed at professionals working with ionizing radiation, in all sectors. The program is in line with the legal requirements of the Belgian Royal Decree of July 20 2001, mentioning the prerequisites for accreditation as Radiation Protection Expert by the Belgian Federal Agency for Nuclear Control. SCK•CEN collaborators contribute to the Dutch course, for 96 of the total 120 hours.

Guidance of PhD students

In a conscious desire to increase its pool of highly specialized young researchers and to tighten the links with the universities, SCK•CEN embarked in 1992 on a program to support PhD candidates and post-doctoral researchers. Since 1992, about 100 students started a PhD in collaboration with SCK•CEN and more than 50 post-docs joined our Centre. Today, about 35 young scientific researchers perform their work in research fields that reflect the priority programs and R&D topics of SCK•CEN, about half of them are working within the field of radiation protection.
Next to this, SCK•CEN experts also work with Master students, and even high school students (sixth year) have the opportunity to use our laboratories and other infrastructures in order to perform scientific experiments to support there thesis work.

Training courses for professionals

Training courses of the international school for Radiological Protection of SCK•CEN cover a very broad offer. Different modules are foreseen as a "standard", but in principle all our courses are tailored to the specific needs, field of operation, and level of the trainees.

Basic modules

The course series *Background and Basic Knowledge* collects general and more specific technical courses on radiological protection. The series consists of seven modules and provides the theoretical and practical knowledge required for implementing technical aspects of radiological protection in a medical or industrial working environment, both in the daily practice and in the management in the long term:

- Basic principles of nuclear physics
- Interaction of radiation with matter
- Radiation and dose measurements
- Biological effects of ionizing radiation
- Gamma spectrometry
- Standards and legislation
- ALARA and safety culture

Referring to questions such as *'what is radioactivity?'*, *'how can we use it?'* and *'how can we protect ourselves against it?'*, the series starts with an introduction to nuclear physics that is then linked to a practice-oriented part on radiation and dose measurements and spectrometry. The module on biological effects of ionizing radiation presents an understanding of the effects of high and low level doses of ionizing radiation on the human body. The series is completed with a state-of-the-art overview of standards and legislation and a rationale on ALARA and safety culture, including a demo session with virtual dose assessment software tools.

When composing a custom-made program, the course could start from this basic series, but some modules may be omitted and other more specialized modules can be added upon request.

Specialized modules

The *nuclear and radiological expertise modules* are follow-up modules that fit in directly with the basic course series, but provided sufficient foreknowledge, they may be taken separately. The series addresses technical practice-oriented issues with a link to radiological protection and relies fully on the nuclear expertise of SCK•CEN. The series include amongst others:

- Transport of radioactive materials
- Radon and increased natural radioactivity
- Ethical aspects of the radiological risk
- Management of radioactive waste
- Internal dosimetry assessment from bioassay measurements
- Quality assurance in nuclear safety
- Decommissioning and dismantling techniques
- Good safety practices in controlled areas (practical training)
- Organization of emergency planning
- Misuse of radioactive materials: prevention and response (safeguards)
- Radiochemistry

Practical exercises and visits

In the course programs, lectures and practical training sessions can be alternated with visits to relevant laboratories and installations of the SCK•CEN. These technical visits enable to enrich and illustrate the participants' acquired knowledge with the practice of 'real-life' situations, as well with regard to safety culture in controlled areas, as the techniques and know-how of the applications of radioactivity as such. SCK•CEN installations and laboratories that can be visited include:

- BR1, the 'natural uranium – graphite – air' type research reactor;
- BR2, the high neutron flux material test reactor;
- BR3, the first prototype Pressurized Water Reactor in Europe, and the first now in dismantling phase;
- The HADES underground laboratory for waste disposal research;
- The radioactive decontamination wing of the medical services;
- The emergency planning and follow-up room;
- The whole body counter laboratory (antropogammametry);
- The radiobiology and microbiology laboratories;
- The radioecology laboratories;
- The nuclear calibration services.

Practical organization

The international school for Radiological Protection is based on the site of the Belgian Nuclear Research Centre SCK•CEN in Mol, Belgium. The regions of the municipality of Mol and the adjacent municipality of Dessel have a historical concentration of nuclear activities of more than half a century, hosting research, nuclear fuel fabrication and waste treatment and storage.

All installations and labs that are taken up in the list of possible technical visits are located on the SCK•CEN site. On request, the course lectures can also be organized in the SCK•CEN offices in Brussels, or at the venue of the trainees, eventually completed with technical visits to laboratories and installations on the technical domain of SCK•CEN in Mol.

Lecturers

Among the isRP lecturers are technicians, physicists, biologists, medical doctors, engineers and social scientists who all bring insights and ideas from their specific background into the course programs. As SCK•CEN staff members, they have a solid knowledge and experience in their field, and can thus directly transfer their theoretical knowledge and practical experience into the various courses.

Transdisciplinary aspects

Understanding the benefits and risks of radioactivity requires technical insight and training, but also an insight in the context and a sense for the social and philosophical aspects of the situation. isRP concentrates on how to integrate this transdisciplinary approach in education and training programs.

In cooperation with the SCK•CEN PISA group (program of Integration of Social Aspects into Nuclear Research), isRP has build up experience with the theory and practice of participation and involvement in technology assessment and has set up a course module on ethical aspects in radiation protection. On various occasions, the two groups organize round tables, workshops and focus groups with schools and local communities, and this on topics such as medical applications of radioactivity, (nuclear) energy policy and radioactive waste management.

Policy support

The implementation of a coherent approach to education and training becomes crucial in a world of dynamic markets and increasing workers' mobility. Through networking and participation in international programs, SCK•CEN contributes to a better harmonization of education, training practice and skills recognition on a national and international level.

Covering electricity production, medicine and several activities within the non-nuclear sector the spectrum of applications of ionizing radiation is very wide. Although working with a variety of responsibilities and specific professional aims, practitioners have a triple common need:

- basic education and training providing the required level of understanding of artificial and natural radiation,
- a standard for the recognition of skills and experience,
- an opportunity to fine-tune and test acquired knowledge on a regular basis.

From an executive perspective, education and training are undoubtedly the two basic pillars of any policy regarding safety in the workplace. The radiological protection rationale that serves as the basis for this policy is the same all over the world, going beyond cultural differences and disciplinary applications. In this sense, the implementation of a coherent approach to education and training in radiological protection becomes crucial in a world of dynamic markets and increasing workers' mobility.

Through networking and participation in international programs, SCK•CEN aims to contribute to a better harmonization of training practice and skills recognition on a national and international level. In this frame, specific issues of interest to SCK•CEN in general and the isRP in particular are the standard requirements for course programs and educational material, the development of transdisciplinary training programs, e-learning and distance learning, the link between radiation safety and conventional safety, the organization of experience feedback, international exchange of knowledge and experience and the sharing of lecturers, training facilities and educational source material. These are the topics covered in European networks such as EUTERP (European Training and Education in Radiation Protection Platform – www.euterp.eu) and ENETRAP (European Network for Education and Training in Radiation Protection – www.sckcen.be/enetrap2), in which SCK•CEN is playing a prominent role.

Nuclear Training Centre experience in radiation protection culture

Avadanei, Camelia[1]; Rosca Fartat, Gabriela[2]; Grigorescu, Enric Leon[3]
[1] "Horia Hulubei" National Institute of Physics and Nuclear Engineering, ROMANIA
[2] Romanian Radiation Protection Society, ROMANIA
[3] "Horia Hulubei" National Institute of Physics and Nuclear Engineering, ROMANIA

Abstract

This paper aims to present Nuclear Training Centre (CPSDN) Romanian experience in education and training in order to achieve the required competences in radiation protection with a view to future recognition within the EU countries.

Carrying further education and training activity started with almost 50 years ago by the Institute of Atomic Physics and University of Bucharest-Faculty of Mathematics and Physics, CPSDN organized over 750 programs and trained more then 18500 participants.

For each of these programs, CPSDN take into account the following objectives:

- provide adequate training for workers, for radiation safety officers and specialists
- comply with the authorities regulatory requirements
- develop syllabus for general education, specialized training courses and upgrading programs in compliance with CE RP 116 and IAEA recommendations for the groups of professionals that have been identified
- contribute to the national radiation protection infrastructure
- establish the necessary mechanism and to provide appropriate administrative support, qualified and experienced trainers, practical demonstrations and exercises
- cooperate with national organizations developing activities in the field, for example the Romanian Radiation Protection Society, University of Physics, research institutes, main stakeholders.

Being concern by the continuously improvement of its services, CPSDN applied for TUV-CERT certification for the quality management system according to ISO 9001/2000, in 2007.

Introduction

Placed between the Faculty of Physics and the National Institutes of Research and Development for Physics in Magurele Platform, Nuclear Training Centre is developing post secondary school and post university training of the personnel involved in the nuclear field and/or in related areas, contributing, through its activity, to the human resources development and to the implementation of research results of "Horia Hulubei" National Institute of Physics and Nuclear Engineering and the other institutes from Magurele Platform.

Established through the Decision of Ministers Council No. 148/1970, Nuclear Training Centre (CPSDN) assumed the organization of the post university specialization programme entitled "Courses on the Utilization of Radioactive Isotopes" (CUIR), initiated since 1956 by the Institute for Atomic Physics (IFA) in cooperation with the Faculty of Mathematics and Physics of Bucharest University.

Organized as legal unit under the authority of the State Committee for Nuclear Energy (CSEN), CPSDN has yearly developed training methods suitable for the tackled applications, by categories of degrees of responsibilities in radiological safety assurance, such as: training courses, qualification and post qualification courses, post secondary school and post university specialization courses, endorsement and accreditation courses, managers dedicated courses. Training programmes curricula were permanently adjusted both to the technical upgrading of the envisaged fields and to the growing regulatory requirements.

As an illustrative example is the programme for the non destructive examination area entitled "Industrial Nondestructive Testing", which was organized during 1973 – 1989; it has been upgraded in methods programmes, starting with 1980.

In the medical field the initial "Radioisotopes and Radiation Applications in Medicine" programme has been upgraded and several programmes were developed, such as: "Radiation Protection in Radio Diagnostic Practice", "Protection of Patient and Operators from Nuclear Medicine", "Radiation Protection in Radio Therapy Practice", etc., dedicated to physicians and/or nurses.

Required themes approach envisaged not only participants' information but also their formation as specialists in the related practice by the development of a correct understanding of the physical basic aspects and an individual attitude for the field promotion.

CPSDN constantly benefited of the scientific potential of Physics Institutes from Magurele Platform cooperating with specialists within IFA as lecturers and using the laboratories for the practical applications.

Since 1996 CPSDN has been developed its activities as a Department of "Horia Hulubei" National Institute of Physics and Nuclear Engineering (IFIN – HH).

This kind of organization facilitated CPSDN's access to the IFIN – HH laboratories and specialists.

During 1970 – 2009, CPSDN contribution for training and specialization of personnel involved in practices with radiation sources and advanced physics techniques could be resumed as it follows:

~ 780 training programmes

~ 19.000 graduates.

Main training activities

Taking as reference the technical international bodies recommendations such as ICRP publications, IAEA Basic Safety Standards, European Directives, at the national level the Law No. 111/1996 on the safe deployment, regulation, authorization and control of nuclear activities, republished, was adopted. National Commission for Nuclear

Activities Control, the Romanian regulatory and control body in the nuclear field, issued the Fundamental Norms for Radiological Safety (NSR 01) and other norms requiring the specialization of the staff at the level of operators and mainly at the level of coordinators, with responsibilities in the assurance of radiological protection for population, environment, professionals, patients in medical applications. As the radiological protection aspects were the most significant requirements, CPSDN organized different kind of training envisaging the utilization radiation sources under radiological safety conditions in a specific practice. During the last period the following training programmes are constantly developed:

1. Radiation Protection on the Utilization of Measurement Systems with Radiation Sources
   – Participants are secondary school and university graduates involved in the management or operation of gauges with radiation sources or X fluorescent analyzers, electronic microscope, etc.
   – Schedule: 40 hours, Licensed by CNCAN for the level 1 (licence at operators level)
2. Radiation Protection on the Utilization of Radiological Facilities for Packages Control
   – Participants are secondary school and university graduates operating facilities for packages control (post office, customs, airports, army, etc.)
   – Schedule: 30 hours, Licensed by CNCAN for level 1
3. Radiological Safety in Uranium and Thorium Mining and Milling
   – Participants are university graduates developing activities in the field of uranium and thorium ores mining, processing, transport
   – Schedule: 90 hours. Licensed by CNCAN for level 2 (licence for persons with responsibilities in the controlled units).
4. Radiation Protection in Radio Diagnostic Practice
   – Schedule: 30 hours (Radiologist Physicians)/64 hours (Radiologists nurses)
   – Licensed by CNCAN for level 2
5. Radiation Protection of Personnel and Patients in Nuclear Medicine
   – Participants are university graduates – Physicians, Physicists, Chemists
   – Schedule: 80 hours, Licensed by CNCAN for level 2.
6. Radiological Safety on the Utilization of Radiation Unsealed Sources
   – Participants are university graduates
   – Schedule: 80 hours. Licensed by CNCAN for level 2.
7. Radiological Safety on the Utilization of Radiation Sealed Sources
   – Participants are secondary school and university graduates
   – Schedule: 70 hours. Licensed by CNCAN for level 2.
8. Applications of Radio Isotopes and Nuclear Radiation Sources
   – Post university specialization course for coordinators in laboratories with radiation sources from all fields of activity: mining, industry, medicine, education, research, army.
   – Schedule: 180 hours. Licensed by CNCAN for level 2, all domains
9. Radiological Safety on the Utilization of Sealed Sources (SI)/Unsealed Sources (SD)/Radiation Generators (GR). Knowledge Upgrading
   – Schedule: 30/40 hours. Licensed by CNCAN for level 2.

CPSDN is developing focused programmes for various domains of the nuclear field and, consequently, it organizes, on requirement, training programmes on a certain application, according to the related requirements and competence level.

In this respect, we could mention:

– training of personnel involved in the nuclear power programme, developing activities in the design, equipment and components supply units for Unit 1 of Cernavoda Nuclear Power Plant (NPP)
– radioecology specialization programmes organized for the Ministry of the Environmental Protection
– training programmes for the personnel involved in the activities related to VVR-S Research Reactor decommissioning
– training programmes for radioactive materials carriers
– training programmes on radiological safety in radioactive logging.

Results of the last years

Synthesis of activities developed during the last years (2004 – 2009) represents a relevant example of those above mentioned.

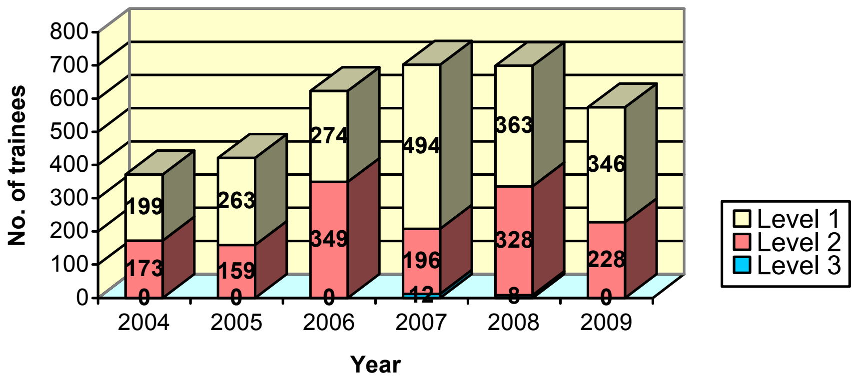

Fig. 1. Training activities during 2004 - 2009 and authorization levels.

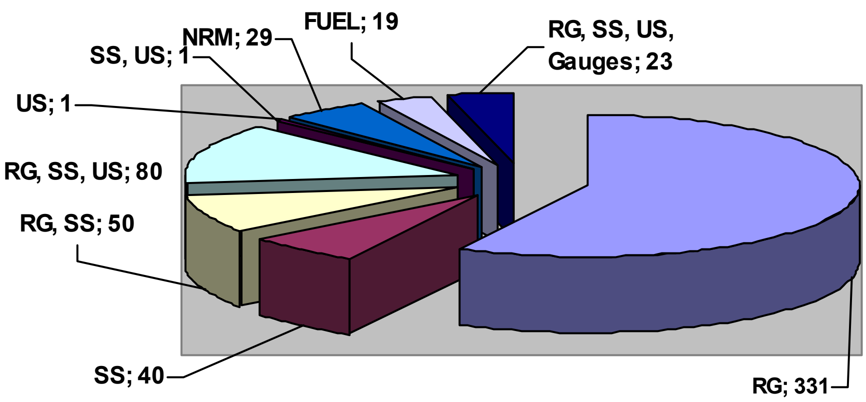

Fig. 2. Trainees and training fields in 2009.

SS – Seales Sources
RG – Radiation Generators
US – Unsealed Sources
NRM – Nuclear Raw Materials
Comparing the results, one may conclude the following:

(i) a spectacular increase in the number of trained persons in compliance with technologival development and new regulatory requirements
(ii) the number of programmes increased and the weight of various programmes reflects a RG and SS higher double specialization.

Future development of the Centre

CPSDN future objectives are in compliance with the CPSDN quality policy major objective, respectively:

Continuous improvement of training services quality by diversifying the training offers and improving services performances.

In this respect, CPSDN activity is focused on the following objectives:

- maintaining the Quality Management System certified by TÜV HESSEN
- diversification of training dedicated to radiation sources practices in the medical applications and other fields
- updating of web page for the dissemination of Centre's activities and improvement of communication with past and future beneficiaries (forum)
- development of web page for improving public information and customer relationship management
- e-learning implementation for knowledge upgrading of licensed workers
- new electronic/carbon copy training materials on radiation protection (manuals, booklets, etc.)
- development of training programmes dedicated to experts in radiation protection according to the national and international requirements.

Conclusions

- CPSDN represents a long history of training in the field of radiation protection.
- Training programmes cover a wide area according to the various requirements and applicants' needs.
- CPSDN resources benefits of continuous upgrading in order to comply with the new challenges in the field.
- CPSDN envisages being much more involved in the European programmes and is ready to develop national and European partnerships to respond to actual training needs.

The study of radon to understand the radioactivity and to know the environment

Abstract

The work describes the collaboration among many Italian research groups that pursue since seven years the objectives to make students of secondary schools aware of the problematic of the radioactivity and of the ionising radiations, introducing they, when possible, in real research activities. For reach this goal, many approaches where adopted around the main path starting with the measurement of indoor radon concentrations and continuing considering most complex themes. The project obtained very good results from many points of view, and each year many schools that carried out their activity want to insert in the experience new students and news schools joined to the project. This implied a continuous increase of the students that approach themselves these problems and, through this contact, the world of the research and of the university;

Meetings and conferences have been regularly organized, in which the students communicate to a wide public their experience; and often students, teacher or researcher are invited in several contexts to describe the developed activity. Year by year the number of proven techniques increased and from the indoor measurements carried out with passive techniques, it has been passed to the dose measurements, to the analysis of materials, to the comparison of more techniques, to the use of active instrumentation which is often home made. Starting from 2008, the study of the artificial radioactivity in environmental samples, originated by radioactive fallout, began. These results were possible thanks to the 'commitment of research groups involved. A further increase of the schools involved would entail too great an effort to sustain. To avoid that, are being prepared various kinds of materials that can help schools continue to use this useful method of investigation of science topics, usually treated just in schools, but by shifting the focus of the operation on them.

Introduction

The project "ENVIRAD-SPLASH" collects the activities carried out in the within of the National Institute of Nuclear Physics (INFN) in the field of the spread in the Italian schools of the culture of the radioactivity and involves seven groups of six Italian regions working in the field of the Environmental Radioactivity [Esposito et al., 2005]. Each group has chosen their own strategy to reach this common objective in full autonomy, but privileging always the direct and practical approach of the students to the studied topics [Balzano et al., 2006]. This has been realized of time in time with: their direct participation in the development of simple instruments, in the running of experiments finalized to the measurement of physical and/or radiometric parameters, in the observation and measurement of environmental parameters, in the participation in first person to true research activities. The umbrella of the INFN has allowed to create a network that has optimized the effectiveness of these experiences, creating in this framework easy opportunities of comparison and exchange of experiences between the investigators, the teacher and the students, with positive feedback on the result that such activity can produce.

The inclusion of the students in these activities has produced a very good success in the scholastic community, as it is testified by the great participation and by the continuous demand of new entry. Beyond these good results in the educational field, a secondary but equally important objective reached has been the knowledge of the exposure of the students to radon and its decay products, which, for the region of the South Italy, has been estimated for the first time topics [Venoso et al., 2009].

Material and methods

The general topic proposed at the beginning to the students has been that one of the natural radioactivity, in particular the program consisted in the measurement of the concentration of radon in the scholastic buildings, using passive detector techniques. This continues as the main activity in many cases, also because it answers to a requirement of monitoring and control of sensitive atmospheres, control that in many regions comes completely disregarded. Later on, with the acquisition of experience by the students, the interest, and therefore the activity fields, included also other objectives, like the carrying out of the same measurements in buildings outside of the participating schools, the measurement of the activity concentration in minerals and soils, the measurement of the dose, the practice with more sophisticated instrumentation., the evaluation of the risk depending on the exposition to the ionizing radiations.

An other topic, previewed since the beginning, has been the monitoring of the radon concentrations in the ground, using a system set to point in the frame of the experiment [Roca et al., 2006]. This experience, which started in the schools, had important developments and allowed to begin a research path that will be carried out in collaboration within the Earth Science community.

In the framework of the project, they have been developed also some kits dedicated to specific applications, like the treatment in the schools of passive radon detectors, the realization of simple alpha and gamma-ray spectrometers, built by the students, the measurement of radiometric parameters, like the lifetime of a radionuclide, or the efficiency of a detector All these activities, developed following suitable educational pathways, contributed to approach the students to arguments that the ordinary scholastic programs generally neglect and that instead they touch very actual topics. Simple numerical simulations realized using the ordinary electronic sheets have supplied a useful support to the understanding of basic concepts (comparison between behavior of the single radionuclide and that one of the relative species, analogies between various phenomena (radioactive decay and interaction of the electromagnetic radiations with the matter), difference between the interaction of directly and not directly ionizing radiations,…) or the estimate of experimental parameters, like the energy resolution of a detector, as well.

Results

In the first place it goes emphasized the dimension of the impact that the experiment had on the world of the school. A row estimate allows to count just about 120 schools for a total of approximately 2500 students directly engaged in the activities. This number can be increased of at least a factor 3-4 if it is believed next to the number of not directly engaged students but that they have been "perceived" from the job of the companions and the teachers. Also in the familiar ambit the experience of the boys had an echo that has brought back terms, data and problematic linked with the radioactivity. Probably, therefore, it is not exaggerated to say that 10000 persons, thanks to this plan, have been encouraged to make reflections more or less complex, on various aspects of the radioactivity This is a argument a lot neglected as well as in the scholastic ambit, how much in that one of the information, where it only bounces in case of accidents and comes systematically and exclusively associated to disaster and risk contexts.

Since the treatment of the passive detectors has been made following well known and correctly applied techniques, the radon concentrations measured with one year long exposures can be considered absolutely correct (on the scientific side) results. This finding is particularly important because, as it as been yet said, for South Italy, these were the first available data relative to this kind of exposure.

An mainingfull aspect of a scientific activity is the communication of the results. To aid the students in this part of their work, each year a series of annual meetings has been carried everywhere, in which the students presented very effectively the job carried out in front of hundred of their colleagues, with the participation of academic authorities, personality of the INFN, experts of the national agencies that take care of the measurement and the effects of radiations (ENEA, APAT, ISS), managers of local agencies and the participation of representatives of the press.

Result obtained within this experience have been shown to national and international conferences. Many result have been produced also in other fields, and their have consisted in doctorate and bachelor thesis, participation to various initiatives, like the International Year of the Physics, the activation of courses in the curricula of the School of Specialization to the Instruction, contacts between different thematic areas, contacts with the local agencies, that often have been transformed in full collaborations and also have some times carried financial contributions in the project.

Discussion

A careful reflection on the developed activity has allowed to evidence the following points

The plan seems to be deep-rooted in the zones in which has been lead. The schools find its follow-up natural, year after year, and therefore they encourage the participation of new students in substitution of those which complete their cycle of studies

New schools that have indirectly known the project ask to participate to it, demonstrating to appreciate the contribution that the character naturally to multidisciplinary of the dealt arguments supplies to the continuous attempt to l ink the ordinary scholastic issues, than generally are considered from the students like not communicating sections. The degree of agreement and assimilation of the new topics by the students has been also studied proposing to they some questionnaires whose analysis has supplied information useful to correct the carried out action

In these years of collaboration with the schools, they have been tried and predisposed various study patterns, informative material, many experimental projects, laboratory kit directly entrusted to the students and their teachers, and a lot of other material that has been experimented on the field and that opportunely selected and organized it could continue to produce positive results in the future.

Also the university and in general the world of the research draws advantage from an activity that serves to establish with their basin of user a stable tie, deriving from a engagement of articulated common job on two years. For this community, moreover, also good scientific data come from the work with the schools.

All these considerations have convinced to bring at the project some modifications suggested from the experience, from the availability of schools and teachers who already have lived this experience, from this historical moment, that sees reopen the debate on the nuclear energy, and with the aim to place the bases of a stable activity to put on hand of the schools also to outside of the logic of a classic experiment, which usually is strictly limited in the time. In short, a new proposal will be soon made, based on few strategic and methodological points. On the strategic side, more attention will be dedicated to organize data produced from the students campaign, extending the look also to the search in the environment of radionuclides of artificial origin and proposing in the more favourable situation (motivated teaching expert and interested classes) more complex problematic, deriving more or less directly from the job already carried out;

On the methodological side, a critical analysis of the applied methods and of the available materials will be accomplished, in order to predispose a catalogue of arguments, projects, suggestions, instruments, didactic materials, verification test, useful to aid the work of the students groups interested to start or to continue the work in the project. These instruments will be all thought for two levels: the first useful to the activity of the schools that for the first time enter in the plan, oriented to a basic formation in the field of the radioactivity; the second, made of more specific arguments, destined to students already expert (as an example students of the fifth year with already a pair of years of experience) and followed from the more able and interested teachers.

A great attention will be turned at the formation of the teachers. In fact, indispensable circumstance so that the proposed piano runs and that the offered catalogue can be useful for the students, is that the teachers are capable to ménage the activity and the instruments that are included into it. To allow the developing of these points, the redaction of an adequate and detailed program is underway.

If this result will be reached, two objectives strictly linked will be reached together. Te set to point of a method to introduce students to the study of then radioactivity and to its practice, and the possibility to obtain in this framework results that, from a scientific point of view are fully valid.

In this way, the system constituted by the researcher community and the involved schools, will produce both didactical and scientific results. This method, which produced so useful results in the field of the evaluation of the radon daughters exposure, could be expanded to study of other parameters interesting for a better knowledge of the environmental. The topics which can be studied in this way are in fact many. The first one could be the search in environmental samples of artificial raduonuclides. The presence in the environment of small ^{137}Cs concentration is well known and easy to verify and quantify. Its systematic observation could be an useful "zero point" for the environmental monitoring in view of the possible re-starting, in Italy, of the activities linked to nuclear energy production.

Conclusions

The project Envirad-Splash pursues the objective of carry out in the secondary schools an experimental activity in the field of the radioactivity, in which the students have an direct and intense implication. Many good results have been obtained up to now, both in the educational and scientific field. This activity has been organized in the framework of the activities of the National Institute of Nuclear Physics and it has been designed as an normal experiment, with a project phase, a run phase and a conclusion. The good reached results have suggested to go over this schema and the experiment has enjoyed more than one extension. To consent to other schools to have such opportunity, a method which could allow to develop this activity also out of a normal experiment is under study.

Abstract

In Italy the "nuclear issue" was for a long time a taboo. A lack of information will lead to unwarranted fears, which will distort the risks we take in everyday life. In other words the subjective perception (sensation) of the risk doesn't correspond very often to the objective and real risk of human activity. In particular, our perception of radioactivity is often misleading because of the lack of accurate information. A way to approach this theme to make the public more trusting of nuclear issues is to discuss radioactivity and ionizing radiation starting from young students. An experimental activity that involves secondary school students has been developed. The approach is to have students engaged in activities that will allow them to understand how natural radioactivity is a part of our everyday environment.

On this basis started a project that gave students and teachers of the Italian secondary school system the opportunity to discuss and to experiment with nuclear related experiences. The students were provided basic but correct information and with the added benefit of being able to experiment. The core idea is that: a) to provide the students a furnished laboratory at their school so that they can measure the natural component of the radioactivity that surround us. In this exercise the measurement of the ^{222}Rn concentration is particularly well suited b) to show the different types of radiations including ionizing radiations and how they each relate to the other; c) to demonstrate how easily ionizing radiations can be measured; d) and to prove the fun a student can derive from discovery and detection of ionizing radiation in the environment.

One other interesting outcome has been that the measurements have been made in accordance to Italian radiation protection law. Therefore, the data collected could be used to determine the radon concentration mapping of the school buildings.

RadiaX – Radiac simulation for first responders

Gårdestig, Magnus; Halse, Tore; Pettersson, Håkan B. L.
Radiation Physics, Div. of Radiological Sciences, Dept. of Medical and Health Sciences, Linköping University, SWEDEN

Abstract

As a complement to the training of first responders in their preparedness for accidents and incidents involving radiation, a radiac simulation, called RadiaX, was developed.

RadiaX has a threefold purpose; to teach (i) the handling of specific instruments, (ii) the proper procedures in missions and (iii) basic principles in radiation physics and radiation protection. The simulation is developed as a modification of Half-Life 2, a famous computer game.

Introduction

Swedish preparedness for accidents and incidents involving radiation includes equipping and training first responders with radiation indication instruments. The intensimeter SRV-2000 (Rados Technology Oy, Finland) was introduced in Sweden in 2001 by the Radiation Protection Authority (SSM). 1200 instruments were distributed to about 300 fire brigades as well as 300 municipalities and other organisations involved in the national preparedness organisation. The Swedish Civil Contingencies Agency (MSB) provides annual training on the SRV2000 for all Swedish municipalities and county councils. The training includes a basic education about ionizing radiation and threats (MSB 2007). The missions are predicted to include evacuation, triage with subsequent personal decontamination, establishing boundaries of the safety and security perimeters and, in extreme situations, to secure and move sources (Runesson 2003, MSB 2008). Currently a new, complementary intensimeter with an optional gamma/beta probe is placed in service at fire brigades, emergency rooms and police departments. Training is important for building confidence in the ability to solve the task once an incident occurs, regardless of the likelihood of occurrence. The lack of training instruments and the difficulties and costs of safe exercises on dedicated training areas result in a need for a complementary training solution.

Computer games with an intention to convey to the gamer real life useful skills are categorized under many various labels with even more definitions. One popular label is “Serious Game”, somewhat simplified defined as a game with the goal to educate rather than entertain. A serious game has rules, objectives, and motivated consequences of the player’s actions. (Michael, Chen 2005). Yet another label is “Lightweight Simulation”, which refers to computer-based training systems designed to teach specific mission skills (Alexander et al 2005).

RadiaX has a threefold purpose; to teach (i) the handling of specific instruments, (ii) the proper procedures in missions and (iii) basic principles in radiation physics and radiation protection. Therefore it can fit both the labels mentioned above.

The gamer, the user of RadiaX, is henceforth denoted as the trainee and RadiaX is in the same way simply referred to as the game.

Material and methods

To provide an easily accessed and widely distributed training system the game is made as a modification based on an existing game, Half-Life 2 (HL2). Development cost and time is cut by starting from a released game and modifying and reusing modules from the original game, only adding the needed code for radiation simulation.

HL2 is a commercial computer game of the type FPS (First Person Shooter). HL2 is developed by Valve Corporation (Valve Corporation, USA) and was voted Game of the Year 2004 in several publications and engages over 10 million players. The game uses the 3D game engine Source and a modified version of the Havok physics engine. Utilizing the Source SDK user modifications (mods) are made possible and can be distributed to any holder of a license for HL2.

The levels are created in Valve Hammer Editor, included in Source SDK. It is the official Source mapping tool, and once mastered it is a powerful tool.

Creating levels requires only minor programming experience, and is intended to be attainable by the training instructors for ad-hoc or local debriefings and demonstrations. The existence of a mature content creation tool chain is a major factor in deciding to base a game on an existing engine instead of developing one from scratch.

The radiation model, including radiation sources, background radiation, photon attenuation and dose accumulation (for the trainee and instruments independently), is added to the engine using C++, compiled with Microsoft Visual C++ 2005 Express.

The ambient dose equivalent rate (ICRU 1998) at the trainee's position, $\dot{H}^*(10)_{trainee}$, is calculated momentarily as a function of gamma-ray constants applied to specific ideal point sources (Tschurlovits et al 1992), the distance (inverse-square law) and the attenuation in different materials in the pathway between the radiation source and the instrument (Beer-Lambert law). The calculations are formalized in equation 1 below. The gamma-ray constants, Γ, are given for 1 meter source distance.

$$\dot{H}^*(10)_{trainee} = \Gamma \cdot \frac{A \cdot e^{-\mu \cdot x}}{d^2} \quad [\mathrm{mSv/h}] \qquad (1)$$

where Γ = gamma-ray constant [mSv m^2/MBq h]

A = source activity [MBq]

μ = linear attenuation coefficient of attenuation material [cm^{-1}]

x = material thickness [cm]

d = distance between source and receptor [m]

The existence of attenuating material and its thickness is determined by tracing rays from the radiation source to the specified measurement point. Attenuation coefficients (Hubbell 1982) are chosen from an internal table depending on the material used (e.g. wood, concrete) for each piece of intersected level geometry (set by the level designer during level creation). This allows the game to use HL2's existing library of materials, and also allows levels to be designed without the level designer having any knowledge of radiation physics. Instead, attenuation accuracy simply becomes a function of mapping accuracy.

Dose accumulation is modelled through summation of discrete dose quanta. At fixed time intervals, for each radiation source the current dose rate is calculated at the trainee's position and the corresponding dose quantum is added to the trainee and to each simulated instrument the trainee carries and have switched on. This is done independently, the actual dose received and the instrument-measured dose may be different. Due to the Source engine design, the maximum attainable frequency at which the dose quanta can be calculated is 50 Hz. However, since the attenuation path calculation is computationally time demanding, the dose accumulation update frequency is intentionally kept lower, at 20 Hz, to keep the systems requirements down.

The radiation sources placed by the level designer are ideal point sources that are invisible and have no physical interaction with the world. They can however be coupled to other physical game objects, allowing movable, fully interactable radiation sources using Source's built-in rigid-body physics engine. When placing radiation sources, the level designer selects a nuclide name (e.g. Cs-137) from a list and specifies an activity (Bq) as seen in Figure 1. Appropriate gamma-ray constants and attenuation coefficients are retrieved from an internal list automatically by the game.

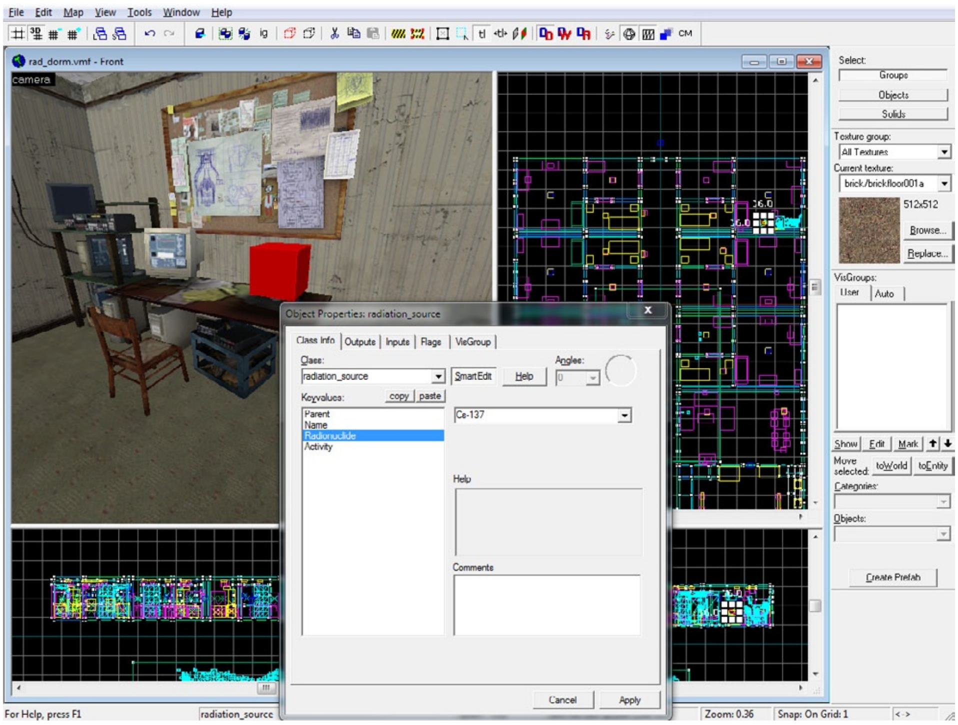

Fig. 1. A screenshot from placing and editing a radiation source using the mapping tool Hammer. The radionuclide (here Cs-137) and its activity is specified in a dialog window. The position of the source is shown in the floor plan (a white square in upper right corner) and in the camera view as a red box. During live training the source itself is invisible but coupled to any other object.

Background radiation is simulated uniformly across each level with stochastic fluctuation around a set mean value.

In accordance with the instrument specifications, inaccuracies are added to the calculated dose rate values, and time constants as well as delays are applied. Alert and alarm signals and adjustable level functionalities are implemented.

The dose rate error is modelled as having both a dose rate-invariant (absolute) component and a dose rate-relative component. This gives good error fidelity under both low dose rates, when the absolute error dominates, and high dose rates, when the relative error dominates. The errors are assumed to be normally distributed, with the deviations set on a per-instrument level.

Levels can be designed to present the trainee with a short in-game debriefing upon conclusion of the mission. This takes the form of a pop-up window showing, among other things, the trainee's accumulated dose during the mission, together with easy-to-understand information of the received dose. This information, e.g. “equivalent to x months' worth of background radiation”, is designed to help the trainee to gain an intuitive understanding of radiation doses and to gauge the real-life risk involved in the simulated tasks.

Supporting tools such as a distance measuring device and a position marker (paint spray can) is added to the arsenal.

The game is complemented by two separate user manuals. The first is intended for the trainee and includes installation manual, optional game settings, the game commands for movement and instrument action and a brief background. The second manual is intended for instructors, extended with more in-depth information (e.g. level design, radiation protection, instrument manuals and dose evaluations).

Results

Specified or observed features of the instrument SRV-2000 are implemented. Each setting and mode is accessed through standard keyboard and mouse by the corresponding buttons on the instrument as in real life. The SRV-2000 is always virtually held in the left hand (Figure 2) in front of the trainee, most of it visible at all times (buttons and display).

Fig. 1. A screenshot from RadiaX. The SRV-2000 is virtually held in the trainee's left hand and the buttons are selected using specified keys or mouse buttons. Each button is highlighted for a second when selected.

Table 1. The present set of game levels with a short description of their contents and purposes.

Game level	Brief description	Learning goals
Exercise: Basic motion	Obstacle course	Move around in the game environment using keyboard and mouse
Exercise: Characteristic features of SRV2000	Pinpoint hidden source among 17 boxes using different indicators	Start-up, buttons and the characteristic time constants of the SRV2000
Exercise: Basic radiation protection, part 1	Approaching a radiation source and observe the inverse-square law,	Fundamental principles of radiation protection: Distance
Exercise: Basic radiation protection, part 2	Different materials of different thickness between source and detector	Fundamental principles of radiation protection: Shielding
Exercise: Basic radiation protection, part 3	Accumulated dose during exercise and time spent.	Fundamental principles of radiation protection: Exposure time
Scenario: Dorm	Suspected hidden source for antagonistic objectives in student dorm	Search for radiation source
Scenario: Warehouse	Incident in warehouse with radiation sources in stock. In-house personnel remaining.	Search for radiation source, evacuate victims, establish boundaries of the safety and security perimeters using distance tool and marker.

The game levels are divided into exercises and scenarios. In the exercises the trainee is guided through the course and the radiation source is often visible. The exercises are either specific for SRV-2000 with the learning goals to teach characteristic features of the intensimeter, or general with the learning goals to teach fundamental principles of radiation protection.

In the scenarios the trainee is expected to solve tasks based on a specific scenario. Current scenarios (Table 1) are a demonstration of the capabilities of the game, while the exercises are general for the game or specific for SRV-2000.

Discussion

A simulation tool is a complement to live training by offering possibilities for debriefing, classroom as well as individual training, demonstration and increasing the repetition frequency as well as the numbers of trainees. Using existing standard PCs the training is cost effective and easy to distribute. This increases the availability of the training and might inspire to "off-hours" individual training.

The learning goal to teach radiation protection includes the awareness of accumulated dose levels in certain circumstances. The doses are maybe lower than the trainee first expects.

Extensive testing is required during development to ensure accurate reproduction of instrument behaviour, as simply reading the specifications might not be enough to cover all cases. If the real-life behaviour of a device differs significantly from the simulated behaviour, simulator training might have a detrimental rather than beneficial effect.

Further development

At present only one specific intensimeter is implemented. MSB and the National Board of Health and Welfare together with SSM have recently distributed a complementary instrument with a gamma/beta probe, the Intensimeter 28/T, a slightly modified AN/UDR-13 (Canberra Industries Inc, USA). The Swedish national preparedness organisation under SSM holds a wide and diverse range of instruments. The intensimeter 28/T particularly and many other instruments are justified to add to the arsenal available to the trainee in the game. This extends the target group to include customs staff, medical staff as well as radiation protection experts.

Further development (table 2) aim to include all scenarios listed in table 3. Exercises and tutorials supplementing new instruments and scenarios add to the table. Demonstration and reassess levels of occurred incidents or established training scenarios are of interest.

Giving feedback, perhaps the most important part, is a demanding and often neglected part of the preparations of a radiac exercise. Giving the mission of each game level scenario in-game and presenting the result, e.g. dose, time and effectiveness, to the trainee are important parts of all future game levels.

Table 2. A selection of intended future additional set of game levels with a short description of their contents and purposes.

Game level	Brief description	Learning goals
Exercise: Characteristic features of Intensimeter 28/T	With and without probe	Start-up, buttons and characteristics of the instrument
Tutorial: Basic body scan	Demonstration of body scan procedures	Scan strategies
Exercise: Basic body scan	Body scan with visible sources	Practice scan strategies
Scenario: Decontamination	Body scan and triage	Practice scan strategies for decision support
Scenario: Transport accident	Transport accident involving radioactive material and contaminated victims and bystanders	Search for radiation source, evacuate victims, establish boundaries of the safety and security perimeters. Triage.
Scenario: Urban RDD	RDD in an urban environment	Life saving prior to radiation risk

Table 3. Predicted scenarios (TMT handbook 2009, IAEA 2006).

Suggested scenarios
Radiological Exposure Device (RED)
Radiological Dispersal Device (RDD), “Dirty bomb”
Attack on, or incident with transport of, radioactive material
Contamination of food and water supplies
Attack on, or incident in, nuclear installation or installation containing radioactive material
Improvised Nuclear Device
Uncontrolled dangerous source

Conclusions

RadiaX is a novel complement in radiac preparedness training. It offers easily distributed and changeable training in a non-lethal environment.

Radiac training is well suited for simulation when the fidelity of the instrument is the primary focus and other simulations secondary, since the radiation does not need any tactile or visual simulation.

RadiaX has been demonstrated to training instructors and first responders and was well received.

Further development, with added instruments and scenarios, and evaluation of the training transfer is in progress.

Radiological emergency exercises facing the collaboration issue of different response authorities

Östlund, Karl[1]; Samuelsson, Christer[1]; Finck, Robert[2]
[1] Lund University, SWEDEN
[2] Swedish Radiation Safety Authority, SWEDEN

Abstract
In Sweden, two large radiation emergency exercises with international participation were held in 2001 (Barents Rescue) and in 2006 (DEMOEX). Experiences from these exercises showed that conducting "close reality" emergency situations utilizing real radioactive sources was very valuable in the training of radiation experts and first responders. In the years 2007-2009 this concept of combined training was further developed in a set of smaller-scale exercises called Lärmät. The concept was to break down the large scale scenarios to pieces and learn its radiation protection difficulties in detail. This showed to be a successful and appreciated way of conducting exercises for Swedish specialists. The radiation specialist, however, will never have free hands to handle the situation in case of a malevolent act involving radioactive material. The situation would involve combined actions of several authorities. Therefore, Sweden's combined radiological emergency response has an urgent need for exercises where authorities work closely together across authority borders. This issue was specially addressed in the exercise Lärmät 09. Teams were put together from radiation protection specialists, rescue services, police, the National Laboratory of Forensic Science, The National Board of Health and Welfare and the Swedish Customs. The idea was to let people from each profession present their view (in each different scenario) of the situation in order to solve it safe and not destroying potential evidence. In Lärmät 09 six different scenarios were built with real sources and inspired from real radiation accidents. The radiation doses to the participants were kept low by radiation protection planning and technical arrangements. This paper presents the Lärmät 09 scenarios and lessons learned from this joint "close reality" exercise.

Introduction
Real radiation emergencies are extremely rare and experts and first responders only way to improve their practical and organisational skills are to expose them for unknown radiation scenarios. Training the Swedish specialists in radiation scenarios of different kinds has been one primary task for the Swedish Radiation Safety Authority (SSM) since 2006. This suite of exercises originate from the large and appreciated exercise Barents Rescue in 2001 and was followed by DEMOEX exercise in 2006, (Finck et al.

2008) which has been viewed as the starting point to the yearly training program held by SSM. The training is mostly as close to a real radiation emergency as practically possible without jeopardizing full safety and control.

Prerequisites for the exercises

The National Laboratory of Forensic Science (SKL), gave a brief lecture in crime scene behaviour. This was done to add the dimension of radiological difficulties at a crime scene investigation. The Swedish customs has participated in the radiological emergency exercises DEMOEX (2006), Lärmät 07 and Lärmät 08 with success and shown that also non-specialists benefit from this type of exercises. The focus of Lärmät 09 was to train small teams of radiation specialists, first responders and customs officers working together. The disparate background of the team members makes this a challenge. The participants were divided into teams with two radiation experts, two first responders and one customs officer in each team. All medical radiation physicists and persons working within the field of radiation protection were designated as radiation experts. In each team a radiation expert was selected as a team leader and as responsible for the radiological safety of the team members. It should be noted that the radiological issues were the main goal of the Lärmät 09 exercise. The drill of first responders and laymen came secondary.

The exercises

Activity	Container	Dirty Bomb	Strong Source	Bomb Workshop	Indoor malev. act	Contamina-ted person	Mobile Syst. Disp.
No. of Teams	12	6	6	12	12	12	12
Tot. No. Particip.	60	30	30	60	60	60	60

Fig. 1. Showing the number of teams exercised at each activity and number of exercised participants.

1. Container filled with contaminated scrap metal

1.1 Objective

In the last few years Sweden have had several incidents where companies who recycle scrap metal has caught radioactive material in their portal monitors. The objects has been of different kind, such as water filtration units with accumulated NORM and thorium treated air plane engine parts. The wide range of what might be found and the lack of experience how to safely and effectively sort out the radioactive objects from the rest of the scrap metal, called for a controlled exercise.

1.2 Exercise setup

The task for a team was to locate and identify the radioactive material inside the container using hand held instruments of a mobile emergency preparedness specialist team. The container was filled completely with approximately 20 tons of scrap metal. The inactive metal parts, the bulk, was so large in size and weight so moving them by hand was a very ineffective, if at all possible, way to proceed. An excavator, including operator was at hand with a scrap metal processing gripper. The container was prepared with 7 sources of different kind. A flight engine part containing thorium, a stainless pipe coupling contaminated with Co-60, smoke detectors of different kinds and instruments with illuminated paint containing Ra-226, were some examples of sources used. In order to complete the exercise in 3.5 hours the team had to plan their work efficiently. The team was informed that they were responsible for the radiation safety of the person operating the excavator.

Fig. 2. Left picture shows the container before activity start, right picture shows a team in action searching for sources or contamination.

1.3 Results

Several teams expressed their unfamiliarity with this type of scenario. In general the teams didn't move the active metal parts away far enough from the container and therefore had problems with finding radioactive objects remaining in the container. Participants also lacked the ability to explain to the operator what they wanted to be done. Some groups didn't have the correct instrumentation for the task. All sources were found for all 12 teams except one, which missed one NORM object. A few teams found the smoke detectors just by eye. The gloves used by the teams showed low level contamination of NORM activity, such as Thorium, after the completion of the exercise.

2. Dirty Bomb exercise

2.1 Objective

A dirty bomb is a device with the purpose of dispersing radioactive material in the blast. A dispersive device will most certainly have great impact on society infrastructure even if the radiological harm to people is negligible. As emergency teams have to handle a dirty bomb situation properly, training is needed.

2.2 Experimental setup

The scenario was built inside a military Operations Urban Terrain (MOUT) called SIB belonging to the P7 tank regiment outside Revinge in the south of Sweden. A blown up car was placed in a street crossing and the close surroundings of the car were fenced off to ensure radiation safety. Entering into the marked hot zone was strictly forbidden for all participants. A well collimated Ir-192 source of approx. 440 GBq (12 Ci) with its radiation field pointing upwards was placed on the floor in the car, producing only scattered photons and sky shine. The dose rate around the vehicle was under 0.2 mSv/h and inside the fenced off vehicle close to the source were about 1000 times higher.

On the ground, 35 hot particles in the form of small contaminated metal plates were placed to simulate debris.

Fig. 3. Left picture showing a team assessing the radiation field with the supervisor being the person i yellow to the left. Right picture showing the optimal geometry in search of ground contamination and hot particles.

Also two larger contaminated fragments of metal were placed on the ground close to the vehicle to indicate a blown source container. The activities on the small plates were 1-3 MBq and on the two larger fragments 300 MBq each. The radionuclide used in this exercise was Zr-89 with the half life of 78.4 hours. This radionuclide is both a positron and a gamma emitter and is produced at the cyclotron at Lund University Hospital. The purpose of the Ir-192 source was to create a radiation field that strikes out portable spectrometers by producing very high dead time. This forced the team to take samples for analysis, when the fragmented sources were to be characterized.

2.3 Results

One participant was slightly contaminated on the left shoe. One team had to be told that there were radioactive fragments on the ground. One team missed to equip the person closest to the car with a dose rate instrument at all times. The same team took it for granted that the radiation field levels would stay static in time. Problems with documentation during rain showed need for water proof writing pads and water resistant laptops. Few of the teams had the experience of taking smear samples in practice. The portable instrumentation was not well suited searching of fragments on the ground.

3. Strong source exercise

3.1 Objective

Small and very strong radioactive sources exist in society. Very strong sources impose special problems which are rarely dealt with in exercises. The objective of the strong source exercise was to familiarize the participants how to assess a strong source situation.

3.2 Experimental setup

Both geometry and source strength was disclosed to the teams before exercise start. A Co-60 radiographic source of 385 GBq (10.4 Ci) was used as the ”strong source” and was collimated to a cone beam exiting along the earth surface. The source was placed 200 meters in at one end of a large (400x1200m) grass field.

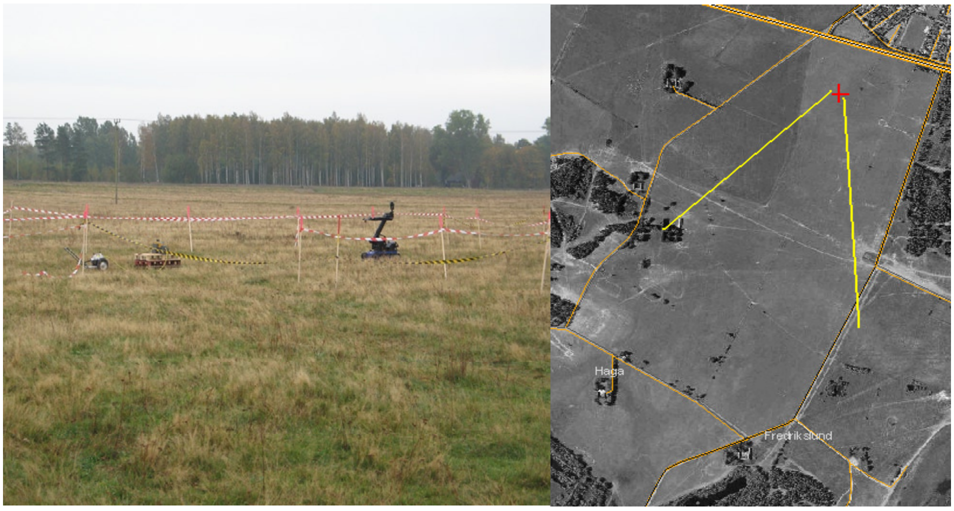

Fig. 4. Left picture showing the police bomb robot closing in on the cobalt source, right picture showing the extent of the radiation field.

Approximately 20 cm of lead and a 4 cm thick tungsten collimator was used as a radiation field delimiter to achieve the desired field geometry. A dose meter with alarm capability was placed close to the shield to indicate if the source got stuck on the way to the collimator or shield. To be able to practice measurements in a safe way, warm- and hot zone was marked by coloured fence posts, positioned at the dose rate levels of 100- and 500 microsievert an hour. The dose rate level was also written on the fence posts for clarification. The participants was allowed to work freely outside warm zone and allowed inside ”warm zone” delimiter only by making a valid request. No participant was ever allowed inside the fenced off ”hot zone” for safety reasons.

3.3 Results

One person chose not to participate in this exercise. The police bomb robot was granted access to the hot zone for practising measurements and also allowed to move freely inside the fenced off area. The Police bomb squad need more practice and guidance to be able to function in situations like this. Almost all teams requested to enter warm in order to test their instrumentation.

4. The Bomb Workshop exercise

4.1 Objective

09 included a exercise scenario illuminating how to preserve forensic evidence at a crime scene contaminated by radioactivity. Earlier exercises have included several

scenarios with gamma emitting nuclides as radioactive contaminant. This time a scenario including only a pure beta-emitter was chosen. The cause for this was mainly to show and train the participants in the complexity of estimating activity and extent of the contamination when only beta sensitive instruments were the proper choice.

4.2 Experimental setup

Two parallel rooms separated from each other where set up with covered windows, a workshop table carefully covered with construction plastic film, necessary tools to construct a explosive device and plastic film covered floors.

Fig. 5. A participant working on mapping the contamination in the Bomb Workshop activity.

Two teams worked on the scenario in parallel without communicating with each other. Contamination was of very low grade but carefully calculated and tested not to give any indication of radioactivity on gamma-only instruments. The nuclide used for this exercise was Y-90, a perfect simulant for the more common Sr-90. The 1.8 MBq/l water solution created a surface contamination of about 10 Bq/cm^2. Invisible, but radioactive, footprints were placed on the floors. On the tables radioactive fields the size of a hand was created to simulate grabbing marks. Not all tools were contaminated and surfaces not likely to have been used were clean.

4.3 Results

Two teams used only gamma detectors when entering the scenario the first time and one of these teams had contaminated members on exit. A couple of teams found it difficult to estimate activity from the beta measurements. Several participants found it hard to do quality measurements with protective suits and mask. Beta instruments with long time constants were hard to use in this scenario. All teams were not properly prepared to convert a cps-value to Bq/cm^2. No instruments were contaminated.

5. Indoor malevolent acts

5.1 Objective

This scenario was compiled out of two different activities introducing different problems. The ”School” scenario was based on a malevolent act playing with the thought of one person wanting to harm school children by placing gamma emitting sources in the school room. The ”Home” scenario presented a house in which a internally contaminated person had stayed. The objective in both scenarios was to assess the radiation fields and contamination levels. The teams should gather information through measurements and estimate radiation doses in both situations.

5.2 Experimental setup

The ”School” scenario was set up in a big room pretending to be a classroom with four tables and eight student chairs. In front of the classroom a teacher’s desk were set up to add realism. A fairly strong Co-60 in the cellar underneath the classroom enhanced the radiation level in the room to several hundred microsievert per hour. Additionally, four Co-60 point sources were located in the classroom underneath the chairs and tables. The ”Home” scenario was built around a home environment. A room with a kitchen, stairs, dinner table and a bed was set up to simulate a home situation. In order to make a traceable chain of contamination, the water was chosen to be the carrier of the activity. Therefore, all things that could have been in contact with water had to be carefully prepared to fit into the scenario. The nuclide used was I-131. Water I-131 concentration in both the coffee maker and sink had to match the activity concentration and the total activity in the earth of the potted plants as well. Also the bed and a reading chair were contaminated in a way to lead the teams to the conclusion of household water as the course for contamination.

Fig. 6. Left picture showing a team working in the ”Home” activity. Right picture is a view showing the farm house to the right where the ”School” activity was held.

A faked well was prepared outside the building in case the teams would search for a water supply in the close proximity. By placing a 30 MBq Iodine-131 point source in the well, it could be detected from a distance and simulate a real well full of contaminated water. A real sample of contaminated water (1.8 MBq/l in a 250 ml plastic can) was also placed in the faked well. The idea was that the team should use the activity concentration of the well water as a possible starting point for dose assessment calculations.

5.3 Results

In the school scenario several teams had difficulties locating the four point sources as they were obscured by the gamma field from the cellar source. A few teams reported wrongly a surface contamination in the classroom. Two out of six teams found all four point sources and completed all scenario tasks in a correct way.

In the home scenario all teams found the source of contamination and found the water sample in the faked well. All teams kept their members uncontaminated and several samples were taken and analysed. A few teams used their mobile spectrometer to estimate the I-131 water concentration. All teams collected enough information and did correct measurements to be able to correctly estimate the internal radiation dose.

One team showed only a calculation error which presented an accumulated dose 1000 times to low.

6. Mobile gamma system display exercise

6.1 Objective

The development and new commitment made by the SSM to enforce the radiation protection nationwide with new modern equipment, has accelerated the development of methods and new custom made software platforms. To show the first responders what instrumentation and equipment Swedish specialists use, a demonstration type of mobile gamma search was set up.

6.2 Experimental setup

Several systems from the Swedish customs, SSM and National emergency preparedness laboratories were set up aside a straight road to monitor passing cars. Several packages were prepared in advance with manmade radionuclides and some packages also included natural occurring radionuclides. Examples were potassium-40 and uranium ore. These packages were placed in one of four cars passing the measuring teams. The teams had to pinpoint any car containing radioactivity and disclose the radionuclide by means of gamma spectrometry. To enhance the test several cars passed the teams with blank packages. The speed of the car convoy was also varied in order to spot any differences in the ability to detect the content.

6.3 Results

The non-specialists found it hard to in some cases to decide with certainty if a weak source had passed the detector or not. It was not clear to all that mobile detection units (cars) often have different sensitivity for sources passing either on the left or right side of the vehicle. Some participants believed that this exercise was less relevant to them.

7. Contaminated person

7.1 Objective

In a radiological accident situation involving injured people the ability to do a quick, correct search for internal or external contamination is essential. In this exercise the goal was to educate the participants how to handle contaminated persons, in this case a contaminated dummy doll.

7.2 Experimental setup

The teams were given a pre-prepared doll with contamination in the hair, on the clothes, in the lungs and a flesh wound containing a hot particle. The activities used were 6, 60, 0.2 and 30 MBq in the previous given order. The radionuclide used was Tc-99m with 6.05 hour half life. The doll had to be undressed outside in a fenced off area and brought inside on a stretcher. The teams should estimate the extent of the contamination and make a report on their findings.

7.3 Results

The activity was much appreciated. The teams had problems with finding the lung contamination since the other contaminations dominated instrument response.

8. Follow up meeting

A vital and successful part of Lärmät 09 was the follow-up meeting two months later. The participants were asked to hand in all results and calculations obtained at each scenario prior to this one-day meeting for compilation. Time was also given for general discussion regarding lessons learned during Lärmät 09.

Discussion

The general response from the participants was very positive. All participants were asked to express their views on the different tasks by completing a questionnaire before leaving each scenario. In the Dirty Bomb and School exercises the standard gamma search instrumentation for Swedish teams was not less useful in the high "background" levels encountered. One team measured and mapped dose rate levels around the Dirty bomb vehicle and thereafter dose rate instruments were considered of no more use when working in close proximity to the vehicle. Acting as if a situation is static in radiation dose levels, thinking there is no need to carry a dose rate meter violates the plan of radiation protection optimization.

The Strong Source exercise showed the need for collaboration between specialists and police bomb squad units. The units in Sweden have different equipment and robots. Distance equipments and robots are indispensible dealing with very strong radioactive sources, but further training is necessary in this field. A part of the strong source exercise, the sky shine geometry, was postponed to a future exercise due to time constraints and the complexity of such a radiation field. The lesson learned from the Bomb Workshop scenario was the preconceived assumption that a gamma detector is enough, scanning a contaminated room, must be abandon.

Since several participants were contaminated more training in contaminated environments is needed. No instruments were contaminated. This showed that the participants handled their instrumentation carefully in this aspect, though, better instrument contamination protection was called for by the participants.

In the School exercise all teams made a survey outside the house before entering the building. Based on this survey most teams suspected a strong source in the inaccessible cellar compartment. Only a few teams asked for better search instruments, a Saphymo was at the teams disposal on place, and did not realized that their standard GR-110 and GR-135 instruments were less adequate in the high dose rate levels in the class room. In the Home scenario no instrumental shortcomings were recognized. The erratic dose calculated by one team was later corrected. All teams found the contamination chain and did a water I-131 concentration measurement which all gave correct results. A few teams who measured their samples in their mobile laboratories on site showed the same accuracy as others.

The Mobile Units Display exercise showed the need of trained specialists to discover sources giving weak signal in the gamma detection systems. The relevance of such a activity was discussed and was considered to be good general knowledge and adding dimensions for also non specialists, making them more all-round. The lack of sensitive neutron instrumentation in the National Radiation Emergency Preparedness Organisation was also highlighted.

The Contaminated person exercise introduced the participants on problems with measuring a contaminated person with different types of contamination. The simulated hot particle made it hard to find the much weaker lung contamination.

In general, in a real radiological event, the specialist upon arrival must gather information quickly to compile a first situation estimate and communicate this to the responsible authority. Lärmät 09 revealed that specialists in several cases didn't fulfil this role adequately. In order to function properly the specialists need more education and training. During the exercise the teams collected measurement data and samples in 3.5 hours, the predefined time slot chosen for all scenarios. In a real malevolent situation it can be expected that the demand from media, press and authorities, after such a time interval or less, are strong for a first verbal report from the radiation specialist. Details and calculated doses were later presented by each group during the follow up meeting. This meeting was much appreciated and gave participants and planners a sense of what to expect in present time and what field to focus on for improvements. The issue of effective surveying and reporting is recognized as very important. This will be addressed in Lärmät 10, which is to be held October 5-8, 2010.

Conclusions

The involvement of observers from SKL came out successfully and added new perspectives how to behave at a radiological crime scene. The set of Lärmät exercises has shown to be a good test and indicator of present status of the Swedish emergency preparedness organisation. It is believed that the Lärmät concept of small yearly exercises is a productive way to ensure ability and also control the status of a chosen radiological emergency organisation. The radiation protection planning and optimization kept the radiation doses below 100 microsievert for all participants during Lärmät 09.

New educational technique using radiation sources fabricated from chemical fertilizers

Kawano, Takao
National Institute for Fusion Science, JAPAN

Abstract
Potassic chemical fertilizers contain a small amount of potassium-40, which is a naturally occurring radioisotope. The potassium-40 emits beta and gamma radiation. Therefore, potassic chemical fertilizers are often used for classroom demonstrations of natural radiation sources along with kelp, mushrooms, sinter, and others.

A previous study proposed a new educational approach to enhance understanding of radiation that is naturally emitted from potassium contained in fertilizer. This educational technique involves the use of radiation sources fabricated from several chemical fertilizers containing different amounts of potassium. In the present study, the educational approach was evaluated using five disk-shaped radiation sources fabricated using a compression and formation method from five chemical fertilizers containing potassium from 5 to 50%. The technique was evaluated by examining the relation between radiation strength (radioactivity count emitted from the fabricated source) and potassium amount of the raw fertilizers based on 10- and 1-minute integration times. Radiation strength was directly related to potassium amount, indicating that the substance emitting radiation must be potassium.

1. Introduction
Many materials on earth contain naturally occurring radioisotopes such as ^{40}K, ^{232}Th, and ^{238}U that release radiation. However, many people do not realize that such naturally occurring radioisotopes exist. Therefore, radiation education is important to improve understanding of the existence of natural radioisotopes and radiation. Chemical fertilizers containing potassium are often used for this purpose in educational courses on radiation. Naturally occurring potassium consists of three isotopes: ^{39}K, ^{40}K, and ^{41}K; the ^{40}K naturally emits a 1.33-MeV beta particle and a 1.46-MeV gamma ray.

A previous study described development of a compression and formation method for fabricating disk-shaped radiation sources from raw materials such as potassium chloride, kelp, chemical fertilizer, and sinter, which contain naturally occurring radioisotopes. The fabricated natural radiation sources were examined for educational use in a radiation protection course. The results indicated that the natural radiation sources were easy-to-use educational tools for demonstrating the principles of radiation protection relating to time, distance, and shield thickness.

In the earlier study (Kawano 2010), the compression and formation method was applied to 13 commercially available chemical fertilizers containing different amounts of potassium. The fabricated disks are natural radiation sources, referred to as chemical fertilizer radiation sources or fertilizer sources. The suitability (size, weight, solidness, and smell) of the 13 fertilizer sources as educational tools for radiation education was examined. Results indicated that all of the fertilizers but one could be used as natural radiation sources. The one exception was too fragile to fabricate into a disk using the compression and formation method. The radiation strength (count rate) and potassium content of the other 12 fertilizers were measured, and the relation between potassium content and radiation count was examined. Results showed that a linear relation existed between the radiation count emitted from the fertilizer sources and the percentage of potassium in the chemical fertilizers. This linear relation demonstrates that the count rate corresponds to the percentage of potassium. Therefore, a new educational technique using the fertilizers can demonstrate that the radiation emitted from the fertilizers can be attributed to the potassium contained in the fertilizer sources. However, these results were obtained by compiling all of the data obtained by 12 fertilizer sources; in some cases the relation between radiation count and potassium percentage was inverted. This inversion might be caused by differences in components other than potassium, nitrogen, and phosphorus. Therefore, to demonstrate that the substance emitting radiation is potassium, the selection of fertilizer source material is very important.

In the present study, five brands of chemical fertilizers containing different amounts of potassium were selected as source materials and fabricated into disks using a compression and formation method. As before, the relationship between radiation count emitted from the fertilizer sources and the percentage of potassium in the fertilizers was investigated based on 10- and 1-minute integration times. The results showed a linear relation with no inversions, indicating that the radiation count was directly proportional to the potassium content.

Thus, this educational technique is useful for explaining that the substance emitting radiation in chemical fertilizers is potassium. The results also show that the radiation sources fabricated using chemical fertilizers can be handled safely and easily in radiation courses.

2. Chemical fertilizer radiation sources

2.1 Chemical fertilizer

Nitrogen, phosphorus, and potassium are three important elements for plants. Chemical fertilizers generally contain all of these elements. As a chemical fertilizer radiation source and application for radiation education, potassium is very important because naturally occurring potassium consists of three isotopes: ^{39}K, ^{40}K, and ^{41}K, of which ^{40}K emits a 1.33-MeV beta particle at a rate of 89% and a 1.46-MeV gamma ray at a rate of 11%. Because the half-life of ^{40}K is long (1.28×10^9 years), the chemical fertilizer radiation source is suitable for use as an educational radiation source.

In the present study, five commercially available chemical fertilizers were purchased for producing chemical fertilizer radiation sources, which contain different percentages of potassium, a small proportion of which is radioactive potassium-40.

These chemical fertilizer brands were sold for use in the family garden. Consequently, radiation sources fabricated from the chemical fertilizers can be handled safely, since they are only pressed and formed before use in the classroom.

The five brands of chemical fertilizer were called “sulfate of potash,” “phosphorus and potash,” leaf and vegetable,” “organic chemicals,” and “bulbaceous fertilizer” (words used in their brand names). The amounts of the main elements in these fertilizers are summarized in Table 1, obtained from ingredient labels on the fertilizer packages. The “sulfate of potash” brand contained 50% potassium out of, which was the maximum amount of potassium in the five fertilizers. The “phosphorus and potash” brand contained both phosphorus and potassium at 16% and 15%, respectively. The other three fertilizers contained all three main components. The five fertilizers each contained five different potassium percentages: 50%, 15%, 10%, 8%, and 5%.

Table 1. Percentages of nitrogen, phosphorus, and potassium in five brands of chemical fertilizers.

Fertilizer	Content (%)*		
	Nitrogen	Phosphorus	Potassium
(1) Sulfate of potash	*	*	50
(2) Phosphorus and potash	*	16	15
(3) Leaf and vegetable	12	8	10
(4) Organic chemicals	8	8	8
(5) Bulbaceous fertilizer	3	7	5

*Based on “Ingredient labels” on the packages

2.2 Method of fabricating chemical fertilizer sources

For fabricating chemical fertilizer radiation sources from the chemical fertilizers, about 20 g of fertilizer were micronized with a mortar. This fertilizer powder was placed into a cylindrical stainless steel form and then pressed. The fabrication setup is shown in Fig. 1. The cylindrical stainless form had an inner diameter of 35 mm and a height of 30 mm. A hydraulic hand pump (Osaka Jack Co. Ltd., Model TW-0.7) and a jack (Osaka Jack Co. Ltd., Model NT20S12.5) were used to compress the fertilizer powder in the form with a force of approximately 160 kN to produce disk-shaped radiation sources from the fertilizers.

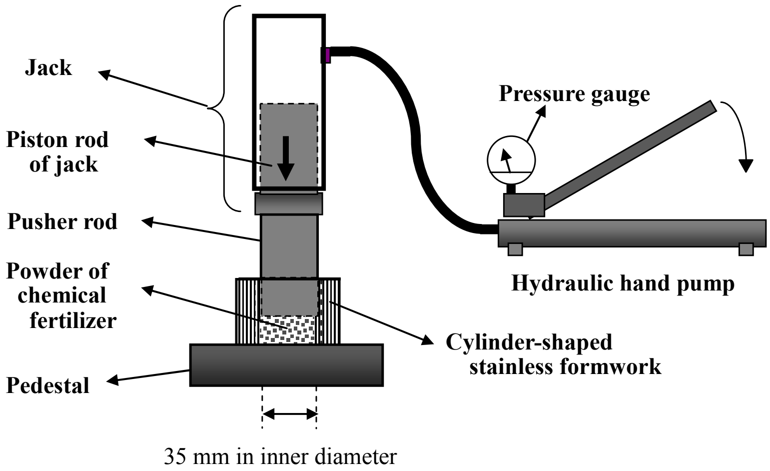

Fig. 1. Fabrication setup for compressing chemical fertilizer powder into disk-shaped radiation sources

3. New educational technique

3.1 Evaluation of new educational technique using five fertilizers

The five fertilizers containing various percentages of potassium were used as raw materials for fabricating radiation sources. The radiation strength of the fabricated fertilizer source was estimated by the radiation count emitted from the fertilizer source. Radiation counts were measured using a GM survey meter (Aloka TGS-146), and were compared with the percentage of potassium among the three main fertilizer elements. The element percentages could be obtained easily from ingredient labels attached to the fertilizer packages. The radiation count was derived by subtracting the background count (measured without the fertilizer source) from that of the fertilizer source. To measure radiation strength, a fertilizer source was placed at the center of the surface of a GM survey meter probe. The measurements were obtained in integration mode. An integration time of 10 minutes was used for both source count and background count, and net count rates at one minute were calculated.

The results obtained are shown in Fig. 2(A)-(C). Figure 2 (A) represents a typical result, in which radiation count is plotted as a function of percentage of nitrogen. It is clear to see that the count does not correlate with nitrogen percentage, because no linear relationship is present. Figure 2(B) shows similar results between count rate and phosphorus fraction. In both Fig. 2(A) and 2(B), radiation counts of about 300 cpm and 120 cpm were obtained from samples with zero nitrogen (A) and zero phosphorus (B), which is explained in Fig. 2(C). Consequently, neither the nitrogen nor phosphorus in the fertilizer sources emits radiation. Figure 2(C) shows the relation between radiation count and potassium percentage. The counts for the five brands of chemical fertilizer were distributed around the line representing the correlation between radiation count and potassium percentage. These experimental results show that radiation strength linearly increases with potassium percentage of the radiation source, meaning that the substance emitting radiation must be the potassium present in the raw fertilizers. Thus, the radiation counts of 300 cpm and 120 cpm observed at zero nitrogen and zero phosphorus, respectively, also result from potassium.

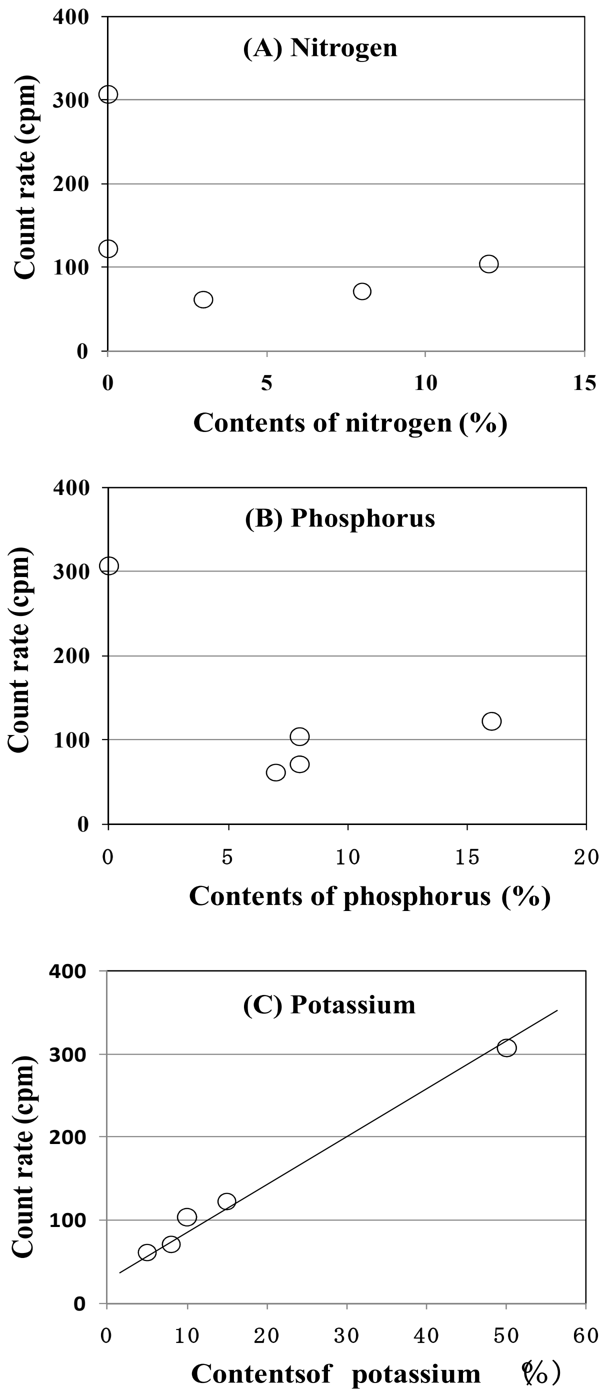

Fig. 2. Relation between component percentage and radiation count obtained with 10-minute measurements

3.2 Evaluation of new educational technique with one-minute measurements

Five fertilizer sources were fabricated from the five chemical fertilizers selected as raw materials. The educational method proposed in a recent study was applied using the five fertilizer sources. Results demonstrated that radiation was emitted from the potassium in the chemical fertilizers. However, this result was based on 10-minute integration time, which may be too long for an actual educational radiation course because younger students may not stay focused for multiple ten-minute measurements. For this reason, the integration time for a single measurement should preferably be one minute or less to allow collection of many data points without loss of student focus. Therefore, further experimental studies were conducted based on one-minute integration times for simulation of an actual educational radiation course.

For the studies using a one-minute integration time, the measurements were repeated ten times. Each set of measurements were conducted for all five fertilizer sources. The results are shown in Fig. 3 and are similar to those shown in Fig. 2(C) based on ten-minute integration time. The average radiation counts for one minute plotted as a function of potassium percentage exhibited a linear relation with a standard deviation of less than 10%, which indicates that count rate reflects the potassium content.

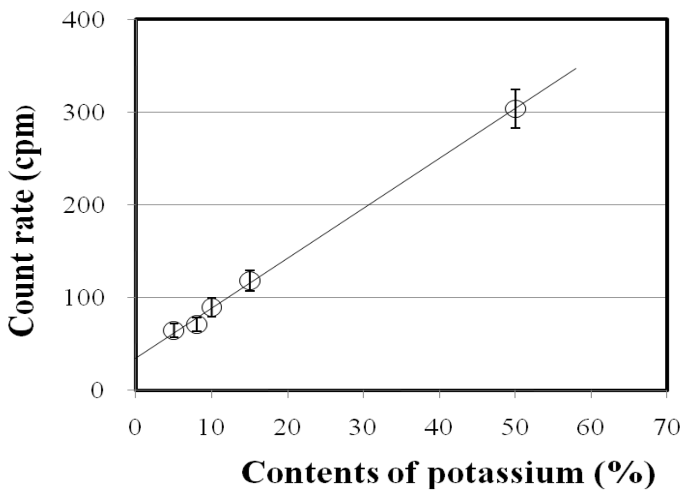

Fig. 3. Relation between potassium percentage and radiation count obtained with one-minute measurements.

4. Conclusions

In a previous study, a new educational tool was proposed for understanding that potassium in fertilizer emits radiation. In the present study, that tool was evaluated from a practical view. Five radiation sources were fabricated from fertilizers containing different amounts of potassium and the relation between radiation count (based on one-minute integration time) and potassium fraction was examined. Results demonstrated that a linear relation existed between radiation count and potassium percentage, confirming that potassium is the source of the radiation from the fertilizer.

This approach can be used to teach students enrolled in a radiation educational course that chemical fertilizers can emit radiation. The experimental portion of the course can utilize natural radiation sources that allow students to handle naturally occurring radioisotopes and recognize that radiation can be emitted from natural materials. This experience helps students understand that people are irradiated continuously with low levels of natural radiation emitted from materials containing natural radioisotopes.

Research Center Karlsruhe, FTU, GERMANY

Abstract

The ENETRAP II Project (European Network on Education and Training in Radiation Protection) aims at harmonizing the Education and Training in Radiological Protection RP e.g. by reaching harmonization of the requirements of RP experts and officers within Europe. These "Reference Standards will reflect the needs of the RPE and the RPO in all sectors where ionising radiation is applied. Therefore a remodelled modular European Radiation Protection Course has been developed in the ENETRAP first phase project. One major goal of the present project is to monitor the effectiveness of the proposed methodologies by organising pilot sessions of selected training events within Work package 8. The courses are designed for radiation protection professionals such as Radiation Protection Experts (RPE) and Radiation Protection Officers (RPO) according to the agreed standards and include On-the-Job OJT Training as key element. Domains to be chosen are occupational radiation protection in Nuclear Power Plants, Radioisotope Training in Non-nuclear industry and Research, and Specifities of Waste Management and Decommissioning. In this paper the outcome of the pilot sessions as far as available is evaluated and the results summarised. Preliminary improvements are recommended for further performance.

Work management to optimise occupational radiological protection at nuclear power plants

Abstract

In order to provide guidance to the nuclear community on the best practices of work management in nuclear power plants, the Information System on Occupational Exposure (ISOE), sponsored by the OECD Nuclear Energy Agency and the International Atomic Energy Agency, established an international expert working group to update a report on this topic, previously issued in 1997.

The report, *"Work Management to Optimise Occupational Radiological Protection at Nuclear Power Plants"*, was published in 2009. It provides practical guidance based on the operational experience within the ISOE programme in the key areas of work management to optimise occupational radiation protection, including: Regulatory aspects; ALARA management policy; Worker involvement and performance; Work planning and scheduling; Work preparation; Work implementation; Work assessment and feedback; and Ensuring continuous improvement. The specific aspects of work management applicable to each of these areas are illustrated by practical examples and case studies arising from ISOE experience. This paper summarizes and describes the key messages of the report.

Introduction

Occupational exposures at nuclear power plants worldwide have steadily decreased since the early 1990s. Regulatory pressures, technological advances, improved plant designs and operational procedures, ALARA culture and information exchange have contributed to this downward trend. However, with the continued ageing and possible life extensions of nuclear power plants worldwide, ongoing economic pressures, regulatory, social and political evolutions, and the potential of new nuclear build, the task of ensuring that occupational exposures are As Low As Reasonably Achievable (ALARA) continues to present challenges to radiation protection professionals.

Since 1992, the Information System on Occupational Exposure[1] (ISOE), jointly sponsored by the OECD Nuclear Energy Agency and the International Atomic Energy Agency, has provided a forum for radiological protection professionals from nuclear

[1] For more information, see ISOE web site: www.isoe-network.net

power utilities and national regulatory authorities worldwide to co-ordinate international co-operative undertakings for the radiological protection of workers at nuclear power plants. The ISOE objective is to improve occupational exposure management at nuclear power plants by exchanging relevant information, data and experience on methods to optimise occupational radiation protection.

Key to effective occupational exposure management has been the widespread understanding of the need for careful planning and execution of refuelling and maintenance outages. This approach, referred to as *work management*, stresses the importance of approaching jobs from a multi-disciplinary team perspective, and of following jobs completely through all stages from conception to post-job follow-up.

In order to provide guidance to the nuclear community on the best practices of work management, ISOE established an international expert working group to update a report on this topic, previously issued in 1997. This recognises that while work management is no longer a new concept, continued efforts are needed to ensure that good performances, outcomes and trends are maintained in the face of current and future challenges.

The report, *"Work Management to Optimise Occupational Radiological Protection at Nuclear Power Plants"*, was published in 2009 (NEA, 2009). It provides practical guidance based on the operational experience within the ISOE programme in the main areas of work management. The specific aspects of work management applicable to each of these areas are illustrated by practical examples and case studies arising from ISOE experience.

Principles of work management

Work management is a comprehensive and iterative approach to work. The philosophy of work management is a continuous loop that consists of planning, preparation, implementation, assessment and follow-up in order to make the overall work progressively optimised and using a multi-disciplinary team approach involving all relevant stakeholders (see Figure 1). Feedback is a key component, and such feedback should be obtained both locally and globally. Assessment and feedback is the final stage of work and, at the same time, the first stage of the process. However, work management is also forward looking. Therefore, recognising the constant evolution of many parameters that are included in the above topics, such as ongoing technological advances, as well as using past and current lessons to not only inform future work but also future design and operations, the report closes with a chapter on "Ensuring Continuous Improvement".

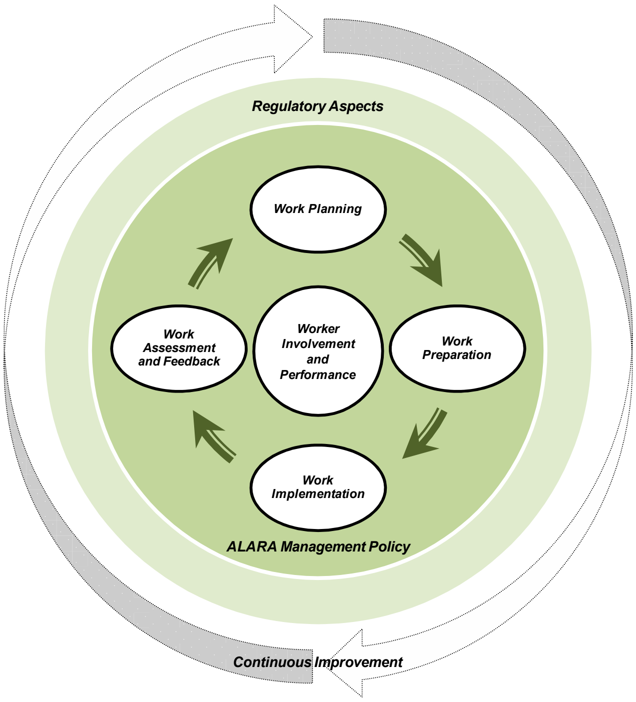

Figure 1. Work management elements and their iterative nature.

Regulatory aspects

While it is the licensee's duty, in the first instance, to ensure that a particular operation is safe from the perspective of nuclear safety and radiological protection, this must be done within the applicable regulatory framework.

National regulatory frameworks are based on radiation protection principles and standards developed at the international level. They aim to secure the maintenance and improvement of safety at civil nuclear installations through regulations addressing nuclear safety, and ensure the protection of workers, public and environment from ionising radiation through regulations addressing radiation protection. Such regulation provides for an effective radiological protection infrastructure which includes a "safety culture" shared by those with protection responsibilities from workers through to management.

In the field of safety, there is an effort to develop and implement "performance based" plant maintenance rather than prescriptive pre-scheduled maintenance. This typically allows reductions in maintenance volume and therefore occupational exposure. In the field of radiation protection, specific rules can be introduced to foster the optimisation of radiation protection. In addition to the regulatory framework, utilities can develop their own radiation protection internal rules, integrating operational restrictions for the management of individual and collective doses.

ALARA management policy

The ALARA approach consists in always questioning whether the best has been done in the prevailing circumstances, and whether all that is reasonable has been done to reduce doses (ICRP 2007).

In order to spread the ALARA "way of thinking" amongst all levels of the management chain, from the company President to the worker on the floor, it is necessary to set up and structure dedicated ALARA programmes that make explicit the goals and objectives of the utility regarding optimisation of radiation protection. The responsibilities associated with the implementation of the ALARA programme should be clearly distributed among the various management levels and work specialisations. The creation of ALARA Committees or other types of specific ALARA organisations are a key element, forming "meeting points" between the main actors in ALARA implementation. This favours their involvement in the ALARA programme as well as the common elaboration of ALARA plans. Finally, plant management must be willing to support, in policy and budget, a multi-disciplinary team approach to plan, schedule, implement, and follow-up jobs.

Worker involvement and performance

ALARA cannot be achieved without worker involvement. It is the worker that is exposed, and it greatly depends on the worker himself to reduce the exposure. The involvement of workers at all levels is one of the most important aspects of an effective work management programme. By engaging the worker in the task being performed, the worker is more likely to be motivated to perform the job to the best of his/her abilities, and this will be reflected in lower job doses as well as in higher job quality. To ensure the full involvement of workers, conditions should favour the creation and continuation of such involvement. It should also implicate workers at all the stages of a job (planning, scheduling, preparation, implementation, follow-up) and assure that there is a mechanism for matching individuals and their skill levels with appropriate tasks.

It is also important to improve worker performance for ALARA implementation. This requires an appropriate level of education and training to ensure that workers possess the correct tools and competencies. Involvement of all levels is also necessary: senior and mid-level management, job foreman, shift supervisors, etc. Good communications between different levels of the hierarchy and among the different disciplines should be a management priority.

Finally, top management must also be committed to this process and favour a structure that encourages and takes into consideration the feedback of workers. Worker incentive programmes will help to improve and maintain worker motivation and involvement, and should pay for themselves in terms of savings in time, dose and costs, and in job quality.

Work planning and scheduling

The planning stage is an essential period within which to implement work management actions and optimise radiation protection.

Work activities must be carefully planned to ensure that radiological protection is optimised. Work planning and scheduling should integrate radiation protection criteria and use feed-back experience and benchmarking to ensure that the most effective approaches are implemented. Planning must recognise not only the sequence of job steps, but also their relationship and their multi-disciplinary nature. The location of job planners can be optimised by centralising all appropriate workers (planners, engineers, schedulers, etc.), thus fostering and facilitating interdisciplinary communications. In addition, the proper scheduling of jobs to co-ordinate the use of services, scaffolding, installed shielding, water shielding in pipes and tanks, etc., and the use of scale models for planning purposes (as well as training and worker orientation) contribute to the efficient use of resources.

Particular attention should also be paid to the optimisation of outage duration. Key issues in the selection of work include the use of realistic assumptions when deciding upon the necessity for performing work, the selection of only those jobs which are "necessary" to the safe and efficient running of the plant and the implementation of a tight but not rushed schedule to reduce the risk of rework.

The scheduling of jobs in relation to each other, the identification of potential work interferences and hazards in the work zone, and the identification of dose intensive jobs are critical to the optimal use of resources and job success.

Finally, the planning stage should also integrate actions for the preparation of personnel, such as pre-job briefings or mock-up training, in order to improve worker performance and reduce occupational exposure.

Work preparation

The success of work greatly depends on the quality of the preparation. Work preparation in the context of this report covers all activities considered or performed before and during a job in order to prepare the site and the work crew. It addresses factors affecting the source term, the duration of work and the number of workers exposed.

Source term removal, decontamination, reduction by shielding or continuous control are effective for achieving dose rate reductions. Various tools and equipment that support work implementation are also appropriate. It is important to take advantage of these techniques as part of work preparation since many effective methods have been developed and a great deal of experience has been accumulated. Finally, support tasks such as optimisation of the work schedule and job co-ordination in the work area are also key components of work preparation.

Work implementation

The work implementation phase refers to the actual performance of the work and to those actions taken during this time which affect or facilitate the work.

There are several areas where work management can effectively contribute to lowering dose as well as time and cost. These includes organisational aspects such as the presence of radiation protection personnel and specific procedures and technical aspects such as remote monitoring and access control systems. Efficient work process control will help to assure that the objectives set during the work planning phase are met. The reduction of transit exposure and unnecessary dose will be facilitated by providing workers with sufficient radiological, plant and job specific information. Finally, the collection of feedback information will assist in real-time work management and facilitate the preparation of future work.

Work assessment and feedback

The philosophy of work management is a continuous loop that consists of scheduling, planning, implementing, assessing, following-up, making modifications as per lessons learned and repeating the process for the next job to be undertaken, thus making the work cycle progressively optimised and in line with current technological developments. "Assessment and feedback" is the final stage of work and, at the same time, the first stage of the continuous loop.

In a generic approach, two levels of information may be necessary to provide complete feedback on work implementation: the "internal" level, which consists of an analysis of in-plant performances, and the "external" level, which will provide national and/or international data favouring the exchange of new ideas and allowing the plant to assess its position with regard to other plants of the same type.

In terms of post-job review, it is essential to have a multi-disciplinary team conduct the review and to include as much direct input from the workers, including contractors, as possible. The follow-up of recommendations and lessons learned should then, ideally, be performed by the same multi-disciplinary team which conducted the post-job review.

Normally, follow-up will lead directly into the next implementation of the operation under consideration such that a certain closure (job conception, scheduling, planning, implementation, assessment and follow-up, job modification as per lessons learned, scheduling, planning, etc.) occurs and the job becomes progressively optimised and appropriately modified to keep up with current technological developments.

The lessons-learned, both good practices and areas for improvement, should be collected in a diligent manner, and exchanged not only with the work team but also with colleagues at the plant, industry and international levels. RP managers should recognise all available information sources and use them effectively as well as share their own information and experience.

Finally, work management implementation should be audited periodically to assure that it is functioning properly.

Ensuring continuous improvement

While work management is an iterative process, it is also forwarding looking, seeking continuous improvement and continuous vigilance to ensure and maintain a high level of radiation protection. Such improvements therefore seek to incorporate, through information and experience exchange, lessons learned and ongoing technological advances to not only inform future work activities, but also in the longer term, new design, new build and new operations to ensure that doses are maintained ALARA.

In addition to experience exchange through programmes such as ISOE, there is a range of new technologies in various fields relevant to exposure reduction. These include technologies addressing source term reduction, decontamination, and mechanisation, automation and remote monitoring. The development and further application of such technologies should be considered in light of the radiation protection issues that will become important in the future, including exposure reduction in newly constructed or newly designed plants (of potentially increasing importance), large-scale modification works expected to be needed in association with aging and lifetime extension of nuclear reactors, and reactor decommissioning.

Conclusion

Safety and radiation protection are the most important factors for the safe operation of nuclear power plants. Experience in occupational radiation protection has shown that radiation protection measures should be adopted in all phases of the nuclear power plant life cycle, from design to operation to decommissioning. This not only allows source term removal or reduction as part of design, but also consideration of how exposure reduction methods or procedures can be most effectively implemented during operation.

Many methods that can be considered by all those with a role in occupational radiation protection at nuclear power plants have been described in this report. This multi-disciplinary, practical experience in work management, based on lessons drawn from many years of nuclear power plant operations, in addition to approaches that are still under development or will be realised in the future, are important elements in the optimisation of occupational radiation protection and for ensuring continuous improvement in the face of current and future challenges and opportunities.

Abstract

The development of an up-to-date radiation protection system for medical staff working with radiations requires data on field (type of radiation, energies, scattering materials...), exposure (time, activities, position of operator..) and protective devices (barriers, glasses, gloves and aprons) which are only partially available in the radiation protection routine practice. Local high exposures in interventional radiology (IR) and nuclear medicine (NM) are due to the closeness of medical staff to the direct and scattered field, in the first case, and to the direct handling of radionuclides, in the second.

Many studies in IR have shown that the doses can vary a lot, even for the same type of procedure. The routine monitoring of the extremities (hands, forearms and legs) is difficult to be performed thus only data for whole body, fingers and wrists are reported.

Moreover, eye lens dose is rarely estimated, even if there is some evidence that cataract is an increasing effect in exposed population. In NM the main topic is the skin dose, but is generally unknown which part of the hand receives highest doses and which is the dose distribution in the hand itself. Indeed, the use of unsealed sources with high

activities and beta emitters in therapeutic NM can worsen the situation for the involved personnel.

These aspects are studied within the ORAMED (Optimization of RAdiation protection of MEDical staff) project, funded by EU-EURATOM FP7, studies in which a series of European laboratories and hospitals participate. The project is subdivided in 5 work packages: extremity and eye lens dosimetry in IR and cardiology (WP1); development of practical eye lens dosimetry in IR (WP2); optimisation of the use of active personal dosemeters in IR (WP3); extremity dosimetry in NM (WP4); and training and dissemination (WP5). In the present work the state of the art of the main tasks performed in WP1, WP2 and WP4 is briefly summarized.

Introduction

The ORAMED project, funded through the FP7, was set up to optimize radiation protection in Interventional Radiology and Cardiology (IR/IC) and Nuclear Medicine (NM) focusing the attention to the dose to the extremities and eye-lens.

The published studies on the doses to the medical staff [Donadille et al. 2008, Ginjaume et al. 2008, Kim and Miller 2009, Martin 2009, Vanhavere et al. 2008, Vano et al. 2008, Zorzetto et al. 1997] report a large variability of the estimated values due to the patient scattering, the followed procedure (for the IR/IC), the kind of radionuclide (for NM), the skill of the operators and the radiation protection devices used (for both) and all of them underline the need of a radiation protection optimization. Moreover, regarding eye lens doses, there is some evidence that cataracts can be produced at lower doses level [Junk et al 2008] and the ICRP itself [ICRP 2008] is moving to this direction.

In IR/IC procedures the medical staff is likely to receive significant radiation doses to their hands and parts of their body not covered with protective equipment (as legs and forearms) because physicians are close to X-ray field. In NM practices the dose to the hands is the main issue, especially when unsealed sources are used. About eye-lens the recent evidences of cataracts at lower doses pointed out the lack of an optimized dose assessment for such organs. $H_p(3)$ is seldom used in the routine radiation protection practice: when required, it is usually deduced from $H_p(0.07)$ and $H_p(10)$ evaluation.

The ORAMED project (http://www.oramed-fp7.eu) started in the beginning of 2008 and will run for 3 years. Within the project a coordinated measurement program in selected European hospitals is presently on-going. The measurement campaign is accompanied by a series of numerical simulations of the most representative workplaces/procedures to determine the main parameters that influence the extremity and eye lens doses. The project is structured in 5 work packages (WPs) all devoted to investigate the medical staff doses in IR/IC and NM. In WP2 $H_p(3)$ operational quantity has been investigated and a suitable dosemeter responding in terms of $H_p(3)$ has been produced. In the present paper the state of the art of WP1 (extremity and eye lens dosimetry in IR/IC), WP2 and WP4 (extremity dosimetry in NM) is summarized.

Material and methods

WP1- Extremity and eye lens dosimetry in IR/IC

The objective of WP1 is to obtain a set of standardized data on doses for staff in interventional radiology and cardiology with the aim of optimizing medical staff radiation protection. The coordinated measurement program in some selected major European hospitals, established in the first year of the project, is still in progress. The procedures to be followed were chosen on basis of a retrospective study from hospital data on the frequency of procedures and the respective KAP (kerma air product) values. The final list includes 3 cardiac procedures- cardiac angiographies (CA) and angioplasties (PTCA), radiofrequency ablations (RFA), pacemaker implantations (PM) - and 5 general interventional diagnostic and therapeutic examinations - angiographies (DSA) and angioplasties (PTA) of the lower limbs (LL), of the carotids (C) and renal (R), embolisations and endoscopic retrograde cholangiopancreatographies (ERCP).

The measurements have been performed according to a protocol supplied to each hospital allowing the homogenization of the collected data. Parameters such as the KAP values, the radiation protection equipment used by the staff and the staff position during the practice have been noted down in order to correlate them with the evaluated doses.

TL dosemeters (LiF:Mg,Cu,P) were used for the measurements. Eight TLDs were sealed in small plastic bags and taped on the parts of the body to be monitored: 2 for the ring fingers, 2 for the wrists, 2 for the unshielded part of the legs (about 5 cm below the lead apron) 1 between the eyes and 1 near the left/right eye, depending if the tube is on the left/right side of the doctor respectively. The measurements during preliminary tests showed that these positions are the most exposed. A previous intercomparison exercise, in which TLDs were irradiated to ^{137}Cs and X-ray beams on the ISO slab phantom, assured that all partners could evaluate comparable doses in terms of $H_p(0.07)$.

Due to the complexity of establishing the main parameters influencing the doses in IR/IC, it was decided to perform a numerical analysis using anthropomorphic models with MCNPX Monte Carlo transport code [Pelowitz 2005]. A first simulation intercomparison was performed in order to work on a common basis for the numerical campaign. The input simulates a typical irradiation scenario: the anthropomorphic MIRD-ORNL [Snyder et al. 2008] model was modified extracting arms from the body structure and arranging forearms and hands in a way that is more similar to that expected for the cardiologist during the insertion of the catheter. A second model, representing the patient, is laying in front the physician that stands at the patient’s femur. Eyes, a thyroid collar, a lead apron of 0.5 mm thickness and the Image Intensifier tube have been added in order to better simulate the real situation (Figure 1). A simulation protocol has been established after a preliminary test that demonstrated the need for variance reduction techniques - MCNPX DXTRAN spheres [Briesmeister 2000]- especially for the small tallies (hands and eyes).

Since the number of the simulations that was finally agreed was too high it was decided to perform the whole analysis (called sensitivity analysis) on three simplified phantoms, a cylinder, (for IR practice in the head) and two phantoms representing the thorax and the whip (for the different IR/IC procedures of those anatomical regions) and to adopt detailed models only to check some parameters (as shielding) or for particular tests.

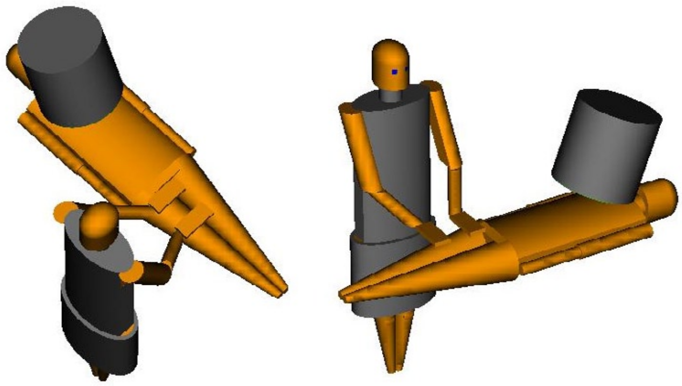

Fig. 1. The modified ORNL-MIRD type models employed in the IR/IC simulation.

WP2- Eye lens dosimetry and $H_p(3)$ dosemeter development

The objective of WP2 is to investigate the theoretical framework within which the operational quantity $H_p(3)$ is defined and the posibility to develop a dosemeter responding in terms of the operational quantity itself.

Until now $H_p(3)$ conversion coefficients were not reported in the official recommendations and the only available data were calculated by GSF (now Helmoltz Institute) for a 30 x 30 x 15 cm^3 4 element ICRU tissue-equivalent slab phantom [Till et al 1995]. The operational quantity should be defined in a phantom able to reproduce the interaction and scattering properties of the part of the body considered. This is the reason why the 4 element ICRU tissue-equivalent slab phantom (representing the thorax) is not well suited to represent the human head. For instance, a preliminary study allowed to investigate if $H_p(3)$ could be defined in a cylindrical phantom of 20 cm diameter and 20 cm height. The shape and the dimensions of this model were defined on the basis of the morphology of the head of the ORNL-MIRD anthropomorphic phantom, which was created according to the characteristics of the standard man expressed by ICRP 23 [ICRP 1975] and ICRP 89 [ICRP 2003]. The calculated $H_p(3)/K_{AIR}$ for slab and cylindrical phantoms, for monoenergetic photons and different angles were compared to the reference ICRP limiting quantity eye-lens equivalent dose $H_{T(eye\text{-}lens)}$ [ICRU 1998].

A cylindrical PMMA calibration phantom, with the same dimensions of the theoretical model, filled with water, was developed for the following dosemeter type-testing (Figure 2). A series of MCNP simulations was performed in order to determine the backscatter properties of the proposed model [Mariotti and Gualdrini 2009]. Mono-energetic and ISO narrow beam spectrum series at different incident angles and distances from the phantom lateral surface were considered. The Monte Carlo simulations were validated through a series of measurements of the kerma in air with and without the corresponding plastic phantom using a small volume ionization chamber. The characterized calibration phantom was used in the rest of the work.

Starting from these studies the dosemeter development was planned. A series of Monte Carlo simulations was employed to determine which of the available plastic materials was more suitable for the expected 3 mm soft tissue attenuation related to the $H_p(3)$ definition. The chosen material was used to provide the encapsulation of the TL

MCP-N (LiF:Mg,Cu,P) chip. The study of the complete dosemeter (TL + plastic encapsulation) response with respect to the imparted $H_p(3)/K_{AIR}$ was carried out through a series of Monte Carlo simulations at various incident angles. The developed prototype is being tested at CEA laboratories at ^{137}Cs and standard RQR X-ray beams on the cylindrical phantom. The characterized dosemeters will be used in the selected hospitals in order to evaluate the eye-lens doses for IR/IC procedures.

Fig. 2. The cylindrical calibration phantom for eye-lens operational quantity dosemeter testing.

WP4- Extremity dosimetry in NM

The objective of WP4 is to evaluate extremity doses and dose distributions across the hands of the medical staff working in nuclear medicine departments. To achieve this, an extensive measurement and simulation program has been started.

A measuring working plan was established following a defined protocol: the labelling and administration of radiopharmaceuticals for diagnostics (^{99m}Tc and ^{18}F) and therapy procedures (Zevalin and DOTATOC labelled with ^{90}Y) were taken into account (other radionuclides as ^{32}P, ^{177}Lu or ^{153}Sm were also considered). The procedures were selected according to their frequency in the collaborative hospitals.

To measure the skin dose across the hands, special gloves were designed with high sensitivity thermoluminescent dosemeters (TLD) specific to beta and gamma radiation placed at a minimum of 11 different positions on each hand (Figure 3). The TLDs inserted in the plastic envelops could reproduce adequately the quantity $H_p(0.07)$. For each procedure a minimum number of measurements was required. Each procedure had to be performed by two operators and in two hospitals assuring an adequate evaluation of the intrinsic variability in the expected doses.

An initial comparison of the different TLDs used by the WP4 participants was performed with ^{137}Cs and ^{85}Kr sources in order to establish a common basis for the measurement campaign in the different nuclear medicine departments.

In order to check the different parameters contributing to the dose and to the dose reduction to the operators (position with respect source, adopted shieldings etc..), it was decided to perform a series of numerical simulations (called sensitivity analysis) reproducing the most common scenarios encountered during the measurements. 2 different scenarios for injecting and 3 different ones for labelling have been selected: handling of a syringe, handling of a vial directly with or without forceps. Hand phantoms made of paraffin have been produced by SMU and scanned using a CT. Voxel models of the phantoms were created by IRSN and employed as input for the sensitivity analysis (Figure 4). The numerical models were validated through a series of measurements done using the paraffin phantom in laboratory in controllable conditions. The sensitivity analysis is ongoing.

Fig. 3. The operator's gloves equipped with dosemeters for the dosimetric study in WP4.

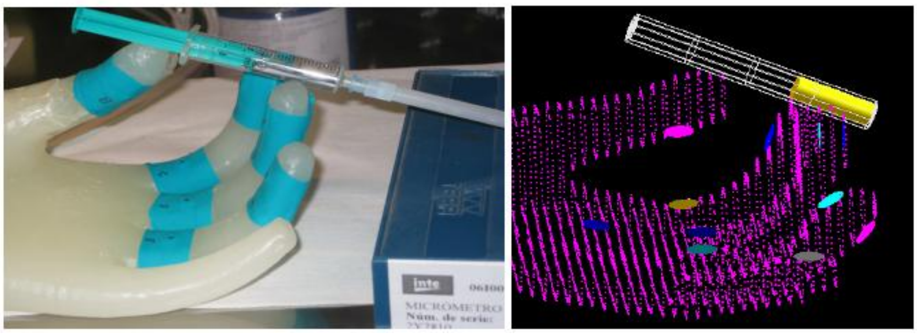

Fig. 4. The paraffin hand used in validation and its voxel model representation.

Results

The measurements and simulation campaigns are in progress; therefore the presented results are only preliminary. Here only few examples of the analysis are reported, a complete investigation of the outcomes will be presented at the final ORAMED workshop.

WP1

For the measurements part, up to now 797 interventional procedures (377 cardiac, 277 general angiographies and 143 Endoscopic Retrograde CholangioPancreatographies, ERCP) in 33 European hospitals have been performed.

The measured KAP values vary from 0.46 Gycm^2, recorded in PM procedure, to 942 Gycm^2 in embolisation. Generally high KAP values are encountered when large number of images/frames is acquired. The KAP values present high distribution even within the same type of procedure, which shows the complexity of the procedure, the variability in the techniques and the influence of the skill of the physicians. The median doses for general angiography procedures are usually higher than for cardiac and ERCP and the left side of the operator is the more exposed to the scattered radiation from the patient (Figure 5).

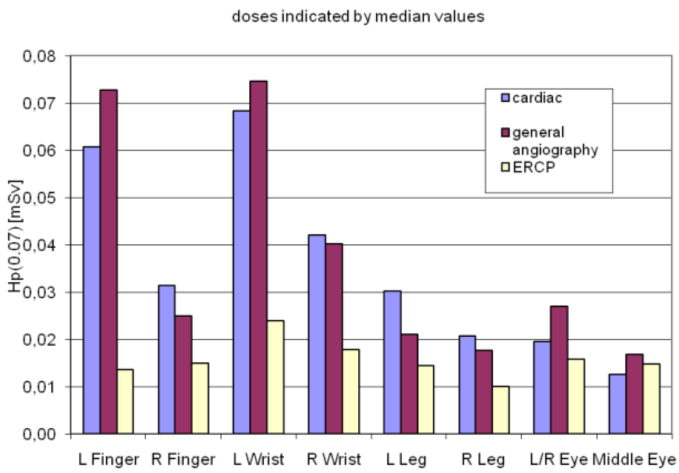

Fig. 5. Mean Hp(0.07) values in mSv for cardiac, genaral angiography and ERCP procedures.

The maximum dose that was recorded was at the left finger in a CA and PTCA procedure (2.08 mSv, KAP=380 Gycm^2). The maximum eye dose (1.28 mSv) was recorded in the embolisation with the highest KAP value.

For CA and PTCA procedures, the fingers received slightly higher dose than the wrists, and the legs higher than the eyes. For the RFA procedures, the finger and wrist doses are higher than the leg and the eye ones as in the CA and PTCA procedures.

For the PM interventions the $H_p(0.07)$ values are generally low due to the short fluoroscopy time and the absence of image acquisitions, although values up to 0.4 mSv/procedure were recorded in the finger region. In those cases the hands were very close or sometimes even inside the beam. In PM implantations the operator's position can be closer to the patient compared to the other interventional procedures so it is not easy to use the protective equipment of the table and ceiling.

In DSA, PTA of lower limbs and carotids the finger and wrist doses are higher than the leg ones. In the embolisations, the wrist doses are higher than the fingers which are in agreement with Whitby and Martin [2005]. Finally the doses recorded in the ERCP interventions are small varying from 0 to 0.03 mSv.

About the sensitivity analysis the tube voltage was changed from 60 to 110 kVp and filtration from 3 to 6 mm Al and from 0 to 0.9 mm Cu. Calculations were performed for different beam projections: PA, LAO and RAO (30°, 60°, 90°), caudal and cranial (20° and 40°) combinations of them. A total of 3300 calculations for the simplified study and at least 220 detailed ones were performed. For all projections, the results showed that doses received by the operator decreased with increasing tube voltage and filtration. When the slab phantom was used the maximum doses for all tallies were observed for the LAO90 beam projection and the minimum ones for the RAO30. In the case of the cylindrical head phantom the maximum doses for all tallies were observed for the CRAN40 beam projection and the minimum ones for the RAO90 and RAO30. As expect the increasing beam aperture increases also the doses in particular for the wrists and the hands, for example, for the slab phantom the doses to the hands and wrists are reduced more than 3 times when the field size changes from 40 to 20 cm in diameter. The effects of the tube voltage and of the filtrations on the doses depend strongly on the irradiated part of the body and the beam projection.

WP2

The simulations demonstrated the validity of the performed analysis on $H_p(3)$ definition. In figure 6, $H_p(3)/K_{AIR}$ calculated for monoenergetic photons employing the cylindrical model and the 30 × 30 × 13 cm^3 4-element ICRU tissue-equivalent material are compared with the $H_{T(eye\text{-}lens)}/K_{AIR}$. As it can be seen the operational quantity defined in the cylindrical phantom is able to reproduce better the ICRP limiting quantity; a complete analysis can be found in an ENEA report [Mariotti and Gualdrini 2009]. The conversion coefficients for $H_p(3)$ were calculated in Kerma approximation, assuming the energy of the secondary charged particles deposited locally. A parallel investigation considering the electron transport was performed by CEA, using the Penelope code [Salvat et al. 2006] and demonstrated, as expected, the overestimation of the conversion coefficients calculated in the kerma approximation at 3 mm depth in soft tissue for energies above 1 MeV [Daures et al. 2009].

The dosemeter development was based on a series of Monte Carlo simulations. In Figure 7 the response of the complete (capsule + TL chip) RADCARD™ dosemeter, normalized per imparted $H_p(3)$, are presented at normal incidence angle for monoenergetic photons for different encapsulation material.

WP4

At the moment, 635 measurements coming from 32 nuclear medicine departments across Europe have been introduced in the database. Results are from diagnostic and therapeutic procedures and include both phases: preparation and injection.

To compare measurements from different departments, measured doses were normalized to the manipulated activity. A large spread of results, due to the influence of many factors, such as the type of protections used and the experience of the technicians is observed. The complete statistical analysis of the results is under progress.

From the 11 measuring points across the hand, it has been observed that the most exposed positions are the tip of the index finger and the thumb, usually of the non dominant hand.

The data analysis is ongoing, the preliminary comparison showed that for ^{99m}Tc administration the maximum dose is 1.5 (mSv/GBq) at index tip. This is the lowest registered maximum dose being 3.7 (mSv/GBq) and 11.2 (mSv/GBq) the evaluated maximum index tip doses for the ^{18}F and ^{90}Y respectively. These values change for the labeling case: 2.0 (mSv/GBq) for ^{99m}Tc 4.4 (mSv/GBq) ^{18}F and 32.0 (mSv/GBq) for ^{90}Y.

Usually labelling delivers higher doses than the administration of the radiopharmaceutical because the activities manipulated for labelling are higher than those manipulated for the administration of the radiopharmaceutical and some of the labelling steps are performed with an unshielded source whilst the administration is usually performed with a shielded syringe.

The impact of placing the routine monitoring dosemeter at a different position than the one corresponding to the maximal hand dose has been estimated by computing dose ratios between the position corresponding to the maximum in the hand (usually the index tip) and the position normally used for routine monitoring (usually the base of the index or the ring finger). The calculated ratios vary from 1 to 7 depending on the radionuclide and the procedure.

About the simulations the established protocol has the scope of evaluating changes in extremity doses varying different parameters. The outcome of these calculations will be used to define practical guidelines. To verify the consistency between measurements and simulations, several measurements were done in laboratory conditions: in Figure 8 ^{18}F injection with unshielded syringe measurements on paraffin hand are compared with the same data obtained with the computational voxel model. The agreement between the data is satisfactory. The sensitivity analysis is in progress.

Conclusions

The ORAMED project aims at developing methodologies for better assessing and reducing exposures to medical staff. In the present paper the activities related to the working groups 1,2 and 4 have been summarized.

WP-1 - Measurement and calculation of extremity and eye lens doses in interventional radiology and cardiology: a set of standardized data on doses for staff in interventional radiology and cardiology have been collected. A series of recommended radiation protection measures to optimize staff protection will be prepared on the basis of the outcomes of the wide numerical simulation campaign that is ongoing.

WP-2 - Development of practical eye lens dosimetry in interventional radiology: the operational quantity has been investigated, producing a new set of conversion coefficients for $Hp(3)/K_{AIR}$, a new calibration phantom was adopted and the first prototype of the dosemeter, responding in terms of $H_p(3)$, was developed. The dosemters will be supplied to IR/IC medical staff of a selected number of hospitals in order to assess eye-lens doses for radiation protection optimization.

WP-4 – the optimization of the extremity dosimetry of medical staff in nuclear medicine: a set of doses across the hand for administration and labelling of radiopharmaceuticals have been registered for a selected number of European hospitals. The data allowed to study the maximum dose and to determine the relationship between that maximum and the dose registered in the usual position where the routine dosemeter are worn. The simulations are still in progress, and they will be used to determine the effect of parameters influencing the radiation protection in those medical practices.

ORAMED project final workshop

ORAMED, Optimization of RAdiation protection for MEDical staff is a collaborative project funded in 2008 within the 7th EU Framework Programme, Euratom Programme for Nuclear Research and training. The final International Workshop of Optimization of Radiation Protection of Medical Staff will be held in **Barcelona, 20–22 January 2011.** The research leading to these results has received funding from the European Atomic Energy Community's Seventh Framework Programme (FP7/2007-2011) under grant agreement n° 211361.

Increased extremity doses for staff in the preparation and administration of beta-emitters and PET nuclides in nuclear medicine

Linder, Reto; Stritt, Nicolas
Swiss Federal Office of Public Health, Radioprotection Division, SWITZERLAND

Abstract
Due to the continuous increase in extremity doses in nuclear medicine departments, the Swiss Federal Office of Public Health (SFOPH), in its capacity as the supervisory and regulatory authority dealing with ionising radiation, has investigated the reasons for this and introduced measures aimed at their reduction. Since the mid-90s, the SFOPH has observed a continuous increase in extremity doses of persons occupationally exposed to radiation in nuclear medicine departments. Whereas only a few persons in the 50 facilities had accumulated an extremity dose greater than 25mSv/year in 1996, ten years later there were almost 10 times more. This development was all the more worrying because it is assumed that the extremity dosimeters used actually record only a fraction of the extremity dose effectively accumulated, especially when dealing with beta-emitters. In facilities with high patient throughput and frequent therapeutic uses, it is therefore possible that the dose limit (500mSv/y) is occasionally exceeded. The SFOPH looked into this radiation protection problem and since 2006 has undertaken audits in the relevant nuclear medicine departments to determine the reasons for the increased extremity doses, to optimise doses as far as possible and to order corresponding actions. It was established that there is considerable optimisation potential not only in the preparation of radiopharmaceuticals but also in their application, such that a marked reduction of extremity doses is possible. However, this partly depends on investment in systems, which automate dose-intensive manipulations, such as the loading and activity determination of injection syringes or even the injection into patients. When staff are aware that even a brief manipulation with unscreened therapeutic doses could result in high extremity doses, they generally use the shielding aids more conscientiously and adopt work plans and procedures that optimise radiation protection.

Introduction
The Swiss Federal Office of Public Health (SFOPH) is responsible for enforcing the radiological protection legislation [1] in Switzerland. In its role as the supervisory and licensing authority in radiological protection, the SFOPH monitors the radiation doses of persons occupationally exposed to radiation, of patients and the general population. Over the last 10 years the SFOPH has observed a continuous increase in extremity

doses for persons occupationally exposed to radiation in the approximately 50 Swiss nuclear medicine departments monitored. Fig. 1 shows the trend in extremity doses (greater than 25 mSv and greater then 50 mSv per year) between 1989 and 2006. Four years ago this led the SFOPH to focus on this topic in order to determine the causes and to initiate possible measures for the reduction of doses.

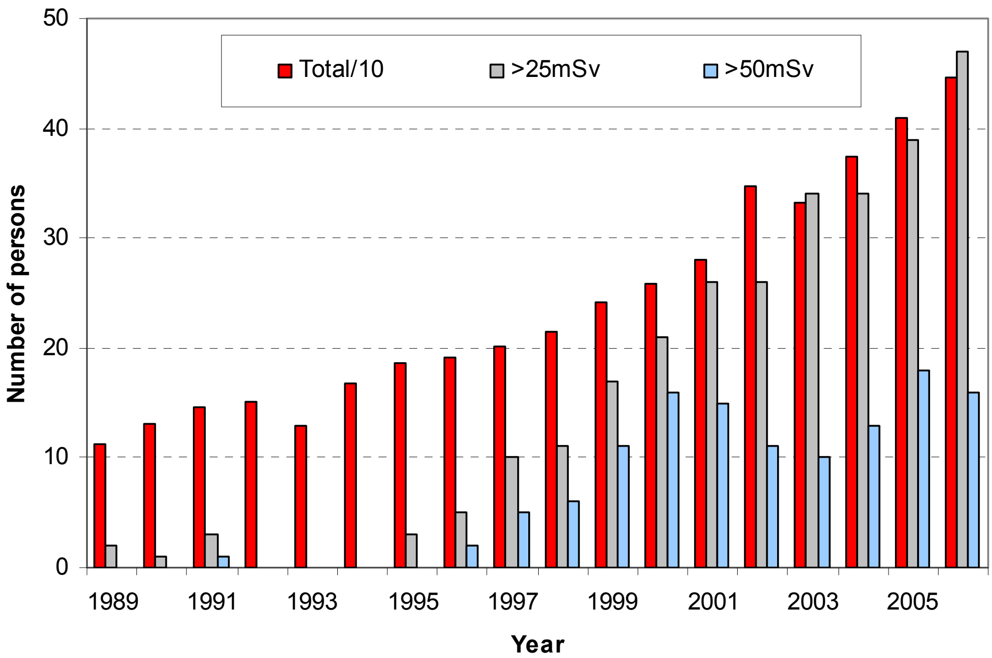

Fig. 1. Trend of extremity doses in nuclear medical facilities from 1989 – 2006.

The main raison for this trend is the growing use of new radiopharmaceutical products for therapeutic use (see Fig. 2) and the increase of departments that carry out PET examinations. Ten years ago there were 5 PET units in operation, nowadays there are already more than 20. Consequently, the use of F-18 has also correspondingly increased.

In a first step all the services concerned were audited in order to determine the current radiation protection practice and in which areas the radiation protection could be further improved. The findings from these audits are intended to be used in a second step to elaborate and publish recommendations for radiation protection and training programmes for the personnel concerned.

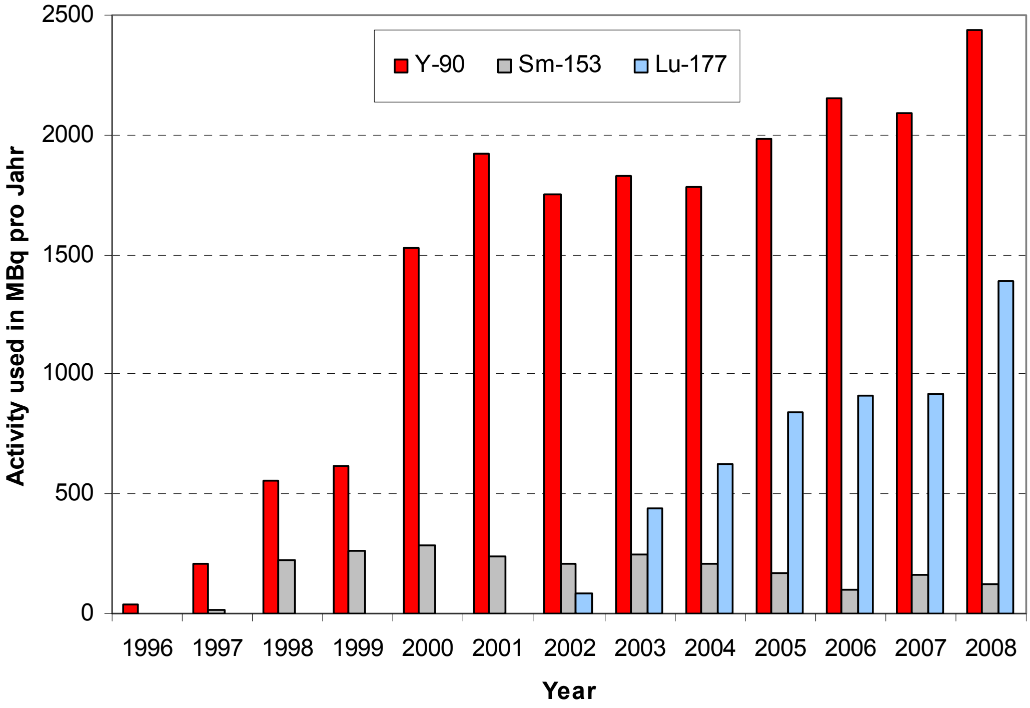

Fig. 2. Use of beta emitters for therapeutic purposes 1996-2008.

Material and methods

Nuclear medicine departments to be audited were selected on the basis of the use of F-18 and beta emitters (Y-90, Lu-177, Re-186, Sm-153, etc.). Data for increased extremity doses (greater than 10mSv/year) were consulted as a further criterion using the Swiss Central Dose Register. A total of 30 departments that handle beta emitters and/or PET nuclides were identified. The remaining 20 nuclear medical institutes work predominantly with Tc-99m, where increased extremity doses are rarely observed. In the audit, the personnel who are responsible for the organisation and monitoring of the radiation protection in the facility were interviewed. In addition, specialist staff (physicians, radiographers, chemists, laboratory technicians), who carry out preparation work in the isotope laboratory and administer radiopharmaceuticals to patients, were consulted as needed. In the planning of the questions for the audit, emphasis was placed on the 4 following topics:

1 Organisation of Radioprotection

Monitoring of radiation doses by means of external dosimetry (extremity dosimeters and whole body dosimeters) is an important instrument for reviewing working procedures. However, this is only valid if the dosimeters are worn consistently and in the right position. Investigations in a service with a high volume of Y-90 have shown that the highest doses are accumulated on the left palm of the hand (for right handed individuals). These results were also confirmed in a study [3] carried out under contract for the SFOPH (Fig. 3) by the Lausanne University Institute of Applied Radiation Physics (IRA).

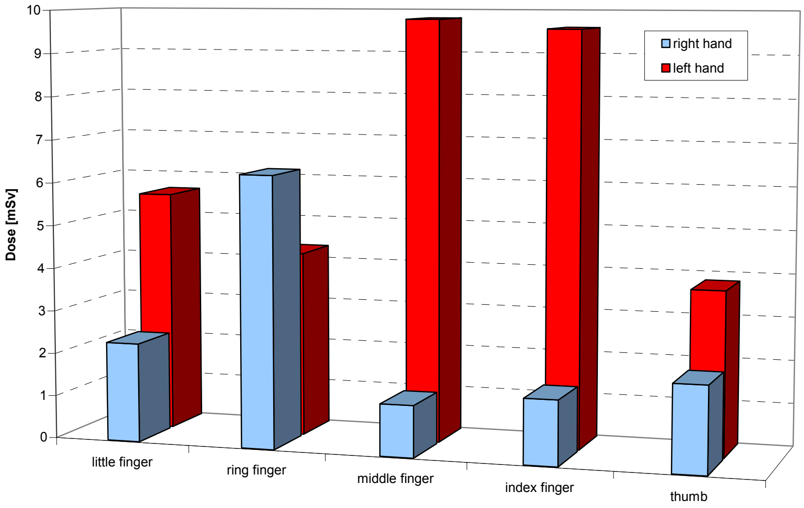

Fig. 3 Doses to fingers of the hands in the course of a preparation of a Zevalin® application (right handed individual).

The radiation protection expert in each service has the task of quickly clarifying increased or even regular doses, and to demonstrate how they can be avoided or reduced. If unusually high extremity doses are recorded in a department, then the persons in question must be quickly notified in order to clarify how this could have occurred. An important aspect is also the organisation of the distribution of the radiation doses. In this regard, unavoidable dose-intensive work should be distributed among as many staff as possible. Having said that, it must also be ensured, that the staff have adequate working routines so as to quickly and safely carry out these procedures.

2 Radiation protection training and continuous professional development

Persons occupationally exposed to radiation must have the relevant technical knowledge and competence, i.e. must at least be aware of radiation protection rules and dose-optimised work practices. In order to maintain this technical knowledge, the person who is responsible for radiation protection in the department must regularly organise continuing training for themselves and their colleagues. Prior to introducing new applications, all working steps with radioactive substances have to be planned and practiced from the viewpoint of reduced dose work techniques. Personnel who mainly work with conventional radionuclides (Tc-99m) used in nuclear medicine must be instructed that when manipulating beta emitters and F-18 there is an increased risk of accumulating high hand doses.

3 Equipment

Isotope laboratories used for the preparation of radiopharmaceuticals and administration rooms must be equipped in such a way that radiation sources are shielded as much as possible in order to reduce the dose to the personnel. Suitable containers must be available for the storage of radiopharmaceuticals and radioactive waste ([4] Ordinance for the use of unsealed radioactive substances). When manipulating radiation sources, short distances and easy access must enable fast and safe work.

4 Aids and auxiliaries for radiation protection

When using beta emitters, suitable Plexiglas shielding must be present and consistently employed (Fig. 4 and 5). When using F-18 for PET diagnostics, thick-walled lead or tungsten shielding has to be used in order to reduce the dose rates (Fig. 6). Vials containing radioactive substances or syringes, into which a radiopharmaceutical is aspirated, must be consistently shielded when manipulated. Manipulations lasting a few seconds without shielding can lead to doses of several mSv to the hand. Direct contact with unshielded syringes and vials should be avoided at all costs; indeed, should the situation arise, then remote handling devices such as gripping arms and tweezers should be employed. Because even small splashes can cause considerable skin doses, it is vital to wear gloves for all manipulations. As according to [2] latex gloves provide only inadequate protection from contamination, vinyl or nitrile gloves should be worn when handling beta emitters with high specific activity. With high patient turnover and extensive nuclide use, increased extremity doses can generally only be avoided if suitable automatic dispensers are utilised for filling syringes and administering the radiopharmaceuticals.

Fig. 5. Syringe shielding for beta emitters.

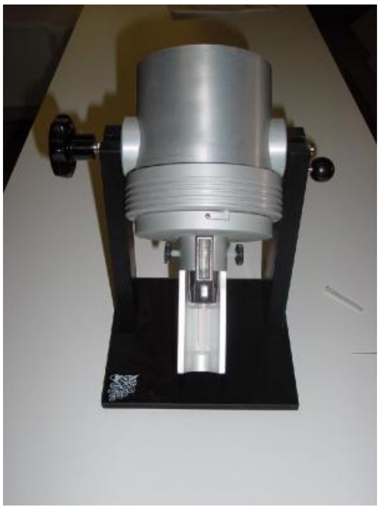

Fig. 6. Lead shielding for F-18.

Results

The radiation protection audits in the nuclear medicine departments generally aroused a high interest and were considered to be useful. The persons responsible for radiation protection and their colleagues are well aware that repeated use of beta emitters and PET nuclides leads to increased accumulated doses and especially extremity doses. Moreover, specific measurements of hand doses on the fingertips have demonstrated that the doses recorded by ring dosimeters, especially when working with beta emitters, do not reflect the maximum accumulated radiation doses. It can be assumed that the effective maximum hand doses are higher by a factor of 3 to 5. When comparing the monthly accumulated radiation doses with the therapies carried out, it could be further established that high values often correlate with individual beta therapies. An analysis and review of the radiation protection situation in the various departments yielded primarily the following two findings:

1 Organisation, training and continuous education

Audits in the different services have shown that the personnel and the responsible persons are well aware of the problem of increased extremity doses. However, training in this field must be further improved. The working procedures are partially configured from experience of handling conventional nuclides such as Tc-99m and the work places are correspondingly designed. There is a lack of awareness that unshielded beta emitters, even when manipulated for a few seconds, can already induce extremity doses of several mSv. Contrary to widespread belief, the time factor plays a minor role compared with shielding (a 10mm Plexiglas shielding reduces the dose rates by a factor of 1000). Discipline in regard to wearing extremity dosimeters is generally good. It is not universally known on which part of the hand the highest doses are to be expected, and hence where the dosimeters should be worn. The “radiation protection culture” in the services is generally well understood but can still be improved. Repeated high doses for staff are partially taken for granted and consistent optimisation is not sought after. In contrast, dose-intensive work is generally distributed as well as possible among the available staff, taking into consideration adequate training and procedures.

2 Facilities and resources

In nuclear medicine services where beta emitters are only used occasionally, the work places are often not set up in such a way as to enable the handling of radioactivity over the shortest possible distances. Moreover, ready-for-use radiopharmaceuticals are often directly syringed out of the suppliers’ shielded containers, which do not ensure adequate shielding above the top. Generally, remote handling devices such as tongs and tweezers are mainly employed when handling vials and syringes (Fig. 7). However, the temptation to intervene directly with ones hands for tricky work is great and often occurs even without thinking. Attaching and removing needle tips and three-way stopcocks (Fig. 8) is often carried out by hand. Even with attached shielding, needle tips are insufficiently shielded. Although there are some devices for this, their use is mostly felt as too laborious.

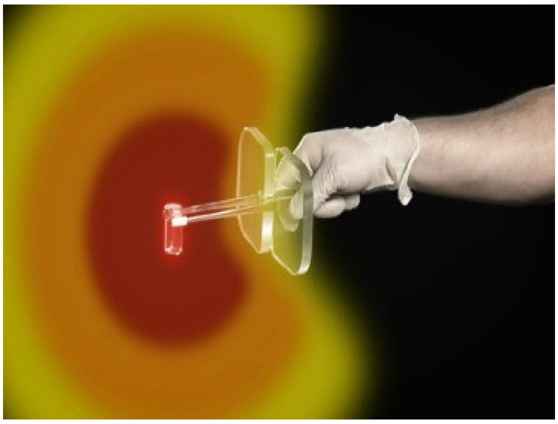

Fig. 7. Tweezers with Plexiglas beta shielding.

Fig. 8 Attaching the tip to a 3-way stopcock.

Prior to the administration of the radiopharmaceutical to the patient, the charged activity in the syringe has to be measured and verified in an activimeter [4]. As the syringe for this has to be removed from the shielding and this procedure is often carried out several times for an accurate dosage, this manipulation is dose-intensive. For this reason particular care must be taken to ensure that the arrangement of the workspace and the location of the activimeter allows fast working. If the activimeter is suitably calibrated, then the measurement of the activity of F-18 can also be carried out with the shielding in place. In some facilities syringes can also be filled automatically. However, practice-proven systems are expensive and also require a lot of space. For this reason devices of this type are primarily installed in services where the purchase and installation can be financially justified by a high patient turnover. Recently however, simpler, cheaper systems have also become available on the market. Nevertheless they still have to be proven in practice before they can find widespread use. A facility that has high turnovers of Y-90 and Lu-177 and consequently also carries out costly labelling, employs radiation protective gloves for some manipulations. Measurements have demonstrated that with these lead gloves - which are also used in interventional X-ray diagnostics - the hand doses can be reduced by a factor of 3 to 4. The methods of administration, depending on the application, are often very different in various institutes even within the same application. This presents a considerable potential for optimisation in this work procedure. If long-term administrations are also carried out in some hospitals with manual injections, they are carried out elsewhere automatically with syringe perfusions. A newly developed PET infusion system, developed in one of the services, actually allows a fully automatic dosing and injection. Following the audit of the SFOPH, binding measures for optimising radiation protection were agreed with the responsible persons. In addition to organisational aspects, such as intensifying the internal training and continuous education or verifying regularly how dosimeters are worn, these measures also include in-depth investigations by the service for the potential optimisation of specific dose-intensive work procedures and appropriate possibilities for assessment are submitted to the supervisory authority.

Discussion

With the SFOPH conducting audits, awareness about increased extremity doses was raised. Accordingly, tangible improvements were successfully introduced in the majority of facilities. The success of these efforts is also shown by the fact that between 2007, when the audits began, and 2009 the extremity doses in nuclear medical services have decreased by 23% (annual doses greater than 25 mSv) and 31% (annual doses greater than 50 mSv). An evaluation of whether individual working procedures can be optimised regarding radiation protection of the extremities, can however not be exhaustively made during an audit. For this reason it is intended to make a detailed examination of the operational procedures in various services, as has also been recommended in a statement by the Federal Commission on Radiological Protection and Monitoring of Radioactivity (CRP) to the SFOPH [6]. In order to detect and record possible errors and their effects, the maximum finger doses should be measured with TLDs on the finger tips during critical manipulations (Fig. 9). The work procedures could also be filmed in order to subsequently analyse the causes of the accumulated doses. Automated dosing and injection systems offer a high capability for reducing the hand doses. Experiments in a PET Centre with a fully automatic doser/injector have shown that a dose reduction by a factor of greater than 10 is possible [5].

However, proven systems are rare and expensive and are only available in institutes that have high numbers of patients and corresponding financial means. More cost efficient systems have still to be tested in depth and must provide evidence that the quality of the dosing or the injection is at least as good as in a manual procedure.

Fig. 9. TLD for the determination of the maximum dose to extremities.

Conclusions

Developments in nuclear medicine show that applications involving PET nuclides and beta emitters will probably increase further. For this reason, additional measures must be provided for the training and continuing education of the staff in order to avoid any further increase in extremity doses. The SFOPH will therefore produce and publish a continuing education DVD, which will illustrate optimised radiation work procedures when handling beta emitters and PET nuclides. Furthermore, a recommendation for radiation protection is intended to be drawn up for this topic and practical continuing education courses will be offered. In addition, the question of whether automatic systems should be made mandatory for dose-intensive work procedures will be examined.

Morphological dependence of lung counting efficiency for female workers

Farah, Jad; Broggio, David; Franck, Didier
Institut de Radioprotection et de Sûreté Nucléaire, IRSN/DRPH/SDI/LEDI, BP-17 F-92262 Fontenay-aux-Roses Cedex, FRANCE

Abstract

In vivo lung monitoring of female workers is routinely performed using calibration coefficients calculated with a male thoracic mannequin since no female model exists. More appropriate calibration coefficients can be obtained using numerical models. In this work, flexible 3D Mesh and NURBS (Non Uniform Rational B-Splines) geometries were considered to design representative female thorax. Lung counting efficiencies were simulated for typical germanium detectors and the parameters of their morphological dependence were defined.

A library of 24 different 3D female models was created representing the most common female breasts with various cup sizes (A to F) and chest girths (85 to 120). Monte Carlo simulations were then achieved to investigate the chest girth and cup size effects on the counting efficiency. It was shown that for the 59.54 keV Am-241 gamma ray, the counting efficiency decreases of about 15% between the 85A and the 85B phantoms. Moreover, a 55 fold decrease in efficiency was observed at 22 keV between the 120C and the 85C phantoms.

An equation was developed, involving simple physical assumptions, which defines any counting efficiency as a function of chest girth, cup size and a reference efficiency curve. Morphology-dependent parameters were calculated in order to estimate the efficiency curve of any female subject (any breast size and morphology) if a reference efficiency is provided. Furthermore, the developed equation was able to describe the relation between the calculated female efficiency and the Livermore calibration data. It was found that the simulated 85A efficiency curve is in close agreement with the calibration measurements performed with the Livermore and its first extra-thoracic plate. Since this agreement depends notably on the chosen counting position for females, it was also shown how to transform calibration measurements performed with other thoracic plates.

This work enables a better assessment of the *in vivo* calibration coefficients improving the female workers monitoring.

Introduction

After an intake of radionuclides, *in vivo* counting and bioassays are the only two available techniques enabling the assessment of the retained activity (ICRP 1988). To correctly estimate the contamination using *in vivo* spectrometry, counting systems accurate calibration is required. The latter is typically done using anthropomorphic physical phantoms (ICRU 2003). However, there is no female torso phantom even though the female morphology can significantly influence the count. Hence, Monte Carlo (MC) calculations and numerical models of the human body are used to obtain realistic calibration factors, compensating for the absence or poor realism of physical phantoms (de Carlan *et al.* 2007, Hunt *et al.* 1998, Kramer *et al.* 2009)

The first numerical models (mathematical phantoms) represented the human complex anatomy by simple equations. Later, the voxelized phantoms were introduced in radiation protection to offer a more realistic representation than the mathematical phantoms (Zankl *et al*. 1988) and the ICRP has recently released reference male and female voxel models (ICRP 2009). Recent developments in 3D formats and associated tools enabled the design of more flexible anthropomorphic 3D models. Indeed, Mesh or NURBS formats can be easily manipulated and transformed to obtain various representative postures or morphologies (Xu *et al.* 2007, Lee *et al.* 2007).

Here we address the question of the morphological dependence of counting efficiency curves for *in vivo* lung monitoring of female workers. For this purpose a library of 24 female torsos, representing the most common breast sizes and morphologies, was designed using Mesh and NURBS formats. MC calculations of the counting efficiencies of a typical Germanium counting system were achieved for all phantoms. Next, a simple analytic formula was derived to describe the morphology effect on counting efficiency. Finally, a practical example is given to show how an experimental reference calibration curve, obtained with the Livermore phantom, can be transformed to provide efficiency corrections for most common breast morphologies.

Material and methods

This work first presents the Monte Carlo calculations carried out with the designed phantoms. Then, it focuses on the parameterization of the morphological dependency of the counting efficiency. The definition of an analytic formula is given to describe the relation between efficiency curves obtained for each female phantom. This equation is validated using Monte Carlo simulated data and tested with experimental efficiencies obtained with the Livermore phantom.

1. Simulation of in vivo lung counting measurements

A flexible female library of 24 torso models, representing most common breast morphologies, was created starting from the ICRP Adult Female Reference Computational Phantom (ICRP AF-RCP) (ICRP 2009). When creating the female thoracic 3D models, breast cup size variation was achieved by adipose tissue adding according to plastic surgery recommendations (Turner and Dujon 2005). Realistic variation of the chest girth (from 85 to 120), internal organs volumes, compositions and densities were also achieved. For the 85 and 90 chest girth phantoms, internal organs volumes were the same. For the 100, 110 and 120 chest girth phantoms, these volumes were modified taking into account height dependant correlations (Clairand *et al.* 2000).

Counting efficiency variation with energy was calculated for the 24 different models to identify the morphology effect, namely cup size and chest girth (i.e. internal organs resizing), over the count. Chest wall thickness variation with cup size proved to have exponential attenuation effect over the count as the Am-241 ray at 59.54 keV suffered a counting efficiency loss about 15% when comparing the 85A simulation and the one of the 85B phantom. On the other hand, chest girth variation proved to have greater effect since a factor of about 55 was noticed at 22 keV between the counts with the 85C phantom and the 120C one. This is mainly due to the fact that internal organs volume was changed with chest girth. More details concerning the library creation methodology and Monte Carlo MCNPX simulation results can be found in a previous publication (Farah *et al.* accepted).

2. Parameterization of the morphological dependence on counting efficiency

Counting efficiency is given in terms of source activity and the count of the detectors and is directly related to radiation attenuation by body tissue. Therefore, if phantoms' geometry changes, this attenuation also varies. This work aims to develop an equation that enables a correct and reliable estimate of this variation.

The series of created phantoms have different chest wall thicknesses (cup size and chest girth) and modified internal organs volumes (for the 100-110-120 models). To correctly relate two simulated counting efficiencies, the observed morphology changes are taken into account. In the case of a difference in chest wall thickness, exponential radiation attenuation is involved. The latter is highly dependant on crossed tissue nature. For simplification reasons, the adipose tissue mass attenuation coefficient was considered to represent the whole suffered attenuation by chest structures.

Hence, the new efficiency would be written as follows:

$$\varepsilon' = \varepsilon \times e^{(\mu_{adipose} \times chest \quad thickness)}.$$

In the case of internal organs volumetric differences, it is the loaded organ's volume that is involved. As shown by Farah (Farah et al. 2010), detectors' counting efficiency varies with the inverse of the lung volume in the case of volumetric uniform activity distribution. Hence, the ratio of the reference lung volume and the new one should also be taken into account and the new efficiency would be written as follows:

$$\varepsilon' = \varepsilon \frac{V}{V'}.$$

The equation relating two counting efficiencies is then of the form:

$$\varepsilon_2(E) = \varepsilon_1(E) c_1 e^{-c_2 \mu(E)} \quad (1)$$

Where ε_1 represents the reference counting efficiency, ε_2 the unknown efficiency and E the energy. The parameter c_1 should vary with the inverse of the lungs volumes and c_2 should take into account chest-wall thickness variation. Finally, $\mu(E)$ is the mass attenuation coefficient for ICRU-44 adipose tissue (7 compounds) (ICRU 1989) obtained with the online NIST-XCOM tool (Berger *et al.* 2005).

This developed equation was first used to reproduce the simulated experiments. However, it remains of limited interest if not applied to experimental measurements. Thus, the next step was to investigate the possibility of using calibration measurement as the reference efficiency of Equation (1).

Results

1. Application to simulated experiment

Equation (1) is applied to the MC simulated efficiency curves, taking the 85A model efficiency as the reference. The parameters c_1 and c_2 are found with a linear regression, considering the variables $Y=\ln\left(\frac{\varepsilon_{phant}}{\varepsilon_{ref}}\right)$, $X = \mu(E)$ and writing $Y = \ln(c_1) - c_2 X$.

When applied to the 85 and 90 (chest girth) models, the lung volume is the same as for the 85A model, hence the c_1 parameter is directly set equal to 1; this is not the case for the three biggest girths. Table 1 resumes the c_1-c_2 obtained values for all the 85 chest girth models starting from the 85A simulated efficiency.

Table 1. Values of the c_1-c_2 parameters and associated R^2 for the 85 chest girth and B to E cup sizes with the 85 A model being the reference.

Phantom	Parameters		
	c_1	c_2	R^2
85 B	1	0.856	0.9982
85 C	1	1.179	0.9967
85 D	1	1.467	0.9995
85 E	1	1.867	0.9928

These parameters are then used in Equation (1) and the resulting efficiency is compared to the MC simulated values. The maximum difference between the MC efficiencies and those obtained with equation (1) is a practical indicator of the validity of the proposed model. For the 85 E phantom, the highest relative error between the simulations' counting efficiencies and the calculated ones is about 6.4% and is observed for the lowest energy photons at 15 keV. For the 90 chest girth models the highest difference was found to be about 6% for the 90E phantom at 15 keV. Moreover, for the 100, 110 and 120 models, MC simulated efficiencies and the calculation results do not differ by more than 5%. Figure 1 compares the MC and calculated counting efficiency curves for 85B, 90C, 100D, 110E and 120F models.

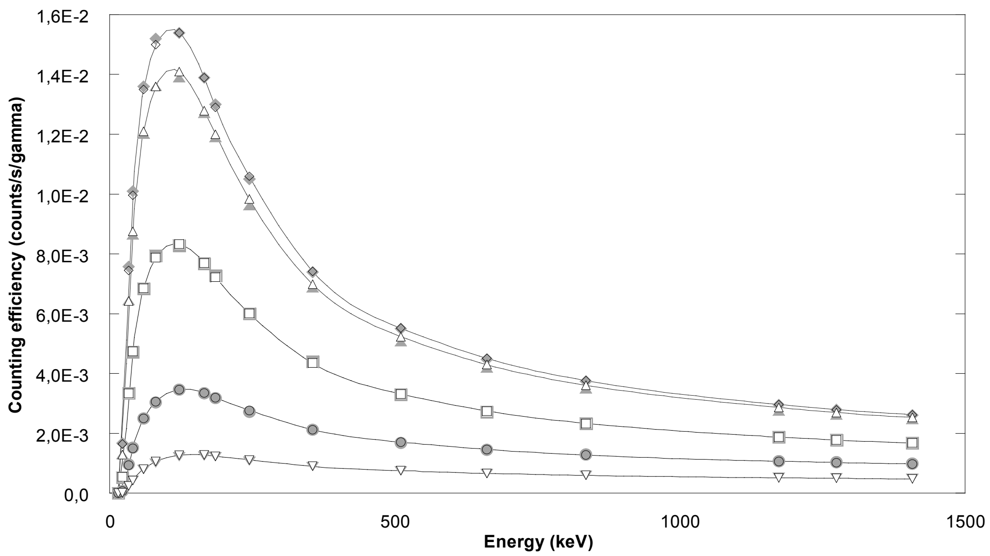

Fig. 1. Counting efficiency variation with energy. Comparison between MC simulated values (empty markers and solid lines) and the equation calculated values (filled markers) for the 85B model (diamonds), 90C (triangles), 100D (squares), 110E (circles) and 120F (inverted triangles); 85A simulation being the reference.

2. Application to measured experiment

In order to use the developed equation for reproducing experimental calibrations, the existing morphological differences were first identified and then their effect over the count included to transform the Livermore (Griffith *et al.* 1978) calibration curve to a MC simulated one.

The Livermore measurements carried out at the AREVA NC reprocessing plant were used for this study. The results included 5 different associated plates (P0 – P4) of thicknesses ranging from 1.8 to 4.3 cm. The Livermore lungs volume (loaded organs) is also different from the one of the female models. Moreover, detectors positioning induces significant variations in the lungs covered regions since it was not the same in both cases. Nevertheless, to a good approximation, moving the detectors away from the source is equivalent to changing the volume of the source without moving the detectors; this is taken into account with the same constant (c_1).

The c_1 - c_2 parameters of Equation (1) were calculated taking the Livermore calibration data as the reference efficiency and the 85A MC efficiencies as the unknown value. The obtained c_1 - c_2 values are given in Table 2 along with the associated R^2 coefficients describing the linear regression quality. According to this table, the best fit of the 85A efficiency is obtained with the Livermore P4 plate measurement being the reference.

Table 2. Values of the c_1-c_2 parameters and associated R^2 obtained to estimate the 85A efficiency from the various Livermore measurements and associated plates.

Livermore plate measurement	Parameters		
	c_1	c_2	R^2
P0	0.963	1.194	0.964
P1	0.990	0.184	0.206
P2	1.045	-0.140	0.192
P3	1.197	-0.999	0.982
P4	1.295	-1.910	0.990

Using the c_1 and c_2 parameters found in the P4 case, the 85A MC counting efficiency is reproduced with a maximal relative difference of 8.7% for the Eu-152 ray at 40 keV. It is hence now possible to transform the P4 plate measurement to any of the 24 female phantoms of the library as shown in figure 2.

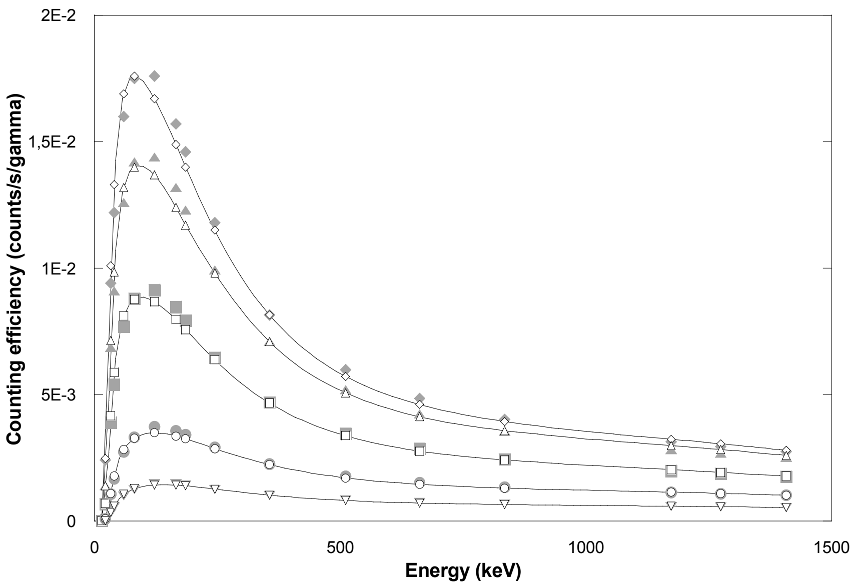

Fig. 2. Counting efficiency variation with energy. Comparison between MC simulated values (empty makers and solid lines) and the equation calculated values (filled markers) for the 85B model (diamonds), 90C (triangles), 100D (squares), 110E (circles) and 120F (inverted triangles). P4 measurement being the reference.

Discussion

Equation (1) uses the adipose tissue mass attenuation coefficient, which is tabulated and easily available, and two parameters. This part focuses on the study of these parameters' dependency with volumetric change (case of c_1) and chest wall thickness variation (c_2), the main implicated morphological factors.

For the 100, 110 and 120 models c_1 is expected to be close to the ratio of the reference lung volume (2.3 L) and the modified lung volume (2.99 L). Since the three biggest chest girths have the same lungs volume, they should have the same c_1 constant regardless of the cup size and its value should be about 0.77. The c_1 value for the 100 chest girth (0.73) is acceptable; this is far from being the same for the 110 and 120 phantoms (0.53 and 0.34 respectively). However, detectors positioning significantly alter these values since the 2 cm distance to the skin could not be systematically used for all models to prevent any collision with breast structures. As a consequence, the solid angle covering lungs changes and c_1 cannot exactly represent the ratio of lung volumes.

However, considering the small difference between calculated and MC efficiencies, it can be deduced that the model given by Equation 1 is useful, as long as we consider that obtaining a counting efficiency with an uncertainty of 5-10% is suitable.

To give a practical relation for the choice of c_1 and c_2, we examined the correlation of these parameters for the 100 to 120 chest girth. Figure 3 shows c_1 as a function of c_2 and demonstrate a linear tendency. This correlation is of particular interest since it enables the calculation of the counting efficiency as a function of female worker morphology. It enables the calculation of the c_1 value if a good estimate of c_2 is available, *i.e.* an estimate of the cup size variation. For example, this equation can be used in the case of a 105D chest girth where no numerical model was created.

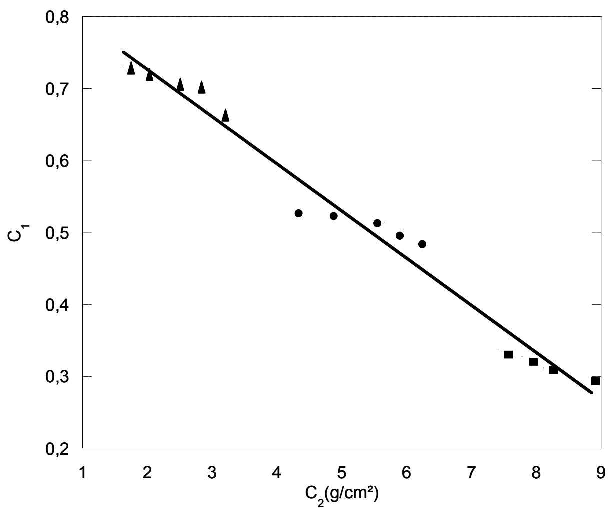

Figure 3. c_1 variation with c_2 for the 100 (triangles), 110 (circles) and 120 (squares) chest girths and associated cup sizes; linear fit plotted by Microsoft Excel 2008™: y = -0.0656 x + 0.8574, R^2=0.9728.

Conclusions

In this work, a new generation of anthropomorphic phantoms using Mesh and NURBS 3D flexible formats was created to optimize the monitoring of workers with internal contamination risks. The study focused on the lung monitoring of female worker for whom no physical calibration phantom is available.

For a typical 4-Germanium detectors *in vivo* counting system, counting efficiency curves were calculated for 24 typical female morphologies, taking into account different chest girth and cup sizes. The MC results are satisfyingly explained by a simple equation relating a reference and the unknown efficiency. The developed equation enabled a good estimate of the counting efficiency for every possible female subject and would be of great interest especially when no numerical model is available.

Acknowledgements

This work was carried out under the PIC DOSINTER project, a collaboration between AREVA and the IRSN. The authors would like to thank Mr Xavier Lechaftois and the AREVA NC Medical Department team who provided the Livermore measurement data and Dr Patrick Min for efficient and friendly collaboration in the use and improvement of the Binvox program.

ALARA – Education for personnel involved in the plant modification process

Nilsson, Virva
Forsmark Kraftgrupp AB, Vattenfall, SWEDEN

Abstract

In order to achieve optimal worker protection at a nuclear power plant the radiological protection aspects should be considered in an early stage of the plant modification process. It is of utter importance that staff involved in the planning of and in the plant modification process itself is well informed on how the ALARA-principle can be applied. Today no specific ALARA-education exists for the staff involved in these tasks. A development of suitable education and information material for the personnel in question has been initiated at Forsmark NPP.

The work to develop an education package "ALARA for Personnel Involved in the Plant Modification Process" has been started by assessing the present level of knowledge and understanding as well as the need and interest for education. An enquiry was sent out to the department managers involved in plant modification process to spread in their organizations.

The percentage of received answers was less than 15% of the number of personnel involved in these tasks. This clearly indicates that the ALARA-principle has not been among the highest priorities in this area. About 50% of the personnel that answered the enquiry were interested in obtaining more knowledge and practical examples on how to apply the ALARA-principle early in the planning stage of plant modifications.

There is an interest and demand for more knowledge in the area but only among a limited group of the personnel. Our goal is to make ALARA-principle more commonly known and to make it an every-day tool used in all the possible steps in the plant modification process.

Reduction of dose around a storage pool by changing the position of BWR irradiated control rods

Ródenas, José; Abarca, Agustín; Gallardo, Sergio
Departamento de Ingeniería Química y Nuclear, Universidad Politécnica de Valencia, Apartado 22012, E-46071 Valencia, SPAIN

Abstract

BWR control rods are irradiated into the reactor by the neutron flux and consequently activation reactions are produced in the materials composing the rod, mainly in stainless steel components and impurities. The dose produced by this activity is not important inside the reactor, but it has to be taken into account when the rod is withdrawn from the reactor and stored into the storage pool for irradiated fuel of the plant at a certain depth under water. The neutron activation has been modelled with the MCNP5 code, based on the Monte Carlo (MC) method. The pool containing hanger devices with irradiated control rods has been also modelled with the MCNP5 code. Doses potentially received by plant workers in the area surrounding the pool edges as well as in a platform moving over the water surface have been also calculated with the same MC code. In previous works, all these models have been validated. Results of the activation model proved that the rod handle is the most irradiated part of the control rod. Inverting the position of the rod into the storage pool with the handle at a deeper position under water should be a suitable method to reduce the dose out of the pool. In this work, the MC models are applied to verify the expected reduction of dose when the irradiated control rod is hanged in an inverted position into the pool.

Introduction

Control rods are activated by neutron reactions into the reactor. The activation is produced mainly in impurities contained in stainless steel as well as in the elements composing the steel alloy. The activity so generated will produce a dose around the rod, not important while it is inside the reactor, but it has to be taken into account when the rod is withdrawn from the reactor.

Activation reactions have been simulated with the MCNP5 code (X-5 Monte Carlo Team 2005), based on the Monte Carlo (MC) method and the number of reactions calculated can be converted into activity. When rods are withdrawn from the reactor, they must be stored into the storage pool for irradiated fuel of the plant at a certain depth under water. The storage is disposed to hang up 12 rods in a hanger device specially designed for this goal. Several hangers can be installed at various positions throughout the pool close to the walls. Doses potentially received by plant workers in the area surrounding the pool edges as well as in a platform moving over the water surface should be calculated to assure their adequate protection. Spent fuel elements are stored at the bottom of the pool while controls rods are nearer the surface. Therefore, doses out of the pool are mainly due to control rods.

In previous works (Ródenas et al. 2010a, 2010b), a simplified model was developed to estimate the activity generated as well as the dose around the storage pool. Afterwards, a detailed model of the control rod was developed (Ródenas et al. 2010c) considering all its components: handle, boron tubes, gain, and central core, dividing the rod into 5 zones to take into account the different axial exposition to neutron flux into the reactor. A further MC model was developed to estimate doses produced at points corresponding to these 5 zones. By comparing these doses with experimental measurements near an irradiated BWR control rod, it was validated the model developed. It was also validated the model developed simulating several groups of twelve control rods stored in the irradiated fuel pool of the NPP to calculate dose rates around the pool (Abarca et al. 2009).

Results of the activation model proved that the rod handle is the most irradiated part of the control rod. In this work, the developed MC models has been applied to verify the expected reduction of dose when the irradiated control rod is hanged in an inverted position into the pool.

Material and methods

Activation

The activity generated in the control rod depends on reaction cross sections, neutron spectrum, neutron flux distribution, concentration of precursors of each radionuclide, irradiation time and control rod history. After withdrawing the rod from the reactor, activities decrease with time and disintegration constants.

It is necessary to estimate the interaction rate Q (reactions /cm^3-s):

$$Q = C \int \Phi(E)\, \sigma(E)\, dE \qquad [1]$$

for each reaction, being C a normalization factor (at/barn-cm) depending on the target concentration; $\Phi(E)$ the neutron flux (n/cm^2-s); and $\sigma(E)$ the microscopic cross section of the reaction (barn).

On the other hand, for each j-isotope generated, a matter balance can be done:

$$dN_j/dt = Q_j - \lambda_j N_j \qquad [2]$$

integrating, the concentration (nuclei/cm^3) of j-isotope is obtained (being t_i the irradiation time):

$$N_j(t) = (Q_j/\lambda_j)\,(1 - \exp(-\lambda_j t_i)) \qquad [3]$$

For a cooling time (rod out of the reactor) t_e the concentration N_j becomes:

$$N_j(t) = (Q_j/\lambda_j)\,(1 - \exp(-\lambda_j t_i))\,\exp(-\lambda_j t_e) \qquad [4]$$

and multiplying by λ_j to obtain activity:

$$A_j(t) = Q_j\,(1 - \exp(-\lambda_j t_i))\,\exp(-\lambda_j t_e) \qquad [5]$$

It is a volumetric activity (Bq/cm^3). To obtain the total activity it is necessary to multiply by the cell volume. The maximum activity will be the asymptotic value, Q_j, considering an irradiation time very long (~∞) and neglecting the cooling time.

Major activation reactions are produced in steel mainly in gains and handle and mostly in some alloy components and impurities. Reactions considered and isotopes produced are listed in Table 1. Nevertheless, only those isotopes emitting gamma rays and with half-lives greater than 60 days have interest from the point of view of dose calculation. Consulting disintegration schemes (JANIS database 2005), they remain the following: Mn-54, Sc-46, Co-60, Zn-65, Nb-94, Ag-108m, Ag-110m, Eu-152, Eu-154, and Hf-178.

Activation model

Monte Carlo models developed (Ródenas et al. 2010a, 2010c) to assess the activity generated in control rods of a BWR are based on a detailed geometry that includes an axial division of the rod to consider the different periods and lengths of insertion during its permanency in the reactor core, so that the movement of control rods during reactor operation can be taken into account in the activation assessment. This detailed model can be seen in Fig. 1 drawn with SABRINA (Van Riper 2003) and VISED® (Carter and Schwarz 2005).

The interaction rate Q is calculated by MCNP using F4 tally and FM4 (tally multiplier card), which provides data for the reactions included in the calculation.

Dose rates around the control rod have been calculated and compared with measurements in order to validate the activation model (Ródenas et al. 2010c).

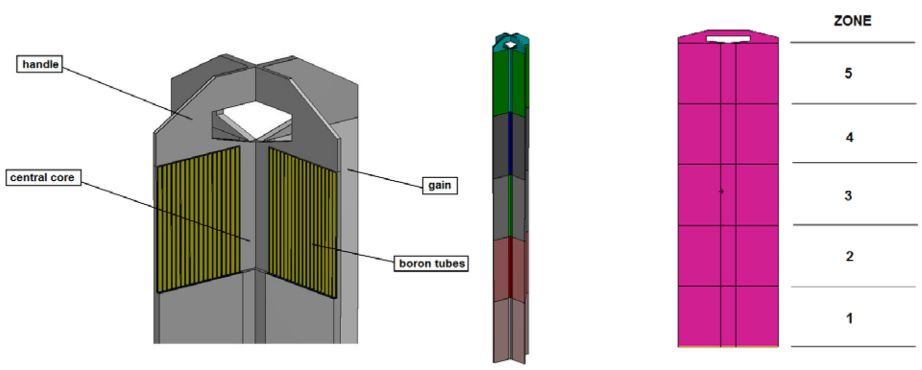

Fig. 1. Components of the control rod model and axial division of the model.

The neutron spectrum used in calculations is based on a mean value of the neutron flux throughout the reactor core, modified by a different probability in each zone that considers the control rod history. Fluxes have been obtained by means of the CASMO code (Knott et al. 1995) for a GE14 fuel element with 20 GWd/t of burnup and 40% of void fraction without control.

Pool Model

The spent fuel storage pool considered in this work has hexahedra shape, 11.375x5.258 m section and 13.1 m depth. The concrete walls and bottom of the pool have 1 m thickness. There are 30 cm of air over the upper level of water. Spent fuel elements are stored at the bottom of the pool while activated control rods are stored over them at about 3 m from the surface. The ground plan and elevation of the pool are represented in Fig. 2, where it can be seen the position of spent fuel elements and hangers for control rods.

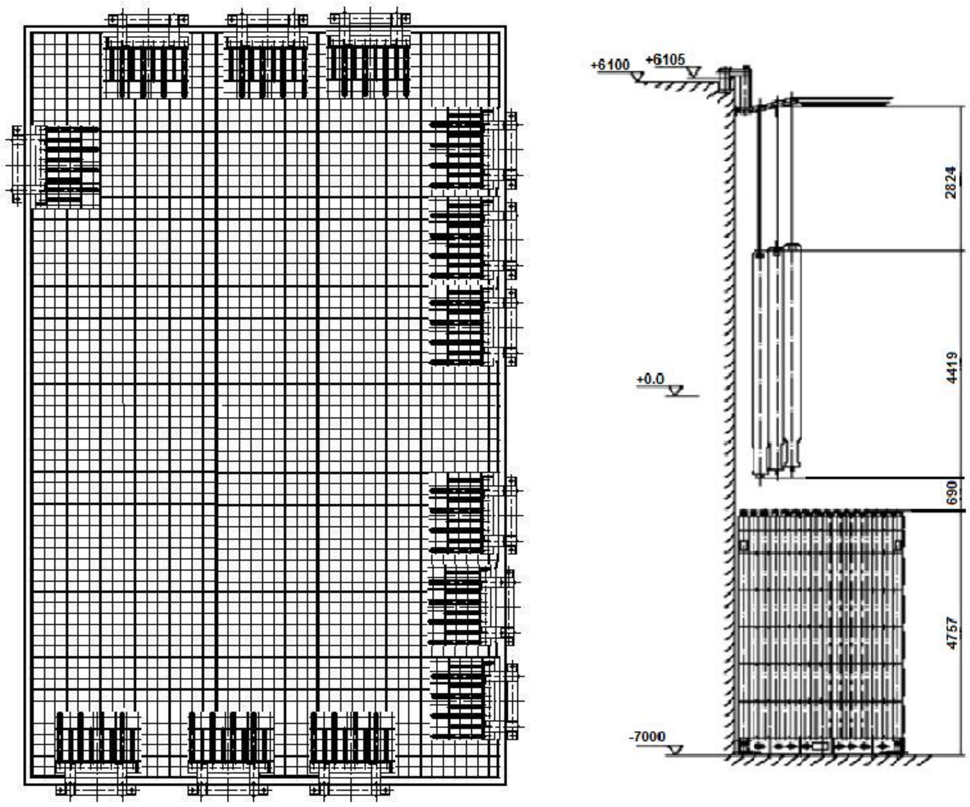

Fig. 2. Position of control rods hangers in the pool.

The pool has been modeled by a lattice with control rods in appropriate positions and the other cells filled with water. A VISED® (Carter and Schwarz 2005) scheme of the pool MC model can be seen in Fig. 3. It is shown in this figure, concrete walls, water filling the pool, hangers with control rods, and the air zone above the water where doses shall be calculated. Fuel elements either rod control hangers are not modeled as they do not practically interfere with the dose calculation.

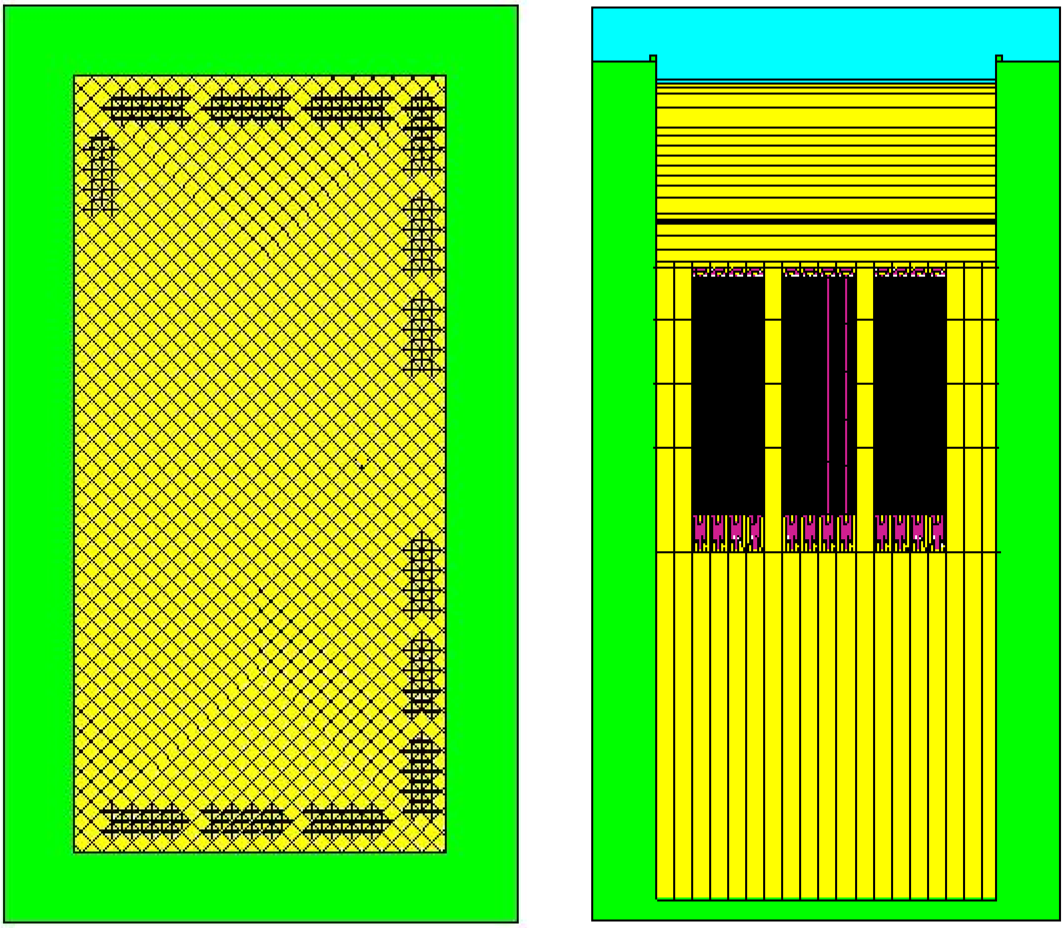

Fig. 3. VISED® scheme of the ground plan and elevation of the pool model.

Source Model

A cylindrical volume source with cell rejection option has been programmed. Furthermore, a defined volume distribution should be used in combination with the CEL variable to sample uniformly throughout the interior of a cell.

Each element of control rod presents different activity. Therefore, each cell in the source must have different photon emission and probability. To do it possible, the FCEL option has been used for energy specification in the source definition card. A repeated structure format shall be used in the CEL card to simulate sources in all the lattice elements occupied by control rods stored in the pool.

Variance reduction techniques

The main problem in the developed model is that very few photons reach the pool water surface. Therefore, statistics is very poor and large uncertainties are associated with results. To improve statistics, the water volume over the control rods is divided into several slabs with increasing importance values. They can be seen in Fig.3 right side.

An important reduction of computing time can be achieved using the SSW/SSR technique. In this technique, a first simulation containing the Surface Source Write (SSW) card is run. Those photons emitted from the source (activated control rod) that pass through a defined plane are recorded in a file with all its characteristics (energy, direction, etc.). This surface source file is used for subsequent MCNP calculations where the input deck contains the Surface Source Read (SSR) card. In the second and subsequent simulations, the number of particles can be strongly increased, but the source is simplified as it is just a plane and the recalculation of all interactions before arriving to this plane is avoided. Therefore, statistics can be improved with slowly increasing computer time.

Dose reduction model

The activation model previously validated (Ródenas et al. 2010c) has been applied to a BWR control rod obtaining the activities listed in table 2, where it can be seen that the maximum activity for all nuclides considered is located in the handle. An expected result because the handle is always into the reactor core while the other parts of the rod can be more or less introduced. Therefore, rotating 180º the rods into the storage pool with handles at a deeper position under water should reduce the dose out of the pool.

Table 2. Total activity (Bq) in the different parts of a control rod.

Results and discussion

The same MC model used for dose calculations around the pool (Abarca et al. 2009) can be applied to verify the dose reduction obtained when BWR control rods are hanged in an inverse position into the pool. It is just necessary to change the cells corresponding to control rods in order to represent the new position, as shown in Fig. 4 where the zone corresponding to control rods has been enlarged. It can be seen the handle in the opposite position than in Fig. 3. The rest of the model doesn’t change and the same variation reduction techniques are applied.

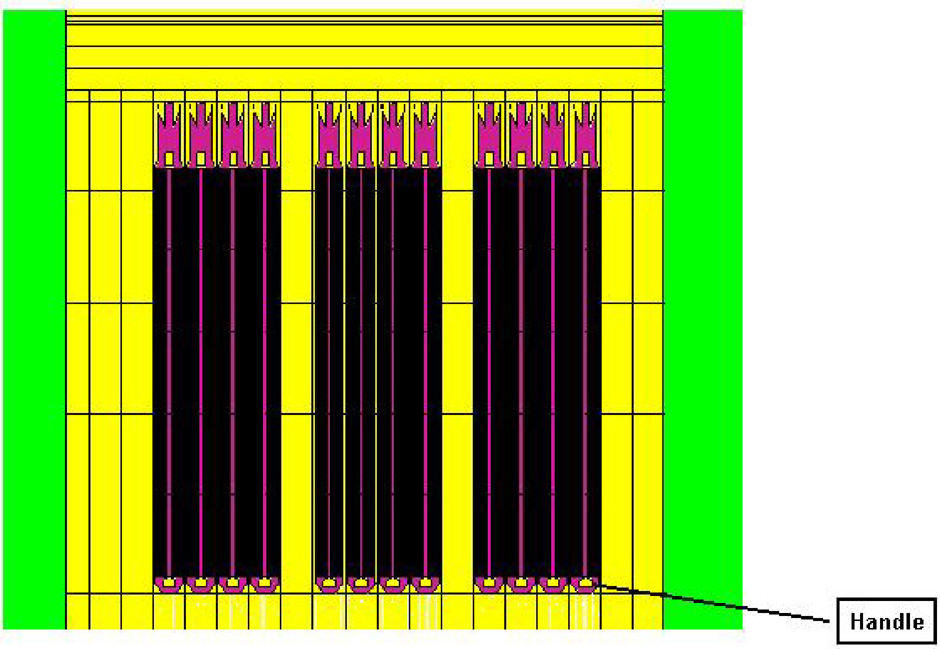

Fig. 4. VISED® scheme of the elevation of the pool model with control rods rotated 180º.

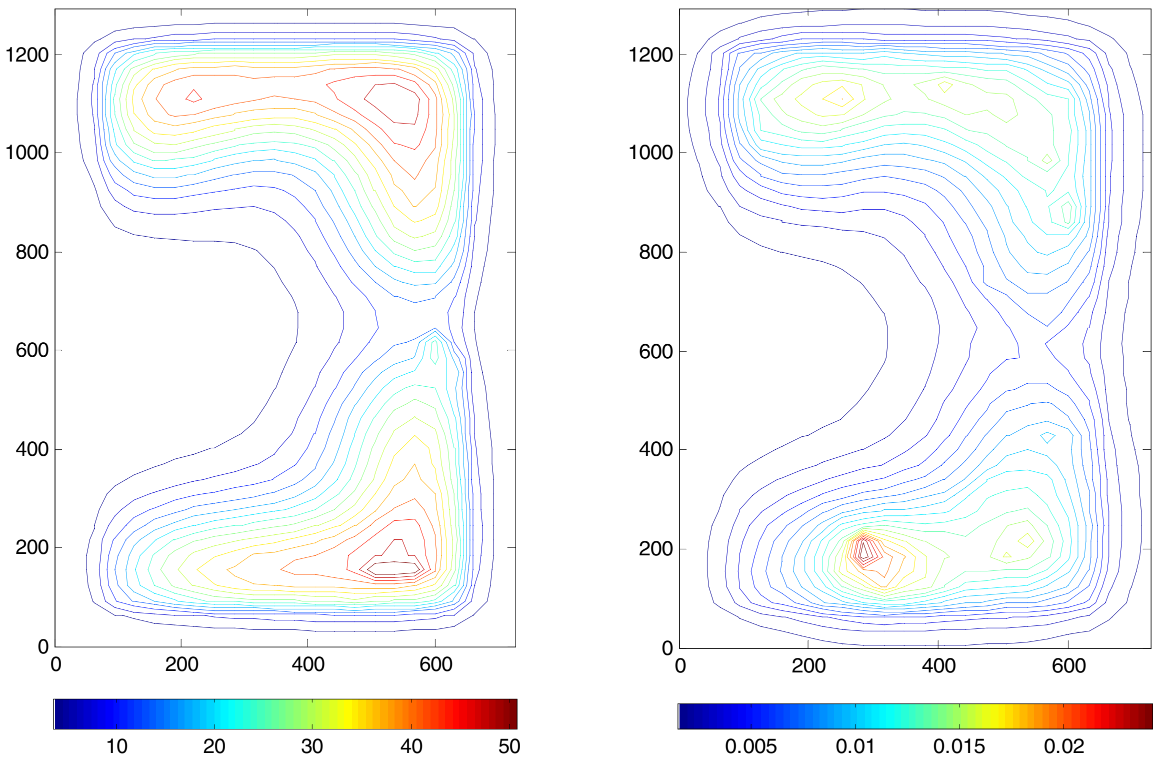

Fig. 5. Dose rate (μSv/h). Left: normal position. Right: reverse position.

Again a F4MESH tally has been used to determine dose rate in a mesh in air over the piscine, the zone 1 m above the free water surface and 1 m beyond piscine walls marked in cyan blue in Fig. 3.

Calculated dose rates (μSv/h) are represented in Fig. 5. At left side for control rods in the normal position, while at right side they are rotated 180º. Uncertainties associated with calculated doses are lower than 10%, except around the red lines in the right graph where it is about 25% due to the fact that few particles reach the water surface from these points.

Really the number of particles reaching the zone where dose rates are calculated is again a problem, even worst than for normal position as photons have a longer pathway when they are started from the handle where the activity is the largest.

In any case, as it can be seen in the isodose maps represented in Fig. 5 the dose rate over the pool can be reduced more than 2,000 times changing the storage position of control rods. A comparison between dose rates (μSv/h) calculated for both control rod positions is done for 5 points: maximum, meaning the point where the dose rate is maximum for normal position of control rods; middle of the pool; and the four corners of the pool (right lower, right upper, left lower, and left upper). In table 2 these values are listed together with the dose reduction and the ratio between doses at normal and inverse position.

Table 3. Dose rate and dose reduction in selected points over the pool.

	Dose rate (μSv/h)			
Calculation points	**Normal Position**	**Reverse Position**	**Dose Reduction**	**Ratio**
Maximum	50.00	0.0161	49.979	2500
Middle of the Pool	7.58	0.0037	7.576	2048
Right Lower Corner	22.15	0.0092	22.141	2408
Right Upper Corner	21.47	0.0089	21.461	2412
Left Lower Corner	13.61	0.0043	13.606	3165
Left Upper Corner	29.38	0.0102	29.369	2880

Dose ratios are represented in Fig. 6 where it can be seen the huge reduction of dose for the area surrounding the pool obtained when the irradiated control rods are stored in a position rotated 180º. In this area, it is more probable the presence of operators.

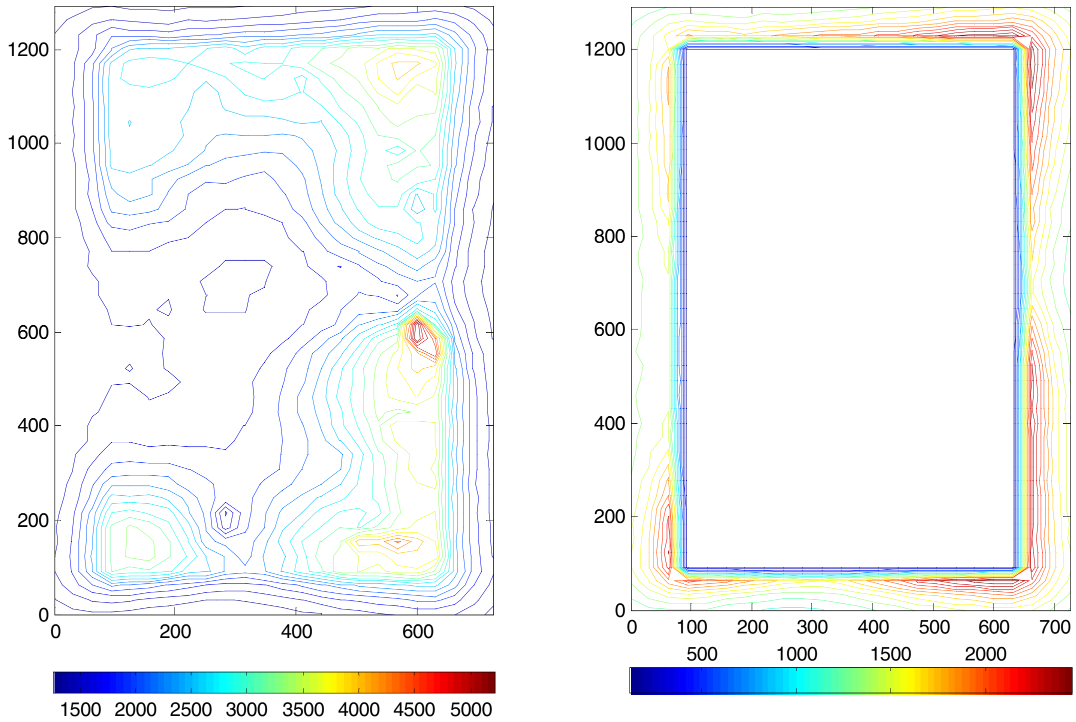

Fig. 6. Dose rate ratio. Left: over the pool. Right: around the pool.

Conclusions

The activation of control rods due to neutron irradiation during its stay into the reactor core is more important for the rod handle as in BWR it is always into the core while the other parts of the rod can be more or less introduced. Therefore, an inversion of the position of control rods stored into the irradiated fuel pool will produce an important reduction of the dose around the pool.

Monte Carlo models developed and validated to assess activity produced in control rods and dose rates in the area surrounding the storage pool have been applied to the case of a BWR power plant, considering the usual position of the control rods and the reverse position into the storage pool.

Results show an important reduction of dose rate, by a factor of 2000 approximately, in the zones where operators are usually working.

Therefore, it is very advisable to introduce the appropriate changes in the hanger devices in order to achieve this important dose reduction.

Periodic review and update of the company ALARA program – Continuous improvement in the field of radiation protection

Hennigor, Staffan
Forsmarks Kraftgrupp AB, Safety and Environment – Radiological Safety, SWEDEN

Abstract

The presentation will show how continuous improvement in the field of radiation protection may be achieved by actively follow up the results from the existing company ALARA program at Forsmark NPP and depending on this updating the program for the next period. Our ALARA-program consists of the following parts:

– Collective and individual doses to the personnel
– Releases of radioactive substances to the environment
– Organizational acceptance of the ALARA principle.

By trending and monitor performance it is possible to focus on the most significant areas. In the presentation examples will be given from Forsmark NPP in all of the above mentioned areas.

ISEMIR: a new international system for improving occupational radiation protection in medicine, industry and research

Lefaure, Christian[1]; Le Heron, John[2]; Czarwinski, Renate[2];
Van Sonsbeeck, Richard[3]; Padovani, Renato[4]

[1] Consultant, FRANCE
[2] IAEA, AUSTRIA
[3] Applus Rtd, NETHERLANDS
[4] University Hospital S. Maria della Misericordia, Udine, ITALY

Abstract

The Information System on Occupational Exposure in the Medicine, Industry and Research (ISEMIR) was set up by the IAEA in January 2009 to focus on very specific topical areas where radiological protection stakes for the workers are not trivial, and where there are still pending issues and deficiencies. The first two selected areas are:

– Interventional cardiology, and
– Industrial radiography.

2009 – 2011 is a test period for checking the ability of the system to cope with its main objectives, as stated in its terms of reference: "To help to improve radiation protection programmes in medicine, industry and research, and in particular:

– To facilitate the implementation of ALARA practices and effective exposure management;
– To internationally benchmark specific task-related occupational exposures in order to identify good practices as well as gaps; and
– To define follow up actions to address identified gaps and disseminate lessons learnt; To contribute to minimizing the likelihood of accidents, e.g. by identifying pre-cursors, user feedback and experience."

This presentation will present the organisation of the system (advisory group, secretariat, working groups) and the first one and half years of experience. In particular it will describe what the Working Group on Interventional Cardiology, which will have already met three times, has performed and achieved, including the results of 3 simple questionnaires dealing with radiation protection practices and occupational exposures addressed to individual interventional cardiologists, chief interventional cardiologists, and radiation protection regulatory bodies. A total of 329 responses from 75 countries were received across the 3 surveys. Finally the complementarities and relationships with other international systems (e.g. UNSCEAR and ISOE) and networks (such as ALARA networks) will be addressed.

Problems of the radiation protection and health effects monitoring in Ukrainian radiation workers

Bebeshko, Vladimir[1]; Bazyka, Dimitry[1]; Likhtarev, Ilya[1]; Gaevaya, Liudmila[2]; Chumak, Vadim[1]

[1] Research Center for Radiation Medicine, UKRAINE

[2] ENERGOATOM National Energy Generating Company, UKRAINE

Abstract

Nuclear energy sector in Ukraine includes 50,000 workers of the 15 power and research units, uranium mines, radioactive waste storages, staff of the Chernobyl zone and the “Shelter” object. Creation of a centralized registry with dosimetry and health data is essential and such understanding exists at the governmental and local levels. However, de facto this work is initiated slowly due to lack of budgetary funding. An analysis was performed of the existing sources of health and dosimetry data information. Two surveys defined the general status of dosimetry monitoring and number of occupationally exposed workers. The local data sources will be used including individual data from the local medical-sanitary departments, dosimetry shops and regional registries for radiologists. Cancer statistics of sufficient quality of case identification and pathological data could be obtained by linkage from the National cancer registry. The extended health data and dosimetry including external irradiation and transuranium elements are available for staff of the “Shelter” object at the RCRM. The existing experience of French and other international registries as well as of the State registry of exposed after Chernobyl, the Clinical-epidemiological registry, and dosimetry databases gained in the Research Center for Radiation Medicine from the prospective follow-up studies could help for practical implementation of the nuclear workers registry. Several tasks are foreseen that could be successfully implemented with international cooperation: a survey of professions, types of jobs and radiation qualities; development of qualification criteria and accreditation procedures for personal dosimetry services; pilot study of medical registry of occupationally exposed workers. Establishment of a new multi-thousand cohort for both prospective and retrospective biomedical and epidemiological studies will allow more precise estimated of the low dose effects of ionizing radiation.

EPR: Comparative approach of the French and Finnish regulatory reviewing process and optimization of radiation-protection at the design phase

Arial, Emmanuelle[1]; Couasnon, Olivier[1] ; Latil-Querrec, Nevena[1]; Evrard, Jean-Michel[1]; Riihiluoma, Veli[2] ; Beneteau, Yannick[3] ; Foret, Jean-luc[3]

[3] Electricité De France - CNEN (EDF), 165, avenue Pierre Brossolette, BP 900, 92542 Montrouge Cedex, FRANCE

Abstract – Introduction

Following the assessment of the EPR[1] (European Pressurized Reactor) preliminary safety analysis report in France, the purpose of this paper is to present a comparative approach of the French and Finnish reviewing process.

The overall picture drawn in this occasion is dedicated:

- to remind the history of EPR (from the decision to implement studies in the 90's to the French and German cooperation and finally to the construction of a unit in Finland and another one in France);
- to compare French and Finnish safety evaluation systems: in France, the safety authority in charge of the authorization process is not directly linked to its technical support which leads the technical instruction. In Finland, the safety authority is in charge of the evaluation of safety analysis. In this process Technical Support Organizations (TSO) can be requested for example in some comparative calculations.
- to present the dose targets (calculated reference doses) planned by the nuclear operators in the design phase as well as the global radiation-protection optimization process. In France, for example, EDF performed a detailed optimization analysis on selected tasks known to have a major contribution to the annual average collective dose (thermal insulation, logistics, valve-maintenance,

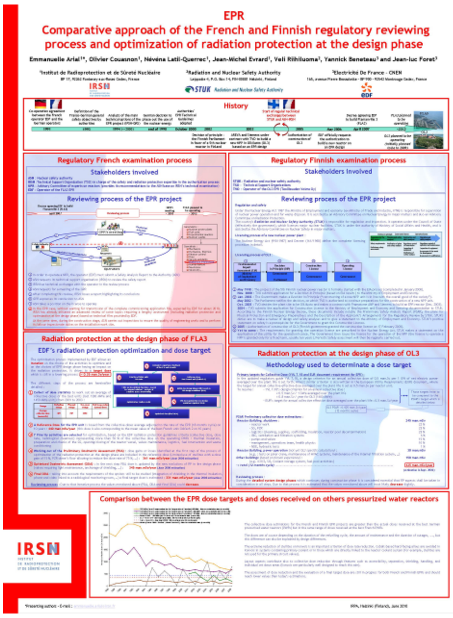
[1] EPR appears now with the sign TM (for trademark) when applied to business relationships. It is a distinctive sign used by AREVA to signify that the EPR is an unregistered trade mark (a mark used to promote or brand goods) which identifies the EPR as a product of AREVA.

opening/closing of the vessel, preparation and checks of steam generators, on-site spent fuel management and waste management). The optimization process is set in France on an iterative method. In Finland the optimization of annual collective dose has to be described in a separate topical report. In every phase of system descriptions the radiation-protection aspects have to be taken into account to meet the requirement stated in specific regulatory guides.

- as a conclusion, to draw a comparison between the EPR collective dose target and doses received on other pressurized water reactors that are close to the EPR design (Konvoi of German design, "best French units", …).

This paper has been jointly written by the French operator (EDF), the French TSO (IRSN), and the authority of nuclear safety in Finland (STUK).

It allows to summarize more than 15 years of partnership and studies, focusing on radiation-protection, in the design phase of the EPR.



History

At the beginning of the 90s, the basic safety provisions were defined and assessed of the basis of a French and German cooperation (Figure 1):

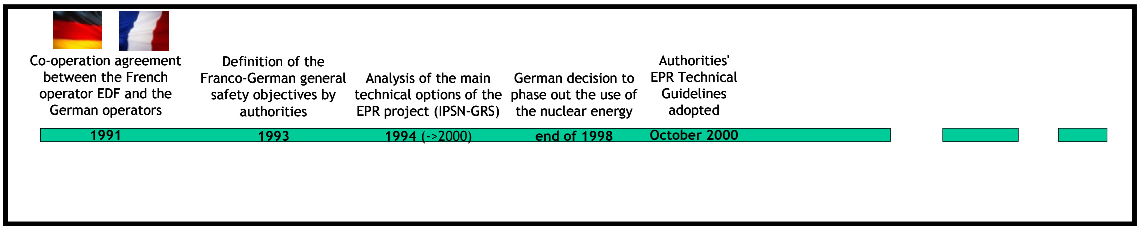


Figure 1. French and German cooperation.

From 2002, on the decision of principle to build a new NPP in Finland (based on an EPR concept), a new kind of cooperation started between French and Finnish stakeholders (figure 2):

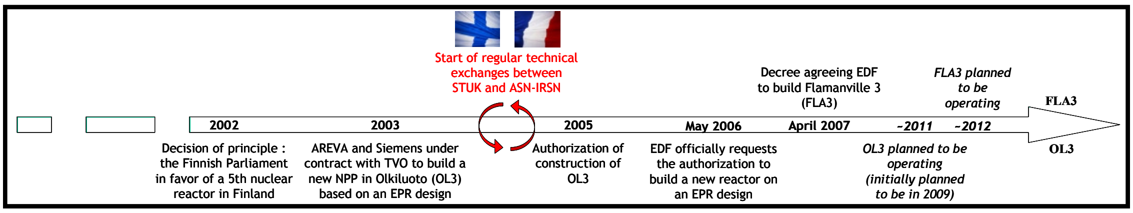

Figure 2. French and Finnish cooperation.

Regulatory examination process

In France:

In France the main stakeholders involved in the reviewing process are:

- ASN: Nuclear safety authority;
- IRSN: Technical Support Organization (TSO) in charge of the safety and radiation protection expertise in the authorization process;
- GPR: Advisory Committee of experts on reactors (provides its recommendations to the ASN on the basis of IRSN's technical examination);
- EDF: Operator of the Flamanville 3 EPR.

The reviewing process from the authorization decree to the operating licence for the Flamanville 3 NPP is described in the figure 3:

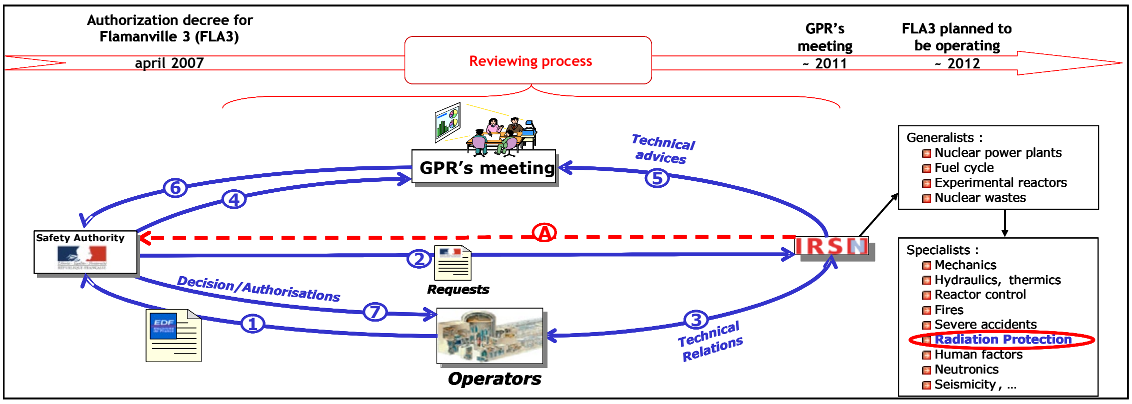

Figure 3. French reviewing process.

The main steps of this reviewing process are the following ones:

1. In order to operate a NPP, the operator (EDF) must submit a Safety Analysis Report to the Authority (ASN);
2. ASN requests its technical support organization (IRSN) to review the safety report and requests the GPR to express its opinion on the conclusions of this review 4;
5. After completing its review based on technical exchanges with the operator 3, IRSN issues a report highlighting its conclusions;
6. GPR expresses its conclusions to ASN;
7. ASN takes a position on the licence to operate;

Ⓐ In the Flamanville 3 NPP case, without waiting for transmission of the complete commissioning application file, expected by EDF for about 2010, IRSN has already initiated an advanced review of some topics requiring a lengthy assessment (including radiation protection and optimization at the design phase) likely to have potential impact on the design. This review is based on technical files provided by EDF.

At the same time, during the construction stage, ASN carries out inspections to ensure the quality of engineering works and to perform its labour inspectorate duties on the installation work site.

In Finland :

In Finland the main stakeholders involved in the reviewing process are:

- STUK: Radiation and nuclear safety authority;
- TSOs: Technical Support Organizations;
- TVO: Operator of the OL3 EPR (Teollisuuden Voima Oy).

Under the Nuclear Energy Act (1987) the Ministry of Employment and economy (ex-Ministry of Trade and Industry, KTM) is responsible for supervision of nuclear power operation and for waste disposal. It is assisted by an Advisory Committee on Nuclear Energy in major matters and also an Advisory Committee on Radiation Protection.

The country's Radiation and Nuclear Safety Authority (STUK) is responsible for regulation and inspection. It operates under the Council of State, which licenses major nuclear facilities. STUK is under the authority of Ministry of Social Affairs and Health, and is assisted by the Advisory Committee on Nuclear Safety in major matters.

The Finnish licensing process of a new nuclear power plant is described hereafter in the figure 4:

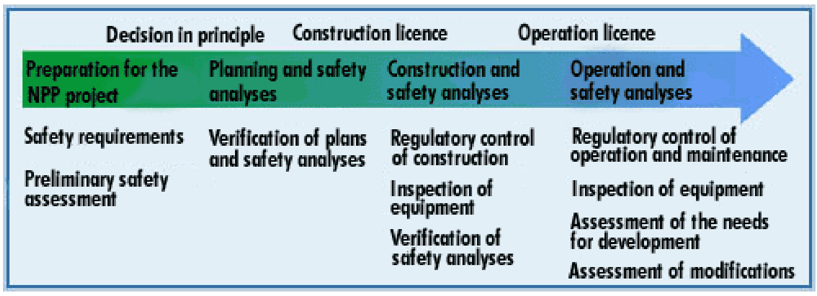

Figure 4. Finnish licensing process.

The Nuclear Energy Act (990/1987) and Decree (161/1988) define the complete licensing procedure in detail. The licensing process of OL3 is described on the figure 5 hereafter:

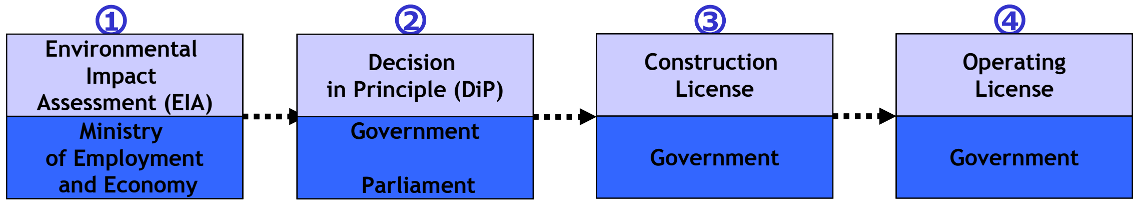

Figure 5. Licensing process of OL3.

① May 1998: The project of the 5th Finnish nuclear power reactor is formally started with the Environmental Impact Assessment (EIA) process (completed in January 2000) ;
Nov. 2000: TVO submits application for a Decision in Principle (based on EIA results) to the Ministry of Employment and Economy ;

② Jan. 2002: The Government makes a Decision in Principle ("constructing of a new NPP unit is in line with the overall good of the society") ;
May 2002: The Parliament ratifies the decision, on which TVO is authorized to continue preparations for the construction of a new NPP unit ;
Oct. 2003: TVO decides the plant site to be Olkiluoto and makes a contract with Framatome ANP and Siemens to build an EPR reactor (Dec. 2003) ;
2004: TVO submits the application for Construction License to the Ministry of Employment and Economy and the licensing documentation to STUK. According to the Finnish Nuclear Energy Decree, these documents include notably the Preliminary Safety Analysis Report (PSAR), the plans for Physical Protection and Emergency Preparedness and the Description of the Applicant's Arrangements for the Regulatory Review by STUK. STUK's duties are to make a review of design and safety analyses and to give a statement to the Ministry of Employment and Economy. STUK's positive statement on safety is a prerequisite for the Government to grant the Construction License ;

③ 2005: Authorization of construction of OL3 (Finnish government granted the construction license on 17 February 2005).

④ Yet to come: The requirements for granting the operation license are prescribed in the Nuclear Energy Act. STUK makes a statement on the application of the utility for the operation license. The Government then issues the license for the operation of the NPP (the license to operate a NPP is granted only for a fixed term, usually ten years). Periodic Safety assessment will then be regularly carried out.

Radiation protection at the design phase

In France (FLA3) : EDF's radiation protection optimization and target dose

The optimization process implemented by EDF allows iteration on the choice of the activities to optimize and on the choices of EPR design phase having an impact on the radiation protection. It drives to a target dose (< 0.35 man.Sv/year) which is still in a lowering process.

The different steps of the process are presented on figure 6.

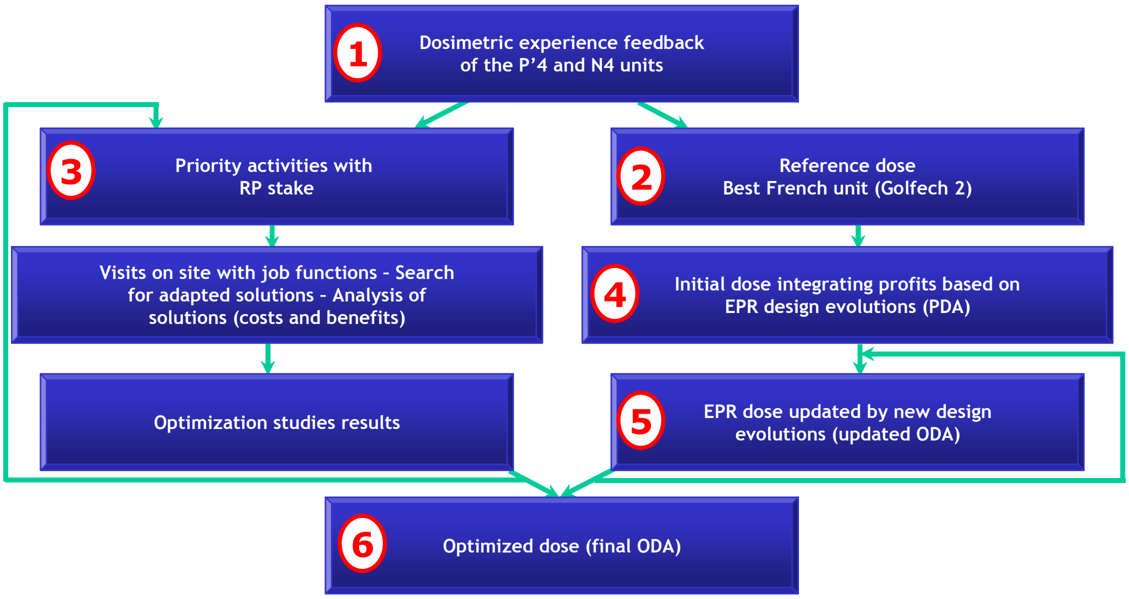

Figure 6. optimization process implemented by EDF.

① The first step aims to collect the dose statistics to work out an average of collective doses of the best units (last 1300 MWe and 1450 MWe units) from 2001 to 2003 :

Table 1. average of collective doses of the best units from 2001 to 2003.

Outage	Refueling outage	Planned outage	Ten-years outage	Unit in operation (annual dose)
Average collective dose (man.mSv)	329	527	1352	89

② A Reference Dose for the EPR unit is issued from the collective doses average adjusted to the rate of the EPR (18 months cycle) on 10 years : 440 man.mSv/year (this dose is also corresponding to the mean value of the best French unit Golfech 2 on 10 years);

③ Seven Priority activities are selected for optimization, based on the EDF radiation protection guidelines criteria (collective dose, dose rate, radiological cleanness) representing more than 50 % of the collective dose on the operating PWRs: thermal insulation, preparation and checks of the Steam Generators, opening/closing of the reactor vessel, valves maintenance, logistics, fuel intervention and waste conditioning;

④ The Preliminary Dosimetric Assessment (PDA) is carried out to integrate in the reference dose the dose gains or losses identified at the first step of the process of optimization of the radiation protection at the design phase (Limited use of stellites with a dose gain of 15 %, pressurizer dome's floor allowing to reduce the dose rate of 75 %, …). As a result, the PDA leads to a collective dose value of 361 man.mSv/year (estimation in June 2008);

⑤ Following an Optimized Dosimetric Assessment (ODA); the PDA dose is updated by the new evolutions of RP in the design phase (valves requiring light maintenance, anchorage of shielding,…). The ODA leads to a collective dose value of 345 man.mSv/year (estimation in June 2008);

6 Eventually, a final ODA is carried out by taking into account the requirements of the options still to be studied (phone and video linked to a radiological monitoring room,…). The final target dose is estimated to be 331 man.mSv/year (estimation in June 2008). However, the official collective dose target is yet set to 350 man.mSv/an (from the version of the Preliminary Safety Analysis Report of 2005).

Due to that iterative process the values mentioned above (PDA, ODA and final ODA) could decrease slightly before the end of the process.

In Finland (OL3): Methodology used to determinate a dose target

As in France, primary targets for collective dose have been set forth .

In the updated regulatory guide YVL 7.18, a design criterion for an annual collective dose of 0.5 man.Sv per 1 GW of net electric power averaged over the plant life is set forth (< 0.8 man.Sv / year for OL3 - 1600 MWe).

Almost similar criterion is also written in the European Utility Requirements (EUR) document, where the target for annual collective effective dose averaged over the plant life is set as 0.5 man.Sv/year per reactor unit.

Those targets have to be compared to the OL3 Preliminary Safety Report (PSAR) target of 0.425 man.Sv/year on 12 months cycle which is detailed below.

<u>PSAR Preliminary collective dose estimations :</u>

Reactor Building, shutdown :	*245 man.mSv*
- reactor work	22 %
- SG, PZR	23 %
- logistics[2]	23 %
- I&C, ventilation and filtration systems	6 %
- pumps and valves	15 %
- management, operations team, health physics	10 %
- NDE, hydraulic tests	1 %
Reactor Building, power operation[3] :	*30 man.mSv*
Other buildings[4] :	*150 man.mSv*
-> total (12 months cycle, estimation in September 2006) :	*425 man.mSv/year*

During the detailed system design phases which continues during construction phase it is considered essential that RP aspects shall be taken in consideration in all steps. Due to that process it is estimated that the values mentioned above will most likely decrease slightly, before the end of the process.

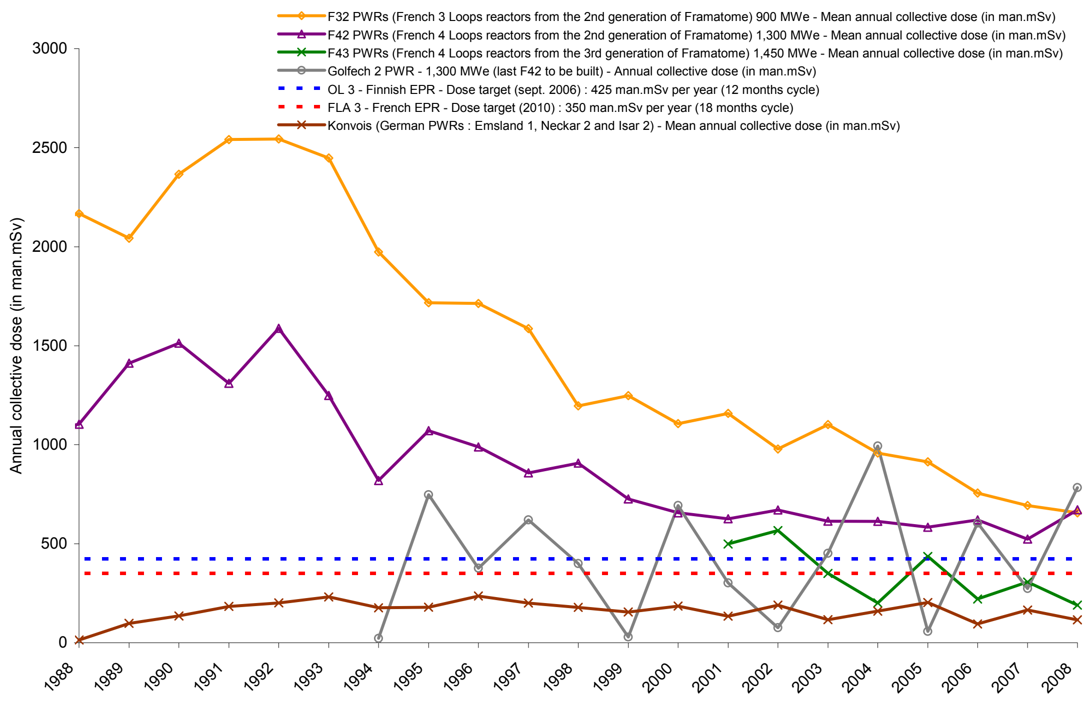
[2] Cleaning, supplies, scaffolding, insulation, reactor pool decontamination.
[3] Not yet OL3 specific calculation (e.g. : tests on polar crane, maintenance of HVAC systems, …).
[4] Based on Konvoi experience (e.g. :CVCS, SIS, Coolant storage system, fuel pool activities).

Specific EPR design in comparison with Finnish and French existing PWR

One of the main specific options in the EPR design is the « two-rooms » concept : this concept is devoted to allow interventions in the reactor building when operating to prepare the outage. It consists in a red zone collecting the leakages of the primary circuit (inaccessible zone) and a green zone (the other part of the RB accessible) which is required to have a total dose rate < 25 µSv/h (and a neutrons DR < 2.5 µSv/h).

Conclusion: comparison between the EPR dose targets and doses received on others pressurized water reactors

The graph shown hereafter gives a good overview of the annual collective dose benchmarking for French PWR compared to the EPR's targets.



Graph 1. Annual collective dose benchmarking (in man.mSv) for French PWR (first 900 MWe excepted) between 1988 and 2008 compared to the EPR's targets (source : ISOE[5] database).

The collective dose estimations for the French and Finnish EPR projects are greater than the actual doses received at the best German pressurised water reactors (PWRs) but in the same range of doses received at the best French PWRs. The doses are of course depending on the duration of the refuelling cycle, the amount of maintenance, the duration of outages, ..., but this difference can also be explained by design differences.

The extreme reduction of stellites on Konvois is an important criterion of dose rate reduction. Cobalt-based hard-facing alloys are avoided in Konvois in systems

[5] Information System on Occupational Exposure

containing primary coolant or in those which are directly linked to the reactor coolant system (for example, stellite is not used for the primary circuit valves).

Layout aspects contribute also to collective dose reduction through features such as accessibility, separation, shielding, handling, and individual set down areas (Konvois are particularly well designed to reach this aim).

The assessment of dose reduction and the evaluation of a final target dose are still in progress for both French and Finnish EPRs and should reach lower values than today's estimations.

Individual doses monitoring for external exposure during the transportations of nuclear fuel bundles performed by Nuclear Fuel Plant Pitesti

Ivana, Tiberiu; Epure, Gheorghe
Nuclear Fuel Plant Pitesti, Campului St. 1, 115400 Mioveni, ROMANIA

Abstract

Nuclear Fuel Plant (FCN) is a facility that produces nuclear fuel bundles CANDU-6 type for CANDU nuclear power plant based on natural and depleted uranium. The transportation of nuclear fuel bundles from FCN to Cernavoda Nuclear Power Plant is performed by FCN authorised trucks (about 340 km between the two locations). FCN has the activity of transportation and the vehicles authorised by Romanian regulatory body National Commission for Nuclear Activities Control (CNCAN). In addition each transfer of nuclear material is authorised by CNCAN.

About 15 nuclear fuel transportations were performed in year (20 wooden crates with 720 nuclear fuel bundles, containing 15 tons of natural uranium dioxide corresponding with 14 tons of natural uranium). From 1996 until now 120 transportations of nuclear fuel bundles were occuring.

A crew is trained and authorised for these kinds of activities. The components of crew are monitored everytime for external exposure. Different type of instrumentations was used for conforming with radioprotection programme of transportation of radioactive material national and international norms. The doses registered are reported each year to CNCAN.

Compared with the registration level (RL) of doses imposed by CNCAN norms, the doses received during transportation don't exceed this value. Starting with 2009 each occupationally worker is monitored with TLD and electronic devices. Due that the workers from the transportation crew are exposed to the ionising radiations category A, the annually estimated dose that can be received is around 6 mSv per year. Nobody of participants to the transportation of nuclear fuel bundles reach this value during 14 years of activity.

1. Introduction

Nuclear Fuel Plant (FCN) is a subsidiary of National Society NUCLEARELECTRICA SA (SNN-SA), a company that has in subordonance another nuclear facility Cernavoda Nuclear Power Plant. FCN is a facility for manufacturing of the nuclear fuel bundles CANDU type with 37 elements, based on *natural uranium* (0.711% U-235) and *depleted uranium* (a small quantity with 0.25% U-235 and 0.52% U-235). FCN is located at 130 km from Bucharest in Mioveni town on the nuclear site that belonging FCN, Institute for Nuclear Researches (INR) and Nuclear Agency and Radioactive Wastes (AN&DR).

The annual production is about 10,000 fuel bundles CANDU type that means about 200 tons of natural uranium in UO2. The depleted uranium is processing in campaigns only at the starting of a new unit from Cernavoda NPP.

The production of the plant was about 5,600 nuclear fuel bundles. In 2007 the Unit 2 of Cernavoda NPP was commissioned and for this reason the capacity of the plant was doubled at about 10,000 fuel bundles per year. This means that the quantity of uranium throughout in the plant stored and processed was doubled and normally the number of nuclear fuel bundles transportations to Cernavoda NPP.

The personnel working in FCN is about 430 people, and the activity is continuously and about 20 people are involved in packaging, final inspection, loading, movement, transferring and monitoring the shipments from FCN to Cernavoda NPP.

The distances from FCN and Cernavoda NPP for delivery the nuclear fuel bundles is about 340 km.

2. Nuclear national framework

The regulatory body for control of nuclear activities is National Commission for Control of Nuclear Activities (CNCAN). The legislation in this field contains law, norms, regulations, orders, etc.

The Romanian law issued in nuclear field is Law no. 111/1996 for deployment, regulation, licensing and control of nuclear activities, republished in 2006 [1]. The law is following in each nuclear area, upon the specific of activity, by orders, norms, guides, etc.

For FCN the group of norms with direct application to the specific activity are: *norms for radiological safety, norms for radioactive mining, norms for quality management, norms for physical protection, norms for nuclear safeguards, norms for management of the radioactive wastes*, ***norms for transportation of radioactive material.***

3. Nuclear plant licenses

The regulatory body issued for FCN during the period 2010-2012 several licensees that cover the activities in nuclear field using radioactive material. The documentations sending by FCN are based on **Norms for Radiological Safety** and **Norms for Radioactive Mining** requirements**:**

a) **Possesion, Using, Handling, Processing of the nuclear raw material, Producing of the nuclear fuel bundles, Temporary Storage and Supplying**
b) **For Personnel Dosimetry Laboratory CNCAN** has issued an accreditation for 2008-2011
c) **For Transportation of Radioactive Material FCN** is authorized by CNCAN for the period 2009-2014, one of activity being nuclear fuel bundles [1], [2].
d) **For Quality Management System CNCAN** has issued an authorization during the period 2008-2010 [1].

4. Short history of transportation of nuclear fuel bundles

The activities for Radioactive Material Transportation starting from 1996 and until now 126 shipments of nuclear fuel bundles was occur. Three conveyaces formed by trucks with two trailers was used for this activity.

From 1996, over 126 transportations of nuclear fuel bundles (1.4 millions kg of natural and depleted uranium) to Cernavoda NPP were performed, over 88,000 nuclear fuel bundles CANDU-6.

All the activities for radioprotection, dosimetry, physical protection, safety and security related with transportation of radioactive material are under Quality Management System.

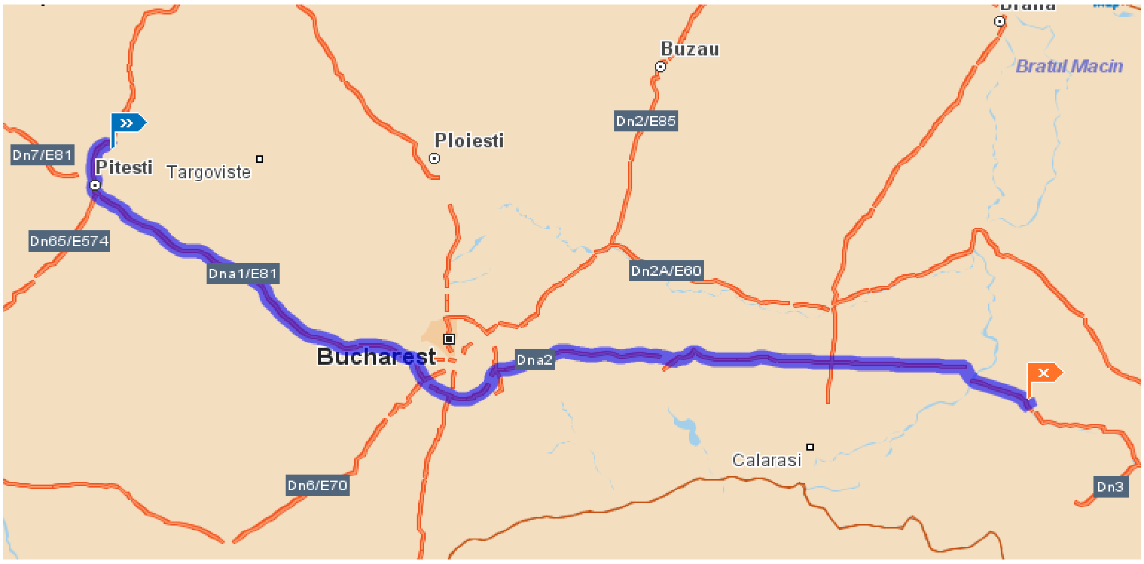


Fig. 1. The itinerary of transportation for nuclear fuel bundles.

5. Performing the transportation of nuclear fuel bundles

The consignor and carrier is FCN and the consignee is Cernavoda NPP.

For radiological safety purpose a Radiation Protection Programme (RPP) for nuclear fuel bundles transportation was developed in the **Quality Management System (QMS)** part of **Integrated Management System (IMS)** in FCN. The principles for elaborating and implementing the RPP for radioactive material transportation in FCN are detailed in **Manual of Radiological Safety** (MSR).

Additionally, the transportation is escorted and physical protection assuring by guard team, special trained for this type of transportation.

From FCN several teams are dedicated to the activity for sending the nuclear fuel bundles to Cernavoda NPP.

5.1. The transportation team, is formed by :

- Transportation chief ;
- consellor ;
- driver 1 ;
- driver 2 ;
- mechanical worker ;
- health physicist.

5.2. The team involved in packaging, labelling and placarding

5.3. The team for loading the truck

5.4. The team for surveillance the loading

Fig. 2: the truck for radioactive material transportation.

6. Description of the final product and package

The final product for FCN is the nuclear fuel bundle CANDU-6 type with 37 elements based on natural and depleted uranium.

The main characteristics of nuclear fuel bundle CANDU-6 type are:

Table no. 1. Description of the package.

The description for package with nuclear fuel bundles		
Package with nuclear fuel bundles	**1.**	**Nuclear fuel bundle CANDU 6** (natural uranium and depleted uranium).
	2.	**Polyethilene foil for wrapping each nuclear fuel bunlde.** Each nuclear fuel bundles is wrapped in polyethilene foil and is streching with a plastic ring. Over the third layer is putting a polyethilene foil
	3.	**Collective from polystiren and plaques separated made from cartoon**
	4.	**Container for transportation (wooden crate)** The wooden crates are made from wood

7. Description of package, storage and discharging the wooden crates

7.1. Parameters of package [7] are described in Table no. 2.

No. of package per load, large truck	-	**20**
Loads per day, large truck	d-1	**0.05**

7.2. The wooden crate with 36 nuclear fuel bundles is the package for transportation. The package is authorised by CNCAN [1] and it is stored temporary in the storage for fresh nuclear fuel bundles (DCNP), storage provided with sprinkles and under video surveillance

7.3. The loading of wooden crates in the truck is the responsibility of FCN. Four persons are involved in this activity (loading team). The discharging of wooden crates is the responsibility of the Cernavoda NPP employees. The Fig. 6 is showing an image of these discharging.

Fig. 3. discharging of wooden crates.

8. Organization for nuclear safety in FCN and transportation of radioactive material

The top management of FCN is focused for the major priorities of plant to quality control, nuclear safety and environmental protection. The system applied by management is **Integrated Management System (IMS)** that has until this time three components: **Quality Management System**, **Environmental Management System**, **Labour Health and Safety System** all based on international standards: ISO 9001:2005; ISO 14001:2005; ISO 18001:2006. According a special place for nuclear safety, the management has proposed for a new organizational chart of FCN.

Taking in account the priority of safety starting with 01 October 2007, FCN has a new organisation chart creating a new department dedicated to nuclear safety. So, it was created the Nuclear Safety Department (DNS) reporting to FCN Director.

The main DSN tasks are to apply the FCN policy, the SNN-SA nuclear safety policy and the Romanian nuclear safety policy. These are:

- To protect employees
- To protect visitors and contractors
- To protect population and public
- To protect environment
- To assure security and safety for nuclear material during the transportation
- To train the participants of the radioactive material transportation
- To inform the public

9. Radiological safety/radioprotection

9.1. Exposure of the participants at transportation

It is obviously that in the condition of doubling the capacity of the plant the doses monitoring of personnel involved in nuclear fuel bundles transportation for comparison became important for radioprotection programme [6].

All the participants at the nuclear fuel bundles transportation are from category A of exposure and they have an estimation dose of 6 mSv/year to be received.

During the transportation, the nuclear material is presented in itemized form so only the gamma dose rate and dose is important for evaluating the exposure to the ionising radiation.

1. External Exposure. The doses arising from the presence of nuclear material based on natural uranium are not high. The monitoring is performed with TLD (Termoluminiscent Dosimeter) PANASONIC type. Changing of TLDs, measurement, interpretation of doses, assessment, irradiation of TLDs, and reports to sanitary authority and CNCAN are done by DNS, Laboratory for Personal Dosimetry.

FCN Laboratory for Personal Dosimetry has the accreditation from CNCAN [1] for this type of activity. The results obtained from an experience of 125 nuclear fuel bundles transportation from FCN to Cernavoda NPP is presented in Table no. 3

Table no. 3. Doses measured during one transportation.

No.	Participants	Minimum value of Dose (µSv)	Maximum value of Dose (µSv)	Medium value of Dose (µSv)
01	Transportation chief	0.9	6.4	2.46
02	Consellor	1	6.2	2.52
03	Driver 1	6	18.9	7.99
04	Driver 2	3.8	13	6.13
05	Mechanical Worker	1	1.3	1.11
06	Health physicist	1	6.2	1.62

Compared with the registration level (RL) of doses imposed by CNCAN norms [8], the doses received during transportation don't exceed this value.

2. Internal Exposure. Being a facility where nuclear material is processed and handled in bulk form, taking in account the contamination hazard of air and surfaces, the internal exposure is very important and must be treated with carefully. These is reflected in contamination measurements of the packages and vehicles, contamination which can cause the releasing of uranium particles in airborne

3. Contamination Monitoring. Direct measurements (total contamination) and indirect measurements (loose contamination) on the surfaces of fuel bundles, wooden crates, trailers are performed. For these reason the contamination of packages and trailers is done after cleaning, at each shipment. The measurements for all contamination registered is under 0.1 Bq/cm^2

Table no. 4. The value of surfaces contamination

No.	Nuclide	Dose (mSv/a)/(Bq/cm²)	Surface activity leading to 1 mSv/a (Bq/cm²)	Medium surface activity measured	Fraction
01	U depleted	$4.8x10^{-01}$	2.39	0.00156	0.065%
02	U natural	$6.2x10^{-01}$	1.61	0.00177	0.109%

9.2. Public exposure times and distances

Occupancy times and distances for members of the public were allocated to the steps in the transport operations for each package type where the exposure of members of the public is likely/ possible.

The occupancy times will not be limited by working hours as in the case of workers; in one instance they are in excess of 90 hours/year. Members of the public will always be at a greater distance from the transport (10 meters in medium) operations than will transport workers for each step. Their exposures are, therefore, expected to be much lower than that of the transport workers. However, the dose criteria applicable to members of the public are generally lower and, therefore, their exposures should be assessed to determine if they are more limiting in some situations.

In this case the evaluation of the values for dose rate at the contact of the truck is relevant. The Table no. 5 show us that this dose rate at the maximum level don't imply a dose rate over the background at 10 meters from the vehicles.

10. Conclusions

1. The doses received during one transportation are very low and don't have the significance on the total exposure of the participants ;
2. Due the very low of contamination of wooden crate and of the surfaces of vehicle the internal doses have negligible values ;
3. The doses received by public during the transportation are very low in the accountancy of the dose effective limit for population .

Abstract

The Joint Research Centre of Ispra, one of the research Sites belonging to the European Commission, Directorate General JRC, was created in the late '50s, in order to steer European research on nuclear industry. It currently hosts numerous nuclear facilities, some of which are maintained in operation, while others were shutdown in past years or are currently being decommissioned.

Since 2003, a Radiopharmaceutical facility has been set up at the JRC Cyclotron Laboratory, in collaboration with General Electric Healthcare, for the production and commercialization of [^{18}F]FDG. This Radiopharmaceutical Laboratory has been the first FDG production facility to be officially authorized by the Italian Health Ministry and has been operating since 2003 without any interruption.

During these years, some upgrades in the capacity and maximum activity produced by the Lab have been performed. Two different beam lines and one irradiation vault have been devoted to FDG production in order to increase the production capability.

The paper, thus, is a review of Radiation Protection activities performed in the Lab during its years of operation and in particular the distribution of the dose related to the activity and the daily personal dose trend, subdivided between FDG production and Quality Control (QC), will be shown and discussed. Further, a recent internal contamination dose assessment campaign will be presented and the results discussed.

Introduction

Radionuclides played and still play an ever greater role in Medicine and especially in Nuclear Medicine, which is based on the use of radiolabelled tracers. Against this backdrop, a close collaboration between JRC and General Electric Healthcare started in 2003 to set up the first commercial [^{18}F]FDG production facility in Italy. The entire production system can be subdivided into three main parts: the cyclotron itself, under the direct responsibility of JRC; the target, in which ^{18}F is produced; the two FDG production laboratories, both of which are under the responsibility of GE Healthcare. To achieve satisfactory operational conditions, all these components required more than a year of fine tuning: in March 2004 the first FDG vials were commercialised. Since then, the system has undergone two major target updates: both its capacity and the irradiation current were increased and with them the activity produced. Until May 2005, ^{18}F production was on average between 80 and 100 GBq per run: it increased to a maximum of up to 180 GBq after the first upgrade and of up to about 300 GBq per run after the second upgrade in April 2008. Production may be run more than once per day. Of course, with the increase in the activity produced, the dose to the exposed personnel also increased, not only during the normal working activities, but also during ordinary or extraordinary maintenance.

Two operators staff the laboratory: one in the FDG synthesis room (Clean room) and one in the Quality Control (QC) room. They can receive dose during any type of target maintenance performed in an irradiation room, a target foil exchange, accidents and normal operation. This last contributor is then subdivided into dose from the Clean room - where FDG is synthesised - and dose from the QC room - where the biological analyses are performed.

About once a month, it is necessary to change the foils of the target because further deterioration would lead to impurity releases that may affect FDG synthesis. Before April 2008, target foil maintenance was performed on Fridays, in the late afternoon. Starting in April 2008, new Radiation Protection requirements have been introduced to further reduce exposure of the personnel. First, the target exchange is performed on Sundays nights, at 10 p.m., when decay after the last irradiation, which took place on the previous Friday, has reduced the dose rate inside the irradiation room and the target itself. Second, a short briefing (during which the type and length of work are concisely reviewed), the mapping of the dose rate distribution inside the irradiation room (to identify the different hot spots close to the working position and advise the personnel involved recommending, when necessary, the use of suitable shielding), and preparing the tools before starting operation (to avoid spending time unnecessarily in the irradiation room resulting, again, in an effective reduction of exposure) have become standard practice. Also, the yield of the FDG synthesis modules (i.e. the FDG quantity produced per unit activity) was improved, thus resulting in less activity being left in the modules after each run. Further changes were introduced inside the QC room. The ambient dose inside the room was reduced shielding the bin used for disposable items such as pipette tips, vials, etc., the plastic pipe of the High Pressure Liquid Chromatographer (HPLC) – which carried a large amount of activity – and a pH meter.

During the production of [^{18}F]FDG, the operators incorporate minute amounts of ^{18}F due to trace levels in ambient air and slight contamination of the tools. For this reason, γ emission at 511 keV from the body tissues of the operators slightly increase during the FDG production week. The scale and time dependence of this phenomenon was studied by measuring the internal body radioactivity at JRC-Ispra's Whole Body Counter (WBC) Lab. The actual level of internal radioactivity together with the identification of the nuclide and information on its distribution - incorporation time etc. - allows an assessment of internal dose and the associated long-term risk to the workers.

The aim of this work is to show monitoring methods, how the operators' dose changed over time with the amount of activity produced and also to provide a quantitative estimate of the impact of Radiation Protection interventions.

Material and methods

To better identify the areas in which Radiation Protection interventions would be most effective, dose contributions were separated in 5 categories: routine, scheduled target exchange, ordinary maintenance, extraordinary maintenance and incidents.

- *Routine operation*: this is the dose to the operators from FDG handling. This dose is received in the Clean and QC rooms. In routine conditions operators do not need to access the target room.
- *Scheduled target exchange*: this is the monthly target exchange. It may be performed by the Clean room operator or the QC room operator.
- *Ordinary maintenance*: it is performed, every year, in three well identified time periods, and involves maintaining the targets (foil and O-ring exchange, helium leak test) and the synthesis modules.
- *Extraordinary maintenance*: it is performed when beam line or target malfunctions occur.
- *Incidents*: in this context, "incident" indicates unforeseen circumstances that should present inside Clean or QC room.

All daily dose data were measured with electronic personal dosimeters (EPD. Model DMC 2000 S, MGP Instruments, France). EPD data are normally read out with the associated time stamps any time the operator leaves the controlled area but are reported as day by day aggregates. However, since a calendar day typically spans two different shifts (i.e. previous night and following evening), to assign dose contributions to the correct categories, it was key to cross-check the time data with the Radiation Protection Register in which the activities performed during all shifts could be found. The dose breakdown is reported in pie charts separately for the QC and Clean room.

The trend of the routine dose inside the Clean room (where it depends on the total amount of activity produced) and the QC Room (where it depends on the quota of [^{18}F]FDG sent to analysis) was analysed next. Before April 2008 the volume of FDG sent to analysis was 1000 μL, with an average activity of 1.5 GBq (1.5 MBq/μL); after the upgrade it was 600 μL, with an average activity of 2.5 GBq (4.2 MBq/μL).

Daily dose vs. time was investigated for both the QC and the Clean room before and after the target upgrade of April 2008. In both cases n dose points were studied with two different techniques: the t-test specific for unequal sample size and unequal variance (Zimmerman W.D., 1997) and simple linear regression (Douglas C.M. *et al.*, 2001) with a least-square method. Linear regression yielded the slopes of linear fits, which were indicated with β. Confidence intervals for β were derived under the hypothesis of a normal distribution of the errors: this allowed the construction of the interval as the product of the (1-γ/2)-th quantile of the Student's t-distribution with ($n-2$) degrees of freedom and the estimated standard errors. γ was chosen to be equal to 0.01, so that the confidence levels were equal to 99.5%.

In the case of the Clean room, further considerations were possible. First, the activity vs. time data were fitted separately before and after the target upgrade. Then, the daily dose normalized to the activity produced was also studied as a function of time, again keeping track of the time at which the target was upgraded. It is important to specify that in this analysis only the productions between Tuesday and Friday were taken into account. In fact, for data consistency, Monday productions were excluded because the activity to which data would have been normalised would have been artificially low due to the extended decay period (to the previous Friday) inside the modules.

For the campaign of internal dose assessment both operators underwent WBC examination daily from Monday to Friday directly after the end of the production shift, and in the morning of Saturday and Sunday. In this last case, the measurements were performed to investigate the variability of the ^{18}F level with time. During the WBC examination, qualitative and quantitative assessments of internal radioactivity were conducted with a direct method. Both scintillation NaI(Tl) and HPGe detectors were used. A brief description of the characteristics of both detectors is presented in Table 1. The NaI detector provided information on the whole body activity, whereas HPGe detectors were employed for lungs counting. Comparison of the results so obtained yielded the nuclide distribution inside the body.

The geometry of the measurements is shown in Fig. 1. For the assessment of ^{18}F

Table 1. Selected characteristics of three detectors employed in WBC laboratory of Ispra site.

Detector Type / Code	Position	Energy Range [keV]	Efficiency at 511 keV	Energy Resolution at 511 keV
NaI(Tl) / det. 1	stomach	50 – 2500	$5.55 \cdot 10^{-3}$	43.46 keV
HPGe / det. 2	left lung	10 – 800	$4.01 \cdot 10^{-4}$	1.06 keV
HPGe / det. 3	right lung	10 – 800	$3.63 \cdot 10^{-4}$	1.88 keV

Fig. 1. The geometry of the WBC measurements on GE Healthcare staff.

internal activity, the 511 keV gamma line originating from positron annihilation was used. Body and lung counting was performed simultaneously for an acquisition time of 45 minutes during each examination. The acquired gamma spectra were stored on a dedicated PC and then evaluated to obtain the levels of internal radioactivity. A long time background measurement for all three detectors was acquired during the weekend before the WBC scans to correct for environmental background. Data were collected for 180000 s with the not contaminated Livermore phantom placed in front of the detectors to simulate the presence of the human body. The net peak areas at 511 keV were measured and corrected for environmental background. MDA calculations were performed using the method described by Currie (Currie, 1968). To calculate the operators' dose, additional assumptions were necessary:

- Since the exact time of intake was not known, the most conservative hypothesis (i.e. the intake occurred at the beginning of the night shift) was assumed. Indeed, intake occurred probably throughout the night and with

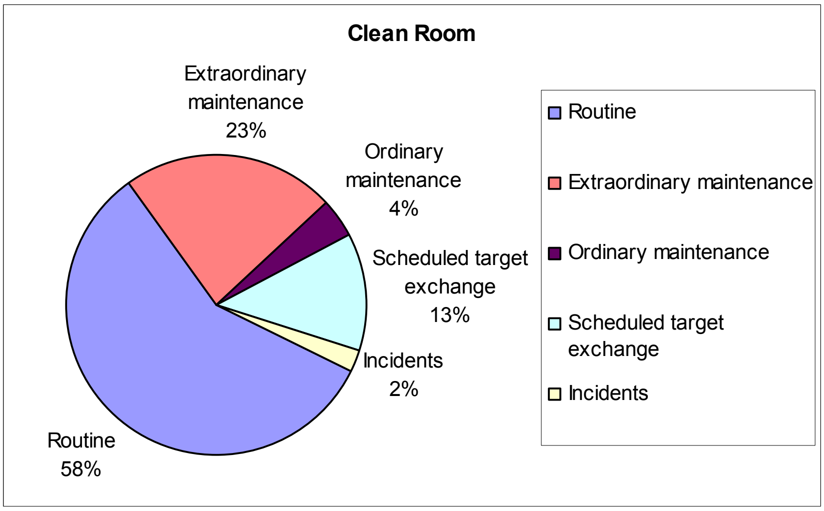

Fig. 2. Attribution of the total dose in the Clean room in the period from September 2007 to January 2010.

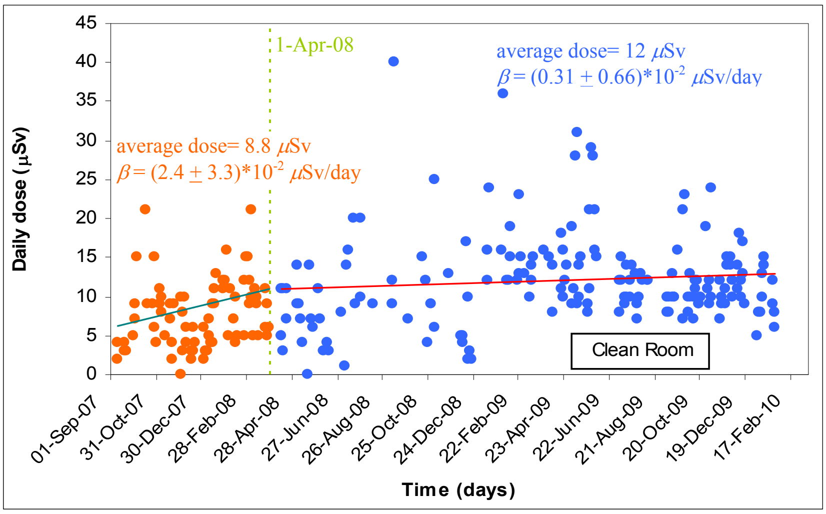

Fig. 3. Daily dose vs. time inside Clean room before and after the target upgrade of April 2008.

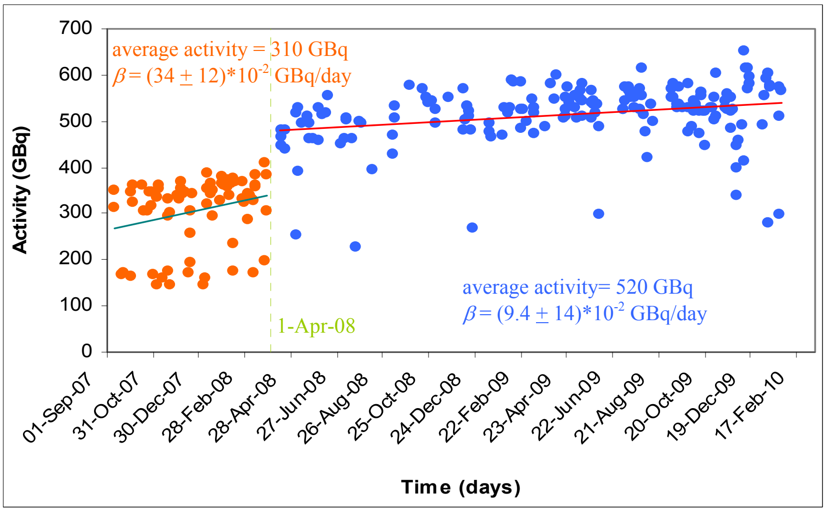

Fig. 4. Total activity produced during a night shift as a function of time.

different rates, depending on air concentration and task performed.

- The ^{18}F distribution was taken as "whole body contamination" according to results of WBC examination and in agreement with literature data (Calandrino et al, 2009).

Finally, the dose coefficient $9.30 \cdot 10^{-11}$ Sv/Bq was used to calculate the committed effective dose to the operators. This value is given by Italian law (D.Lgs. 230/95 All. IV Tab. IV.1) for ^{18}F intake by inhalation and whole body distribution of contamination.

Results

Clean Room

The attribution of the total accumulated dose in the period September 2007 – January 2010 is presented in Fig. 2: routine operation provided the greatest contribution (58%); extraordinary maintenance (23%) and scheduled target exchange (13%) are the second and third source of dose, whereas ordinary maintenance and incidents accounted for only 4% and 2%, respectively.

Fig. 3 shows the daily dose as a function of time before and after the target upgrade. Before April 2008, the slope ($\beta = 2.4 \cdot 10^{-2}$ μSv/day) is positive but not statistically different from zero (confidence interval: $-1.0 \cdot 10^{-2} \div 5.7 \cdot 10^{-2}$ μSv/day). After April 2008, β is still positive ($0.31 \cdot 10^{-2}$ μSv/day) and still not different from zero with statistical significance (confidence interval: $-0.36 \cdot 10^{-2} \div 0.97 \cdot 10^{-2}$ μSv/day). Before the target upgrade the average daily dose is 8.8 μSv; after it is 12 μSv. The t-test indicates that the difference in the averages is statistically significant with p-value = $3.7 \cdot 10^{-5}$.

The average daily activity produced before April 2008 was $3.1 \cdot 10^{2}$ GBq; after April 2008 it was $5.2 \cdot 10^{2}$ GBq (Fig. 4). The activity produced increased over time with statistical significance only before April 2008: $\beta = 34 \cdot 10^{-2}$ GBq/day (confidence interval: $22 \cdot 10^{-2} \div 46 \cdot 10^{-2}$ GBq/day); after April 2008, $\beta = 9.4 \cdot 10^{-2}$ GBq/day, (confidence interval: $-4.6 \cdot 10^{-2} \div 23 \cdot 10^{-2}$ GBq/day), which is statistically significant only to a confidence level of 89%.

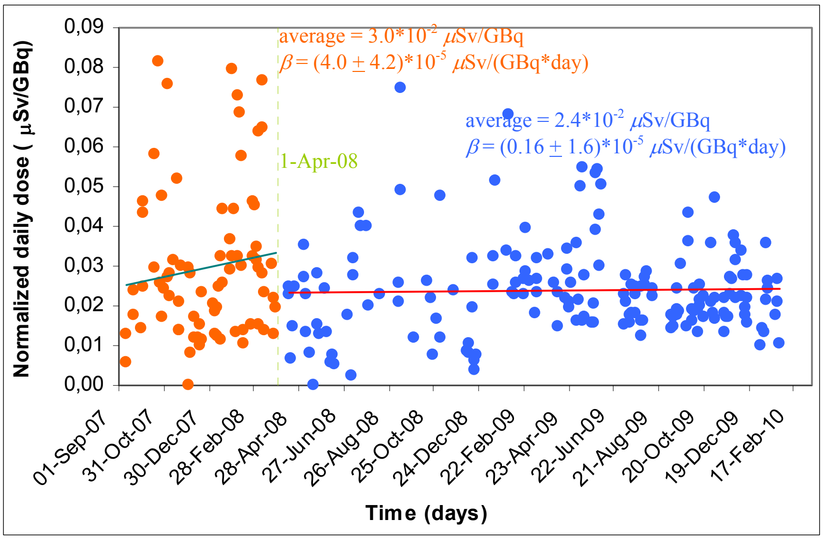

Fig. 5. Daily dose normalised to the total amount of activity produced in the previous working day vs. time.

Fig. 5 shows the dose normalised to the total activity produced as a function of time. Before April 2008 the increase is not statistically significant ($\beta = 4.0\cdot10^{-5}$ μSv/(GBq·day), confidence interval: $-0.26\cdot10^{-5}\div8.2\cdot10^{-5}$ μSv/(GBq·day)); after the target upgrade the slope of the curve is still not statistically different from zero ($\beta = 0.16\cdot10^{-5}$ μSv/(GBq·day), confidence interval: $-1.4\cdot10^{-5} \div 1.7\cdot10^{-5}$ μSv/(GBq·day)). Furthermore, the mean values of the two datasets are different: $3.0\cdot10^{-2}$ μSv/GBq and $2.4\cdot10^{-2}$ μSv/GBq, respectively – with a p-value = $5.8\cdot10^{-3}$.

Quality Control Room

The distribution of the total accumulated dose in the period September 2007 – January 2010 is presented in Fig. 6: routine, again, provided the greatest contribution (58%); scheduled target exchange (17%) and ordinary maintenance (16%) are the second and third source of dose, whereas extraordinary maintenance and incidents together accounted for less than 10%.

Fig. 7 shows the daily dose as a function of time: before April 2008 the average daily dose was 8.3 μSv and the graph presents a non statistically significant increase ($\beta = 5.6\cdot10^{-3}$ μSv/day, confidence interval: $-2.2\cdot10^{-3} \div 3.3\cdot10^{-3}$ μSv/day); instead, after April 2008, the mean daily dose was higher – 12 μSv – with β not different from zero ($\beta = -3.8\cdot10^{-3}$ μSv/day, confidence interval: $-12\cdot10^{-3} \div 4.1\cdot10^{-3}$ μSv/day).

Internal Dose assessment by WBC

The internal dose assessment of both operators was performed based on the whole body count results. Sample spectra are shown in Fig. 8. For both operators, Fig. 9 shows the changes of internal body activity due to ^{18}F, whereas Fig. 10 presents the calculated internal dose. The results of the dose calculations are presented in Fig. 10.

Discussion

The main contribution to the operators' total dose comes from routine, everyday work. Incident doses are, in practice, negligible, whereas scheduled target exchange, ordinary and extraordinary maintenance contribute in a different way depending on the operator. For the Clean room operator doses due to extraordinary maintenance are roughly one fourth of the total, but only about 8% for the QC operator. This is explained by the fact that these interventions are usually performed by the Clean room operator because he is the more experienced of the two and the dose rate inside the irradiation room and close to the target is usually much higher than during normal and scheduled maintenance. Since shielding has already been optimised, further reduction of this dose contribution can be only achieved via fast interventions and thorough planning in preliminary briefings.

The target upgrade resulted in a jump in the activity produced (Fig. 4), but not in a jump in the dose to the operator (Fig. 3). After the upgrade, the average activity production increased by about 70% (520 / 310 ≈ 1.7), while dose to the operator did not, remaining constant at about 12 μSv per day, a 40% increase over the average of the previous period (12 / 8.8 ≈ 1.4). This might be explained with the increased yield of the FDG synthesis modules. These considerations are also evident in Fig. 5, where it is

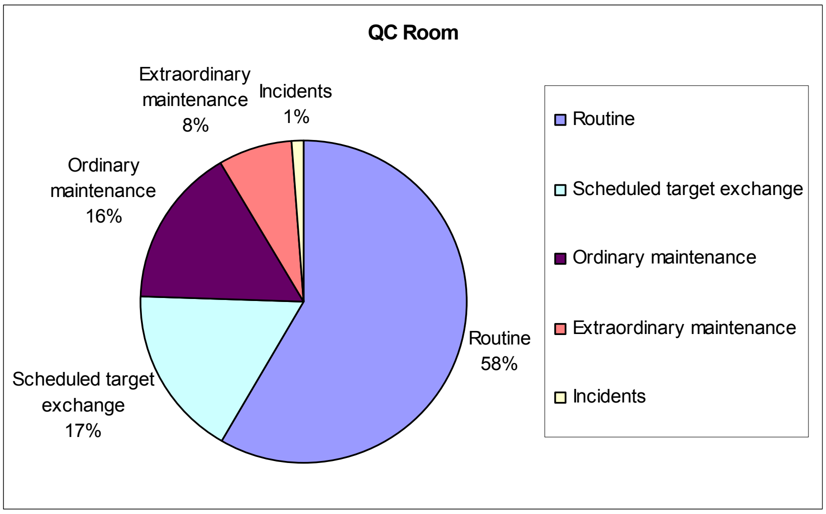

Fig. 6. Attribution of the total dose in the Quality Control room during the period September 2007 – January 2010.

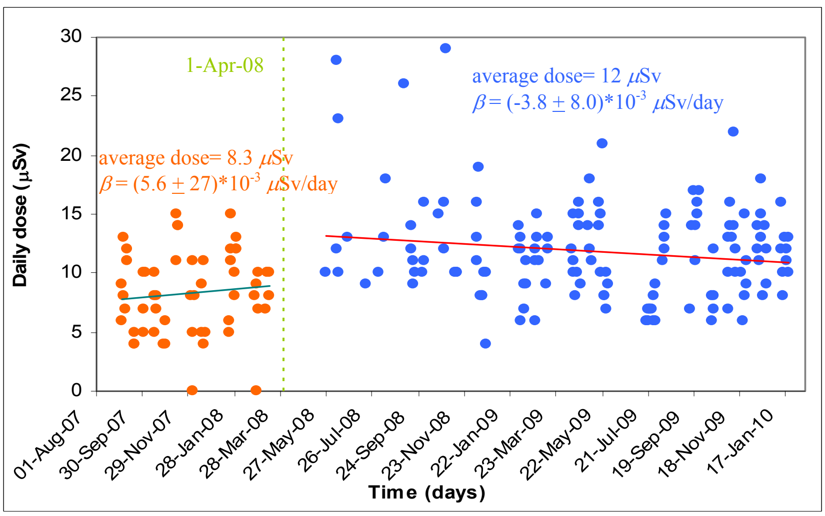

Fig. 7. Daily dose distribution vs. time inside Quality Control room.

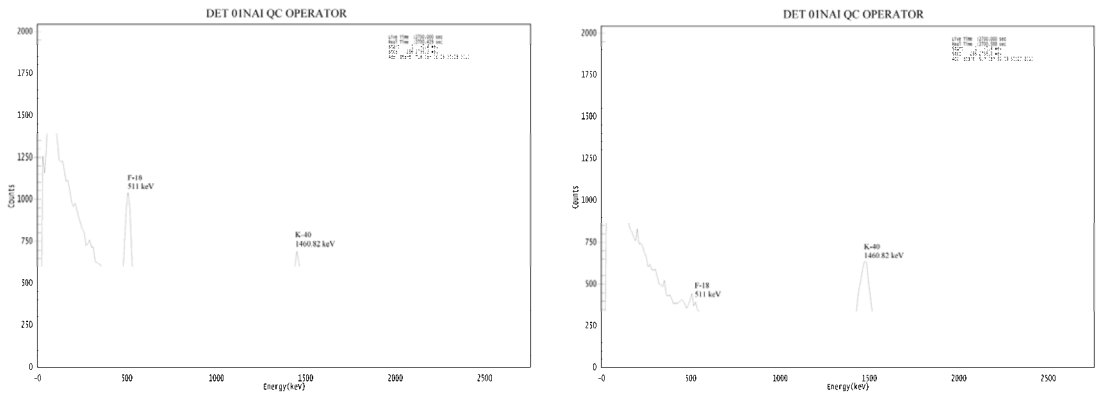

Fig. 8. The "highest" (left) and "lowest" (right) gamma ray spectra of QC operator body radiation.

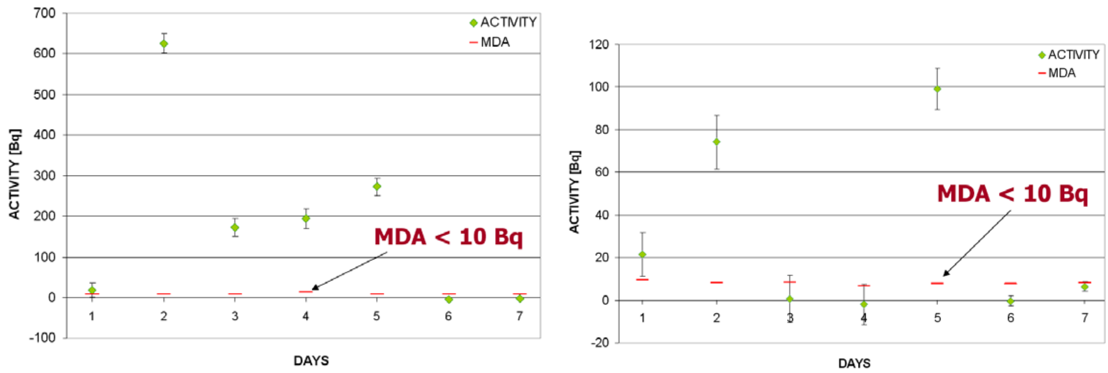

Fig. 9. The ^{18}F whole body activity of both, the QC – (left) and the production – (right) operators during the following days of survey.

shown that, after the target upgrade, the dose per unit activity suddenly drops by 20% ($2.4{\cdot}10^{-2}$ / $3.0{\cdot}10^{-2}$ = 0.80).

A jump in the dose to the QC room operator was also expected as the activity delivered to the room increased by about 1000 MBq, i.e. 1000 MBq / 1500 MBq ≈ 66%. Fig. 7 shows that the daily dose increased by about 40% (12 / 8.3 ≈ 1.40), and therefore less than expected from the increase in activity delivered. This might be explained by the additional shielding placed in the room.

The improved familiarity of the operators with the handling techniques are expected to show in the time trends of the normalised dose. To date, any improvements have not achieved statistical significance.

The values of measured body activity (Fig. 9) and also of the related dose received (Fig. 10) clearly show that, during FDG production, both operators incorporate just a minute amounts of ^{18}F, but the QC operator is a few times more exposed than the other. However, in both cases the doses are still at least two orders of magnitude less than the average dose due to natural background. During the weekend, when no production is performed, the observed activity was smaller and below MDA. It was possible to explain the maximal values of the activity measured during the production period to special events, such as more FDG produced or in vials checked by QC operators (this is the case of day 2); or later-than-usual begin of production due to machine related problems (day 5).

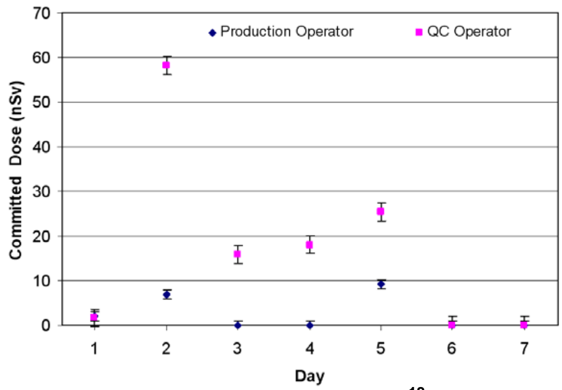

Fig. 10. Values of committed effective dose due to ^{18}F intake for both operators.

The WBC internal contamination assessment campaign was performed recently for the first time and its result is valid for the last period only. There are no reference values from the past. However, since there were no significant changes in protection against spread of ^{18}F contamination in the past and the amount of produced radioactivity used to be lower, it can be expected that the levels found in the present survey to also be representative of past internal dose.

Conclusions

The main contributor to operator dose at JRC-Ispra's FDG production facility is daily routine operation. Production malfunctions, in spite of potentially exposing personnel to the highest dose rates, in practice contribute to total dose only up to a few percent.

The target upgrades resulted in a significant increase of the activity produced (+70%). However, this increase did not result in a similar increase in the dose to the operators. In the Clean room, dose increased only by 40%, probably due to the improvement in the chemical synthesis modules. The activity delivered to the QC room increased by 66%, but dose increased only by 40%; this is likely due to the introduction of additional shielding.

The values of committed effective doses obtained from the WBC measurement campaign are very small. They confirm that ^{18}F internal contamination during routine FDG production night shifts results in negligible health hazards for both of the operators. This conclusion can be extended to all operators working in standard conditions.

Radiation protection organization in the Joint Research Centre of Ispra

Giuffrida, Daniele[1]; **Macchi, Giovanni**[1]; **Osimani, Celso**[2]

[1] Joint Research Centre, Ispra, European Commission, Radiation Protection Sector, ITALY

[2] Joint Research Centre, Ispra, European Commission, Nuclear Decommissioning Unit, ITALY

Abstract

The Joint Research Centre of Ispra, one of the research Sites belonging to the European Commission, Directorate General JRC, was created in the late '50s, in order to steer European research on nuclear industry. It hosts numerous nuclear facilities, some of which are maintained in operation, while others were shutdown in past years, namely: two research nuclear reactors, hot cells facilities, radiochemical laboratories, one Cyclotron (still in operation), facilities for studies on fissile material (in operation), and some facilities for the treatment and storage of liquid and solid waste (in operation). The JRC accounts for 21 nuclear licences, 14 Controlled Zones and 12 main Surveilled Zones, on its Ispra Site. This paper will discuss the organization which has been developed, during the years, and put in place to guarantee maximum safety in all radiation work activities at the JRC-Ispra: the Radiation Protection Sector -which belongs to the "Nuclear Decommissioning Unit"-, the Radiation Protection Assistance Contract, and the role of Consultants and other External Contractors. The internal work authorisation processes, together with the work activities' preparation, assistance and reporting will be discussed: methods for the internal dissemination of experience and good practices will be reviewed. Some Laboratories give internal services to the Radiation Protection Sector: the Dosimetry Laboratory, the Whole Body Count Laboratory, the instruments' Calibration Laboratory, the Electronics Laboratory: their roles and functions will be presented. The Medical Service and the Radiotoxicological Laboratory give external support to the Sector: their role will be discussed. Emergency preparedness and response at the JRC will be reviewed, with emphasis on internal Emergency Squads training and integration. A brief outline of Radiation Protection permanent training organization at the JRC, and a summary of Radiation Protection archival methods will also be presented.

Support service of radiation protection in JRC Ispra (Italy) using the methodology applied in Spanish nuclear power plants

[2] Iberdrola Ingeniería y Consultoría, S. A.

Abstract

In the Joint Research Centre (JRC) of Ispra (Italy), there are different nuclear facilities, which are most shutdown and in a pre-decommissioning phase:

- Experimental dismantling reactors
- Research facilities to be dismantled
- Hazardous Liquid Waste Treatment Area
- Waste Storage and Decontamination Area
- Cyclotron, for F-18 production (still in use)

Since 2006, a Service Provider Company (LAINSA) and an Engineering company (IBERDROLA) have collaborated on support services of Radiation Protection in the JRC-Ispra. These companies have managed to introduce the operational radiation protection model applied in Spanish Nuclear Power Plants into the JRC.

The support service consists of the development of radiation protection assistance and technical consultancy, related with the following topics:

1. Assistance during Safety & Maintenance / Decommissioning Activities
2. Assistance during Nuclear Transport
3. Assistance in specific activities (SAS tents, glove boxes, hot cells)
4. Routine Activities
5. Electronic Laboratory
6. Whole Body Count / Dosimetry/ SIT+LMR Laboratories
7. Documental Activities, technical consultancy, formative actions

During the development of this project, a high quantity of radiological surveillances (surface contamination, air sampling and dose rate), spectrometry analyses, technical reports and RP procedures have been carried out, responding to the necessities of the JRC.

More than 200 radiation and contamination detectors (fixed and portable) are managed in the E-Lab. Routine operational controls, repairs and training courses are the main activities in the Laboratory.

Other RP services have been started during 2009, concerning the technical support to the Whole Body Count (WBC) and to the Dosimetry and Calibration Laboratories (SIT).

From the work performed in the Centre, excellent results are being achieved by a highly qualified team of professionals with different technical profiles, having a high ability for adapting to the changing conditions of the JRC policies.

Introduction

LOGISTICA y ACONDICIONAMINTOS INDUSTRIALES SAU (LAINSA), with IBERDROLA INGENIERÍA Y CONSULTORÍA, S.A, exposes in this proceeding the most significative work areas concerning radiation protection assistance (RPA) carried out from 2006 in the JRC-Ispra (Joint Research Center).

RPA activities have been divided in:

1. Assistance during Safety & Maintenance / Decommissioning Activities
2. Assistance during Nuclear Transport
3. Assistance in specific activities (SAS tents, glove boxes, hot cells)
4. Routine Activities
5. Electronic Laboratory
6. Whole Body Count / Dosimetry/ SIT/LMR Laboratories
7. Documental Activities, technical consultancy, formative actions

Methodology has consisted of assistance carrying out surface contamination, air sampling and dose rate measurements, fulfilling radiological surveys; routine controls; checking RP procedures at works with radiation and contamination risk; management of electronic instrumentation (i.e. contamination monitors, dose-rate monitors…); assistance in environmental measurements laboratory; assistance in SIT - Dosimetry - WBC laboratories.

Material and methods

Staff organization

LAINSA-IBERDROLA staff is composed by:

IBERDROLA (3)	LAINSA (20)
Site Manager (1)	Team Leader (3)
Team Leader (Deputy Site Manager) (1)	RP Technicians (8+1)
Team Leader (1)	Electronic Technicians (2) WBC/Dosimetry/SIT+LMR Technicians (3+1)
	Archive Support (1) Documental activities (1)

Team Leaders coordinate activities at works, being the interface of JRC Supervisors with RPA Technicians, communicating changes and difficulties, being proactive and developing RP procedures and technical reports.

LabEl Technicians assist electronic laboratory instruments and other equipments fixed on nuclear facilities, carrying out repairs and performance tests.

WBC/SIT/Dosimetry/LMR Technicians carry out activities such as supporting maintenance of whole body count detectors, calibrating electronic instruments and TLD dosimeters, verifying nuclear instrumentation, analysing samples and software.

Planning and distribution of RP Technicians must be flexible; therefore, movement of technicians between areas is important for delivering a right service.

1. Assistance during Safety & Maintenance / Decommissioning Activities

Decommissioning is the last stage in the life of a nuclear facility. JRC-Ispra is in a state of functional shut-down, and decommissioning activities are planned in the future. Safety & Maintenance activities cover efficiency tests to instrumentation (ventilation, radiation monitors, HVAC equipment…), absolute filters change…

Up to now, pre-decommissioning activities have been carried out in nuclear facilities, consisting mainly in nuclear transport, POCO (Post-Operational Clean-Out) waste management and radiological characterisation for waste inventory. Furthermore, waste management area (Area 40) has built several facilities for pre-treatment and measurements of radioactive waste.

RP Assistance, carried out by RP Technicians consists of verifying Personal Protective Equipments (PPE) by workers, prescribed in the Radiation Work Permit (Scheda di Lavoro): protective gloves, protective coverall, overshoes, mask, filter.

RP Technician will perform radiological surveys before carrying out works, including results in the corresponding *Scheda di Lavoro*. These surveys consist of measuring dose rate in work areas, removable surface contamination and air sampling. In the case of contaminated areas, a transit point will be included.

RP Technician, in special work conditions, will follow procedures assisting during dress/undress, controlling transit points, SAS tents, using radiation and contamination monitors.

Fig. 1. Radiological control of surface contamination with a Berthold LB124.

2. Assistance during Nuclear Transport

RPA during nuclear transport in the JRC-Ispra has consisted of:

- Measurements of removable surface contamination before opening empty casks
- Measurements of removable surface contamination of nuclear packs
- Measurements of dose-rate before transport
- Estimation of transport index

3. Assistance in specific activities (SAS tents, glove boxes, hot cells)

RPA in specific activities includes SAS tents, glove-boxes and hot cells. Ventilation and filtering are basic parameters for ensuring confined areas for working (engineering controls)

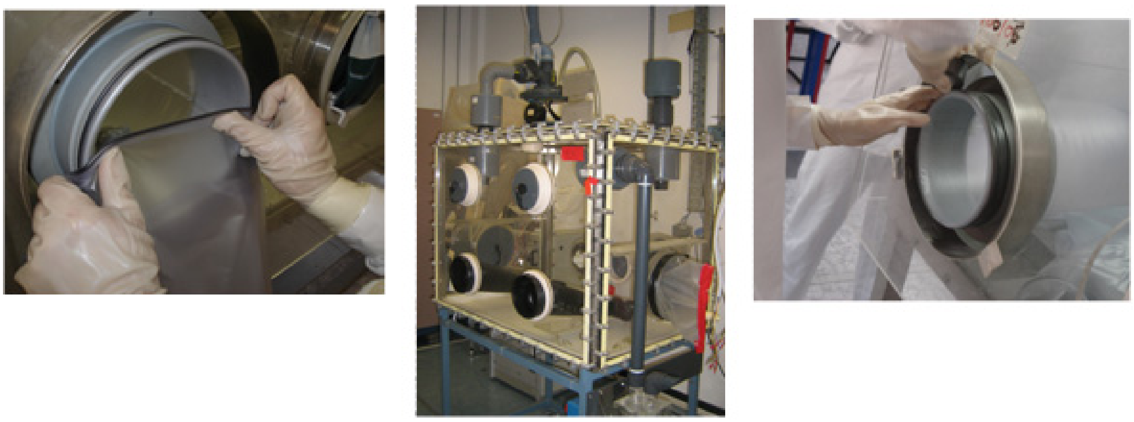

Fig. 2. Assistance to glove-boxes: sleeve and glove change.

Some activities require setting up SAS tents for radiation control, avoiding any Spreads of contamination (i.e. mechanical cutting, handling of radioactive materials, decontamination, clearance …).

Fig. 3. Assistance in a Hot Cell (ATFI).

4. Routine Activities

Some activities carried out for JRC-Ispra is the routine checking, defined by post-operational licensees and RP Sector: periodic removable surface contamination, dose rate measurements, air samplings, routine performance of nuclear instrumentation, environmental dosimeters change. Specific forms have been developed for each Controlled Area of each facility, identifying routine control points (figure 4).

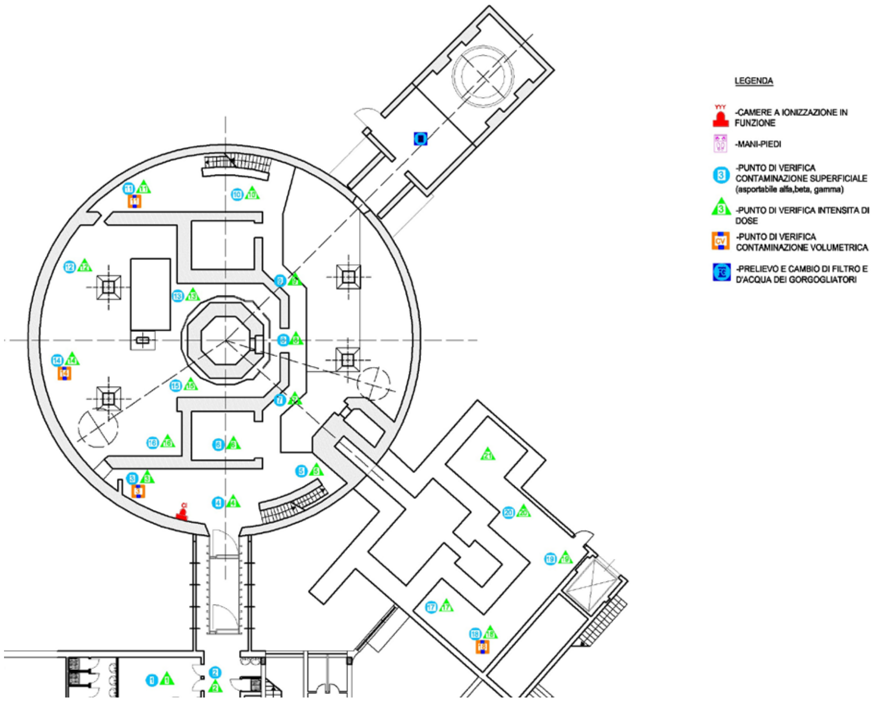

Fig. 4. Signaling controls to carry out trough simbols (Autocad 2007).

Fig. 5. RP Technicians carry out measurements in established points.

5. Electronic Laboratory

LabEl Assistance consist in repairing and verifying the right functioning of measurement equipments, with periodicity stated in Italian norms and JRC procedures. Some activities of LabEl have been listed:

a) Routine performance checkings
b) Electronic Calibrations
c) Repairs
d) Software development
e) Formative actions (i.e. courses)

Contamination monitors (Berthold LB124) are checked every day with alpha and beta/gamma radioactive sources, for verifying that efficiencies are in a valid range, checking that mylar is in good state and battery status. Furthermore, contamination on the contamination monitor is also surveyed. A check-up of state of hand-foot monitors is also carried out each week.

6. Whole Body Count / Dosimetry/ SIT + LMR Laboratories

RP assistance to external laboratories has been a request of Radiation Protection Sector during 2009, including previous assistance to LMR laboratory (environmental laboratory).

7. Documental Activities, technical consultancy, formative actions

Some procedures have been developed for several areas, being approved by the JRC-Ispra:

- Set up Transit Point
- Dress/Undress PPE
- Clearance
- Routine controls
- RP assistance in SAS tents

Radiological surveys forms have been developed for including removable surface contamination, air sampling and dose-rate measurements, including ALARA studies. A technical report in a Technical Gallery, used for channelling pipelines from discharge of hot cells. Radiation levels are showed in figure 5.

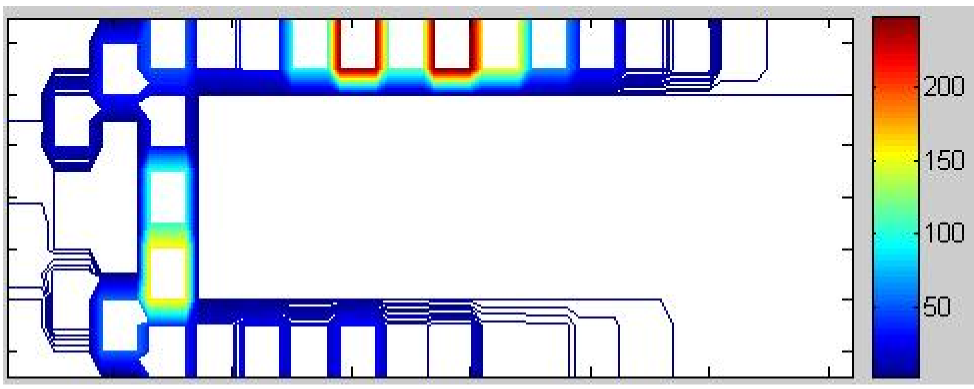

Fig. 6. Visual distribution of effective dose in a Technical gallery in μSv/h (Matlab 7.0).

Another report has been the development of a program for estimation of absorbed doses for staff during production of F-18.

Conclusions

During the development of this project, a high quantity of radiological surveillances (surface contamination, air sampling and dose rate), spectrometry analyses, technical reports and RP procedures have been carried out, responding to the necessities of the JRC.

Other RP services have been started during 2009, concerning the technical support to the Whole Body Count (WBC) and to the Dosimetry and Calibration Laboratories (SIT) and Formative Actions.

Effective doses received by staff have been lower than 1 mSv/worker/year.

From the work performed in the Centre, excellent results are being achieved by a highly qualified team of professionals with different technical profiles, having a high ability for adapting to the changing conditions of the JRC policies.

The pilot study of the radioactive aerosol particle size distribution in the air from the uranium mine Rožínka, Czech Republic

Rulík, Petr; Mala, Helena; Hulka, Jiri
National Radiation Protection Institute, Prague, Czech Republic, CZECH REPUBLIC

Abstract

The radiological importance of the radioactive aerosol particles depends not only on the kind of radionuclide and its chemical form but also on the aerodynamic properties of the particles mainly on their size. Our aim was to determine the aerosol particle size distribution connected to uranium and its daughter products in the environment of the Uranium Mine Rožínka (Czech Republic) – the last place where the uranium is mined in the Czech Republic – in dependence on conditions of the mine and the ore mill. We also tried to estimate the percentage of radon emanation from the aerosol. The 6-stages cascade impactors were repeatedly placed in three places where the maximum dustiness was expected – close to the workers at the crushing plant, at the face of the shaft and at the collecting site at the end of the ore chute. Gamma spectrometric analysis was performed using HPGe detectors to determine the activities of radionuclides on each collection substrate from individual stages and on the back-up filter. The results of gamma spectrometry were used to evaluate the particle size distribution for individual radionuclides in terms of the activity median aerodynamic diameter (AMAD) and the geometric standard deviation (GSD). The first results from all places show that the distributions are slightly bimodal with the boundary under 0.4 µm and that AMAD is about 6 – 7 µm and GSD about 3 in agreement with the literature. The total activity concentrations were in an order of magnitude 10^{-3} – 10^{-2} Bq/m^3. The ratio of the activity concentration of the radon daughter products (^{214}Bi, ^{214}Pb) to the ^{226}Ra ranges around 0.5. Approximately 20 – 30% activity is attached to particles with aerodynamic diameter (AP) > 10 µm and more than 50% activity to particles with AP > 4 µm; about 10 – 20% of the activity is attached to aerosol particles with AP < 0,39 µm.

The characteristic of long-lived radionuclides in the uranium mine atmosphere in Dolní Rožínka in the Czech Republic

Otahal, Petr; Burian, Ivo; Vosahlik, Josef
SÚJCHBO, v.v.i., CZECH REPUBLIC

Abstract

Miners of uranium mines are exposed by three ways: the irradiation of external gamma rays, the dose which is caused by the inhalation of RnDP (radon decay products), and also long-lived products of the uranium series. The presence of ^{232}Th and its decay products is not taken into account.

The derived limit for intake of the mixture of long-lived radionuclides which emit alpha particles is 1850 Bq per year according to the Decree valid in the Czech Republic.

The measurement for studying the mixture of long-lived radionuclides in the atmosphere of the last uranium mine (Rožná I) in Central Europe is realized as a part of the SUJ 200407 project. The mine is situated in central Moravia which is in the varied series of Moldanubic, represented mainly by biotitic up to amphibolites gneiss. This is affected by strong migmatization.

Measurements were performed in two typical workplaces underground (in the forefield, at the filling of corf) and one workplace in the crushing plant. The concentrations of radon and decay products (EER – equilibrium equivalent of radon) were also measured. The concentration and the properties of aerosol particles and the climatic parameters were also registered.

The mean concentration of long-lived radionuclides in the case of workplace A was 0.34 Bq·m^{-3} and in the case B lower - 0.06 Bq·m^{-3}. The mean concentration of radon was 5700 Bq·m^{-3} and the mean concentration of RnDP was 320 Bq·m^{-3} in forefield A. The low factor F (the ratio of EER and radon concentration) is caused by intensive ventilation. All parameters vary strongly influenced by the type of work operation.

Introduction

The total dose (E) for miners in a uranium mine consists of three parts: the effective dose from external photon irradiation (E_{ext}), the effective dose which is caused by the inhalation of radon daughter products ($E_{\mathrm{int},Rn}$), and the effective dose which is given by the inhalation of compound of the long-lived alpha radionuclides that are members of uranium series ($E_{\mathrm{int},alpha}$).

$$E[mSv] = E_{ext} + E_{\mathrm{int},Rn} + E_{\mathrm{int},alpha}$$

The concentration of long-lived radionuclides in the mine's atmosphere is influenced by many factors. The level of concentration is affected by concentration of long-lived radionuclides in ore and by working activity. The decrease of the concentration is affected by the intensity of ventilation and by the level of artificial humidification during individual working processes.

The results of personal dosimetry [1] in the case of uranium miners indicate that the intake of long-lived radionuclides contributes to about one half of the total effective dose. The results of personal dosimetry over the past five years are presented in Figure 1.

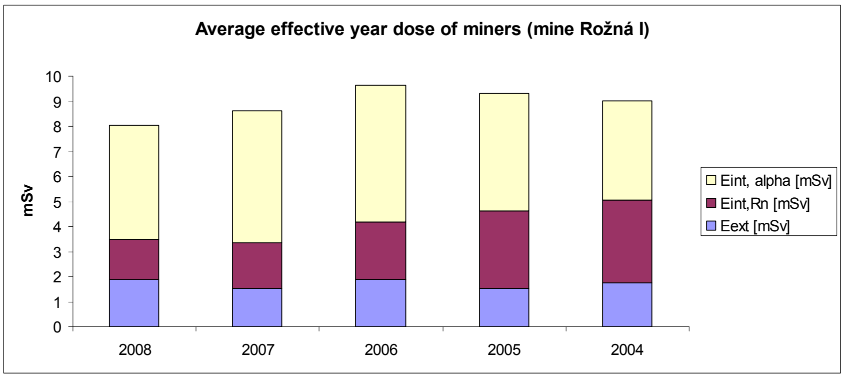

Fig. 1. Effective Yearly Dose for Uranium Miners in the Rožná mine.

The radiotoxicity of long-lived radionuclides which are members of the uranium family in the mine's atmosphere do not depend only on the total concentration of this compound, but also on the chemical form of radionuclides, on the composition of long-lived members of the uranium family, and on the aerodynamic characteristics of aerosol particles that carry attached radionuclides.

There were two underground workplaces (the stope and the place where the ore is placed in the mine truck) and one surface workplace chosen where one could anticipate the higher level of concentration of long-lived radionuclides. The surface place was the crusher house. This was the selected point beside the ore crusher with a permanent presence of a crew.

The size of distribution of aerosols particles should be divided [2] into three modes: the Aitken nuclei mode has a size range from 0.003 to 0.08 μm, the accumulation mode has a size range from 0.08 to 1 μm, and the coarse particle mode has the size range from 1 to 40 μm.

Material and methods

The radon daughter products were sampled on an open-face filter (glass fiber). The alpha activity of the filter was determined with help of the MAAF alpha spectrometer.

The concentration of radon was measured with help of instantaneous sampling of air put to scintillations chambers. The obtained sample was measured using a LUK device.

The climatic condition was determined with help of the Commeter climatic probe. The wind velocity was measured by the TESTO thermal probe.

The determination of concentration and size distribution of non-active aerosol was realized by CPC 3025 and SMPS 3071 (TSI). A setting was used that allowed to measure aerosols of diameters between 15 nm and 750 nm.

The determination of concentration of long-lived radionuclides in the mine atmosphere was carried out with help of two types of open-face filters (glass fiber and membrane filters). The determination of this activity was estimated by the MAAF semiconductor spectrometer and Canberra multichannel alpha-spectrometer.

The detailed sampling of active aerosol was performed by the Andersen 10-stages ambient cascade impactor model 2110K. The intervals of classification of aerodynamic aerosol diameters are listed in Table 1. The impactor was operated at 7 $l \cdot min^{-1}$ flow rate

Table 1. Series 210-Aerodynamic Equivalent Particle Diameter at 50% Collection Efficiency.

Impactor stage	**Cut-point diameter**
1	18 μm
2	11 μm
3	4.4 μm
4	2.65 μm
5	1.7 μm
6	0.95 μm
7	0.53 μm
8	0.32 μm
9	0.16 μm

A new method was developed for the determination of activity of individual stages of the impactor. This method is based on the interaction of alpha particles with sensitive surfaces of KODAK LR115 foil. The surface of detecting foil is covered by another foil, reducing the energy of alpha particles to needed energy (1-3 MeV).

Results

Most of the results were collected at the two places on the 21st floor (about 1100 m under the Earth's surface) in the Rožná I mine. These places were selected for their higher concentration of uranium ore.

The concentration of activity in the stopes was determined with help of the described instruments. The next tables summarize these results.

Table 2. The concentration of radon and EER in the A stope.

A Stope				
Time	**Concentration of radon [$Bq \cdot m^{-3}$]**	**EER [$Bq \cdot m^{-3}$]**	**F (= EER/concentration of radon)**	**Unattached fraction of EER**
16:00	4210 ± 132	682 ± 42	0.16	0.039
19:00	3166 ± 111	213 ± 25	0.07	0.183
0:15	11288 ± 206	295 ± 26	0.03	0.022
9:15	4182 ± 122	711 ± 46	0.17	0.014

Table 3. The concentration of radon and EER on the B stope.

Stope B			
Time	**Concentration of radon [Bq·m^{-3}]**	**EER [Bq·m^{-3}]**	**F (= EER/concentration of radon)**
15:25	1256 ± 87	57.1 ± 8.7	0.05
17:33	444 ± 53	38.9 ± 5.2	0.09
23:15	913 ± 74	22.2 ± 3.5	0.02
0:40	1085 ± 79	38.3 ± 5.2	0.04
2:40	334 ± 52	33.1 ± 4.6	0.10
7:26	1107 ± 79	53.8 ± 5.4	0.05

One can see that at both workplaces there was a high changing of air. The relative humidity on the stopes was about 90%, the average temperature was 23°C, and the mean air velocity was 0.21 m·s^{-1}.

The concentration of long-lived alpha activity was determined with help of two independent parallel open-face filters. In the case of the A stope, the concentration was 0.34 Bq·m^{-3}, in the case of the B stope, it was 0.06 Bq·m^{-3}.

The additional analyses were made using filters collected at the B stope. Filters were covered by foils, allowing the detection of alpha particles with different energies. One foil allows the detection of alphas emitted by ^{234}U, ^{230}Th, ^{226}Ra, and ^{210}Po and the second foil allows the detection of alphas emitted only by ^{210}Po. The detection foil was Kodak LR115. The advantage of this method is a relatively long duration for measurement. In the case of filters from stope B, a concentration of ^{210}Po was determined of about 3 mBq·m^{-3} and the total concentration could be estimated as 10 mBq·m^{-3}. So, the ratio between the before-radon and after-radon branch is 3.4.

The influence of self-absorption was not included; it is one of the possible reasons for differences.

The next table summarizes our results.

Table 4. The summary and comparison of results by various methods of evaluation.

Workplace	**Method**	**Concentration**	**AMAD**	**Concentration of nonactive aerosol**
		Bq·m^{-3}	µm	particle.cm^{-3}
B stope	Grab sampling, glass-fiber filter, 17 l/min	0.07		
B stope	*covered by foil to detect only Po*	0.003		
B stope	Grab sampling, membrane filter, 19 l/min	0.05		
B stope	*covered by foil to detect only U+Th+Ra+Po*	0.01		
B stope	Sum of results obtained by the Andersen impactor application – filters were covered by a system of foils (Po detected)	0.01	4,2	
B stope	TSI			19000 – 47000
Typical result after grab sampling in the case of uranium mines dosimetric service monitoring		0.1		
Typical result after use of personnel dosemeter		0.2		

The sampling with help of the cascade impactor was performed in the presence of the crew in the workplace. The volume of the sample was 4.1 m^3. The next graph documents the size distribution of airborne ^{210}Po.

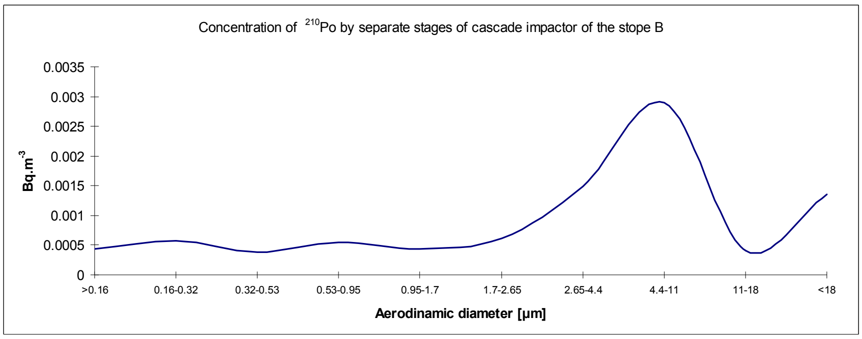

Figure 2. The results of evaluation of the cascade impactor.

The gained size distribution of active aerosol could determine the AMAD of about 4.2 μm and GSD of about 4.75. These results are preliminary and they will be confirmed with help of further measurements.

The determination of concentration and size distribution of non-active aerosols was performed in the B stope. The samples were taken during working activity, except for explosions. The sampling time was set to five minutes. The next graph shows the concentration of aerosol particles during separate working processes.

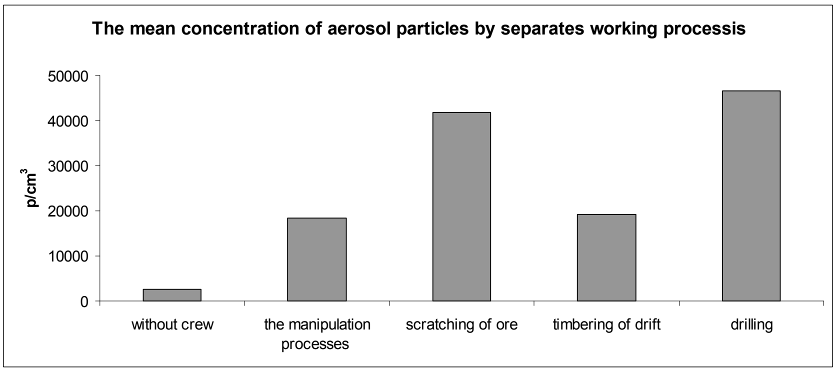

Figure 3. The typical concentration of aerosols particles by differents working proceses.

The typical size distribution during drilling is demonstrated in the next graph.

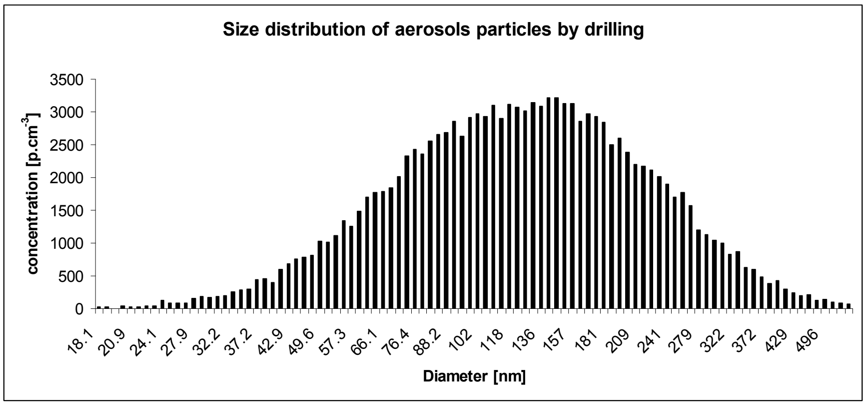

Figure 4. The typical size distribution of aerosols particles by drilling.

Discussion

To determine one of the important parts of the effective dose for uranium miners, it is necessary to know the detailed information about long-lived aerosol particle radioactivity.

With help of the TSI analyzer, it was determined that the size distribution of non-active aerosol is in the range from 15 to 750 nm. The maximum distribution is in the 80 nm area. The parameters were set in this way so that the aerosol coarse mode was not registered.

A new method was developed for the determination of activity of separate stages in the cascade impactor. It is necessary these methods confront and confirm new approach.

The coarse mode is observable with help of the cascade impactor. The maximum cut-point is 18 μm. The maximum size distribution of active aerosol is in the range from 1 to 10 μm.

The high concentration of aerosol particles causes the low unattached fraction of radioactive particles, of course.

Conclusions

The mean concentration of non-active aerosol particles was $4.5.10^4$ particles·cm^{-3} through drilling. The maximum concentration was $1.35.10^5$ particles·cm^{-3}. These values correspond with the published values by [3], there values less than 2.10^5 particles·cm^{-3} where registered. Working processes and the structure of rock influence the concentration and the size distribution of aerosol particles intesively.

The total concentration of long-lived alpha-emitting radionuclides varies of course with the concentration of these radionuclides in mining ore.

ROBOSCAN: an advanced method and system that ensures a total radioprotection of the operators working with mobile vehicle scanners

Tudor, Mircea; Sima, Constantin; Bizgan, Adrian
MB Telecom-Ltd. S.R.L., ROMANIA

Abstract

The radiological scanning of vehicles containers is a non-intrusive inspection method capturing the interest of many current researches. It is realized by using a gamma ray source (Co^{60}, Cs^{137}, Ir^{192}) or a linear accelerator emitting a well collimated radiation beam. The radiation beam penetrates the inspected vehicle and reaches a system of detectors. An electronic system converts the radiation image into a corresponding visual image displayed on a high-definition monitor. The image can be saved and archived after visual inspection.

The detection system and the radiation source are mounted on a special designed vehicle that was approved for travelling on public roads. The vehicle is robotized and is remotely operated from a command centre placed outside of an exclusion area protected by infrared barriers. Any intrusion into the exclusion area is reported to the command centre and triggers the automated turn-off of the radiation emission.

Due to the fact that during the scanning operation the operator is situated outside the exclusion area, the radiation dose that he receives is situated within the limit of the natural background.

The paper presents the technical achievements, the radiological safety measures and the operation of ROBOSCAN 1M, a scanning system that implements the concept of total radiological protection of the operator. Such systems are currently used by custom officers on the Romanian borders for inspecting the vehicles and containers entering the European Union. Using personnel radiation monitoring equipment we proved that the equivalent dose is under the limit for the public. The obtained values are close to the radiation natural background and confirm the theoretical estimations and the efficiency of the radiological protection provided by the ROBOSCAN concept implementation. ROBOSCAN has won in 2009 the Grand Prix of the “Salon des Inventions” in Genève, and the “WIPO Best Inventor 2009 Award” at the International Warsaw Invention Show.

Introduction

The increasing growth of terrorist activities, contraband and illegal transportation drives the demand for high performance security systems. Special attention needs to be paid to the area of international cargo transports, which is usually the preferred vector for the contraband with guns, radioactive and explosive materials, narcotics and other forbidden stuff, easy to be hidden inside large volume of goods. The daily increasing volume of transported cargo makes impossible to physically inspect all suspicious transports.

The nonintrusive inspection method and system, that radiographies containers, vehicles and train carriages without having to break seals, open containers or physical control may be used for the scanning of vehicles, to create a radiography, that can be evaluated and from which to result the nature and the quantity of the transported merchandise, to track down smuggling attempts or illegal transports of forbidden or undeclared products (drugs, explosives, weaponry, etc.), for antiterrorist protection, by scanning all vehicles that have access in restricted areas, like airports, maritime and fluvial harbours, border crossing points, access to secure buildings, military bases, etc.

With the purpose of nonintrusive control several scanning methods are known, for which the following radiation sources:

- Gamma radiation sealed sources, double encapsulated radioactive material like: Cobalt, Cesium, etc.
- X-ray generators or linear accelerators of X-ray, gamma radiation and neutrons.

The nonintrusive inspection system principle requires the irradiation of a detector area, linearly placed in front of a thin fan-shaped curtain of collimated radiation through which the scanned object is relatively moved. The detectors' electrical signals are analogically/digitally processed, to generate, line by line, radiography to be displayed on a PC monitor. The relative movement of the scanned object is realized by moving the object relative to a fixed scanner, or by moving the scanner relative to a fixed object. The operation of the entire system is realized from a control cabin, placed close to the scanner, cabin for which extensive radiation shield is mandatory.

This method has the drawback that it exposes the operators to the professional irradiation risk.

Currently, several nonintrusive scanning systems are known that include the technologies presented previously. One of these is the mobile imaging system MIS with gamma radiation, manufactured by the MB Telecom-Ltd., Romania, is presented in fig.1.

MIS, like all other mobile scanning systems, that are presently known, have the operator's cabin mounted on the chassis, exposing the crew of the system to the professional and accidental irradiation risks.

The operating of the known systems is very complicated, needing a minimum three person per shift crew, operator, driver and external supervisor, the last having the responsibility to direct the traffic of the vehicles that are to be scanned in the scanning area, as well as to prevent intrusion in the exclusion area, where the danger of irradiation exists.

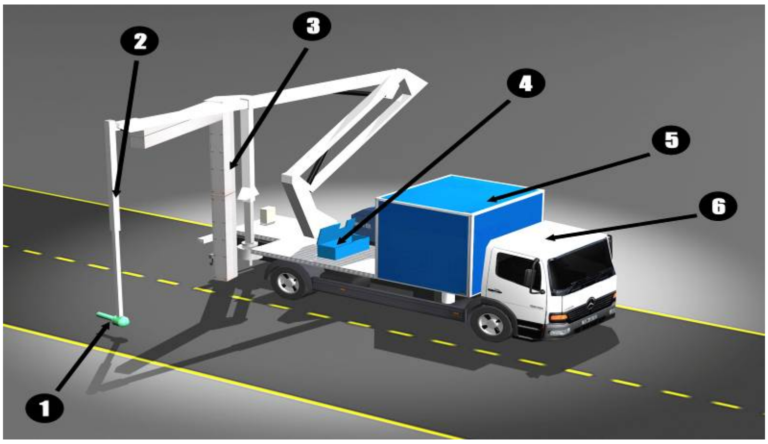

Fig.1. Mobile Imaging System (MIS): 1. Radioactive source in typ A package; 2. Source boom; 3. Detector boom; 4. Transport and repository container; 5. MIS command centre cabin; 6. Driver's cabin.

Material and methods

In accordance with ICRP 60 Recommendation and the IAEA Basic Safety Standard (BSS) the practice of radiographic non-invasive inspection is justified and requiring the optimization of radioprotection and the dose limitation.

This optimisation of radioprotection and dose limitation in the practice of radiographic nonintrusive inspection is implemented in ROBOSCAN - nonintrusive inspection method and system, has been patented in European Union (2006), Romania (2007), Eurasia (2008), Russian Federation (2008) and United States of America (2008).

The subject of the ROBOSCAN invention is the realization of a nonintrusive inspection method and system, that eliminates entirely the professional irradiation risk, by removing the operators cabin (the control centre) from the exclusion area and eliminating the need of a driver and external supervisor, by automation and remote operation of all processes deployed in the exclusion area and the limitrophe area.

The vehicle to be scanned has access in the exclusion area through an automated traffic management subsystem that automatically commands the functioning of the barriers and of the entry/exit semaphores. The vehicle is placed in a marked spot, before its driver leave the exclusion area (where there is the irradiation risk), then the protection of the exclusion area is activated, followed by the initiation of the scanning process by remote commands to the mobile scanning unit and the source, when the radiation source is activated and the slow and constant motion movement of the mobile units is started. This unit is moving rectilinear and uniform on parallel trajectories framing the scanned vehicle. The movement of the mobile unit is automatically controlled by electronic and informatics modules, connected to the control centre in a local area network, through radio modems, centre from which they receive commands, and towards which they send in real time status information and dedicated data. The stopping of the scan is performed automatically in the following situation, when the detector boom has passed the extremity of the scanned vehicle and the detectors receive the maximum level of radiation, at the end of the programmed scan length, when the protection limiter of the movement is triggered, when the protection of the exclusion area has been breached, when the proximity sensor has been triggered indicating dangerous distance between the detector boom and the scanned vehicle, when obstacles close to the guiding paths have been automatically detected by sensors placed on the mobile units. The stopping of the scanning process can be manually commanded by the operator in any moment. During this stage of the process, the image resulted from scanning the vehicle is displayed on the operator's monitor and at the end of the stage the protection of the exclusion area is automatically deactivated, and the vehicle may leave the scanning area. The mobile units move back to the start position and the scanning cycle may be restarted. The system includes also a mobile control centre, that is placed outside of the scanning area and that remotely manages all processes, including a subsystem for acquisition, processing, storage and displaying of scanned image. The system also includes an exclusion area protection subsystem, an automated traffic management subsystem and a computer management subsystem.

The automated traffic management subsystem is endowed with some barriers and traffic lights commanded by radio, directly by a dedicated software application and the exclusion area protection subsystem is made out of some motion detection active sensors, a control module for the sensor's status and an emergency automated radiation source shutdown module in the case that the exclusion area has been breached.

Results

In the first implementing variant ROBOSCAN 1M, presented in fig.2 "in transportation mode" and in fig.3 in scanning position, the major components are:

- Mobile Scanning Unit (MSU)
- Mobile Control Centre (MCU)
- Hydraulic Slow Motion System (HSMS)
- Source Boom
- Detector Boom
- Imaging System
- Automatic Protection of the Exclusion Area (APEA)

Fig. 2. View of ROBOSCAN 1M in transport mode.

The components of the unit (HSMS, source boom, detector boom) are assembled on a truck chassis, resulting MSU on extremely versatile and mobile robotized system.

An essential difference between all competitor systems and ROBOSCAN 1M is that doesn't need a driver to control the truck's movement (drive direction, sense, steering, brakes, vehicle's parameters, etc.). These functions are managed by a "driverless" subsystem that controls all the commands and parameters of the truck.

Fig. 3. View from the right of the ROBOSCAN 1M in scanning position.

In scan mode the operator initiates the scan procedure just by touching the corresponding virtual button, on the touch screen display, inside the MCU and the process is executed in a fully automated sequence, providing to the operator real time data by graphic animation and voice messages.

The MCU, organized inside a caravan that during scanning process is placed outside of the exclusion area and during transport, is towed by the MSU (see fig.4 and fig.2). The MCU manages all the peripherals and subsystems of the inspection system (imaging system, APEA, Graphic User Interface-GUI) in a fully automated process. In scan mode, all processes are managed by the software applications on a Wireless Local Area Network (WLAN).

The truck's transmission is modified by adding a dedicated HSMS capable of engaging direct or reverse drive with very low speed, continuously variable in the range of 0.1m/s up to 1.2 m/s. The operator can define any time the scan length and speed of the scan process. The slow motion in scan mode is initiated by the operator by simply touching an intuitive icon on the Graphic User Interface (GUI) on a touch screen display.

The return of the scanner to the initial position is automatic and the software application receives real time data concerning the position of the MSU inside the scanning lane. The MSU complies with international legal limits for axle load and dimensions, and doesn't need special license or authorizations to access the public roads.

In ROBOSCAN 1M the source boom content double encapsulated Cobalt 60 radioactive source, with the activity (A) of 37,0GBq in special shielded protection manufactured in steel and tungsten. The sizing of the shielded protection is made in accordance with instructions and standards for type A package (7), in accordance with IAEA categorisation of the radioactive source (8), with Co 60 source, in practices of industrial radiography sources, for $A=3{,}7\times10^{-2}$ TBq and dangerous sources for Cobalt 60 (D) $D=3\times10^{-2}$ TBq, the risk $A/D=1{,}24$. In accordance with (8), for $A/D<10$ the Categorisation of radioactive source corresponding for category 3.

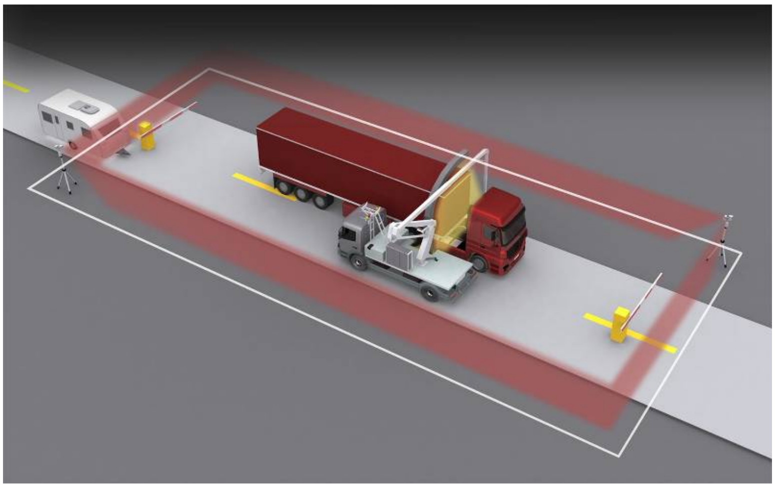

Fig. 4. View of the ROBOSCAN 1M nonintrusive inspection system, placed within the exclusion area.

The Cobalt 60 source is carried by a steel boom assembly which is displayed and stowed by hydraulic cylinders in automated sequences.

In Cobalt 60 shielding a fan-shape cut with an angular opening of 80 degrees is made, in order to collimate a radiation curtain at a width of approximately 18 cm on the detector areas, having placed the radiation source at a distance of five meters from the detector boom. The activation of the source is made through a pneumatic actuator system.

The system used, ensure the automatic retreat of the radioactive capsule in order to stop the radiation, if the actuator would be defective. The activation of the source is signalled acoustically and optically in order to warm the operator and any of the presence of radiation in the exclusion area.

The detector array is made of a special shape and structure of welded aluminium. The ensemble of the source boom and detector boom is automatically deployed and stowed in few minutes, by simply touching an intuitive icon, on the GUI.

The booms have been optimized as shape and structure in order to minimize their own weight and to maximise their performances.

Imaging system content the subsystem for image acquisition, designed to collect, process and analyze different data from the radiation detectors in order to generate the radiography of the scanned object.

The operator can apply on this image different filters and processing algorithms in order to improve the penetration or image quality, just touching intuitive icons on the GUI. The primary image is processed in a proprietary format and can be exported in bmp, jpeg, or other conventional formats (see fig. 5).

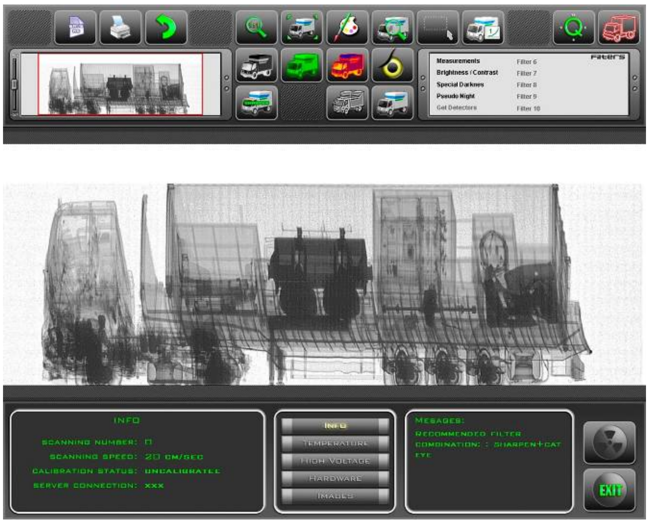

Fig. 5. View of radiography of the scanned truck in imaging software application.

The imaging software application provides multiple choices filters in order to allow optimal image processing like: Low/High Penetration filter, Cat eye, Owl eye, pseudo colour filter, Quick Filter, Pseudo Night and Special Darkness. All filters can be applied on the full image, or only on defined areas of interest.

The command and control software application is displayed on 2 monitors and manages the HSMS, video surveillance, perimeter protection, barriers remote operation and the automation of the scanning process.

All documents related with the transport, as well the front image of the scanned truck, the scanned image and the under view image of the inspected vehicle are saved in complex folder, having as ID the license plate of the inspected vehicle and the date/time stamp. In case of container inspection the container ID is introduced or automatically recognized and used as the folder ID. All commands and status of the sub-systems are registered in a “black-box” can be remotely administrated over a secure internet connection.

The exclusion area protection subsystem is an active radiological protection subsystem, which operates directly the source to automatically shut it down in the case that the exclusion area has been breached. The active sensors of the exclusion area protection subsystem, are placed in groups of two in the extremities of a diagonal of the exclusion area and angled 90 degrees one with the other, they create a virtual barrier two meters high and forty meters long, enough to limit a rectangular surface of maximum 40mx40m (L+30m) (L- is the length of scanned vehicle).These sensors are permanently radio connected with the control centre where they send an alarm signal in case of a breach of the infrared barrier. This signal automatically closes the source and activates a text, vocal and graphical message on the graphical interface of the operator’s software application, indicating the breached side. The subsystem is designed to work in difficult weather conditions like rain, snow, wind, dust, extreme temperatures, etc.

The subsystem for protection of the exclusion area is deactivated to allow the entry/exit in/out of the exclusion area synchronized with the working times of the barriers and when the driver of the inspected vehicle has left the area, the subsystem is reactivated.

The automated traffic management subsystem manages the barriers and the traffic lights placed at the entry and exit in the scanning lane in order to control the access of the vehicles that are inspected. This subsystem is controlled automatically by the operator's software application. On the operator's graphical interface live status info are displayed in real time. The commands and status are sent throughout some corresponding interfaces and radio modems.

The positioning of the mobile control centre outside of the exclusion area, as well as the elimination of the need for a driver during scan, eliminate all risks of radiation exposure and makes possible the reduction of operating crew from minimum three per shift necessary to any existing similar systems, to only one person per shift.

Discussion

Delimitation of the exclusion area, protected by IR barrier is made by the limited dose criteria bellow 0,1µSv, according with the ICRP and IAEA BSS. The resulting estimated dimensions are 40m by (L+30) m, where L is the scanned vehicle length.

The Co^{60} radiation source is protected by a multiple-barriers safety system, with interlocks and special keys accessed only by authorized operator.

According with ISO 3999 requirements, when the scanning is finished, the radiation source is protected by automatically returning it in docking safety position or interrupted due to any unauthorized intrusion in exclusion area or at any malfunction of electrical or pneumatically system.

When scanning process is finished the source boom is folded in transporting mode automatically by the operator command so the source is introduced in ROBOSCAN shielded box and automatically is turned on.

The driver's cabin radiation dose rate, due to the presence of radiation source in transporting mode is less than 0,1 µSv/h.

Any unauthorized intrusion to radiation source or at ROBOSCAN vehicle is turning on the alarm and triggers the guarding security personnel response.

Those measures fulfil the IAEA Security of Radioactive Sources requirements and ROBOSCAN User Manual contains the operating instructions specific to "Security Level B measures" covering all requirements for radiation sources classified in category 3.

The design of ROBOSCAN covers all radiological safety measures according with IAEA BSS and also with Romanian National Regulations, elaborated in accordance with 96/29 Euratom Directive.

The ROBOSCAN has obtained in 2007 the Radiological Safety License (ASR) from Romanian Regulatory Body (National Commission for Nuclear Activities Control).

Five ROBOSCAN 1M are currently used by customs officers on the Romanian border for inspecting the vehicle and containers entering the European Union. Using personnel radiation monitoring equipment we proved the individual equivalent dose for operators is under the limits for the public.

The obtained values are close to the radiation natural background and confirm the theoretical estimation and efficiency of the radiological protection provided by the ROBOSCAN concept practical implementation.

ROBOSCAN has won in 2009 the Grand Prix of the "Salon des Inventions" in Genève, and the "WIPO Best Inventor 2009 Award" at the International Warsaw Invention Show.

Fig. 6. WIPO AWARD for Best Inventor for the invention of ROBOSCAN and The Grand Prix of the "Salon des Invention" - Genève 2009.

Conclusions

Total radiological protection of the operator in scanning with ROBOSCAN system was previously demonstrated. An advantage it represents the reduction of the crew requirement to one single person per shift and the elimination of occupational radiation exposure for end user. Fully robotic automated operations, is key advantages for elimination of the risk of accidental irradiation of the possible intruders in the exclusion area.

The limitation of equivalent dose rate < 0,1µSv at the border of controlled area (exclusion area) is key advantage for radiation exposure of public and environment.

The capability of ROBOSCAN to a later analysis of the functioning parameters and/or operation sequences, by implementing a "black-box" facility, is key advantage for evaluation of custom officer activity and for inspection of users' activity by Regulatory Enforcement.

The optional extend the inspection capability by adding radioactive materials detection, under view video images and documents examination, in a single control procedure, increasing the performance of security control using ROBOSCAN.

Abstract

The Neutral Beam Test Facility (NBTF) will be located in Italy, near Padua, and will be devoted to the testing phase of the Neutral Beam Injector system (NBI) for the International Thermonuclear Experimental Reactor (ITER). NBTF includes two facilities that will be used to test in the same time both the main components of the final system and the whole system. NBTF includes two facilities that will be used to test in the same time both the main components of the final system and the whole system. The facilities are named respectively Spider (the small one) and Mitica (the whole system) and are located inside two distinct shielded bunkers. In each bunker important penetrations for the ventilation, the power supply and the auxiliary systems were arranged, providing that the safety of workers and population is guaranteed.
Tunnels in the underground region, with relatively large dimensions, were needed for both MITICA and SPIDER bunkers in order to allow personnel access for inspection and maintenance of cables and ducts.

Each of these shielding weaknesses needed specific safety analyses that were carried out both making reference to the scientific literature and performing ad hoc calculations.

In the paper the approaches applied to the different safety concerns due to the wall penetrations are considered and described. Reference analyses and computer calculations are reported together with the relevant results.

The outcomes in terms of neutron flux and associated dose data are compared with the regulatory limits and the project constraints, showing that positions and local shielding solutions for the penetrations allow the same level of safety for workers and population as that allocated by the main shielding walls.

Introduction

ITER (International Thermonuclear Experimental Reactor) is a joint international research and development project that aims to demonstrate the scientific and technical feasibility of fusion power. ITER is a tokamak, in which strong magnetic fields confine a torus-shaped fusion plasma. The device's main aim is to demonstrate prolonged fusion power production in a deuterium-tritium plasma.

The experimental Neutral Beam Test Facility (NBTF) under construction in Padua (Italy) will be the testing station for the ITER NBI systems, hydrogen/deuteron particle accelerators based on negative ion technology operating at 1 MeV and 40 A.

The neutral beam test facility (NBTF) is composed by two main facilities: The facilities are named respectively SPIDER (Source for Production of Ion of Deuterium Extracted from Rf Plasma - ion source only) and MITICA (Megavolt ITER Injector Concept Advanced - the main system). Both injectors accelerate negative deuterium ions with a maximum energy of 1 MeV for MITICA and 100 keV for SPIDER, and a maximum beam current of 40 A for both experiments. The safety assessment for the design status of NBTF defined since 2007 was concluded at the beginning of 2008 by issuing a preliminary Site Specific Radiation Safety Report (SSRSR) [1]. Design adjustment and modification were proposed after SSRSR and require new safety evaluations and assessments.

The current work describes the activities performed in the frame of the F4E Grant F4E-2008-GRT-011-01(PMS-H.CD) to adapt the design of the components and the infrastructures for the NBTF. In the following the process for taking the final decision related to the wall shielding and penetration requirement also for the ventilation system is shown and the results are presented and discussed.

Main shielding walls

The general layout for the main buildings of the facility has been defined during year 2008. The main dimensions of the MITICA and SPIDER hall have been fixed. The working procedures and the needing for the staff shifts have been indicated by the research managing. According to this arrangements the main shielding walls have been defined in materials and dimensions taking into account the parametric assessments outlined in a specific report [1]. The shielding assessment was performed for the two main halls, for the different operation phases, considering the neutron radiation produced during D-D operations for some D beam energy scenarios. Neutron attenuation for standard and borated concrete was considered to determine the walls dimensions. In Table 1 and in Table 2 annual dose limits and constraints that have been used for the design are recalled.

In Table 2 the constraints proposed for the design of the NBTF facility were simply stated multiplying the limits by a safety factor of 0,5. The hourly constraints are obtained by considering 2000 hours of working time during each year.

Reference material for the shielding is the standard concrete. The borate concrete has been considered too expensive and regarded as a possible solution only in case space needing would be the main issue. A dose rate constrain of 0.25 µSv/h for the areas adjacent to the MITICA bunker was considered in order to meet the legal requirements for permitting free access even to non exposed workers into those areas.

Table 1. Dose constraints according to the NBTF RPP.

Project Guidelines	
Project guideline for annual individual worker doses	5 mSv/a
Project guideline for individual dose per shift	0.5 mSv/shift
Collective annual worker dose target averaged over life time of plant	0.5 pers-Sv
Interim ALARA Guidelines	
ALARA threshold for dose rates	100 µSv/h
ALARA threshold for collective worker dose to operate and maintain a system for a year.	30 pers-mSv
ALARA threshold for collective worker dose for a task performed less often than annually.	30 pers-mSv
Note, an 'ALARA threshold' is a level that triggers a formal ALARA assessment during the ITER design phase. This does not imply that ALARA reviews will not be performed when the design is below the thresholds.	

Table 2. Limits and constraints for the Radiation Workers.

Categories	Individual Effective Dose Limits (mSv/ year)	Annual Constraints (mSv/ year)	Hourly Constraints (µSv/ h)
POPULATION	1	0,5	0,25
CAT. B Radiation Workers	6	3	1,5
CAT. A Radiation Workers	20	10	5

In Table 3 the attenuation coefficient and the thickness calculated for the walls of the MITICA Bunker are recalled for the specific dose constraint in the adjacent areas, considering the 5 m reference distance from the MITICA vessel.

Table 3. Minimum wall thickness for the MITICA bunker.

	Attenuation coefficients	Standard concrete thickness (cm)
BL VESSEL	1,09E+06	174
BS VESSEL	1,71E+05	151
NB front end	1,22E+06	176
NB rear end	4,12E+04	133

A thickness of 176 cm of ordinary concrete is then required for the areas around the BL vessel and the front end of MITICA; minor thicknesses are acceptable for the portion of the bunker walls in the areas of the BS vessel and of the rear end. Therefore the following minimum thicknesses of ordinary concrete are recommended for the MITICA bunker walls:

- 180 cm from the floor and for an eight of 3 m from the MITICA symmetry axis in the front end and BL vessel areas,

- 155 cm from the floor and for an eight of 3 m from the MITICA symmetry axis in the BS vessel area,
- 135 cm from the floor and for an eight of 3 m from the MITICA symmetry axis in the rear end area,
- the upper part of the MITICA wall, over 3 m from the MITICA symmetry axis, could have a thickness reduced by 30% of the lower one

The evaluation for the shielding of the ceiling has been done in the previous analysis using the approach suggested by NCRP [2] and considering that the main neutron diffusion is due to the atmosphere above the bunker roof. According to this method the needed attenuation required to allow free access to non radiation workers is:

$5{,}0\ 10^2 / 0{,}25 = 2{,}0\ 10^3$

and the related minimum roof thickness is 95 cm of standard concrete. This thickness could be reduced by a 20% factor in the area of the ceiling corresponding to the BS vessel.

Considering that the simulation was performed with a simplified geometry and that not all the detailed structure of the MITICA surrounding was implemented into the model a more conservative approach was adopted in the final design. A 180 cm wall all around the facility was planned and a reduced thickness, of the order of 1 m, was established for the lateral walls in the dome area around the power supply line only. Due to special requirements for the connection of some auxiliary systems (HV and other components) in the upper rear part of the bunker, the wall thickness was reduced accounting for the needed room, meeting meanwhile the recommendation for the minimum shielding thickness reported above.

The SPIDER facility will be devoted to the testing phase of the source section only. The source will operate at a maximum voltage of 100 kV. This testing phase will take place in another area of the same building; thus an independent shielding is required. Even in this case a 0.25 µSv/h dose rate constraint was considered and the consequent shielding thickness for the SPIDER bunker were calculated. Results are shown in Table 4.

For the SPIDER bunker the following minimum thicknesses of ordinary concrete are therefore recommended:

- 120 cm from the floor and for an eight of 3 m from the SPIDER symmetry axis in the front end and BL vessel areas,
- 95 cm from the floor and for an eight of 3 m from the SPIDER symmetry axis in the BS vessel area,
- 80 cm from the floor and for an eight of 3 m from the SPIDER symmetry axis in the rear end area,
- the upper part of the SPIDER wall, over 3 m from the SPIDER symmetry axis, could have a thickness reduced by 30% of the lower one

Table 4. Minimum wall thickness for 100 keV energy.

	0.25 µSv/h
BL VESSEL	116
BS VESSEL	93
NB front end	118
NB rear end	76

For the same level of access a 90 cm ordinary concrete ceiling is needed as well. This thickness could be reduced by a 20% factor in the area of the ceiling corresponding to the BS vessel.

Also in this case the final design was defined according to more conservative considerations and some wall thickness was adjusted where needed only.

Dose evaluation through the walls penetrations

In the MITICA bunker some access-ways are needed to permit entry of personnel and equipment as well as some ducts for cables, radio-frequency (RF) waveguides and ventilation system. Radiation protection assessment for these wall penetrations has been made in order to define dimensions and possible additional shielding where needed.

Utility ducts are much smaller than personnel access penetrations (whose cross-sectional dimensions are about 1 meter by 2 meters, "door-sized"), typically no larger than 0.2 by 0.2 m. Often the utility penetrations are partially filled with cables and other items, and even cooling water in pipes.

Two general rules are advised for the penetrations of an accelerator shielding:

- A penetration should not be arranged so that the primary radiation field is aimed directly toward it.
- For any maze, the sum of the wall thickness between the source and the "outside" should be equivalent to that which would be required if the labyrinth was not present.

The first step in designing penetrations and ducts is to parameterize the reflections of the primary and secondary radiation field. These reflections can be treated through the use of reflection or albedo coefficients.

The MITICA tunnel for the passage of cables and cooling pipes underwent different modifications and more than one configuration was proposed and evaluated in order to meet the radioprotection requirements. In the following the two main solutions are reported along with some consideration and evaluation performed making reference to the related experimental studies available in the literature.

Typical methods for addressing the attenuation of radiation by penetrations involve the use of the results of calculations and semi-empirical formulas derived from Monte Carlo codes. These can be used for both curved and rectilinear labyrinths. Such formulas permit the dose rate calculation at the exit of the MITICA tunnel [4, 5, 6, 7, 8].

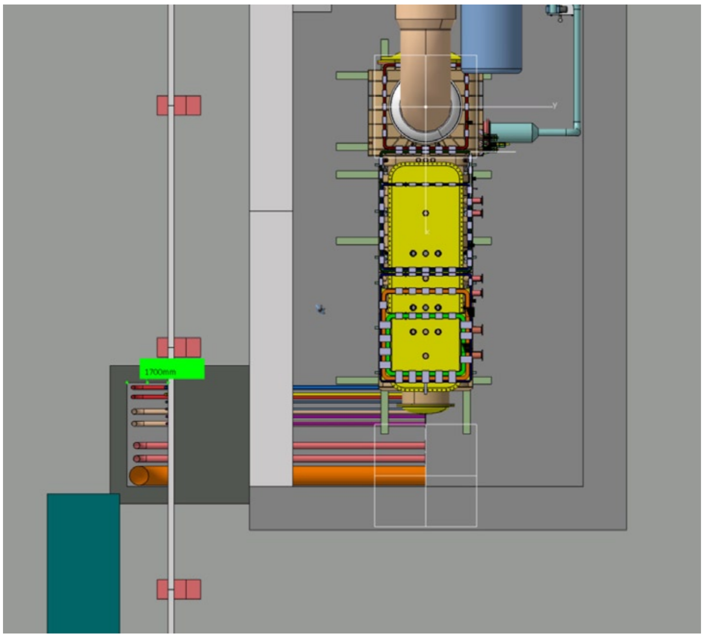

Figure 1. MITICA duct for the passage of cables and cooling pipes.

The tunnel lead to a service room whose dimensions are 10 m x 15 m and which is not accessible during MITICA operations; moreover no worker access is allowed inside the tunnel, and in the area around the tunnel exit during beam-on operations.

The annual average of the dose rate due to three interim campaigns and one final test without shielding walls was assessed in a previous work through Monte Carlo simulation with MCNP Code [3]. In the following the main results are summarized:

(Dose rates in Sv/h)	100 cm	500 cm
From the VESSEL (highest value)	5.41	0.89
From the front end	7.38	1.21
From the rear end	0.28	0.026

Conservatively, the highest of these values was considered (7.38 Sv/h at 100 cm from the front end). Knowing the dose rate at a certain distance from the source, the dose rate at any distance and for any geometrical angle from the beam can be assessed with simple point kernel equations of the form:

$$H(d,\theta) = r^{-2} \cdot H_\theta e^{-\frac{d(\theta)}{\lambda}}$$

which combines the inverse square law and an exponential attenuation through the shield. This equation applies to a point source of a specified radiation where:

- $H(d,\theta)$ is the dose equivalent at depth (d), angle (θ) in the shield
- H_θ constant that may be described as the dose equivalent extrapolated to zero depth in the shield, and corresponding to angle (θ), at unit distance from the point source

- r distance from the source to the point of interest outside the shield
- λ effective attenuation length for dose equivalent through the shield

Over a limited range of shield thicknesses, the radiation transmission could be approximated by an exponential function. For shields of thickness less than 100 g/cm^2, the value of λ changes with increasing depth in the shield because the more easily absorbed (''softer'') radiations are attenuated more rapidly. This process is often described as ''spectrum-hardening''. For the MITICA bunker only ordinary concrete shielding were planned (around 2.35 g/cm^3), with thickness of the order of 100-200 cm. The shielding is therefore always thicker than 100 g/cm^2. For neutrons of maximum energy equal to about 3 MeV (as those coming from D-D reaction), one has $\lambda = 15$ cm.

The source dependence in a tunnel of cross sectional area, A, can be approximated by the following expression:

$$H_1(\delta_1) = \frac{r_0^{\ 2}}{(\delta_1 + r_0)^2} H_0(R) \qquad r_0 = 0.4$$

where:

$$\delta_1 = \frac{d_1 - R}{A^{1/2}},$$

R is the distance from the beam axis (in this case R=0) and r_0 is a fitting parameter. $H_1(\delta_1)$ is the dose equivalent at distance δ_1 in the first leg as measured from the mouth of the passageway in "units" of the square root of the cross sectional area of the first leg. $H_0(R)$ is the dose equivalent at the mouth the determination of which has been previously discussed. Over the domain of $0 < \delta_1 < 9$ the expression is accurate within ± 10 per cent, sufficiently accurate for radiation protection purposes.

Second and successive legs of such "rectilinear" penetrations change the situation dramatically, mainly by modifying the spectrum of the transmitted neutrons. The following recursive expression, reported in NCRP [9, 10], adequately describes this curve, where, δ_1 is the distance in the i^{th} leg measured in "units" of the square root of the cross-sectional area of the i^{th} leg:

$$H(r_i) = \left(\frac{e^{-\frac{r_i}{0.45}} + 0.022 \cdot A_i^{1.3} \cdot e^{-\frac{r_i}{2.35}}}{1 + 0.022 \cdot A_i^{1.3}} \right) \cdot H_{0i} \quad i^{th\ leg}\,(i > 1)$$

The MITICA tunnel is composed by two legs. The first one is an horizontal duct at a level under the MITICA hall floor that goes from the hall to the area outside of the shielding wall. The second leg is a vertical duct that connects the end of the first one to the service room.

Configuration 1. The first configuration refers to a rectilinear 2 legs duct whose cross section is about 0.9 m (height) x 4.6 m (width). After the primary shielding, the tunnel cross section increases up to 2 m x 4.6 m.

For calculation purposes, (even if the first leg is made by a two separate parallel ducts whose height is 0.9 m) a single duct 1.5 m high was considered. This assumption is quite conservative since with these dimensions the cross sectional area of the tunnel is 6.9 m^2 (4.6 m x 1.5 m) rather than 4.14 m^2(4.6 m x 0.9 m).

Configuration 2. This configuration is different from the previous one only for the presence of a concrete shelf whose aim is to attenuate the radiation directly produced by the calorimeter. A concrete shelf with variable thickness (ranging from 0.5 to 1 m), 1.5 m long and 4.6 m wide was designed. Not all the primary neutron beam intercepts the concrete shelf; conservatively, it was assumed that half of the beam is attenuated by the shield, and half passes through the tunnel without suffering any collision (this assumption is confirmed by geometric consideration from CAD drawings).

Results of the calculation are summarized in the table below (Table 1).

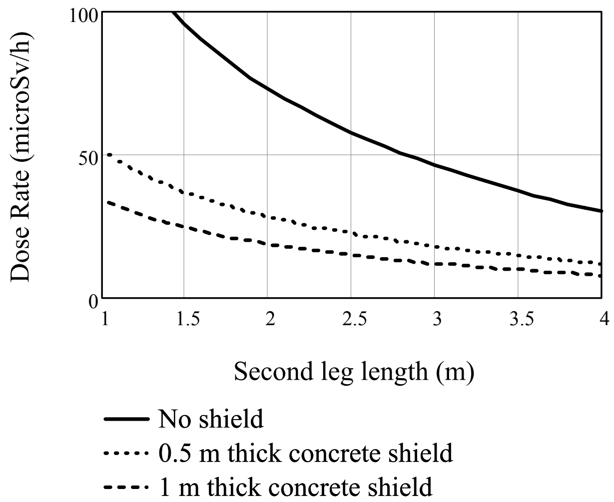

Table 1. Dose rate at the exit of the tunnel according to the different configuration and to different shelf thickness as a function of the second leg length. In the present case, the second leg length is about 3.5 m.

At the exit of the tunnel, i.e. at a distance of 3.5 m from the first leg end (tunnel length), the dose rate is:

$$D_{no\ shield} \approx 30\ \mu Sv/h$$
$$D_{0.5m\ concrete\ shield} \approx 12\ \mu Sv/h$$
$$D_{1m\ concrete\ shield} \approx 8\ \mu Sv/h$$

The presence of a concrete shield reduces the dose rate at the exit of the tunnel by a factor of 3-4, depending on its thickness. In this phase it was thus decided not to take into account a concrete shield, whose design may reveal unpractical and expensive, and whose contribution to the dose reduction is quite poor.

Further analysis was done to assess the dose rate beyond the tunnel exit and the general result showed that neutrons "disappear" rather rapidly because their energy spectrum is heavily dominated by thermal and near-thermal neutrons in all “legs” after the first. The contribution to the dose rate was found to be almost negligible and no additional shielding were designed.

The configuration for the MITICA ventilation ducts consists in Z-shaped ducts. In order to meet the air ventilation requirements, the sectional area of the duct should be about 0.7-0.8 m^2 per single duct. Since the primary shied thickness is 180 cm, the single sections will have a dimension L not bigger than 0.9 m. The number of duct is still to be determined.

The mouth of the duct A is 8.5 m away from the axis. The dose rate considered in the calculations is the highest dose rate obtained during final phase from Monte Carlo simulations. 5 meters away from the calorimeter, the dose rate during the final phase is 2.38 microSv/h and at the mouth of the duct A this value goes down to 0,82 microSv/h.

Z-shaped cylindrical ducts with 3 sections were considered. Different calculations were performed, implementing different duct sectional area sizes and different section length. Dose rate at the exit of the reference duct was calculated to be of the order of few microSv/h (μSv/h) or even lower.

Other penetrations such as an entrance, cable supply, exhaust ducts and pipes go through walls in MITICA facility. As already showed, penetrations are generally designed as bent structures in order to decrease leakage radiations (streaming) through them.

Generally the ducts designed for the NBI consist in long pipes which host cables of different kinds. The ducts leave the vessel from underneath going horizontally towards the primary shield. The ducts penetrate the main concrete shield and emerge with a vertical section from the ground of the MITICA building, adjacent to the bunker where workers are supposed to work/pass/walk during operation. The dose rate values obtained considering Z-shaped ducts are all negligible (< 1 pSv), and even the dose rates obtained with straight ducts are very low (less than 1 μSv/h), the last configuration was thus preferred due to its simplicity. Exit dose rate as a function of the diameter was also evaluated, showing that a duct diameter up to 20 cm yield dose rate acceptable at the exit of the passage. When the duct diameter exceed 0.8 m, the dose rate at the exit is no more negligible and can be as high as 10 μSv/h.

Shielding design for the High Voltage line

The design of the high voltage line is a key issue in the definition of the MITICA shielding solutions. Different changes respect to the first configurations were performed, according to the specific needs and structural requirements. In the following, the different solutions will be briefly described along with some shielding data obtained from analytical calculations.

In the first configuration a long concrete duct (whose dimensions are approximately 6 m x 11.3 m) follows the transmission line for the entire length of the pipe. The thickness of the lateral concrete walls is variable: the lateral primary shields of the transmission line can be sized down to 1.5 m (respect to the primary shield, 1.8 m). The concrete floor is 1 m thick.

This configuration turned out to be quite unpractical; severe shielding requirements were needed given the great sectional area of the duct. In fact, the streaming of neutrons through the duct imposes important shielding thickness on the sides and the roof, with a consequent too heavy concrete load.

A second configuration was then evaluated. The shield of the transmission line is reduced respect to the previous one. The left-lateral wall was brought closer to the transmission line reducing the concrete weight. The right lateral shield thickness was progressively reduced: the initial 1.8 m were sized down to 1.5 m and to 1.2 m as the transmission line gets away from the source approaching to the side of the building.

A wide concrete septum “strangling” the line was designed. Related calculations showed the possibility of avoiding the concrete roof. The septa dimensions are (thickness x width x height): 1 x 7 x 5 m and 1 x 1 x 5 m. Introducing these shields, the streaming of neutrons beyond the septa is allowed only through the void slot produced by the septa themselves.

A further optimization was then applied at the end of the transmission line, where the control room is designed (and where operators and workers are supposed to be without restrictions).

A small maze was introduced in order to bring inside the bunker connection cables, a concrete elbow was located in front of the control room adjacent to the facility and a smoothed concrete wall follows now the transmission line out of the building.

Conclusions

Room shielding for high current NB facilities were designed considering the main wall penetrations. Neutron diffusion throughout tunnels and ducts was studied with an empirical approach, based on the application of approximate formulas. The result shows that such a simplified approach is viable in assessing radiation diffusion through the shielding wall penetrations avoiding the use of specific time consuming Monte Carlo calculations.

Effective dose to staff from interventional procedures: estimation from single and double dosimetry

Kuipers, Gerritjan[1]; Velders, Xandra L.; Piek, Jan J.[2]
[1] AgentschapNL The Hague, NETHERLANDS
[2] Academic Medical Centre (AMC) Amsterdam, NETHERLANDS

Abstract

In the Academic Medical Centre (AMC) in Amsterdam numerous interventional procedures are performed by cardiologists and radiologists. During these interventional procedures the physicians are exposed to ionising radiation. From 2004 on the exposure of the physicians was measured by means of two personal dosemeters. One dosemeter was worn outside the lead apron and an additional one inside the lead apron. The study was set up to determine the added value of a second dosemeter worn inside the lead apron. The doses measured on both sides of the lead apron were used to estimate the effective doses of the physicians using one algorithm for single dosimetry and two algorithms for double dosimetry. With the algorithm for single dosimetry the effective doses ranged from 0.11 up to 0.85 mSv in four weeks while with the double dosimetry algorithms, the effective doses ranged from 0.02 mSv up to 0.47 mSv. The statistical analysis revealed no significant differences between the effective doses estimated with the algorithms for single and double dosimetry. It was concluded that the effective doses cannot be estimated more accurately when two dosemeters are used instead of one.

Introduction

In the Academic Medical Centre (AMC) in Amsterdam numerous interventional procedures are performed by cardiologists and radiologists. During these interventional procedures the physicians are exposed to ionizing radiation. Over the years the doses of the physicians performing interventional procedures were monitored by means of a single dosemeter worn outside the lead apron. Since the doses measured outside the lead apron increased and the doses of several physicians exceeded 20 mSv in one year, it was decided to provide all interventional physicians with an additional personal dosemeter to estimate the exposure under the lead apron as well.

In publication 85 ICRP recommended the use of two personal dosemeters (double dosimetry) to estimate the effective doses of physicians performing interventional procedures more accurately[1]. Despite the ICRP recommendations, double dosimetry is not common practice in the Netherlands. Recently the Dutch Commission on Radiation

Dosimetry (NCS) released a code of practise for personal dosimetry of professionals wearing a lead apron[2]. In this code of practise the use of a single personal dosemeter outside the lead apron is recommended. In addition to this, conversion factors to calculate effective doses from the measurements are recommended.

In this context it was decided to estimate the effective doses of the physicians in the AMC as recommended by the NCS code of practise and compare the results with the effective doses estimated with two algorithms for double dosimetry. The purpose of the study was to quantify the differences in effective dose when using single or double dosimetry. Moreover the advantages and disadvantages of single and double dosemeter were reviewed.

Material and methods

Starting 2004 the exposure of eleven physicians (eight radiologists and three cardiologists) was monitored by means of two personal dosemeters. All physicians were experienced to perform interventional procedures. To receive consistent measurements during all interventional procedures the two dosemeters were worn in a special designed holder that was fixed to the lead apron (Fig. I). The holder with the two personal dosemeters was worn breast-high. The two dosemeters were replaced every four weeks on the same day, while the holder remained fixed to the lead apron during the whole study.

The eleven physicians used lead aprons of 0.25 mm lead equivalent thickness at 100 kVp (Medical Development and Technology B.V., Hilvarenbeek, Netherlands; Scanflex Medical AB, Täby, Sweden). The physicians also used thyroid collars of 0.50 mm during the interventional procedures.

The effective doses were calculated by means of three different algorithms (Table 1). First, the effective doses were calculated using the conversion factor from the NCS code of practice. The conversion factors were used for the doses measured outside the lead apron. Additionally the effective doses were calculated with two algorithms for double dosimetry: the NCRP algorithm[3] and an algorithm described by Clerix et al.[4].

Results

The mean doses measured outside the lead aprons ranged from 0.53 mSv up to 4.24 mSv in four weeks while the mean doses under the lead aprons ranged from 0.01 mSv to 0.18 mSv in four weeks (Table 2).

The effective doses estimated with the NCS conversion factor were higher than the effective doses calculated with the two algorithms for double dosimetry. The effective doses estimated with the NCS conversion factor ranged from 0.11 up to 0.85 mSv (mean 0.42 mSv). The effective doses calculated with the Clerinx algorithm ranged from 0.05-0.47 mSv (0.29) and the effective doses calculated with the NCRP algorithm varied between 0.02 mSv and 0.17 mSv (mean 0.10) (Fig. 2).

The regression analyses revealed a linear relation between the effective doses calculated with the NCS-single algorithm and the effective doses estimated with the two algorithms for double dosimetry (ANOVA, $p<0.05$). The regression coefficient between the effective doses for the NCS and the NCRP algorithm was 4.19 and for NCS and Clerinx 1.50.

The effective doses calculated with the NCRP algorithm were plotted against the effective doses calculated according to the NCS algorithm (Fig. 3). The r-squared (R^2) was 0.86. A similar plot was made for the effective doses calculated with the Clerinx algorithm and the NCS algorithm (figures 4, $R^2 = 0.81$).

A Two-Related-Sample test was performed to compare the effective doses calculated according to NCS and the effective doses according to double dosimetry (NCRP and Clerinx). For the tests the effective doses according to NCS were divided by the regression coefficient from the relation between the NCS algorithm and the algorithms for double dosimetry (4.19 for NCS/NCRP and 1.50 for NCS/Clerinx). The two-related-sample tests revealed no significant differences between effective doses calculated from single dose measurements outside the lead apron and effective doses calculated from double dosimetry (Wilcoxon, $p>0.05$).

Discussion

The effective doses of the physicians performing interventional procedures in the AMC differed based on the algorithm used. With the NCS algorithm the effective doses were higher than effective doses calculated with the double dosemeter algorithms. According to the NCS code of practice the doses measured outside the lead apron were used to estimate the effective doses of the physicians in the AMC. To estimate the effective doses the NCS conversion factor for single dosimetry was used. The conversion factor is the same for all exposure circumstances: different tube voltages and variation in irradiation geometry. As NCS describes the approach is save and the effective dose will not be underestimated. This underlines the idea that the NCS algorithm overestimates the effective dose. Even the algorithms for double dosimetry can still lead to an overestimation of the effective dose. Although the probability is smaller and there is even a risk of underestimation.

Conclusions

The purpose of the study was to determine whether the doses measured inside the lead aprons provide additional information that is necessary to estimate the effective doses more accurately. In this study, the added value of measurements under lead aprons could not be demonstrated. The statistical analysis revealed no significant difference between effective doses calculated with the algorithm for single dosimetry and the algorithms for double dosimetry.

Table 1. The three algorithms used to calculate the effective doses (E) were H_{under} is the dose measured under the lead apron and $H_{outside}$ the dose measured outside the lead apron.

Name	Algorithm
NCS	$H_{outside}$ / 5
NCRP	$E = 0.5\ H_{under} + 0.025\ H_{outside}$
Clerinx et. al.	$E = 1.64\ H_{under} + 0.058\ H_{outside}$

Exposure levels of workers during some surgical procedures

Rossi, Francesco[1]; Bertelli, Duccio[2]; Gori, Cesare[1]; Gugliandolo, Alessandra[2]
[1] Azienda Ospedaliero – Universitaria Careggi, ITALIA
[2] Università degli Studi di Firenze, ITALIA

Abstract

The use of fluoroscopy during surgery is quickly growing up, involving more and more surgical specialties (neurology, urology, cardiology operating rooms, etc.). Such radiological interventional procedures often require long fluoroscopy times, sometimes longer than 30 minutes. It is thus critical the radiation protection of the whole staff (surgeon, nurse, radiographer, anaesthetist), but it is very difficult to evaluate dose.

Worker exposure dose level is thus evaluated almost entirely on an empirical basic. This study is performed with respect to four surgical specialties: urology, orthopaedy, cardiology and radiology (angiography). Exposure levels for each procedure type (e.g. leg, femur, hip for orthopaedy) were measured, collecting data from at least 10 patients for every procedure.

In order to measure average procedure exposure level, each member of the surgical staff was given a TLD dosemeter to be used only for that kind of procedure.

The collected results are also an useful tool to have *a priori* estimation of dose levels for new procedures and to perform classification of workers.

Introduction

It is well known that radiation dose to the staff during all kind of surgical interventions involving X-ray machines is a quite difficult problem, due to:

1) The rapidly spatially varying radiation field;
2) The worker changing his position during the procedure;
3) Many other quantities changing during the exposure (collimation, distance, tube position, x-ray pulse duration...).

Moreover, present-day X-ray machines have automatic exposure controls, thus making more difficult to monitor exposure parameters.

We are usually able to estimate staff dose, with simple measures and the approximate number of patients per month, but a such rough estimate is sometimes too few in order to properly assess workers classification. A lot of work is in progress in order to give more precise values(1), our contribution is to directly measure *in situ* the dose for each member of the staff and for each procedure.

Material and methods

Our choice is to use the same type of dosemeter that is normally used for routine monitoring of that workers, that is, two TLD100 detectors (manufactured by RadCard in Krakow, Polska), the first filtered by 1,5 mm Aluminum. Reader is the automatic *Harshaw 6600* and the whole system is calibrated to X-ray response (using the facility of ENEA in Bologna, Italia). Wrist dosemeters also use TLD100 detectors but each dosemeter has a single detector, and we read them using the *Harshaw 5500* automatic reader. The whole system follows EU recommendations(2).

The surgeons (they are usually two, the first performing the intervention and the second, sometimes a student, helping him) were given each three dosemeters, the first to wear under the protective apron, the second to wear over the apron, and the wrist dosemeter. The remaining members of the staff (nurse, radiographer, anesthesist) were given each only two dosemeters, as the hand monitoring is not useful.

We thus prepared a lot of sets of dosemeters. Each set is composed by 20 whole body dosemeters (10 for the staff plus 10 for background measurement) and 7 wrist dosemeters (2 for the surgeons plus 5 for the background, that we must measure twice as we have different readers). Each set was used for a single procedure, e.g. homerus in orthopaedy: each dosemeter was given to the owner, and collected back after the intervention. Dosemeters of the homerus set were given again when another patient was scheduled for the same procedure, even if members of the staff changed. The dosemeter in this way belongs to a procedure and not to a worker.

A single set has to measure the maximum number of patients, in order to average different operators, with different skill levels, and different fluoroscopy times, due to pathology or difficulty of each intervention. We planned to collect at least 10 patients for each procedure. Some months were spent for each speciality (urology, cardiology, etc.) collecting the maximum number of data, but in some cases it was not possible to collect more than 4 patients, as the procedure is not so common, and it is not useful to wait longer times to keep signal to background ratio as high as possible.

The complete list of procedures, patients collected, mean fluoroscopy time is given in Table 1. Procedures are chosen where staff dose evaluation is more difficult in a theoretical way.

All procedures shown were performed in the different departments of the AOU Careggi University Hospital in Firenze, and data were collected in 3 years from 2008 through 2010.

To assess individual effective dose values we used the Rosenstein-Webster algorithm(3) to weight the dosemeters under and over apron, that is: effective dose = reading over apron times 0.025 + reading under apron times 0.5. Hand doses are the Hp(0,07) readings of the wrist dosemeter.

Table 1. Procedures and number of patients used for these measurements.

Specialty	Procedure	Patients	Mean fluoroscopy time (minutes.seconds)
Urology	Pig-tail positioning	5	4.05
Urology	Ureterorenoscopy	6	4.42
Urology	Lithotripsy	4	1.02
Urology	Renal percutaneous	3	23.17

Radiology	Embolization	1	17.24
Radiology	Flebography	3	14.54
Radiology	Lower Abdomen	4	15.00
Radiology	Cholangiography	2	14.12

Results

Figure 1 shows the data normalizing them to 100 patients, to have realistic exposure of a member of the staff. Data uncertainty is very high, about 0,1 mSv or 20%, mainly due to background subtraction. Another uncertainty source, that cannot be shown, is the difference among each patient,

Discussion

All dosimetric data agree with the rough estimates we had in advance, but are much more precise even with the very high uncertainty. Some values looking somewhat strange (like the dose to the nurse in the femur procedure, much higher than the other procedures) are due to the quite different position assumed by the operator.

Conclusions

We performed direct measurement of staff dose for several surgical procedures. The measuring method is good, but time consuming, even if results are now acquired and there is no need to perform again such measurements. Data collected are useful for workers classification and, as we have already tested, to show to the same workers during training courses, and this is the most important feature. We noticed, while collecting data, that workers are very often not enough trained in radiation protection, and a training course is much more effective if the own dose levels, and not general literature data, are shown.

Fig. 1. Results. Vertical scale is in mSv, and data are normalized to 100 patients.

Abstract

The aim of the study has been to assess the radiation dose to personnel involved in heart X-ray assessments (cardioangiography assessments, CA), as well as some cardiology procedures (such as PTCA, EF). In the study the dose exposure has been defined for each assessment and procedure. Three different types of dose meters have been used for dose assessments. Dose measurement protocols were also examined laboratory conditions at STUK. The study was done by STUK in cooperation with two university hospitals and one procedural unit in a central hospital.

Radiation doses were measured (in head, upper arm, hand and foot/ankle) for approximately 350 different procedures. The dose for the doctor performing the procedure varied significantly depending on the length and difficulty of the operation: the average measured dose for the procedures at the upper arm level was about 50 microSv. The highest measured dose was 576 microSv. The average hand dose was about 150 microSv. The highest dose to the hand was 1093 microSv, to the foot 1003 microSv, and to the head 196 microSv. The average dose for the nurses at the upper arm level during a PTCA-procedure was 19 microSv, and the maximum dose was 199 microSv. The largest measured hand dose for a nurse was 492 microSv. According to the measurements the effective dose for the doctor was about 1 microSv / procedure and maximum dose was 12 microSv. The annual dose limits will not exceeded under normal working conditions. However, the dose limits for hands and feet could be exceeded.

The doses received by the people involved in the procedures can be quite high when compared to the annual dose limits. The appropriate use of radiation shields is necessary. Radiation meters with displays, or meters suitable for direct reading are good for observing working conditions. The information obtained in the study can be used in the hospitals to improve procedural methodologies, planning off training, as well as interventional cardiology.

Radiation doses to occupationally exposed personnel working with radioiodine and technetium

Krajewska, Grazyna; Szewczak, Kamil; Krajewski, Pawel
Central Laboratory for Radiological Protection, Konwaliowa St.7, 03-194 Warsaw, POLAND

Abstract

The I-131 and Tc-99m content in the thyroid of staff members working with this radionuclides has been measured in some Departments of Nuclear Medicine performing therapy and diagnosis of thyroid disease in Poland . The measurements were performed with portable detection unit for „in situ" measurements of radioiodine and technetium.

All individuals actively working with iodine and technetium show measurable amounts of this isotopes in their thyroids. The average measured activity in the thyroid of the nuclear medicine staff was found to be equal at average 600 Bq within the range from 50 Bq to 70 kBq. The average and range of I-131 activity measured in thyroids for all medical units were: 1500 Bq, (100 Bq – 70 kBq Bq), 400 Bq, (30 Bq – 3000 Bq), 150 Bq, (50 Bq – 1000 Bq) for technical staff, nuclear medicine staff and hospital services staff respectively. There is no apparent correlation between the measured I-131 levels and risk categories. Nevertheless the technical and nuclear medicine staff show higher I-131 thyroid level comparing to hospital services staff.

Base on results of measurements, the Effective Dose Equivalent for particular person due to inhalation of I-131 and Tc-99m was calculated.

Calculated average Effective Dose Equivalent for particular exposed person is below 50 per cent of 20 mSv/year.

Introduction

In 1997 the Central Laboratory for Radiological Protection set up programme "The Laboratory for monitoring of radioiodine in thyroid for population in emergency situation". The main goal of this program was to establish monitoring assembly and develop risk assessment methods for internally contaminated people with I-131 in the event of a nuclear accident or radiological emergency. This Laboratory programme takes advantage of unique opportunity for testing monitoring devices and dose estimation methods on the base of measurements of activity of radioiodine and technetium in thyroid of occupationally exposed workers.

Material and methods

The monitoring assembly of the Laboratory consists of two independent measuring units:

1. Stationary Unit for measuring I-131 and Tc-99m with low limit of detection,
2. Portable Unit for "in situ" measurements of I-131 and Tc-99m. It has been mainly foreseen for fast screening population in radiological emergency situation, or for monitoring occupationally exposed people far away from Laboratory.

The measurements of iodine and technetium content of occupationally exposed personnel were performed with portable detection unit (prod. Canberra-Packard) (Fig.1.), which is consist with scintillation detector NaI(Tl) (size 76 x 76 mm, resolution 9%) - battery-powered, portable tube base Multichannel Analyzer Canberra UniSPEC, paired with the notebook computer and Genie-2000 Basic Spectroscopy Software.

In the period 2008 – 2009 the measurements of I-131 and Tc-99m content in the thyroid of staff members working with radioiodine and technetium has been measured in some Nuclear Medicine Units performing therapy and diagnosis of thyroid disease in Poland. The measurements were performed with portable detection unit.

The counting configuration for monitoring personnel was identical to that used in the calibration procedure. Typically, detector set at a neck - to - detector distance of 10 or 15 cm, using a 300 seconds counting time. The background was measured with detector placed 15 cm away from the availably RSD neck phantom, prior to or just following the count performed on the person. The measurements were performed in selected as low as possible background places. The MDA for mobile unit ranges from 10 – 50 Bq at the time measurement of 300 seconds and depends on background condition in particular units.

The measured personnel can be divided into some categories according to internal contamination risk to unsealed sources of I-131 and Tc-99m:

1. Technical staff mainly performing routine diagnostic investigation,
2. Nuclear medicine staff (physician, nurse) working with in vivo administration of I-131 or Tc-99m to patients,
3. Hospital services staff (orderlies, cleaners) performing auxiliary activities to the patients (cleaning of the rooms, changing of bedclothes).

Results

The measurements of radioiodine content in the thyroid were performed in six medical units that use I-131 for therapy and diagnosis of thyroid disease. About of one hundred exposed persons were investigated. The results of measurements are presented in Table 1.

All individuals actively working with iodine show measurable amounts of the radioiodine in their thyroids (Fig.2.). The average measured activity in the thyroid of the nuclear medicine staff was found to be equal at average 600 Bq within the range from 30 Bq to 70000 Bq. The average and range of I-131 activity measured in thyroids for all medical units were: 1500 Bq, (100 Bq – 70000 Bq), 400 Bq, (30 Bq – 3000 Bq), 150 Bq, (30 Bq – 1000 Bq) for) for categories 1, 2, 3 respectively. Nevertheless the 1 and 2 categories show higher I-131 thyroid level comparing to category 3.

	All	70 – 200	150	0.80	

Conclusions

The results of I-131 content in the thyroid of staff members working with radioiodine in four Departments of Nuclear Medicine do not show any correlation between the measured I-131 levels and risk categories. The averages of I-131 thyroid contents calculated for the particular medical unit item differ remarkably. These differences do not necessary depend on I-131 usage in the particular medical unit but rather on its specific and complex work conditions, staff training and so on.

Base on results of measurements, the Effective Dose Equivalent for particular person due to inhalation of I-131 was calculated with somewhat a conservative assumption that I-131 thyroid content remains constant during the whole year. For the occupational exposure limit of 20 mSv it gives the reference I-131 thyroid level is equal to 7 kBq. Calculated average Effective Dose Equivalent for particular medical is below 50 per cent of 20 mSv/year.

Occupational exposures from increased use of F-18 FDG in Denmark

Hybertz Andersen, Tina; Ennow, Klaus; Bjerkborn, Annika; Højgaard, Britta
National Institute of Radiation Protection, Knapholm 7, DK-2730 Herlev, DENMARK

Abstract
In Denmark, the number of nuclear medicine examinations using F-18 FDG has increased greatly in recent years. Theoretically, a corresponding increase in radiation dose to staff in departments performing PET scans might be expected. We have studied annual and semiannual staff doses over three years (2006-2008) and conclude that despite a 270% increase in the number of F-18 FDG investigations over the period, the increase in collective dose to workers is relatively small.

Introduction
Since the national integrated cancer pathways were implemented in the Danish Health Care System in 2007 the number of investigations using F-18 FDG has increased considerably. 6.000 investigations were performed in the year 2006 and in 2008 the number had increased to almost 16.000, meaning that in 2008 13 % of all Danish nuclear medicine investigations used F-18 FDG. Table 1 shows the total number of investigations in nuclear medicine departments and the number of investigations using Tc-99m and F-18, respectively. Figure 1 shows the evolution of the number of PET examinations over the last 9 years.

Table 1. Number of investigations in the nuclear medicine departments.

Year	2006	2007	2008
Total Number of investigations in nuclear medicine departments	108055	120160	121100
Number of investigations using Tc-99m	84200 (78 %)	92160 (77 %)	87290 (72 %)
Number of investigations using F-18 FDG	6093 (5.6 %)	9916 (8.2 %)	15449 (13 %)

There is a concern that the increased use of F-18 FDG is going to affect the doses to the staff in the nuclear medicine departments at the hospitals (Ennow et al **2009**), due to the high energy of annihilation photons and the greater activities administered to patients compared to examinations using Tc-99m. Factors that influence the radiation dose to staff are the activity administered per patient, the number of patients, the methods of dose dispensing and dose administration, and the amount of time spent in close proximity to patients. (Elliott **2009**)

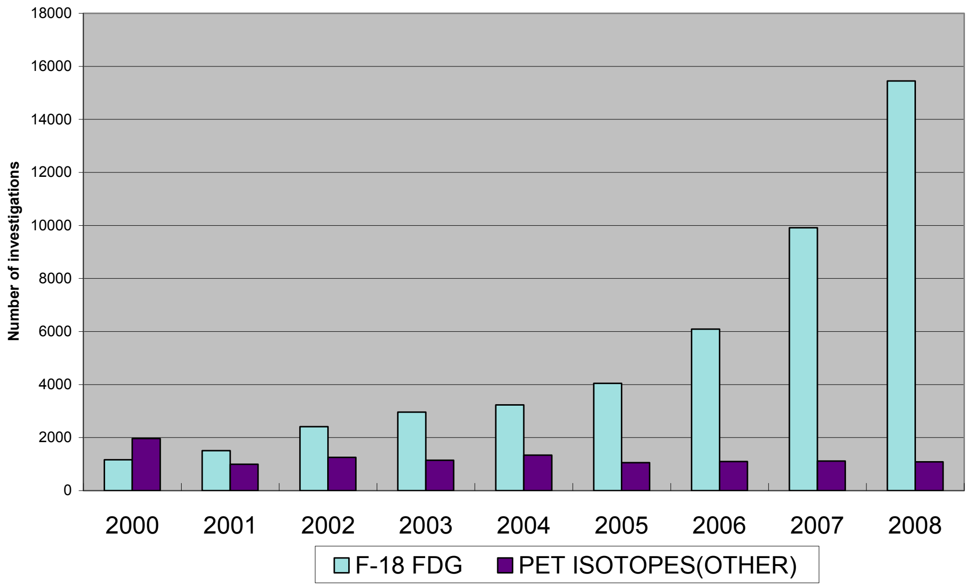

Fig. 1. Number of PET investigations from 2000 to 2008.

Material and methods

The National Institute of Radiation Protection has studied the trends and distribution of doses to staff in the relevant departments in the period 2006 to 2008 by use of the national dose registry. The dose measurements were performed by either TLD or film badges for personal dosimetry. The exposure of the entire staff was assessed by calculating the collective effective dose (ICRP 103 **2007**) every 6 months for all nuclear medicine departments

Values for the annual numbers of PET examinations were obtained from the mandatory annual reports from the nuclear medicine departments of examinations and treatments performed. Over the studied period, Denmark had twenty hospitals with nuclear medicine departments, three of them with cyclotron facilities.

Results and discussion

The study showed that the collective dose to staff increased over the study period in the departments that produce F-18 in cyclotrons, while remaining roughly constant, or even decreasing, in the rest (see figure 2). However, the number of workers receiving annual doses above 1 mSv has increased, especially the number of workers receiving more than 4 mSv/yr. The number of individuals with annual doses exceeding 5 mSv increased from 1 in 2006 to 4 in 2007 to 13 persons in 2008, all employed in departments producing F-18. Figure 3 shows the distribution of annual doses to the staff exceeding 1 mSv over the study period.

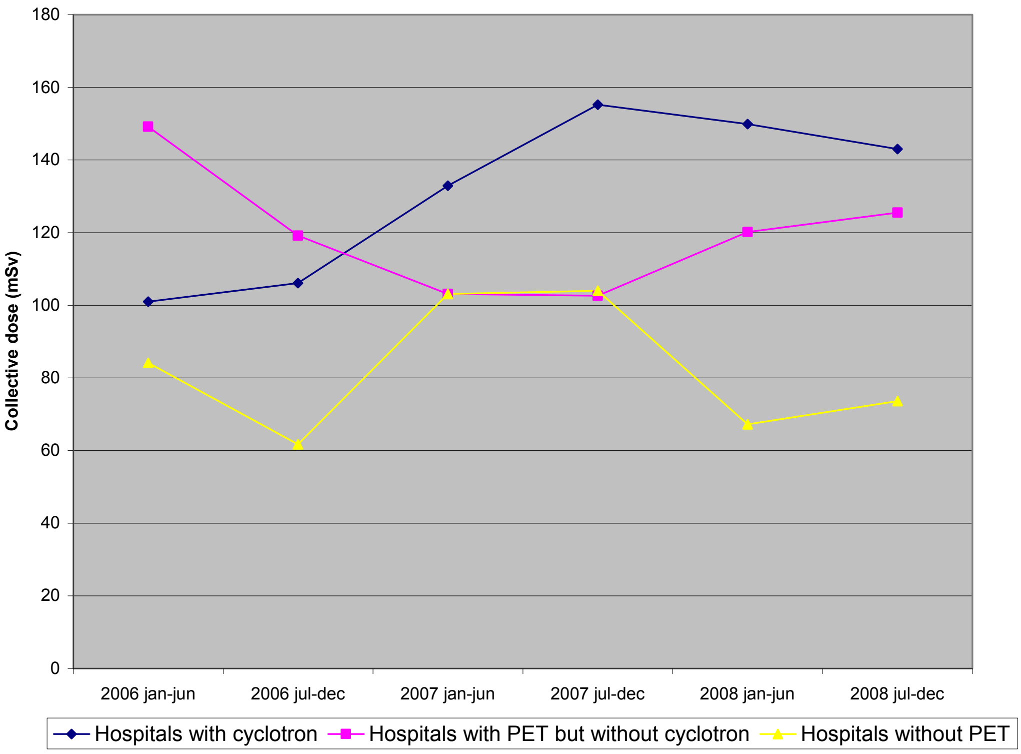

Fig. 2. Collective doses in the nuclear medicine departments from 2006 to 2008.

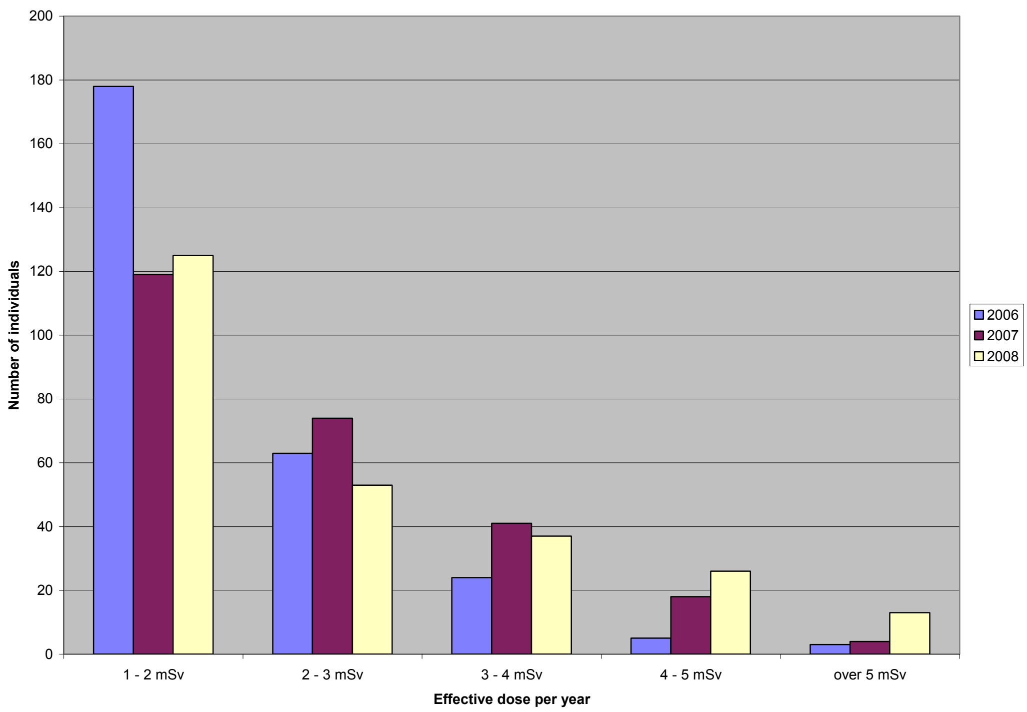

Fig. 3. Number of annual doses exceeding 1 mSv.

Conclusions

The expected raise in doses to the personnel handling F-18 FDG was not seen in this study. It is therefore concluded that the PET facilities have a well established radiation protection programme, and the personnel has been well educated and well prepared for this increase in investigations using F-18 FDG.

Control of radiation protection and occupational radiation exposure doses of medical staff in Ukraine

Stadnyk, Larysa; Yavon, Iryna; Panchenko, Iryna; Smirnova, Inna
Grigorev Institute for Medical Radiology, Central Laboratory of Radiation Hygiene of Medical, UKRAINE

Abstract
According to Ukrainian legislation in radiation protection it is necessary to provide the workplace and individual dose monitoring of occupational radiation exposure. In Ukraine the legislative dose limits for occupational exposure correspond to Basic Safety Standards (IAEA BSS-115). The best way to estimate radiation protection is to evaluate results of individual dose monitoring of occupational exposure. The main purpose is to get information about realistic doses for different groups of staff, compare it with dose limits (category A), estimate the radiation protection of workplaces, inform Regulatory Bodies (in Ukraine these are Ministry of Health and State Committee of Nuclear Safety) about results, and suggest further measures for reduction of radiation exposures. Individual monitoring of occupational exposure for medical staff in Ukraine is carried out since 1979 by Central Laboratory of Radiation Hygiene of Medical Staff at Grigorev Institute for Medical Radiology. Now more than 6500 medical workers from departments of radiation therapy, nuclear medicine and diagnostic radiology from all regions of Ukraine are covered by quarterly TLD-monitoring. In this work, the dynamics of radiation-hygienic parameters during 1980 – 2008, which characterized the state of radiation protection for different professional groups of medical staff, is analyzed. 92 – 98 % of medical staff annual doses are less than 2 mSv. The most exposed groups of medical staff are handlers of radioactive substances and radio-manipulation nurses in radiotherapy, as well as the personnel which is involved in interventional radiology. In some years the average annual doses in these groups were more than 5 mSv. Every year the annual reports with radiation-hygienic statistical analysis of occupational exposure are generated for each hospital, region of Ukraine, different professional groups. These are sent to each hospital and to National Regulatory Bodies for analysis of radiation protection.

The new method of distinguishing static exposure of individual TLD dosemeters

Kopec, Renata; Budzanowski, Maciej; Olko, Pawel
Institute of Nuclear Physics Polish Academy of Science, Kraków, POLAND

Abstract

It is not possible to distinguish between cases of static (against source) and dynamic exposure of thermoluminescence dosemeters (TLD) evaluated in readers with photomultiplier tubes. Budzanowski et al (2006, 2007) demonstrated that using TL reader with CCD camera it is possible to qualitatively identify the cases of static exposure of TL detector covered with an non-uniform filter. Kopec et al, (2010) developed and tested a method, which can be used for automatic detection the cases of static exposure in dosimetric RADOS badge with TL (MCP-N) detectors. Detectors were readout in a novel type of thermoluminescent reader with CCD camera developed at IFJ PAN.

Introduction

In thermoluminescent (TL) dosimetry it is not possible to identify the cases of static exposure against the source, because the signal is detected and integrated by a photomultiplier tube.

Budzanowski et al. (2006, 2007) demonstrated qualitatively that it is possible to identify the cases of static exposure of TL detector covered with a non-uniform filter and evaluated using the new generation of TL readers with CCD camera. Kopec et al (2010) developed a quantitative method of distinguishing static exposure, which can be applied in routine dosimetric service.

Material and methods

The routine personal thermoluminescent RADOS dosemeter comprises four thermoluminescence (TL) detectors. Three detectors are held under Al filter. In this work the standard RADOS personal dosemeter was modified by replacing Al filers with 1 mm thickness Pb or Cu filters with a centrally placed 1 mm diameter hole (Fig. 1).

Fig. 1. The standard dosimetric badge (RADOS) with modified filters made of Pb and Cu with 1 mm diameter hole.

MCP-N (LiF:Mg,Cu,P) TL detectors (4.5 mm diameter and 0.9 mm thick) were applied in the badge. The dosemeters, placed on a 30 x 30 x 15 cm^3 PMMA water phantom. The modified RADOS badges with MCP-N detectors were irradiated on using X-rays and Cs-137. Dosemeters were irradiated to doses Hp(10) = 5, 10 and 20 mSv, in order to verify if the effect is observed at the current dose limits for occupational exposure in Europe. TL detectors were evaluated using laboratory TLD reader with PCO SensiCam CCD camera, developed at the Institute of Nuclear Physics (Fig. 2).

Fig. 2. TLD reader with CCD camera developed in Insitute of Nuclear Physics PAN.

The analysis of image

The typical pictures collected by the TLD-CCD reader are shown in Fig. 3, where the increased intensity of TL light under the uncovered central part of TLD can be observed in case of static exposure.

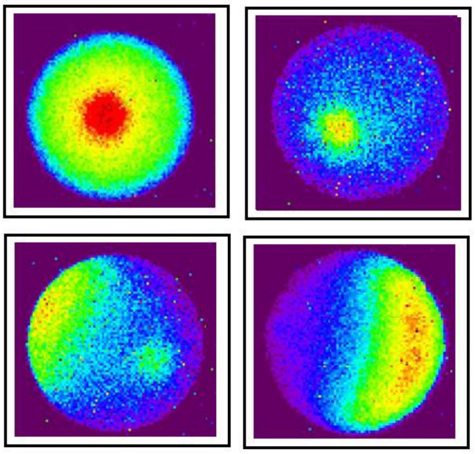

Fig. 3. Two- dimensional TL images obtained for static exposure to 40 keV X-rays. Images are collected for four angles of incidence (0, 30, 45 and 60 degrees). Dosemeters were exposed on a standard PMMA phantom to the dose of 20 mSv.

The images of intensity and were processed using median filter and threshold to removing the background emission outside the detector. The measured level of individual pixels intensity were grouped in form of histogram. The difference between the pixel number with the end intensity, $level_{end}$, and the position of pixel with the number with the most probable intensity, $level_{max}$. was defined as the "coefficient of static exposure" (Fig. 4.):

$$w_s = level_{end} - level_{\max}$$

The value w_S is used to distinguish between static and dynamic exposure. It was found empirical that for all analyzed cases of dynamic exposure (yellow histogram) w_S<=23 (in 256 scale).

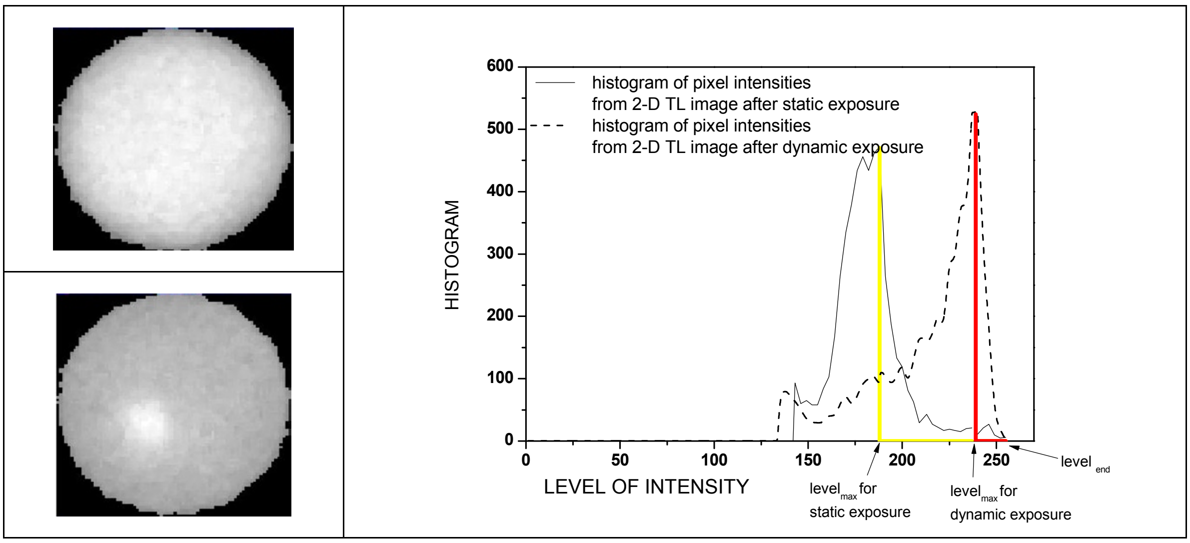

Fig. 4. Left: Images from CCD camera in 256 gray scale intensity of MCP-N detector covered with the 1 mm thick Pb filter with a hole 1 mm in diameter hole after dynamic (up) and static (down) exposure to N40 X-rays, D = 20 mSv. Right: Histograms of pixel intensities. (Kopec, 2010).

Results and discussion

The maximum possible thickness of the filter was limited by the geometry of the RADOS badge to 1 mm. The identification of static exposure is particularly important for doses close or exceeding the limits in radiation protection. Therefore all irradiation in this work were performed for dose range between 5 and 20 mSv For photon energies under 118 keV the proposed method is effective (Fig. 5).

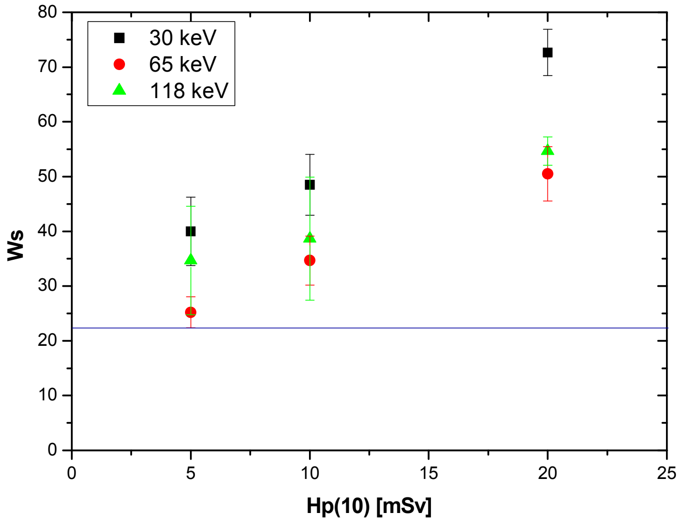

Fig. 5. Dose response of the MCP-N detectors evaluated in TLD reader with CCD-camera for mean energy X-ray 30 keV, 65 keV and 118 keV.

Conclusions

Using the existing setup i.e. using the modified RADOS badges (using the 1 mm thickness Pb filter with 1 mm central hole), MCP-N TL detectors, IFJ PAN TL reader with CCD camera and the analyzing software makes it possible to distinguish the cases of static exposure down to doses of 5 mSv and to X-rays energies up to 200 keV (approximately). The method is based on evaluation of the factor, which can be evaluated from the histogram of pixel intensities. Further work is planned to introduce the system into the routine individual monitoring by the LADIS IFJ dosimetric service.

Occupational radiation exposure in Poland based on results from the accredited dosimetry service at the IFJ PAN, Krakow

Budzanowski, Maciej; Kopeć, Renata; Broda, Ewelina; Chrul, Anna; Dzieża, Barbara; Kiszkurno-Mazurek, Aleksandra; Kruk, Małgorzata; Nowak, Anna; Obryk, Barbara; Pajor, Anna; Sas-Bieniarz, Anna; Włodek, Katarzyna
Institute of Nuclear Physics Polish Academy of Sciences, POLAND

Abstract

Dosimetry service based on thermoluminescence (TL) dosimetry started its activity at the Institute of Nuclear Physics (IFJ) in 1965. At that time dose measurements were done only for 250 IFJ`s workers. In 2002 the new Laboratory of Individual and Environment Dosimetry (LADIS) was formally established at the IFJ and got accreditation according to EN-PN-ISO/IEC 17025 standards.

The service is based on standard thermoluminescent detectors MTS-N (LiF:Mg,Ti) and MCP-N (LiF:Mg,Cu,P), known worldwide. The TL detectors are readout in automatic DOSACUS or RE2000 (Rados Oy, Finland) readers. The Laboratory provides dosimetric service for individual dosimetry in terms of the personal dose equivalent Hp(10) and Hp(0,07) for photon and neutron fields, within the range from 0.1 mSv to 1 Sv; and environmental dosimetry in terms of the ambient dose equivalent H*(10) within the range from 30 μSv to 1 Sv, and also air kerma Ka within the range from 30 μGy to 1 Gy. Dosimetric service is currently performed for ca. 3200 institutions over the whole Poland. Exposure periods are on a quarterly and monthly basis. Measurements are performed mainly for oncology centres, hospitals, dentists, research institutes, food-, light-, fuel- industry, state border officers, police, antiterrorist troops, prisons, museums, and many other sites where X- or gamma-ray systems are used for inspection.

The paper presents results of statistical evaluation of more than 400 000 quarterly effective dose measurements performed in years 2002-2009. The dose records were divided according to a technical or medical institution and a type of measurement performed (individual dosimetry or environmental dosimetry). The results showed that more than 85 % of measurements were below 0,1 mSv/quarter which means that there was no occupational exposure. The remaining 15% was above 0,1 mSv/quarter with cases reaching even several hundreds of mSv/quarter. The cases exceeding the annual limit will also be discussed in this paper.

Introduction

The first thermoluminescent dosimeter was developed at the IFJ PAN and used for routine measurements of doses for the IFJ's workers in 1965. These dosemeters were based on LiF:Mg, Ag and CaF in Teflon. In 1970's new LiF:Mg, Ti dosemeters (MTS-N, TLD Poland), sintered in the form of pellets, were introduced in individual and environmental dosimetry. From 1986 MTS-N has been replaced with the new highly sensitive MCP-N (LiF:Mg,Cu,P), also developed at the IFJ. The first 25 years of TL dosimetry at the IFJ was described in details by Tadeusz Niewiadomski (Niewiadomski, 1994).

Previously, in the Polish Atomic Law only three polish institutions were explicitly mentioned in the text concerning film dose measurements, therefore the IFJ was not able to do any official dose control for workers from outside of the Institute.

In 2000 the new Polish Atomic Law (Act of Parlament, 2000) was issued in accordance with the European regulations and the paragraph related to the dosimetry services was changed. As a result, currently only accredited laboratories are able to get permission for dose measurements of ionizing radiation in Polish institutions where staff are exposed to such radiation.

In 2002 the LADIS laboratory was created and on 31st December it got accreditation after preparation of all documents.

In Poland, the reference levels were specified in the Ordinance of Ministry of Health: "On the conditions on the safe application of ionizing radiation for all types of medical exposure", on 25th August 2005. According to the Polish Atomic Law the individual dosimetry is obligatory for category A workers while for category B workers the workplace environment monitoring is sufficient. However, most of the radiation safety inspectors decide to apply individual monitoring for category B workers as well, for safety reasons. In Poland, the head of an institution is responsible for summarizing annual doses received by his staff and for contact with the central register in the Polish Atomic Agency. The dosimetry service is not obligated to calculate doses annually but only for periods agreed with clients. The Polish Atomic Law permits the monitoring periods to be not longer that three month, so practically 100% of clients order dosimetry service on a quarterly basis. Equivalent dose for the whole body, $H_P(10)$, should be less than 20 mSv a year, according to the agreed dose limits for occupational exposure (cat. A).

Material and methods

Standard, commercially available MTS-N (LiF:Mg,Ti) detectors are used for individual monitoring, while highly sensitive MCP-N (LiF:Mg, Cu, P) detectors are used for workplace environmental measurements. An individual dosimeter badge used for measurements is a standard RADOS Oy one with three Al filters and four MTS-N pellets. For environmental monitoring a RADOS Oy badge without filter is applied. Dosemeters are readout in automatic RE1 and RE2000 (RADOS Oy) TL readers in standard recommended conditions.

The laboratory has developed a data base based on Microsoft Access. The data base contains all necessary information about client's details, dosmeters numbers, and quarterly doses. The LADIS service has got accreditation for measuring $H_p(10)$ in mSv in the range from 0,1 mSv up to 1 Sv, and K_{air} in mGy respectively from 0,03 mGy to 1 Gy (Polish Accreditation Centre). Detailed information about methods used in the laboratory is provided on the website (http://dawki.ifj.edu.pl).

Database

The rapid increase of the number of customers from 250 in 2001 to 30000 in 2010 stimulated the development of the dedicated DosBaz database. The database was built in 2004 using the MS Access platform. The content of the data structure was elaborated according to the EUR 14852 EN recommendations. The DosBaz allows for complete processing of the data, including preparation of the final certificate, reporting to establishment authorities, preparation of the statistics etc.

At the beginning of 1990's dose values for people under the radiation control were stored on the manually updated, individual dose record sheets. After introducing personal computers into the service the dose records were stored semi-automatically on EXCEL worksheets. The main aim of the development of the DosBaz was to decrease the workload associated with the process of preparation of all documents and to facilitate the flow of the documents and information within the service and between the service and the customer. In addition, the database enables the service administrator to have fast access to the data related to the customer, monitored workers, and measured doses. The database has been developed taking into account the *Technical recommendations for monitoring individuals occupationally exposed to external radiation* (EUR 14852) (Christensen,1994) . The *Recommendations* have formulated major milestones in all aspects of modern, European individual monitoring service including dosimetric concepts, requirements for personal dosemeters, their type and performance testing, aspects of management and administration, and the quality assurance system. For statistical purposes the classification (coding) of data is necessary. The coding includes defining work activities specific for the given employee, recognising occupational category of individual workers and identifying sites with the risk of exposure.

Results and discussion

Statistical analysis was performed on ca. 400 000 quarterly recorded occupational radiation doses. Few examples are discussed.

According to the LADIS classification of occupational exposure, the controlled radiation workers were divided into seven main categories:

- Interventional Radiology
- Oncology Centres
- Nuclear Medicine
- Dental
- Industrial Radiography
- Veterinary Radiology
- Radiology

These categories were compared in terms of the radiation doses received by workers. Figure 1 presents whole body dose measurements performed using individual dosemeters - measurement operational value $H_p(10)$. Figure 2 depicts the results of environmental measurements - measurement value K_{air}. The results reflected the fact that occupational exposure from Nuclear Medicine made a prominent contribution to the exposure values for all medical uses of radiation. Also, in the industrial radiography and veterinary sector, occupational doses were higher than the average occupational dose. Depending on the monitored population, usually the majority of the workers did not receive any occupational dose (e.g. Dental uses).

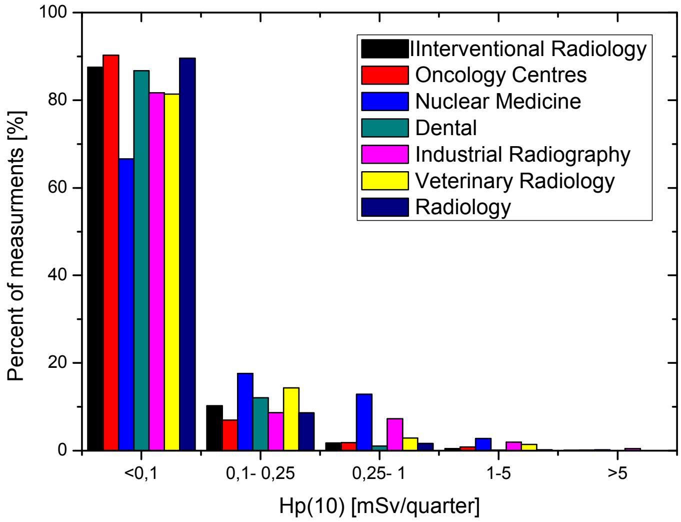

Fig. 1. Percentage of quarterly measurements of photon (gamma, X-rays) doses for different kinds of occupational radiation exposure as a function of dose ranges $H_p(10)$ using the DI-02 dosemeter.

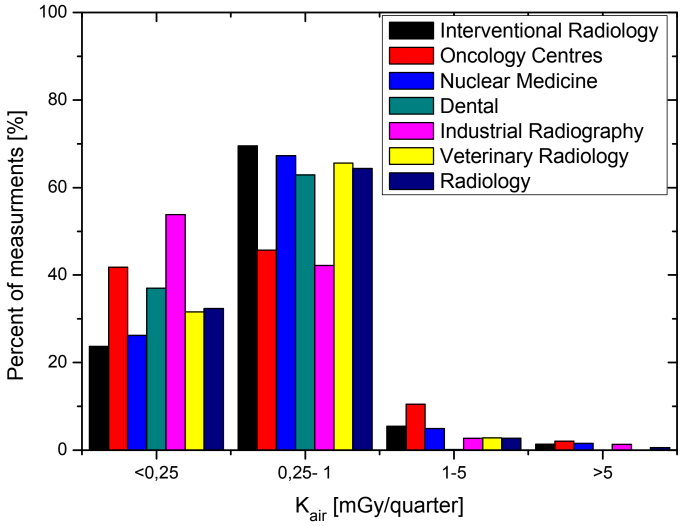

Fig. 2. Percentage of quarterly measurements of photon (gamma, X-rays) doses for different kinds of occupational radiation exposure as a function of dose ranges K_{air} with the environmental dosemeter.

The comparison of ten highest dose values between medical and industrial use of ionizing radiation shown that doses in industrial sectors were much higher than doses in medicine (Figure 3).

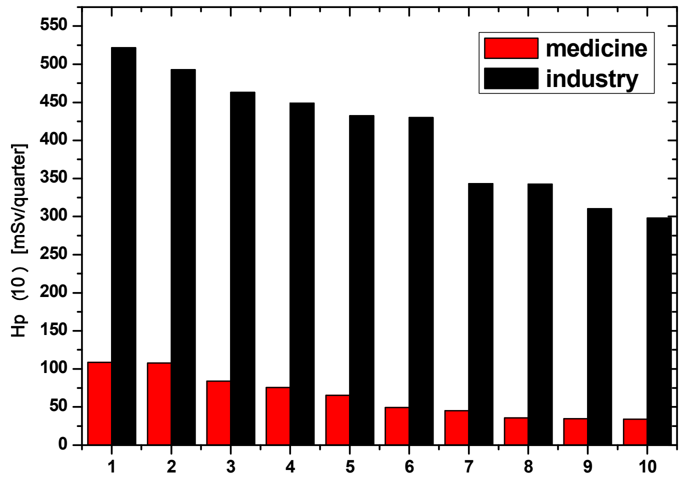

Fig. 3. Ten highest Hp(10) doses measured in medicine and industry with the DI-02 dosemeter.

Conclusions

65% to 90% of quarterly recorded $H_p(10)$ doses were below 0,1 mSv, which is on the level of the natural environmental radiation doses. The natural radiation was the main factor contributing to the exposure dose and occupational exposures made a very small contribution to the average exposure dose of the national population. The results showed that dose levels between 0,1 - 5 mSv/quarter were the most frequent in nuclear medicine, veterinary and industrial radiography sectors. Comparing the medical and industrial radiation uses it can be concluded that the highest doses were registered for industrial applications of gamma and X-rays. These occupational doses were over the dose limit.

Finger doses in Poland in the view of the extremity ring dosimetry results of LADIS Dosimetric Service Kraków

Sas-Bieniarz, Anna; Obryk, Barbara; Pajor, Anna; Kopeć, Renata; Broda, Ewelina; Budzanowski, Maciej
Institute of Nuclear Physics (IFJ) Polish Academy of Sciences, Kraków, POLAND

Abstract

The Laboratory of Individual and Environmental Dosimetry (LADIS) of the Institute of Nuclear Physics (IFJ), Kraków, applies MTS-N (LiF:Mg,Ti) thermoluminescence (TL) detectors to individual monitoring of Hp(0.07) in photon radiation fields.

The TLDs are inserted in a plastic ring holder (internal name PI-01, Fig. 1) that can be adjusted to any finger size. One standard TL pellet, 4.5 mm diameter and 0.7 mm thickness, is placed in a bar coded holder under a plastic cover, 0.4 mm thick. The dosemeter's behaviour during various sterilisation processes, used at the clients' hospitals, has been tested with positive results.

The LADIS laboratory has been performing extremity ring dosimetry measurements for more than eight years. This procedure has been accredited since 2002, according to the quality system based on PN-EN ISO/IEC 17025 standards, for Hp(0.07) personal dose equivalent within the range of doses from 0.1 mSv to 1 Sv. The paper presents the results of evaluation of extremity ring measurements performed by LADIS in years 2002-2009. More than 50 thousand measurements were performed for more than 300 institutions in Poland on a quarterly basis. Radiation fields represented exposure situations for staff in hospitals, as the users of our ring dosemeters were mostly from interventional radiology and nuclear medicine units.

As the results showed, about 70% of Hp(0.07) doses were below 1 mSv/quarter, however, some very high doses were also registered. We found doses exceeding the dose limits and these cases will also be presented. The clients were classified according to their medical activity and the levels of measured doses were found for these categories.

The laboratory participated with positive results in the international intercomparisons of ring dosemeters organized in 2007 and 2009 by the European Dosimetry Group EURADOS, in order to verify performance of different extremity dosemeters used in Europe.

Introduction

In order to assess occupational exposure at the workplace in therapeutic and diagnostic radiology as well as nuclear medicine it is necessary to monitor external radiation.

The LADIS laboratory provides dosimetric service for individual dosimetry in terms of the personal dose equivalent $H_p(10)$ and $H_p(0,07)$ for photon and neutron fields and environmental dosimetry in terms of the ambient dose equivalent H*(10) [1].

In extremity dosimetry we use ring dosemeters to measure radiation exposure (Fig. 1). The laboratory has been performing extremity ring dosimetry measurements for more than eight years. This procedure has been accredited since 2002, according to the quality system based on PN-EN ISO/IEC 17025 standards, for Hp(0.07) personal dose equivalent within the range of doses from 0.1 mSv to 1 Sv. This paper presents results of evaluation of extremity ring measurements performed by LADIS in years 2002-2009. More than 50 thousand measurements were performed for more than 300 institutions in Poland on a quarterly basis. Radiation fields represented exposure situations for staff in hospitals. The users of our ring dosemeters were from interventional radiology, nuclear medicine units, oncology centres, and radiology [2,3].

Materials and methods

The dosimetry service (LADIS) of the Institute of Nuclear Physics (IFJ), Kraków, applies MTS-N (LiF:Mg,Ti) thermoluminescence (TL) detectors (developed and produced at the Institute of Nuclear Physics PAN) for individual monitoring of Hp(0.07) in photon radiation fields. The TLDs are inserted in a plastic bar coded ring holder under a plastic cover, 0.4 mm thick. Each of TL pellets have a 4.5 mm diameter and 0.7 mm thickness. Ring dosemeters can be adjusted to any finger size [4].

Measurements carried out in the Laboratory of Individual and Environmental Dosimetry IFJ PAN using ring dosemeters type PI-01 are based on the process of thermoluminescence.

For dose measurements we use TLD RADOS Dosimetry System. All detectors are annealed and read in an automatic RADOS hot-gas reader system. Post-irradiation annealing at 75°C for 10 minutes is applied to detectors. TLDs are put in TLD RADOS badges which are placed in a cassette and then read in RADOS RE1 and RE 2000 readers, using the routine read-out procedure. During the readout TLDs pellets are lifted by vacuum needle into the measuring chamber inside the reader, which is filled by nitrogen heated to 300°C (1.5 s pre-heat and 11 s read-out time). The emitted light is measured with photomultiplier; the signal from the photomultiplier tube is consequently amplified and eventually measured with the measuring electronics. The computer obtains information about the number of pulses counted in each pellet. The obtained figure is proportional to the cumulative dose on the detector. By comparing it with the number of counts from the calibration detector (irradiated with a dose of a known value), we can calculate the dose for the given dosemeter [4].

Results

Years of experience allow the laboratory to analyze the levels of doses received by workers in medical institutions cooperating with LADIS. Our analysis indicated that most of the doses received by individuals were on the level of the natural radiation background, but some of them exceeded the dose limit (Fig. 3).

The percentage of overdoses was relatively small, however, looking at individual cases the risk of irradiation was noticeable. Therefore constant monitoring continues to be necessary.

The highest extremity doses came from measurements taken in the nuclear medicine and interventional radiology (Fig. 3).

In 2007, the Laboratory of Individual and Environmental Dosimetry IFJ PAN participated in an international intercomparison of ring dosemeters organized by the European Dosimetry Group EURADOS. More than twenty centers conducting dosimetric extremity measurement operating in Europe took part in this project. In 2009 the LADIS laboratory participated in Eurados intercomparison for the second time ("EURADOS Intercomparison 2009 for extremity dosemeters"). The LADIS laboratory participated in both international intercomparisons with positive results.

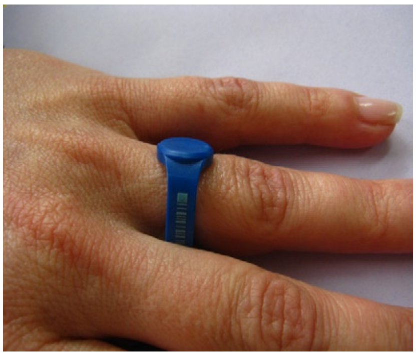

Fig 1. Bar coded ring dosemeter.

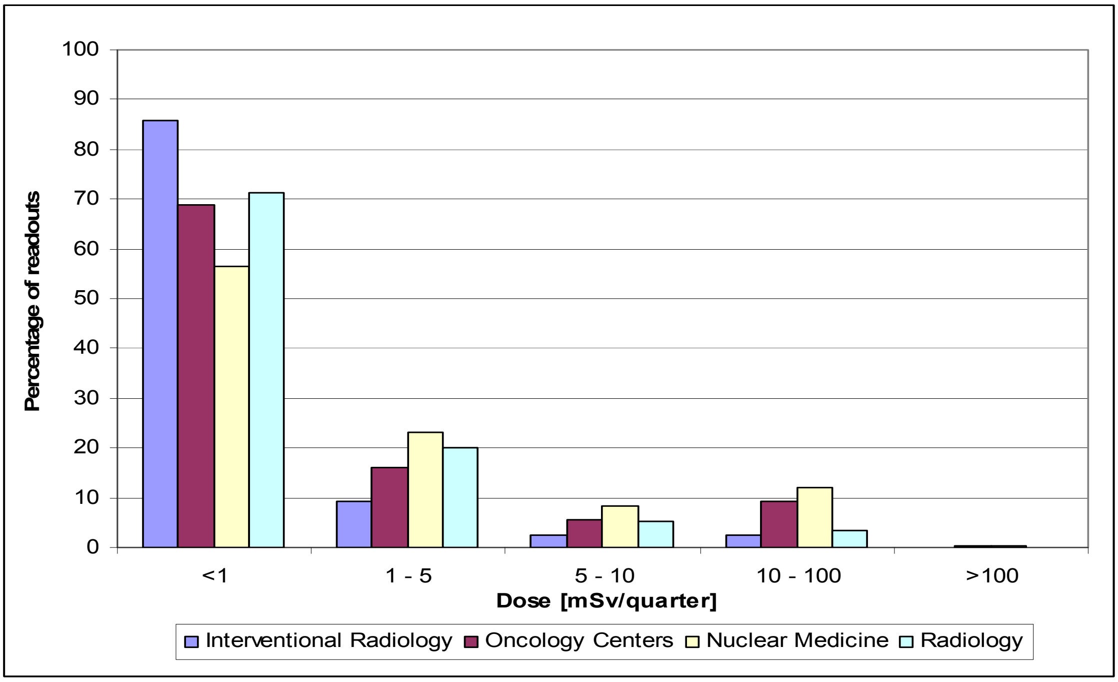

Fig. 2. Summary of extremities dose measurements performed in LADIS.

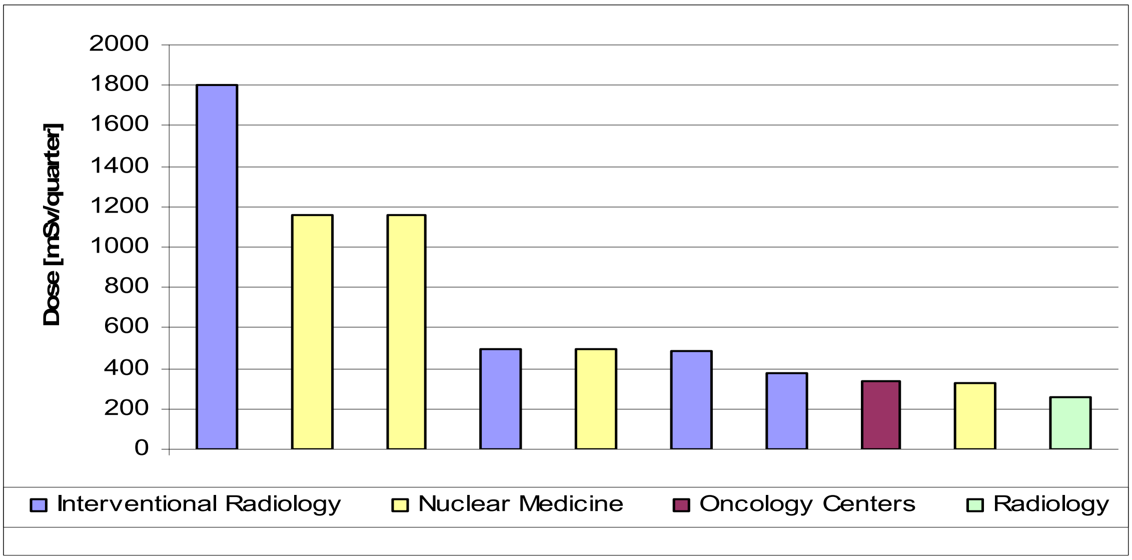

Fig 3. Top ten highest extremity doses.

Discussion and Conclusions

Investigation of cases of overdose led to a conclusion that they were caused by lack of caution, for example leaving dosemeters in the radiation field instead of keeping them on the finger. Consequently, the dose was absorbed by a dosemeter alone but not by a monitored person. Another reason of getting raised doses was incorrect application of radiation shields. Nevertheless, these results still indicate that some degree of risk is present, therefore regular monitoring remains necessary.

70% of all extremity doses in Poland are on the level of the natural radiation background. Dose levels between 1 – 10 mSv quarterly are the most frequent in nuclear medicine and interventional radiology (Fig. 2). The highest dose level above 100 mSv is observed in nuclear medicine. The highest readings of ring dosemeters, exceeding the dose limits, are observed in interventional radiology and nuclear medicine (Fig. 3).

Study of deterministic and Monte Carlo simulation methods for neutron and photon dosimetry at the Royal Surrey Hospital radiotherapy facility

Morrissey, Craig
Atomic Weapons Establishment, UNITED KINGDOM

Abstract

The application of linear accelerators in the treatment of cancerous cells has become increasingly common in the last few decades. During this period the operational beam energies have increased to a point where the dose from unwanted photoneutron production has to be considered. This can add an additional complexity to calculating the dose to the patient being treated and also the potential dose rate external to a radiotherapy bunker. To this end the 10 MeV radiotherapy linear accelerator at the Royal Surrey County Hospital has been used as a template to calculate the photon and neutron dose rates at the entrance of a bunker and to discuss the advantages between the uses of two different dose assessment methodologies.

Calculation of the radiation beam path through the bunker and doses at the entrance have been performed using traditional deterministic methodologies and compared against Monte Carlo model simulations.

The deterministic method examined photon beam energies of 6 MeV and 10 MeV, which yielded entrance dose rates of 0.34 and 0.27 μSv/hr, respectively. However, the use of correction factors, such as scattering coefficients, used in this method placed doubt on the accuracy of the results. The Monte Carlo method was used to simulate the radiotherapy bunker of the Royal Surrey County Hospital to examine the neutron dose at the bunker entrance, yielding a dose of 8 x 10^{-11} neutron/Gy. Further Monte Carlo simulations were conducted with the bunker configuration modified through the addition of shielding and neutron moderators to demonstrate further dose reduction options available in the bunker design.

The advantages of the deterministic and Monte Carlo methods are discussed, concluding that Monte Carlo analysis offers an improved radiation protection tool for the calculation of doses and dose rates where complicated geometries and materials must be considered.

Neutron production

Medical equipment, such as linear accelerators (linacs) are an integral tool in the fight against cancer. Linacs utilise either electrons or photons to destroy cancerous cells in patients. Above threshold energies interactions of these particles with certain materials can result in the production of neutrons. These interactions are categorised as electroneutron (e,e'n) and photoneutron (γ,n) reactions, respectively.

The first opportunity a photon has to produce neutrons occurs in the treatment head of a linac. Figure 1.1 displays the treatment head of a linac at the Royal Surrey County Hospital (RSCH) where electrons have already been accelerated through a waveguide. Subsequently, the electrons have travelled through a flight tube onto an x-ray target resulting in photon production. The cone created by the primary collimators intrudes onto the edges of the target and defines the largest available field size. Collimators are typically constructed out of lead with a steel casing, tungsten, copper alloys or depleted Uranium (DU); ideal materials for the production of photoneutrons at energies as low as 6 MeV. Photons then pass through the beam flattening filter exiting with a uniform dose distribution; monitored by a set of ionisation chambers. The wedge filters are removable and allow the production of a gradient across the x-ray field. Wedges can have a very complex shape in order to produce the required dose distribution. Finally, photons pass through a moveable collimator where the width of the radiation field is minimised and exit through a perspex window.

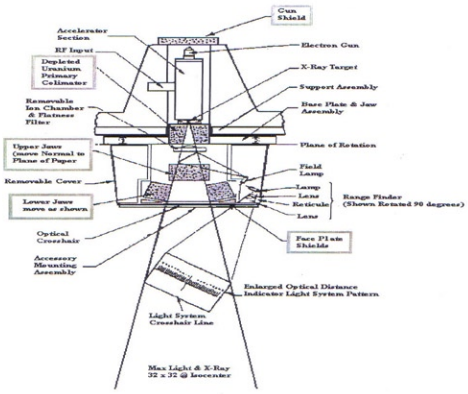

Fig. 1. Treatment head of the new linac at the Royal Surrey County Hospital.

The treatment head consists of several sources of neutron contamination including the walls of the vacuum chamber, the x-ray target, filters, DU collimator, the walls of the waveguide and light localisers (NCRP 79).

Once clear of the treatment head neutron production can arise through photon interactions with the air between the linac and the patient, the tissue in the patient and the bunker itself. Interaction with the bunker can cause further photoneutron interactions if it is lined with a high-density material for photon shielding, such as steel or magnetite. Neutrons can easily scatter of these materials with little loss in energy resulting in neutron escape from the bunker if there is no shielding door.

Photoneutron reactions occur above threshold energies that are dependent upon the cross section of element that the photon interacts with and the photons kinetic energy. When a reaction takes place it is possible for more than one neutron to be produced; therefore the photoneutron production cross-section is the sum of σ(γ,1n), σ(γ,2n) and σ(γ,3n)… etc. with σ(γ,1n) usually contributing significantly (Chin 1999). The only known exceptions to this are the σ(γ,1n) for the odd-Z, even-A nuclides ^{6}Li,

^{10}B and ^{14}N (NCRP 79). The total photoneutron yield cross section, σ(γ,xn), is given by σ(γ,1n) + 2σ(γ,2n) + 3σ(γ,3n) + … etc. The (γ,1n) and (γ,xn) cross-sections for ^{12}C and ^{16}O are shown in Figure 1.3.

Effects on neutron spectra in accelerator head

When a linac is energised the amount of shielding around the target can serve to produce a collimated beam of x-rays. The neutrons produced inside the treatment head are approximately isotropic and penetrate the shielding in all directions. Heavy metals, such as tungsten and lead, are the most common materials used for shielding in the head in conjunction with amounts of copper and iron present in the bending magnets. It should be noted that the majority of photon shielding is in the forward direction as this is where photons are emitted. These materials offer no shielding against neutrons and can facilitate photoneutron interactions. The only significant mechanisms of neutron energy loss from these heavy elements are inelastic scattering and (n,2n) reactions.

Figures 2 (Howerton 1958) displays the neutron interaction cross-sections of tungsten and lead. Shown are the inelastic, elastic and (n,2n) cross sections in the energy region of interest for linacs. It can be seen that inelastic scattering dominates energy losses at lower energies whilst at higher energies loss is primarily due to (n,2n) reactions. However, inelastic scattering can only occur at energies above the lowest excited state of the shielding material. The lowest excited states for some shielding materials are given in Table 1 (NCRP 79). Following an inelastic collision there is an energy loss leading to the excited state of the nuclei; theses nuclei de-excite to their ground states through the emission of photons. The energy loss from this collision cannot be determined but there is a minimum energy loss that equals the energy of the lowest excited state (NCRP 79).

Fig 2. Neutron interaction cross section in tungsten and lead as a function of neutron energy (Howerton 1958).

Table 1. Inelastic scattering thresholds (NCRP 79).

Element	Atomic Mass Number	Abundance %	1st Excited State (MeV)
Pb	206	25.1	0.803
	207	21.7	0.570
	208	52.3	2.61
Fe	54	5.8	1.41
	56	91.7	0.847
W	182	26.4	0.100
	183	14.4	0.047
	184	30.6	0.111
	186	28.4	0.123

In the (n,2n) reactions the emerging neutrons have less energy than the parent neutron. This increases the number of low energy neutrons that will be captured. The sum of the (n,2n) and inelastic cross sections is of the order 1 to 2 barns for the lead, tungsten and iron. Elastic scattering also occurs with theses materials but the energy loss is negligible. However elastic scattering increasing the average path length of the neutrons in the shielding material and therefore increases the probability of further inelastic or (n,2n) reactions occurring.

Room shielding

The majority of linacs are situated in concrete bunkers where design has been centred on the photon hazard. Photons are typically more penetrating than neutrons for the energy ranges in which a linac operates (IPEM 75). The average neutron energy from such machines is never in excess of 1 MeV. This means that adequate concrete shielding for photons should be adequate for neutrons as well due to the hydrogen content in concrete. However, neutron capture is likely to occur in the concrete leading to an increase in the absorbed dose near the walls due to the release of gamma rays.

The neutron field in the concrete bunker is considered to be a combination of neutrons coming directly from the source Φ_{dir}, which follows an inverse square law, a scattered component Φ_{sc}, which is approximately constant throughout the room, and thermal neutrons as a result of neutrons being scattered several times and have attained thermal equilibrium Φ_{the}, which is approximately constant throughout the room (McGinley et al, 1995). This is summarised as the total epithermal neutron flux, Φ, i.e., all neutrons with energy greater than cadmium cut off, 0.41 eV, being $\varphi_{total} = \varphi_{direct} + \varphi_{scattered} + \varphi_{thermal}$

Where: $\varphi_{direct} = \dfrac{aQ}{4\pi\pi^2}$ $\quad \varphi_{scattered} = 5.4\dfrac{aQ}{S}$ $\quad \varphi_{thermal} = 1.26\dfrac{aQ}{S}$

Q is the number of fast neutrons, S is the inside surface area of the treatment room in cm^2, a is the fractional flux transmission of the head shielding (typically 0.85 for tungsten shielding and 1.00 for lead shielding), and R is the distance from the source to the detector in cm.

Maze design

Many linac rooms incorporate a maze design in order to reduce the photon dose rate to a safe level at the exit of the bunker. This enables the room to be constructed without a door allowing easy movement of radiation workers and patients to and from the linac. This is partially a cost saving mechanism as it avoids spenditure on shielded doors and interlocks but also decreases the time required to transport patients and thus increases the number of treatments that can be performed.

Neutrons can easily scatter through large angles with only a minimal loss of energy so the maze needs to be designed with the maximum number of scatters reasonably practicable. The neutrons can also generate capture gamma rays as that can travel around the maze and have been shown to contribute up to half of the dose rate at a maze entrance.

Photons

Photons are produced when energetic electrons interact with the X-ray target material, usually tungsten in the treatment head. The interaction of the photons with matter is random and covers a range of mechanisms that is dependent upon the photons energy. These mechanisms are Raleigh scattering (below 10 keV), the photoelectric effect, Compton scattering (30 keV to 10 MeV) and pair production (5 – 50 MeV). These mechanisms are well understood and will not be discussed further.

The deterministic method

The deterministic method is a straightforward approach to calculate particle transport using formulae. It is relativity fast and does not use random numbers, allowing it to be performed without the use of sophisticated computers.

The method can been used to calculate the photon dose equivalent at the entrance of a radiotherapy bunker. This is by far the most common method used by radiation protection professionals in hospitals and will be outlined below.

Method

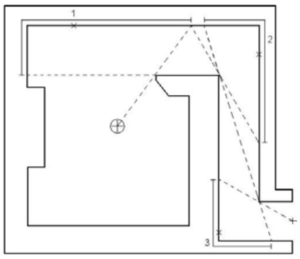
Photon scattering down a maze will come from two main sources – scattering from the patient and the walls of the treatment room. With this method scattering from the floor and ceiling is not considered. Photons will leak from the treatment head however and must be accounted for. The first factors that need to be determined when undertaking scatter calculation is the paths that the photons can take to exit the maze and the areas from which they can scatter.

This is achieved by analysis of the bunker design. Figure 3 shows the layout of the newly commissioned radiotherapy bunker at RSCH. The dose rate, D_Q, received at a point Q from scatter at P is given by, $D_Q = \frac{D_P aA}{d^2}$, where D_P is he dose rate at P, A is the scattering area, d is the distance between the points, and a is the appropriate scatter coefficient.

The first scatter from the patient must include a factor L to account for leakage from the treatment head. This means that the dose rate, D_1, reaching the first wall from scatter in the patient is given by, $D_1 = \frac{D_0}{d_1^2}(a_1A_1 + L)$

Manufacturer guidance dictates that leakage from the head should be less than 0.1% of the main beam dose rate. Therefore a factor of 0.001 is used as a worst-case scenario.

The determination of the scattering areas and distances involves an analytical approach using lines of sight. Whilst photons can feasibly scatter several times around the treatment room and still exit down the maze, it is only those that scatter the minimum number of times that will really contribute to the dose at the maze entrance. Therefore the areas can be determined by working out where on the walls a photon can hit for each scatter and still make it out of the maze in the minimum number of scatters (four in this case, including that in the patient). Figure 3 shows the scattering areas and paths that have been identified for this calculation. The first scattering area, A_0, is the maximum beam size at the surface of the patient (40 cm by 40 cm = 0.16 m^2)



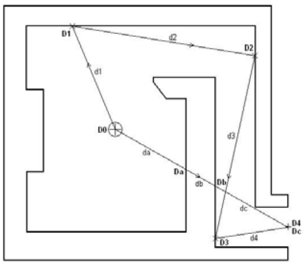


Fig. 3 and 4. Scattering areas and beam paths of photons in RSCH bunker, respectively.

The dotted lines represent the lines of sight used to define the three scattering areas on the treatment room walls. While area one could feasibly be extend to cover most of the left hand wall, the distance travelled by the photons scattering from such points would reduce their energy sufficiently to justify their exclusion from the calculation. The crosses on Figure 3 mark the centre points of the scattering areas. The beam path that scatters from these points has been taken as the average scattering distance for use in the calculation. The path is shown in Figure 4.

The dose at the entrance to the maze will also include a component from the radiation that has scattered in the patient and subsequently penetrated the bunkers secondary shielding. The dose follows the line d_a, d_b, and d_c in Figure 4.3. The total dose at the entrance to the maze will be the sum of the radiation scattered down the maze (D_4) and that penetrating the wall (D_c).

The dose rate reaching the maze entrance from scatter down the maze is given by $D_4 = \frac{D_3 A_3 a_3}{d_4^2}$ where, $D_3 = \frac{D_2 A_2 a_2}{d_3^2}$ etc.

The values of a_0 for the 6 MeV beam have been taken from IPEM Report 75 Appendix VI table VI.2. The corresponding 10 MeV beam value is taken from NCRP Report 144 (Figure 4.14). These values have been normalised to a scattering area of 0.16 m^2. The scatter coefficients used to describe scatter at the walls comes from IPEM Report 75, Appendix VI Figure VI.10. This value assumes equal angles of incidence and scattering and that the walls are made of ordinary concrete. Table 2 shows all the necessary areas and distances of the RSCH bunker.

Table 2. Data for scattered dose calculations.

Photon Beam Energy (MeV)	Parameter					
	D0 (Gy/hr)	A0 (m2)	A1 (m2)	A2 (m2)	A3 (m2)	a0
6	360	0.16	42.28	38.27	29.27	0.00240
10	360	0.16	42.28	38.27	29.27	0.00037

	Parameter						
	a1	a2	a3	d1 (m)	d2 (m)	d3 (m)	d4 (m)
6	0.022	0.022	0.022	4.50	8.10	7.15	3.30
10	0.022	0.022	0.022	4.50	8.10	7.15	3.30

In order to calculate the dose through the wall the tenth value layer must be determined.

The tenth value layer, the distance at which photon intensity is reduced to a tenth of its initial value, must be calculated for the maze shielding. The shielding at the

RSCH is composed of a concrete and magnetite homogeneous mixture; the constituent elements of this mixture are listed in Table 3. The percentage weights of the materials are accurate to within 2 – 3%.

Table 3. Elemental analysis of Magnetite concrete at RSCH.

Element	Weight kg/m3	% Weight
Ca	237	16.6
O	1205	30.5
Si	115	2.9
Al	24	0.6
Fe	2143	54.3
H	20	0.51

The chemical composition was determined to be $Ca_{14}Si_2Fe_{51}O_{30}AlH$. Using a photon cross-section database (XCOM) the mass attenuation coefficient for the compound was determined for a 6 MeV and a 10 MeV beam to be $2.9\text{x}10^{-2}$ and $2.7\text{x}10^{-2}$ cm^2/g, respectively. Tenth layer values of 20.03 and 21.30 cm for the 6 and 10 MeV beams, respectively was calculated using ln10/mass attenuation coefficients.

If the dose rate incident on the inner side of a wall n TVL's thick is D_a then the dose rate D_b coming out of the other side is $D_b = D_A \times 10^{-n}$.

The thickness of the wall along the beam path (d_b) is 120 cm. This means that n is approximately 6.0 for 6 MeV and 5.6 for 10 MeV.

The dose rate, D_c, reaching the maze entrance, a distance d_c from the outside of the wall is then given by, $Dc = \frac{D_A \times 10^{-n}}{d_c^2}$ where, $D_A = \frac{D_0}{d_a^2}(a_0 A_0 + L)$

Results

The dose rates from scatter down the maze (D_4) and leakage through the wall (D_c) are summed to give the total dose rate expected at the maze entrance, D_{TOT}. The results for 6 MeV and 10 MeV beams are summarised in Table 4. The total neutron dose at the end of the maze was calculated to upto four times greater than the photon dose.

Table 4. Dose rates at maze entrance.

Energy (MeV)	D4 (µSv/hr)	Dc (µSv/hr)	DTOT (µSv/hr)
6	0.3397	2.2×10-3	0.3422
10	0.2600	5.6×10-3	0.2656

Discussion

The deterministic method produced a dose rate at the maze entrance of 0.34 µSv/hr for the 6 MeV beam and 0.27 µSv/hr for the 10 MeV. Assuming a 40 hr week, over a 5-day period, a dose rate of 0.014 and 0.011 mSv per week, respectively.

The results show that the higher the initial photon beam energy the lower the dose rate at the maze entrance. This suggests that the higher energy photons are able to penetrate the shielding more effectively, thus resulting in less scatter. This does not imply that the photons will escape through the shielding as the magnetite/concrete mixture has TVL's great enough to attenuation the beam.

The method however relies up on a series of approximations and correction factors to complete the calculations, such as: leakage from the treatment head is assumed to be no worse than 0.1 % of the beams dose rate, there is an average distance travelled by the photons, floor and ceiling scatter is negligible, the tenth value layers rely upon knowing an accurate elemental analysis of the shielding material., the scattering coefficients used are only defined for a water phantom and concrete.

Monte Carlo method

The Monte Carlo method uses random numbers to solve complex problems, as opposed to the deterministic method. It uses simulations to mimic real world process that can occur inside radiation bunkers and produces an expected value from a random variable.

The simulation charts a particles life history within the designed system, from its birth until it ends either being captured or it leaves the system. This is a very complex process due to the probability distribution that governs particle behaviour. For a neutron produced in a linac its emission is isotropic, therefore its direction and location is a function of probability, this leads to random interaction locations within the bunker and so whether the particle is captured or scattered (elastically or in-elastically) is random, hence the term random walk. (Chin 1999).

The Monte Carlo process is then a system that samples statistically the probabilistic distributions governing individual probabilistic events (Chin 1999).

Many Monte Carlo codes have been developed for general and specific purposes. The simulation for this work was created using a general Monte Carlo code for tracking the life of neutrons, photons, electrons, or coupled neutron/photon/electrons, within a bunker.

Original bunker configuration

The total physical dimensions of the radiotherapy bunker were 11.9 x 9.7 x 3.7 m^3. The main linac room is 6.9 m in width and 8 m long and has primary corridor 11.35 m long and 2 m wide. The main room also has a baffle that protrudes 1.7 m inwards with a nib on its end at an angle of 50°. The primary shielding mainly attenuates photons that are initially directed in that field of view as they are emitted from the treatment head and is 1.5 m thick. The bunker entrance is on the other side of the secondary shielding and has no door in order to facilitate the transport of patients in and out the treatment room as mentioned in Section 2.3. This leaves a gap 2 m wide from which neutrons can escape.

Modification of the bunker

Separate simulations were run with the bunker modified to include two baffles in the treatment room, boron lining along the bunker entrance and a boron door. Figure 5 displays the layouts and relative thickness are the materials added to the bunker.

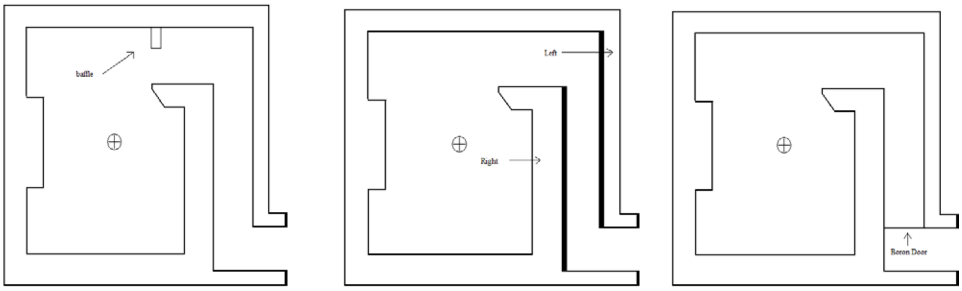

Fig 5. Location of added baffle, boron absorbers and door, respectively.

Results and discussion

The original bunker design, which is in operation at the RSCH, yields a neutron dose of 8 x 10^{-11} per neutron/Gy at the maze entrance for neutrons with an initial energy of 1 MeV. The introduction of the baffle shows a reduction in dose of 40%. This reduction in the neutron dose is due to the increase in surface area of the maze and the effective addition of an extra corner. The increase in surface area acts to minimise the total neutron flux. The fast neutrons have a greater probability of undergoing additional scattering, which in turn lowers their energy and leads to an increase in the number of thermal neutrons. This increases the probability of capture in the bunker. The addition of further corners in the maze result in additional shielding from concrete and thus the hydrogen content is increased.

Addition of boron lining to the bunker walls, reduced dose by 39 % at the entrance. The addition of boron to both walls increases the probability of absorbing thermal neutrons, which accounts for the lower dose.

Addition of a boron door results in a neutron dose rate reduction of 56 % for neutrons in the 1 MeV range. This is due to the characteristics of boron described above and also because the door acts as barrier to scatter the neutrons back into the main treatment area. This increases the average number of scatters that the neutrons will undergo and thus increase the probability of neutron capture within the bunker shielding or the boron door. The dose still delivered to the maze exit is most likely a result of the high-energy neutrons that were able to penetrate the door and then become thermalised and secondary photon emissions from neutrons that were captured by the boron. The addition of the door appears to be very effective but ultimately this must be balanced between the effectiveness of moving the patient in and out of the treatment room, the risk of door interlocks failing and the presences of a partially irradiated door accessible to the public.

Conclusions

The deterministic method produced a dose rate at the entrance of the maze of 0.34 µSv/hr for the 6 MeV beam and 0.27 µSv/hr for the 10 MeV. However, this value does not take into account the neutron dose at the end of the bunker that is stated to be four times larger than that of the photon dose. The results were gained through the use of several correction factors and approximations, such as the floor and ceiling scatters being ignored, an average path length for the beam to travel along and the use of scatter coefficients that only exists for water phantoms and concrete. This means that the results from this method may not be accurate and have to be viewed with caution.

Using Monte Carlo simulations a neutron dose of 8 x10^{-11} neutrons/Gy resulted at the entrance to the radiotherapy bunker. The addition of a baffle resulted in a reduction of dose of 40 % due to an increase in surface area and hydrogen content. This resulted in a greater number of scatters and an increase in the neutron energy loss per collision.

The addition of boron to the maze wall was found to reduce the neutron dose by up to 39 %. This was accomplished due to the large capture cross section of boron for neutrons around thermal energies. Higher energy neutrons scattered off this material towards the maze entrance relatively unaffected by the boron. Scattering neutrons off moderating materials before they reach the boron could increase the effectiveness of the boron by reducing neutron energies to thermal levels

A boron-lined door was then introduced to the bunker, having the effect of reducing the dose by 56. The position of the door along the maze resulted in the scatter of high-energy neutrons back into the treatment room whilst thermal neutrons were captured. The dose still received at the maze entrance is likely to be combination of very high-energy neutrons that were able to scatter through the door and that of secondary photons that were emitted during the capture of neutrons within in the door. Although this simulation resulted in the lowest dose it would probably not be used as it would slow the movement of patients in and out the treatment room.

The simulations demonstrate the effectiveness of using a method such as Monte Carlo. By statistically sampling the probabilities of how a large number of neutrons will interact an accurate process can be simulated. This method may require significant input initially to write the code and collect the inputs needed to create the simulations, such as the shielding constituents and maze design. Once this is complete the simulations do not require the use of correction factors and approximations, producing accurate results with an associated error. The method also allows different variables to be studied in the bunker, such as the neutron flux, and can be modified relatively easily to simulate alternative geometries and shielding.

In relation to the radiotherapy bunker the accuracy and ability to adapt inherent to the Monte Carlo code makes it a far more useful tool than the deterministic method. This accuracy is at the initial cost of the time needed to construct the code but does negate the need to search through literature for scatter coefficients and other approximations.

Practical implications of the RELID (Retrospective Evaluation of Lens Injuries and Dose) project in the radiation protection of medical professionals

Vañó, Eliseo[1]; Durán, Ariel[2]; Ramírez, Raúl[3]; Nader, Alejandro[3]
[1] Complutense University of Madrid, SPAIN
[2] University Hospital Montevideo, URUGUAY
[3] International Atomic Energy Agency – IAEA, AUSTRIA

Abstract

An international study on Retrospective Evaluation of Lens Injuries and Dose (RELID) was carried out under the coordination of the International Atomic Energy Agency (IAEA) with the collaboration of the Latin American Society of Interventional Cardiology (SOLACI). Two surveys were performed during regional congresses of SOLACI and included an evaluation of potential radiation-induced lens opacities in a cohort of interventional cardiologists (IC), nurses and technicians working in cardiac catheterization laboratories, as well as a control group of non-medical professionals whose eyes were never exposed to ionizing radiation. Retrospective eye dose calculations were made by combining data from experimental scatter dose measurements in standard catheterization laboratories with answers to occupational and work-practice details from questionnaires and oral interviews of all participants. Personal dose records were requested to the participants. A total of 116 exposed individuals were screened. A control group of 93 non-exposed persons was included. Posterior sub capsular opacities were found in a 38% of cardiologists and in a 21% of paramedical personnel as compared to 12% of controls. Personal dose records values were practically not available in most of the cases. From the questionnaires fulfilled by the participants, cumulative professional life-time equivalent doses to the lens until several Sv were estimated. The use of personal protection devices reported by the some of the subjects with higher doses was scarce or never used. These findings demonstrate the necessity to improve the education in radiation protection for interventional medical and paramedical professionals especially in the aspects affecting occupational doses and on the importance of using ocular radiation protection tools. Personal dosimetry methodology for these professionals should be revisited and the need of the proper use of personal dosimeters should be highlighted.

Risk of occupational radiation-induced cataract in medical workers

Milacic, Snezana; Djokovic, Jelena
Medical Faculty, SERBIA

Abstract

The cataract is the most common degenerative opacity of the crystalline lens, developing with aging. Physical agents causing the cataract may be as follows: infrared, ultraviolet and microwave non-ionizing radiation, electric power and ionizing radiation. Other risk factors of cataract are the following: alcohol abuse, tobacco smoke, systemic diseases (endocrine and metabolic), impaired eye circulation, ocular pressure, refractory eye abnormalities (myopia), blood pressure, heart conditions, low food antioxidant level. The study involved 3240 medical health workers in Serbia, who used to work within and beyond the area of ionizing radiation. The annual periodical-preventive controls of health workers included the eye examination as well. After visual acuity measurement, the lens was examined by retroillumination method (red reflex) and using the biomicroscope. In case of impaired visual acuity or presence of cloudy lens, the examination was performed in mydriasis. X-ray radiation may be a significant cofactor of cataract in radiological technicians. It is an occupation-related disease and may, along with other impairments, contribute to diagnosis of chronic radiation syndrome as occupational disease. Absorbed doses in exposed subjects with cataract, measured by thermoluminescent personal dosimeter (TPD) ranged from 2.64 (min.) to 48.10 (max), mean value: 7.58 ± 4.78 mSv / 5 years (1.59 ± 30 mSv / year), and were not different from mean absorbed annual doses in the exposed subjects without cataract (1.63 ± 1.45 mSv / 1 g), being below maximally tolerated dose of 100 mSv / 5 years 920 – 50 mSv annually). It is evident that chronic exposure to low doses is not the cause of occupational radiation cataract as an independent occupational disease. The effects of radiation to biological DNA material failed to be proven on cataract development, it was rather related to type of radioactive emission, mode and type of radiation, working burden and working conditions as well as type of job.

Setting up a whole body counting system in Portugal

Bento, Joana; Nogueira, Pedro; Neves, Maria; Silva, Lídia; Vaz, Pedro; Teles, Pedro
Instituto Tecnológico e Nuclear, Unidade de Protecção e Segurança Radiológica, PORTUGAL

Abstract

We have recently set up a Whole Body Counter (WBC) at the ITN in Portugal (type Canberra Accuscan). This system is currently prepared to respond to any type of radiological emergencies adequately, if any should happen in Portugal. Also, in the near future, we intend to start a series of routine measurements of workers both inside and outside the ITN.

The WBC contains a moveable Canberra HPGe type GC 2520 detector, and is calibrated with the help of the GENIE 2K, and the ABACOS softwares. We use a calibration source consisting of a cocktail of several radionuclides, with photon energies within the range [55, 1900] keV. For the calibration, we use a Canberra RMC-II phantom in two different types of measuring geometries: the thyroid and the whole-body – both in BOMAB phantom type equivalent calibration arrangements. The calibration is checked on a daily basis, as well as the background.

This is being complemented by Monte-Carlo simulations. The simulations are being performed using the State-of-the-art MCNPX and PENELOPE codes and recent comparisons of calculations with measured results are extremely satisfactory.

Finally we have established collaborations on the European level to participate in future inter-comparisons, as well as in joint-projects, in the framework of EURADOS, with gradual harmonization with EURADOS and EC recommendations in mind.

In this talk we will discuss the actual and future projects associated with the applications of this equipment in the framework of Portugal's Radiological Protection policies, as well as present in some detail the results we have obtained so far.

Internal dosimetry at the Institute of Atomic Energy POLATOM in Poland

Ośko, Jakub; Golnik, Natalia; Ciszewska, Katarzyna
Institute of Atomic Energy POLATOM, POLAND

Abstract

Nuclear Centre Świerk is the main and the biggest nuclear centre in Poland, where Institute of Atomic Energy POLATOM, the Andrzej Soltan Institute for Nuclear Studies and Radioactive Waste Disposal Unit are located in the same site. Institute of Atomic Energy operates a nuclear reactor and there is also the Radioisotope Centre which manufactures radiopharmaceuticals and other unsealed radiation sources. Waste Disposal Unit collects and treats radioactive waste of low and moderate activity from the whole country.

Monitoring of the internal exposure of employees is performed by Radiation Protection Measurement Laboratory (LPD) of the IAE, which is the only laboratory of this type in Poland accredited by Polish Centre for Accreditation. LPD provides also monitoring of the internal exposure for employees from other institutions and sometimes serves as a public service in case of post accident contamination.

LPD uses a whole body counter and thyroid counter for *in vivo* measurements and performs *in vitro* measurements using flow counters and liquid scintillation analyzers. All measurement results are gathered in data base which contains data since 1986.

This paper shortly describes the procedures used in the laboratory and lessons from intercomparisons. Results of monitoring in 2008 are discussed for the group of 378 persons subjected to the measurements with whole body counter, 128 persons examined with thyroid counter and 122 persons using *in vivo* radiochemical. Occupational contamination with iodine ^{131}I was registered in 21 cases by whole body counter and in 57 cases by thyroid counter. Radiochemical measurements showed 9 cases of contamination (5 with ^{32}P, 4 with tritium, 2 with ^{90}Sr and 1 with ^{35}S). Contamination with ^{137}Cs was registered in 53 cases. This isotope is still present in the environment in Poland after the Chernobyl accident.

Introduction

Nuclear Centre Świerk is the main and the biggest nuclear centre in Poland. It is located 30 km from Warsaw. Institute of Atomic Energy POLATOM, Andrzej Soltan Institute for Nuclear Studies and Radioactive Waste Disposal Unit are located there.
Institute of Atomic Energy operates a research nuclear reactor and a part of it is the Radioisotope Centre which manufactures radiopharmaceuticals and other unsealed

radiation sources. Employees who are working in these units are exposed on internal contamination.

Monitoring of the internal exposure of employees is performed by Radiation Protection Measurement Laboratory (LPD) of the IAE POLATOM, which is accredited by Polish Centre for Accreditation according to the norm ISO/IEC 17025. LPD provides also monitoring of the internal exposure for employees from other institutions and sometimes serves as a public service in case of post accident contamination. All measurement results are gathered in special data base which contains data since 1986.

Other fields of LPD activity are environmental measurements and calibration of dosimetric equipment. LPD is the only one Polish laboratory offering the full range of internal dosimetry measurements.

Measurements methods used in LPD

In vivo measurements methods

There are two stations for *in vivo* measurements in LPD – whole body counter and thyroid counter.

Whole body counter in Świerk is the only one of this type of equipment in Poland. Around 400 measurements per year are performed there.

Whole Body Counter is placed in a special room which walls are built from 20 cm of iron, 5 mm of lead, 2 mm of cadmium and 1 mm of cooper. The equipment used for the measurements is HPGe detector with multichannel analyzer, both produced by SILENA. Measurements are done in chair geometry, time of one measurement is 20 minutes, BOMAB phantom is used for calibration. Whole Body Counter with BOMAB phantom during calibration is presented in figure 1.

Fig. 1. Whole Body Counter in LPD with BOMAB phantom during calibration.

The thyroid counter used for measurements in LPD contains the NaI(Tl) detector produced by CANBERRA and multichannel analyzer Tukan8k produced by Andrzej Soltan Institute for Nuclear Studies [Guzik et al. 2006].

LPD is using own-construction thyroid water phantom for calibration. The water phantom is a cylinder shaped Lucite (PMMA) vessel (128 mm diameter, 165 mm high), with a cover and two small (13 cm^3) cylinder vessels inside. During the measurements, the bigger vessel is filled with distillated water and the small ones, which simulate the thyroid lobes, are filled with the reference solution of radioisotopes. Construction of the phantom makes it possible to move the small vessels in two directions (horizontal and vertical). The whole phantom can rotate on its base and certain angle of rotation can be fixed. There is also a possibility to use the vessels of different volume.

During calibration measurements the whole spectrum of the emitted radiation is measured to determine the ratio of the counting rate in the main energy peak and in the Compton scattering band. The result of calibration is the ratio between detection efficiency and the depth of the ^{131}I source in water thyroid phantom. This method allows to detect the cases of non-typical distribution of the iodine in the patient's neck and to estimate the associated uncertainties of the measured activity. [Ośko et al. 2007A, Ośko et al. 2007B]

The thyroid counter used in LPD is presented in figure 2 and thyroid water phantom is presented in figure 3.

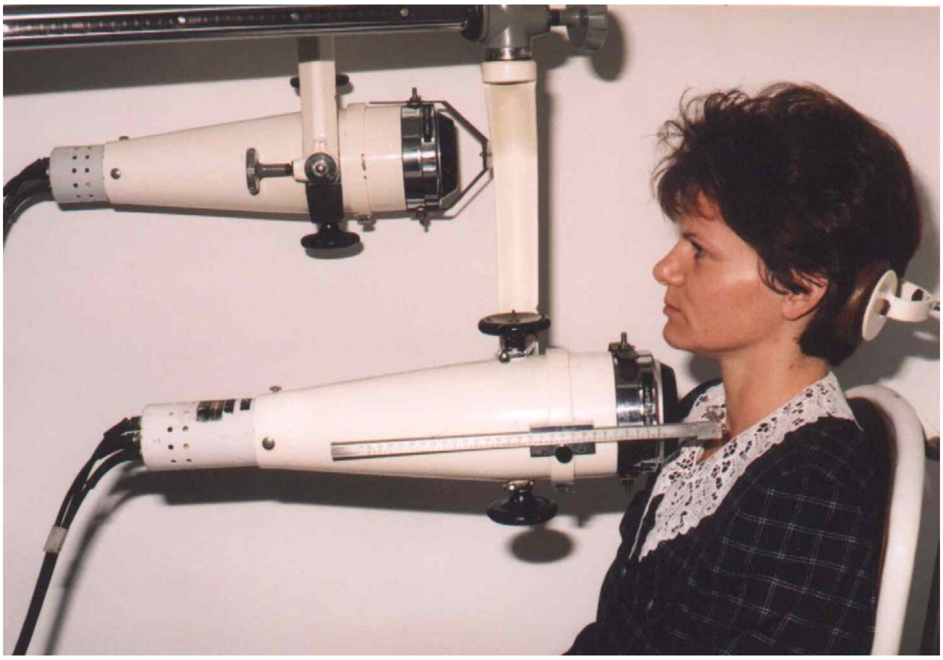

Fig. 2. Thyroid Counter in LPD.

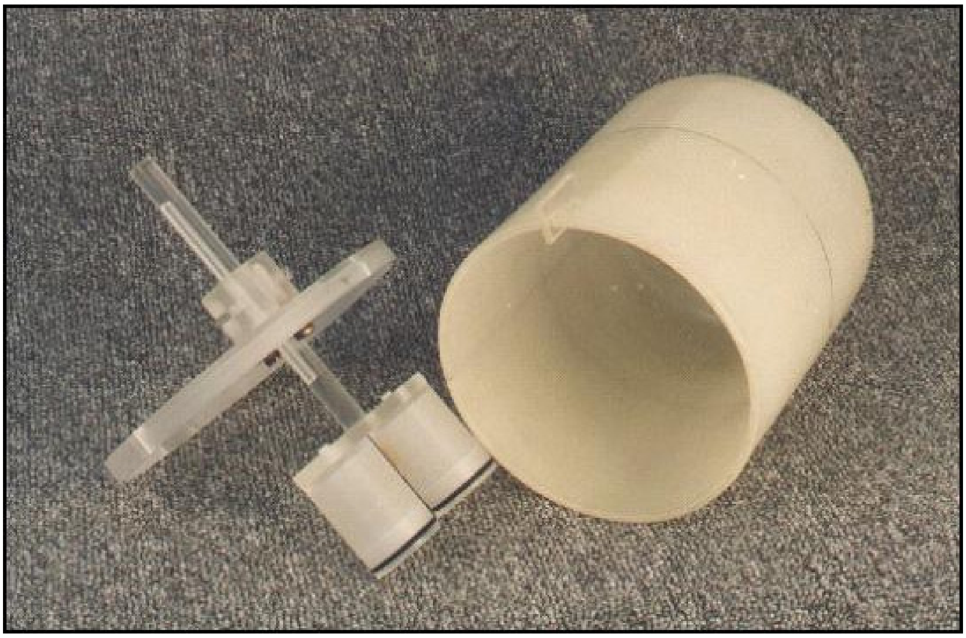

Fig. 3. Thyroid water phantom used for calibration of thyroid counter in LPD.

In vitro measurements methods

Radiation Protection Measurement Laboratory performs *in vitro* measurements to determine:

- contents of radioactive beta isotopes: sulfur ^{35}S, phosphorus ^{32}P, carbon ^{14}C, tritium ^{3}H and strontium ^{90}Sr (procedures accredited by PCA);
- total alpha and beta activity (not-accredited procedures);

in human urine.

The activity of ^{35}S, ^{32}P and ^{14}C in urine is determined by direct measurement in Liquid Scintillation Analyzer (LSC). Definite volume of daily collection of urine is mixed with scintillator. Next beta radiation activity of cocktail is being measured in applicable energetic channel of the counter, which depends on determining element.

The activity of tritium ^{3}H in urine is also measured in LSC. Before measurement the sample must be properly prepared. Urine is discoloured by active carbon, sodium carbonate (Na_2CO_3) and sodium thiosulfate ($Na_2S_2O_3$) are added, next a distillation is carried out. The definite volume of distillate is mixed with scintillator and beta radiation activity is measured with LSC.

Chemical preparation of a sample is necessary to determine strontium ^{90}Sr activity in urine. At the first stage deposit is precipitated in the presence of oxalic acid, with oxalates strontium ^{90}Sr and yttrium ^{90}Y are co-precipitated. After deposit mineralization, the sample is transformed to liquid form. The laboratory determines activity of ^{90}Sr indirectly, the measure of the activity of ^{90}Y, it is possible because ^{90}Sr and ^{90}Y are always in equilibrium. As a result of multi-stage extraction the extract is received and then evaporated on the measuring plate. Next the activity of deposit is determined by measuring system with the proportional flow counter.

The method of determining the total beta activity in urine consist of co-precipitation, in orthophosphoric acid environmental, alkaline earth phosphates. Next the forming deposit is mineralised in muffle furnace to ashes and beta radioactive nuclide of ashes is measured with system with proportional flow counter.

The method of determining the total alpha emitters in urine consist of co-precipitation with calcium phosphate. After mineralization of deposit, the hydrolysis is carried out. Alpha emitters are reduced by sodium sulfite and adsorbed on glass filter. Alpha emitters are eluted from filter by using hydrochloric acid, then sample is evaporated to dryness and after dissolving in nitric acid, sample is transferred to measuring plate. The measurement of deposit activity is made with the proportional flow counter.

The measurements of activity of ^{35}S, ^{32}P, ^{14}C, ^{3}H and ^{90}Sr and total alpha and beta activity in urine are required in order to estimate the value of effective dose.

All measurements data are recorded in special data base and information about registered effective doses are send to National Atomic Energy Agency.

Intercomparisons

As accredited laboratory LPD shall validate developed methods to confirm that the methods are fit for the intended use. One of the techniques which can be used for the determination of the performance of a method is interlaboratory comparison.

Each year LPD participates in international comparison of *in vitro* measurements organised by French association PROCORAD (Association for the Promotion of Quality Control in Radiotoxicological Analysis).

Unfortunately LPD is the only one Polish laboratory which is accredited in whole body measurements and one of two accredited in thyroid measurements (the second is Central Laboratory for Radiological Protection (CLOR)). This is the reason why the national comparisons of *in vivo* measurements are not organized in Poland.

The last international comparison in which LPD was participated was organised in 2002 by International Atomic Energy Agency. The results of this comparison have not been published until now.

LPD organized comparison for thyroid measurements for two laboratories – itself and CLOR in 2008.The measurements has been performed for two thyroid phantoms – LPD water thyroid phantom and RSD thyroid phantom. The results of this comparison are presented in figure 4 [Pliszczyński et al. 2008].

As it was shown, all measurements results were within the uncertainties range ± 25 % as well as for thyroid water phantom and for RSD phantom.

LPD is going to participate in international comparisons organized by IRSN, France. The comparison for thyroid counters will be organized in 2011 and for whole body counters in 2012.

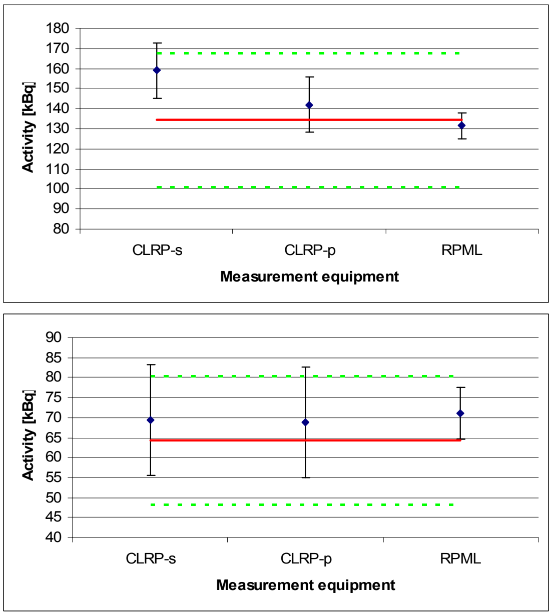

Fig. 4. The measurements results of iodine ^{131}I activity in water phantom (upper) and in RSD phantom(lower). The solid red line represents the standard sample's activity and the dashed lines – the probable error ± 25 % [Pliszczyński et al. 2008].

Measurements results in 2008

The monitoring of internal occupational exposure in 2008 contained:

- 378 measurements with whole body counter of group of 268 persons,
- 128 measurements with thyroid counter of group of 15 persons,
- 122 *in vivo* measurements using radiochemical methods of group of 102 persons.

Occupational internal radiation contamination was registered in 185 cases. All registered radionuclides are presented in table 1.

Table 1. Occupational internal contamination registered in LPD in 2008.

Radionuclide	Measurement method	No. of Cases
^{131}I	thyroid	57
^{131}I	whole body	21
^{32}P	in vitro	5
tritium	in vitro	4
^{90}S	in vitro	2
^{35}S	in vitro	1
total beta	in vitro	95

Contamination with ^{137}Cs was registered in 53 cases. These cases are not presented in table 1 because this is not occupational contamination. ^{137}Cs is still presents in the environment in Poland after the Chernobyl accident. The activity of caesium in human body depends on place of living and diet – especially mushrooms cause the increasing of ^{137}Cs activity.

Iodine activity registered with whole body counter is not used for calculation the effective dose. These measurements are treated as preliminary. In that case patient is sent for thyroid measurement and after that effective dose is calculated.

In all 57 cases of iodine contamination using thyroid counter effective doses were higher then 0.01 mSv, in 11 of them were higher then 0.1 mSv. The highest annual dose for one person was 1.53 mSv which equals 7.65 % of annual effective dose limit for employee category A. For other persons it was below 1 mSv.

Effective dose calculated after *in vitro* measurements were higher then 1 µSv only in 4 cases. The highest registered dose was 4.83 µSv which equals 0.02 % of annual effective dose limit for employee category A.

Conclusions

Radiation Protection Measurements Laboratory provides monitoring of internal occupational exposure for a numerous group of employees from Polish nuclear sites where the sealed radiation sources are used. The level of contamination registered in 2008 was very low comparing with annual effective dose limit. The highest level was registered for employees who work in sector of radioiodine production but it was still much below the limits.

The monitoring results showed that work conditions in Polish nuclear sites are properly kept in according to principles of radiation protection. The results obtained in earlier years also confirmed this. The internal contamination is rare occurrence and even if they are registered the dose level is very low.

Designing and using a veterinary megavoltage X-ray facility

Vos, Cornelis S.[1]; Teske, Erik[2]; Lenstra, Johannes A.[2]
[1] Utrecht University, NETHERLANDS
[2] Utrecht University, Faculty of Veterinary Medicine, NETHERLANDS

Abstract
Until now cancer in companion animals is being treated in the Clinic for Companion Animals of the Faculty of Veterinary Medicine, Utrecht University, mainly by surgery and/or chemotherapy. The Faculty is currently building a megavoltage X-ray facility. In April 2010 treatment with radiotherapy using a linear accelerator will be started. The use of linacs in veterinary medicine is increasingly becoming more common and therefore the building of more structural shieldings in the near future is foreseen in Europe. The design of the structural shielding for the veterinary radiation therapy facility is based on the NCRP 151 (2007). Based on concrete, a shielding design goal (P) of 10 μSv/y, as prescribed by the national radiation control agency, a workload (W) at 1 m from the X-ray target of 17000 Gy/y (91% 6 MV and 9% 10 MV), a use factor (G) of 0.25 and an occupancy factor (T) of 0.25 for the residential environment, the primary barrier has been calculated at 150 cm concrete. The design of the maze without a special entrance door, is relative long and has multiple legs. Because of this only small companion animals (i.e. cats and dogs) can be treated. As the endpoint energy of the accelerator is below 10 MV the presence of photoneutrons and neutron capture gamma rays are disregarded. After presenting calculations of the primary and the second barrier locations, the design of the structural shielding was approved by the national state radiation control agency. Building the veterinary radiation therapy facility and purchasing the linear accelerator has been licensed in January 2009. As soon as the accelerator has been made operational, a preliminary survey shall be carried out to ensure that radiation exposures to the installation engineer and personnel near the facility do not exceed the applicable shielding design goal. Once the accelerator has been made completely operational and an initial calibration has been completed, a complete radiation survey shall be conducted.

Beta doses from handling UO_2 pellets at a nuclear fuel factory; Monte Carlo based simulations and TLD measurements

Pettersson, Håkan[1]; Ullman, Gustaf[1]; Riber Gunnarson, Anders[2]; Gårdestig, Magnus[1]
[1] Linköping University, Dept of Radiation Physics, SWEDEN
[2] Westinghouse Electric Sweden AB, SWEDEN

Abstract

Aim: The objective with this project was to establish beta radiation doses to workers (skin and eye doses) from UO_2 pellet production work in a uranium fuel factory in Sweden.

Material and methods: The beta energy spectra emitted from UO_2 pellet plates were obtained by Monte Carlo (MC) simulations using the MC-code MCNP5, yielding beta fluxes (from Pa-234m decay) at different positions and distance from the source. Also, the dose-rate distributions in soft tissue were calculated in order to obtain skin and eye lens doses. Validation of the MC-calculations were made by TL-based field measurements, where thin TL-discs of (i) LiF-PTFE; thickness 0.13 mm, and (ii) LiF-discs; TL-active thickness 0.04 mm, were used as follows: TL-discs were stacked in PMMA cylinders with a 8 mm deep hole holding the dosimeters and then exposed for 48 hours at various distances above source centre simulating workers hand and eye positions. In addition, the legal personnel badge dosimeters (LiF-discs, thickness 0.9 mm), with one closed position (3 mm plastic cover) to measure (gamma) deep dose and one open position for shallow dose, were exposed at several distances from the source. To assure good quality in the TL dose data, each dosimeter type was calibrated in beta fields from Sr-90/Y-90 at 0, 30 and 60 degrees angle of incidence at known doses (Hp(0.07) at the National Standard Laboratory at SSM in Stockholm.

Results: The MC-calculated beta dose distribution agreed well with field measurement data. Both at positions for workers hands and head/eyes, the beta radiation clearly dominate the contribution to Hp(0.07) over the gamma contribution. The badge dosimeters severely underestimate the shallow beta doses due to their location and orientation but also add dose to the closed position TL-disc which will then overestimate the deep dose. To obtain good beta dosimetry for the workers, i.e. for extremity and eye lens doses, thin TL-dosimeters (e.g. 0.13 mm thickness) in thin plastic bags are suggested.

Review of the constraints of the effective dose levels at OKG NPP

Bauréus Koch, Catrin
OKG NPP, Oskarshamn, Radiation Physics, SWEDEN

Abstract

The maximum level of the effective dose a worker that at a Swedish NPP accumulates during a year or over a five year period is regulated by the Swedish Authorities. In order to meet up to these standards, the NPP at Oskarshamn in Sweden (OKG AB), introduced constraints in the 1990s. These values were mainly based on the standards and limits set by the authorities and not so much the conditions at the NPP or up-to-date research in the field.

Recently a new electronic personal dosimeter system was introduced at OKG AB. It is now possible to determine both the effective dose and the dose rate in intervals as low as one minute and this can be followed online. It opens up for a whole set of possible evaluations, one being the trending of doses and dose rates. This is valuable information for setting our own standards regarding constraints of the effective dose/dose rate levels. The review of the constraints of the effective dose and dose rate levels at OKG AB has been carried out taking into account the trending parameters of the station, estimations given from the electronic personal dosimeter system, latest research results, PR policy at OKG AB, α-value of ALARA and limitations set by the Swedish Authorities.

Low dose radiation-induced non targeted effects – How the changing paradigm impacts radiation protection of biota?

Mothersill, Carmel; Seymour, Colin
McMaster University, Medical Physics and Applied Radiation Sciences, CANADA

Abstract

Ever since the grudging acceptance that non-targeted effects (NTE) can be measured in unirradiated cells or distant progeny of irradiated cells, the discussion has raged about the relevance of these effects for radiation protection and risk assessment. Arguments will be made in this presentation, that NTE may call into question radiation effects pillars such as the LNT model. They may also have relevance to wider mechanisms in cancer biology, population ecology and evolutionary biology concerning process of selection, the transmission of heritable traits, the relevance of “social” interactions between cells, organisms and populations and the mechanism by which cells/organisms respond rapidly to environmental stress. This presentation will also argue that a key consequence of findings in NTE biology is that at any given level of organization, from gene to ecosystem – communication of stress signals and heritability of stress adaptations provide the bridges linking one hierarchical level to the next and enable the rapid propagation of change triggered by stress at one level, resulting in change at a higher (or lower?) level. This addresses a major problem in evolutionary biology because while the molecular mechanisms of natural selection are fairly well understood a major knowledge gap exists in translating mutational drift at the level of the individual cell to natural selection at the ecological level where sociobiological factors are so important. The existence of the mechanisms discovered in the NTE field provides a glimpse of a major way that evolution could be regulated through communicated signals between cells, individuals, and populations, These control and optimize responses at the level of the population and coordinate the emergence of exquisitely tuned systems which can adapt rapidly to micro or macro environmental change. Radiation protection strategies for biota mean that an understanding of the driving mechanisms is vital.

The activities of the IAEA in developing standards on radiological protection of the environment

Proehl, Gerhard; Telleria, Diego; Louvat, Didier
International Atomic Energy Agency, Division of Radiation, Transport and Waste Safety, Vienna, AUSTRIA

Abstract

Radiological protection of the environment is an issue that has been intensively discussed for more than one decade. A great deal of progress has been made during this time regarding the capabilities: (i) of estimating the uptake of radionuclides by flora and fauna in different habitats and ecosystems; (ii) in the development of dosimetric models that allow the calculation of internal and external exposures for a wide range of terrestrial and aquatic organisms; and (iii) in investigating and analysing the effects of radiation exposures to biota.

This paper gives an overview of the IAEA's activities in this field and it describes the interactions with UNSCEAR, the ICRP and other national and international bodies and institutions with regard to the work on analysis and evaluation of exposures to flora and fauna. The current status of the discussion on the integration of environmental protection into the radiation protection system is also summarized. Results of case studies are presented that assess the radiological impact to flora and fauna due to discharges of radionuclides to terrestrial and aquatic environments.

Finally, the paper discusses the factors, assumptions and considerations that are regarded as important for risk characterisation and decision making in relation to radiation exposures to biota. It explores the remaining challenges related to the integration in regulating and controlling dischargeable waste.

Introduction

For a long time, the management of radionuclides entering the environment was in general based on the assessment and evaluation of the radiological impact to humans. However, in the last decades, with an increasing awareness of environmental issues, concerns were raised that flora and fauna might be affected by radionuclides released into the environment; it is now considered necessary to demonstrate that the environment is appropriately protected against ionizing radiation (ICRP, 2007).

Considerations on protection of the environment from ionizing radiation started in the 1960s and 1970s (IAEA, 1961, 1975, 1979; IMO, 1972), one important reason for this interest was the practice of disposing of low-level radioactive waste into the oceans.

Concerns rose that this could harm marine flora and fauna, which initiated detailed investigations on the effects of ionizing radiation to biota.

This original scientific interest has been accompanied by new and developing international policies and agreements. Important milestones were the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (London Convention) (IMO, 1972) and the Declaration of the United Nations Conference on Environment and Development of 1992 (UNCED, 1992), which stimulated the development of policies and approaches to specifically address impacts of radioactive substances on non-human species

Nevertheless, for a long time risk assessment and management of radionuclides released into the environment were based on radiological impacts to humans alone. In 1990, the International Commission on Radiological Protection (ICRP) (ICRP, 1991), the view is held that — as is also the case in the 1977 recommendations (ICRP, 1977) — the environment implicitly is afforded adequate protection by application of standards that provide for adequate protection of humans. The main problem is related to situations where man is absent or not exposed as in e.g., unpopulated areas or in the sea. In the meantime, this indirect approach is considered insufficient (e.g., Strand and Larsson, 2001) and in the most recent ICRP recommendations (ICRP 2007), the development of a framework is proposed to explicitly demonstrate radiological protection of the environment. The IAEA is following progress in this area and is exploring the need for those cases where it could be considered necessary because of an actual radiological risk, as well as the form and content of any improved international standards.

Current status

Objectives of radiation protection of the environment

The objectives of the radiation protection of humans are to avoid deterministic effects and to limit stochastic effects to individuals (e.g., IAEA, 1996; ICRP, 2007). However, the objectives for the protection of the environment are more complex. The protection of individual organisms is not an issue, approaches in environmental protection always target protection on the population and community levels. Therefore, there is a consensus that the objectives of protection of the environment are related to the conservation of species, the maintenance of biodiversity and the protection of habitats, communities and ecosystems (IAEA, 1999, 2002, 2006; ICRP, 2003, 2007, 2008).

Scientific background

Much work has been done in recent years to develop methodologies to assess and evaluate exposures to flora and fauna, taking into account both the terrestrial and aquatic environments (Figure 1). The European Union has launched two projects, FASSET and ERICA (Larsson, 2004, 2008) in order to develop a framework for assessment and evaluation of radiological impacts to biota from radionuclides discharged to, or already existing in, the environment. In 2005, the ICRP established a Committee dedicated to Protection of the Environment with the aim of setting up a framework for assessment and evaluation of exposures to biota. This work has been supported by the approaches developed during the EU projects FASSET and ERICA.

Due to the enormous variability of nature, it is impossible to take all species into account. For this purpose, within FASSET and ERICA a set of Reference Organisms has been defined representing terrestrial, freshwater and marine ecosystems. With the same intention, ICRP developed, in accordance with the system for the protection of humans from ionizing radiation, a set of 12 Reference Animals and Plants (RAPs) covering plants and animals, and different habitats (ICRP, 2008).

During these activities, models and databases were developed that allow for the:

- estimation of activity concentrations in reference organisms from measured or predicted radionuclide concentrations in soil, water or sediments;
- estimation of internal and external doses to aquatic and terrestrial; and
- setup of relationships between exposure and adverse effects to animals and plants.

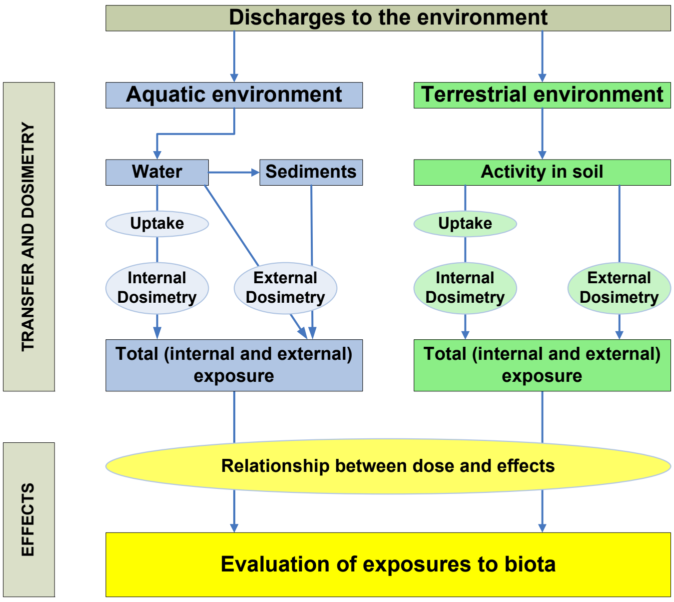

Fig. 1. Overview of the steps to estimate and evaluate exposures to biota in the aquatic and terrestrial environments.

A key issue in considerations on protection of the environment is the evaluation of exposure in relation to effects. However, whereas the objectives of the radiation protection of humans are to avoid deterministic effects and to limit stochastic effects to individuals, the objectives for the protection of the environment are related to the population and community level; as formulated in the ICRP 2007 recommendations, the targets are conservation of species, and to protect habitats, communities and ecosystems.

For this purpose, ICRP has derived a set of Derived Consideration Reference Levels (DCRL) for the 12 RAPs; which usually cover one order of magnitude (Fig. 2). The DCRLs represent bands of doses that are associated with no or very little adverse effects.

Within the EU-funded project PROTECT (Andersson et al., 2009), and on the basis of a statistical analysis of dose-effects relationships, screening levels were derived for vertebrates, invertebrates and plants of 2, 200 and 70 µGy h^{-1} respectively, and a generic screening value of 10 µGy h^{-1} was derived. Due to the approaches used during their derivation, they represent values that can be used to screen out exposure conditions of no concern. These screening values are generally in agreement with the DCRLs.

DCRLs do not represent dose limits, they should be considered as zones of doses at which a more detailed evaluation of the situation would be warranted. Therefore, DCRLs should be applied in a similar way as reference levels for existing and emergency exposure situations.

For this evaluation of the exposure conditions, factors should be taken into account as, e.g., the type of exposure situation (planned, existing, emergency), the size of area that is affected, the time period for such exposures, the fraction of a population of a species that is exposed to such dose levels, the appropriateness of the database used for the dose estimation, and the degree of precaution that is needed for the assessment.

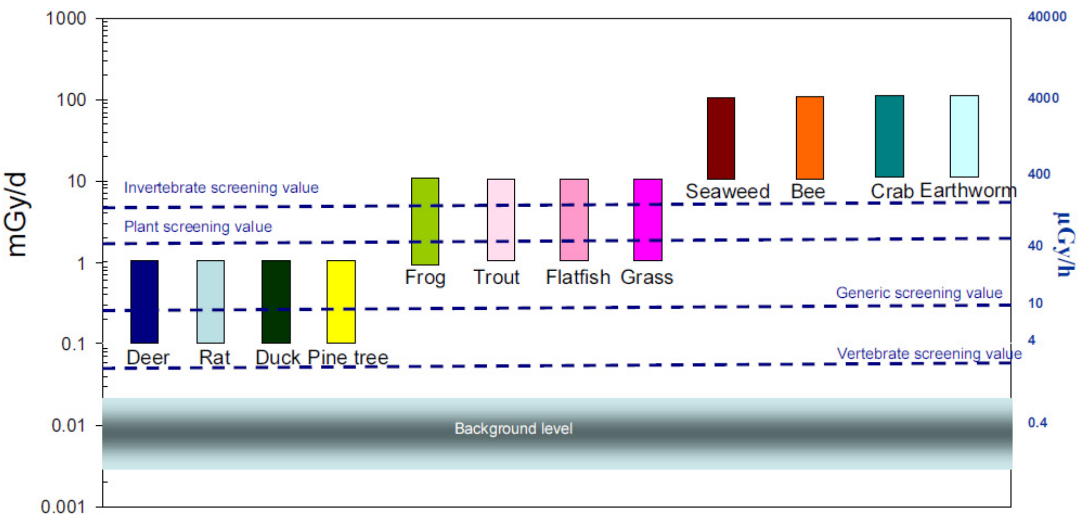

Fig. 2. Comparison of Derived Consideration Reference Levels (DCRLs) for the Reference Animals and Plants (RAPs) as proposed by the ICRP (2008). The figure also gives generic and organism-group specific screening levels as derived within the PROTECT programme for vertebrates, invertebrates and plants, respectively (compared to the generic value, there is less confidence to the organism-group specific values; Andersson et al., 2009).

Examples of exposures to biota as derived from case studies

During recent years, a number of studies were performed to estimate doses to biota under different field conditions. Some results are summarized in Table 1. It should be noted, however, that this list is not complete. The selection given is intended to cover a wide range of contamination situations. Very high exposures are only observed during the early phase of a nuclear accident as illustrated by the examples given for the Techa River, Chernobyl or Kyshtym (Kryshev et al., 1998; Sazykina et al., 1999).

Recently estimated doses to biota in the Chernobyl exclusion zone vary widely as the contaminations vary. The peak values refer to a few highly contaminated areas.

The exposure of biota in Finnish lakes contaminated by the Chernobyl fallout depends on the habitat, i.e., exposures in the water column are low, whereas organisms living on or in the sediments are still exposed at levels of a few µGy h^{-1} due to the persistent contamination of lake sediments with ^{137}Cs.

Table 1. Exposures to biota as estimated in selected studies.

Site and Year	Source of contamination	Radionuclides involved,	Organism	Exposure (µGy h^{-1})	Reference
Techa river, 1951	Nuclear weapons industry		Fish	up to-25000	Kryshev et al., (1998), Sazykina et al. (1999), Brechignac (2003)
Kyshtym, 1957/1958	Nuclear weapons industry		Pines Fish	up to 90000 up to 1000	
Chernobyl 1986	Chernobyl accident,		Pines, rodents	up to 10000	
Chernobyl exclusion zone, 2005	Chernobyl accident, 3 selected sites	^{90}Sr, ^{137}Cs, $^{239/240}$Pu, γ-dose rate=2 – 31 µGy h^{-1} ^{137}Cs in soil: 7-100 kBq kg^{-1}	Small mammals	12-810	Beresford et al, 2008
Lakes, Finland, 2003	Chernobyl fallout	^{134}Cs, ^{137}Cs, ^{90}Sr	Fish, waterplants		Vettiko and Saxen, 2008
			Water	0.03-0.85	
			Sediment surface	2-3	
Loire river, 1999	Chinon Nuclear Power Plant	^{3}H, ^{14}C, ^{131}I, $^{134/137}$Cs	Various plants and animals	$1*10^{-6}$ -$5*10^{-4}$	Berwesford and Howard, (2005)
Norway 2003	Oil and gas rigs	$^{226/228}$Ra, ^{210}Pb, ^{210}Po	Fish, molluscs, phyto- and zooplankton	$5*10^{-3}$ -$7*10^{-2}$	
La Hague, 1996	La Hague reprocessing plant	^{3}H, ^{14}C, ^{60}Co, ^{90}Sr, ^{106}Ru, $^{129/131}$I, $^{134/137}$Cs, $^{238/239/240/241}$Pu, ^{241}Am	Crustaceans, mollusks, round and flat fish, algae	0.05	Chambers et al. 2005
OSPAR region (2005)	Nuclear industry	^{3}H, ^{99}Tc, ^{137}Cs, $^{238/239}$Pu	Macroalgae, crustaceans, vertebrates	10^{-4} - 10^{-1}	OSPAR (2008)

Exposures to biota due to routine discharges of radionuclides, as reported for the Loire River and La Hague, are low. In the latter case, this is also due to strong sea currents at this part of the English Channel, i.e., within a distance of 500 m from the discharge point, the concentrations decrease by a factor of 100 000 (Chambers et al., 2005). Exposures to biota reported for the vicinity of oil and gas rigs are low. In OSPAR (2008), dose rates to marine flora and fauna were estimated; in 2005, the highest estimated dose rates due to radionuclides discharged by the nuclear industry were in the order of 0.1 µGy h^{-1}.

The results indicate that doses to biota above a level of 10 µGy h^{-1} may hardly be achieved under planned exposure situations, since those dose rates are only possible for contamination levels that do not comply with the 1 mSv a^{-1} dose limit for public exposure.

IAEA activities on the development of Safety Guides and Safety Standards in relation to protection of the environment

The IAEA has been active in this field since a long time (e.g., IAEA, 1975, 1988, 1992). One important step during the last decade refers to the Conference "Protection of the Environment from the Effects of Ionizing Radiation" which was held in Stockholm, Sweden in 2003 in cooperation with the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), the European Commission (EC) and the International Union of Radioecology (IUR). The main objective of the Conference was to stimulate the development of an international policy on the protection of the environment from the effects of ionizing radiation (IAEA, 2005).

The findings of this Conference provided the basis for the 2005 "IAEA Plan of Activities on the Radiation Protection of the Environment: An International Action Plan on the Protection of the Environment against the Detrimental Effects Attributable to Radiation Exposure". This plan was developed in cooperation with UNSCEAR, the ICRP, OECD/NEA, the EC and a number of other International organizations and was approved by the IAEA's Board of Governors and General Conference in September 2005. The Plan of Activities is targeted at:

- Fostering the cooperation of relevant international organizations in considering radiation protection of the environment;
- Supporting IAEA Members States in their efforts to protect the environment;
- Elaborating how protection of the environment may be integrated into the system of protection from adverse effects of ionizing radiation.

The main recent activities related to these issues are summarized in Table 2. An important step was achieved in 2006 when the IAEA published the Fundamental Safety Principles as these include explicitly the protection of people and the environment, present and future, against radiation risks (IAEA, 2006). It is important to note that the Fundamental Safety Principles are binding for IAEA activities and constitute a key document for the development of IAEA safety standards for protection against adverse effects of ionizing radiation.

Currently, the BSS (Basic Safety Standards for Protection against Ionizing Radiation and the Safety of Sources) (IAEA, 1996) are under revision; the current draft includes requirements that, subject to national decisions, protection of the environment needs to be taken into account during:

- registration and licensing of activities;
- setting of discharge limits for nuclear facilities; and
- optimization of existing and emergency exposure situations.

These issues will be considered in three IAEA safety guides that are currently under development:

- The first is dedicated to guidance on the application of the Fundamental Safety Principles and the requirements of the revised BSS in relation to protection of the public and environment in planned, existing and emergency exposure situations. This is essential to ensure a consistency of approaches that include an integrated consideration of the radiation protection of the public and the environment. It should be noted that the radiological impact to biota under existing and emergency situations is considered as one factor – among many others – during the optimization process, when planning remediation or mitigating actions.

- A further safety guide is under development to give detailed guidance on the assessment of the radiological impact to the environment arising from authorized discharges to terrestrial or aquatic environments. The preparation of a radiological environmental impact analysis is a key component for demonstrating radiological protection of the environment: For this purpose, a graded approach is proposed in order to ensure that the efforts dedicated to safety are commensurate with the radiation risks. The guide will facilitate the development of a standardised approach; it will promote a common understanding of the process, definitions and methodologies, and it will consider environmental aspects in all stages of the life cycle of a facility.
- Furthermore, the IAEA will integrate the requirements formulated by the Safety Fundamentals and the revised Basic Safety Standards during revision of the safety guide on the regulatory control of radioactive releases (IAEA, 2000).

These activities are accompanied by efforts to stimulate the scientific exchange on protection of the environment: In 2009, IAEA launched the programme Environmental Modelling for Radiation Safety (EMRAS II), which is intended to act as a scientific forum to stimulate model development and testing to improve capabilities for assessments of radiological impacts to the public and the environment from radioactivity in the environment. The programme is scheduled to run until 2011. A total of 9 Working Groups were setup within EMRAS II, three of which work on issues related to protection of the environment:

- Working Group 4 “Biota Modelling” focuses on testing and comparison of dosimetric and radioecological models being applied to assess exposures to biota.
- Working Group 5 “Wildlife Transfer Coefficient Handbook” focusses on the collection, analysis and evaluation of transfer parameters being used for the estimation of exposure to biota
- Working Group 6 “Biota Dose Effects Modelling” concentrates on the analysis of the effects of ionizing radiation to flora and fauna, the derivation of dose effect relationships and the impact of ionizing radiation on populations.

For many years the has IAEA advised the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (London Convention) (IMO, 1972) and the Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR Convention) on questions related to radioactivity in the marine environment and the possible radiological impact to man as well as to marine flora and fauna.

Table 2. Summary of recent IAEA activities in relation to protection of the environment.

Item	Activity	Remark
Safety Principles	Safety Fundamentals, Principle 7: “People and the environment, present and future, must be protected against radiation risks”	IAEA (2006)
Safety Standards	Draft of revised BSS: Consider Protection of the Environment during • Registration and licensing • Setting discharge limits • Optimization in existing and emergency exposure situations	Draft sent out in January 2010 to Member States for Comments
	Implement requirements related to protection of the environment as defined in the Safety Fundamentals and the new BSS in new Safety Standards on: • Regulatory Control of the Releases of Radioactive Material from Facilities and Activities • Radiological Environmental Impact Analysis for Facilities and Activities • Radiation Protection of the Public and the Environment	Development initiated in 2010
Scientific Basis	EMRAS: Environmental Modelling for Radiation Safety:	
	• EMRAS I (2003-2007), working group on ○ Model validation for biota dose assessment	http://www-ns.iaea.org/projects/emras/
	• EMRAS II (2009-2011): working groups on ○ "Biota Modelling" ○ "Wildlife Transfer Coefficient" Handbook ○ Biota "Dose Effects Modelling"	http://www-ns.iaea.org/projects/emras/emras2/
Advisory Work	Giving advice in questions related to radioactivity in the oceans and resulting exposures to man and biota to: • Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (London Convention) • Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR Convention)	

The development of safety standards as specified above requires the integration of issues related to environmental protection into the system for radiation protection of humans. A scheme of an approach for protection of humans and the environment is shown in Figure 3. For all three exposure situations (planned, existing and emergency) the assessment of exposures to both humans and biota start with the radionuclide concentrations in the environment. Exposures are calculated for reference persons and reference animals and plants respectively. Decisions needing to be made in relation to human exposure are guided by comparison with dose limits and constraints for planned exposures and with reference levels for existing and emergency exposure situations. Exposures to biota may be evaluated by comparison with Derived Consideration Reference Levels (DCRLs), taking into account the specific conditions of the exposure situations.

If the releases of radioactivity lead to exposures of the public that comply with the dose limits, it is very unlikely that there is any concern with regard to the exposure to biota at the same location. The situation is more complex if the exposure to biota needs to be evaluated for unpopulated areas. Even in such a case, the radiological impact to biota cannot be considered in isolation since on a planet with a population of nearly 7 billion people also the (unpopulated) environment is at least to some extent always part of the human habitat — or it could become so in the future — and therefore needs to be explored as a actual or potential source of exposures to humans.

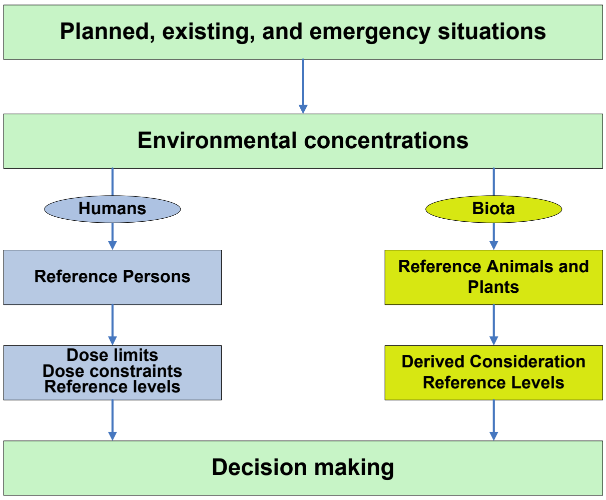

Fig. 3. Scheme for estimating and evaluating exposures to humans and biota (according to ICRP, 2008).

Discussion and conclusions

Radiological protection of the environment is a topic that has been intensively discussed in the last years. Much progress has been made on the development of methodologies to estimate exposures flora and fauna and to evaluate exposures to biota with regard to adverse effects induced by ionizing radiation. Derived Consideration Reference Levels derived by the ICRP for chronic exposure represent bands of dose that indicate the need for a detailed consideration of the exposures and its circumstances. For the most sensitive group of References Animals and Plants, this zone ranges from 4-40 µGy h^{-1}. This agrees very well a screening value of 10 µGy h^{-1} to be applied to identify exposure conditions of no concern for biota.

Doses to biota above a level of 10 µGy h^{-1} may hardly be achieved under planned exposure situations. If doses to humans and biota are assessed for the same habitat, it is difficult to imagine that conditions leading to such dose rates for biota could comply with the 1 mSv a^{-1} dose limit for public exposure.

The development and application of International Safety Standards to ensure protection of the public and environment is a key activity of the IAEA. Currently special emphasis is given to integrate issues related to environmental protection into the system for radiation protection of humans in a manner that is coherent with the ICRP Recommendations and the input of the IAEA Member States.

Dose rates to freshwater biota in Finnish lakes

Vetikko, Virve
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

In recent years there has been growing international interest in the assessment of doses and risks from ionising contaminants to biota. Incremental dose rates to biota in freshwater ecosystems in Finland mainly resulting from exposure to the Chernobyl-derived radionuclides ^{137}Cs, ^{134}Cs and ^{90}Sr were estimated using the ERICA Assessment Tool developed within the EC 6th Framework Programme. Data sets consisting of measured activity concentrations in fish, aquatic plants, lake water and sediment for three selected lakes located in a region with high ^{137}Cs deposition were applied in the assessment. The selected lakes are among those having the highest activity concentrations found in Finland and therefore represent the highest exposure to biota in freshwater ecosystems affected by the Chernobyl fallout. The dose rates to most species studied were clearly below the screening level of 10 μGy h^{-1}, indicating no significant impact of the Chernobyl fallout on these species. However, the possibility of higher dose rates to certain species living on or in the bottom sediment cannot be excluded based on this assessment. In addition, dose rates from ^{210}Pb and ^{210}Po to selected organisms were calculated. Dose rates from these radionuclides were negligible in comparison with the screening level. In the ERICA Tool the parameter "occupancy factor", defining the fraction of time the studied organism spends in a given habitat, can have a considerable impact on the dose rate estimates. The values set for this parameter should be as realistic as possible with respect to the use of the habitat of the studied organisms.

Introduction

In recent years there has been growing international interest in the assessment of doses and risks from ionising contaminants to biota (Andersson et al. 2008; ICRP 2003, 2007, 2009; Larsson 2008). Several models are now available that enable the assessment of radiological risk to biota (Beresford et al. 2008a; Vives I Battle et al. 2007). In this study one of the models, the ERICA Assessment Tool (Brown et al. 2008), was applied to estimate dose rates to biota in freshwater ecosystems in Finland.

The ERICA Tool allows the estimation of dose rates for terrestrial, freshwater and marine ecosystems for a set of default reference organisms or, alternatively, user-defined organisms. The Tool includes databases on radionuclide transfer (Beresford et al. 2008b; Hosseini et al. 2008) and dose conversion coefficients (Ulanovsky et al.

2008) enabling dose calculation to be performed from input data on radionuclide concentrations in biota and/or environmental media such as soil or water.

The aim of this assessment was to estimate incremental dose rates to biota from the late 1980s to the 2000s, as affected by the Chernobyl fallout in 1986. In addition, dose rates from ^{210}Pb and ^{210}Po to selected organisms were calculated.

Material and methods

Study sites and the data

Selection and characterisation of the study sites have been described in Vetikko and Saxén (2010). Existing data sets consisting of measured activity concentrations of ^{137}Cs, ^{134}Cs and ^{90}Sr in fish, aquatic plants, lake water and sediment for three selected lakes located in a region with high ^{137}Cs deposition were applied in the assessment. The selected lakes Päijänne, Siikajärvi and Vehkajärvi are among those having the highest activity concentrations found in Finland and therefore represent the highest exposure to biota in freshwater ecosystems affected by the Chernobyl fallout. Sampling, sample treatment and analyses of the different sample types have been described in Saxén et al. (1996) and Saxén and Ilus (2008). Activity concentrations of ^{137}Cs, ^{134}Cs and ^{90}Sr in perch (*Perca fluviatilis*), pike (*Esox lucius*), bream (*Abramis brama*), lake water and sediment for Lake Päijänne are presented in Table 1. For Lakes Siikajärvi and Vehkajärvi, activity concentrations of ^{137}Cs in perch, pike, water horsetail (*Equisetum fluviatile*), water lily (*Nymphaea candida*), yellow water lily (*Nuphar lutea*), lake water and sediment are provided in Table 2.

The mean activity concentration of ^{210}Po in lake water collected in 2007 from several lakes was 0.0019 Bq kg^{-1} and that of ^{210}Pb 0.0032 Bq kg^{-1}. The corresponding activity concentrations in roach (*Rutilus rutilus*) sampled in 2005 from Lake Päijänne were 1.45 Bq kg^{-1} f.w. for ^{210}Po and 0.24 Bq kg^{-1} f.w. for ^{210}Pb.

Application of the ERICA Assessment Tool

The ERICA Assessment Tool, version 1.0 (April 2008, available from: http://www.project.facilia.se/erica/download.html) was used for estimating dose rates to biota. The ERICA Tool allows the input of site-specific measured activity concentrations in biota and/or environmental media at Tiers 2 and 3 of the three tiers in the model (Brown et al. 2008). In this assessment Tier 2 was used. Best estimate values of measured activity concentrations in biota, lake water and/or sediment were used as inputs at Tier 2, as recommended by Brown et al. (2008). For the geometries and dimensions of the biota, default reference organisms were used in the model, so that for the fish species the reference organism selected was "pelagic fish" and for aquatic plants it was "vascular plant".

In case of missing activity concentrations in sediment, the model uses concentrations in water and a distribution coefficient (Kd, L kg^{-1}) to calculate the concentrations in sediment needed for estimation of the dose rate. Default Kd values provided by the Tool were used in such cases.

The ERICA Tool contains a parameter "occupancy factor", which defines the fraction of time an organism spends in a given location in its habitat. For aquatic ecosystems, the possible locations are the water surface, water column, sediment surface and sediment. As a default in the model, the occupancy factor for vascular plants is entirely assigned to the sediment surface to maximise the dose rate (Oughton et al. 2008). For pelagic fish the default occupancy factor is 1 for the water, which means that fish only occupy the water column. In this study alternative occupancy factors were also used to provide lower and upper estimates of the dose rates.

The Tool performs dose rate calculations from the input data by applying dose conversion coefficients (µGy h^{-1} per Bq kg^{-1} fresh weight; see Ulanovsky et al. 2008) and weighting factors for various components of radiation (10 for alpha, 3 for low energy beta and 1 for beta, gamma as default). A default uncertainty factor of three at Tier 2 was used in the model to account for uncertainties in the assessment method (Oughton et al. 2008).

Table 1. Activity concentrations of ^{137}Cs, ^{134}Cs and ^{90}Sr in fish (Bq kg^{-1} fresh weight) and water (Bq l^{-1}) sampled in 1986, 1988, 1998 and in 2000 - 2006 (mean values), and in sediment (Bq kg^{-1} dry weight) sampled in 1997 from Lake Päijänne (Saxén et al. 1996). Activity concentrations in fish are for edible parts.

Sample	Sampling time	^{137}Cs	^{134}Cs	^{90}Sr
Perch	August 1986	1700	870	5.5
	December 1986	2200	1070	5.5
	1988	2250	625	5.5
	1998	346	-	-
	2000 - 2006	270	-	-
Pike	August 1986	970	500	0.27
	December 1986	1600	720	0.27
	1988	4100	1300	0.5
	1998	376	-	-
	2000 - 2006	250	-	-
Bream	August 1986	1400	660	5.0
	December 1986	1800	900	5.0
	1988	1080	310	5.0
	1998	212	-	-
	2000 - 2006	110	-	-
Water	August 1986	1.65	0.77	0.024
	December 1986	0.6	0.2	0.02
	1988	0.322	0.089	0.017
	1998	0.05	-	-
	2000 - 2006	0.025	-	-
Sediment	1997	18 530	-	-

At Tier 2 the results are given as total, internal and external weighted whole body absorbed dose rates (Brown et al. 2008). The total (internal and external summed) dose rates are compared directly to the selected screening dose rate to enable assessment of the risk to biota from ionising radiation (Brown et al. 2008). A default screening dose rate of 10 µGy h^{-1} provided by the Tool and suggested by Andersson et al. (2008), Beresford et al. (2007) and Garnier-Laplace et al. (2008) was used in the model.

Table 2. Activity concentrations of ^{137}Cs in fish and aquatic plants (Bq kg^{-1} fresh weight), in water (Bq l^{-1}) and in sediment (Bq kg^{-1} dry weight) sampled from Lakes Siikajärvi and Vehkajärvi (Saxén and Ilus 2008). Activity concentrations in fish are for edible parts.

Lake	Sample	Year of sampling	^{137}Cs
Siikajärvi	Perch	2003	4710
	Pike	2003	3610

	Water	1998	0.332
		2002 - 2003	0.304
	Sediment	2003	18 396

Results and discussion

Dose rates from ^{137}Cs, ^{134}Cs and ^{90}Sr to perch in Lake Päijänne varied from 0.05 to 0.6 µGy h^{-1} (Vetikko and Saxén 2010). For pike the dose rates were between 0.05 and 1 µGy h^{-1}(Vetikko and Saxén 2010). The maximal dose rate for perch was observed in December 1986, followed by a small decrease in 1988, and declined to one tenth in 1998 and in the 2000s (Figure 1). For pike the maximal dose rate was shown in 1988, followed by a decline to a level almost two orders of magnitude lower in 1998 and in the 2000s (Figure 1). This temporal variation in the dose rates was associated with the changes in the activity concentrations in fish and water from August 1986 to the 2000s. The missing contributions of ^{134}Cs and ^{90}Sr to the dose rates in 1998 and from 2000 to 2006 may also have influenced the lower dose rates then observed.

For bream in Lake Päijänne the dose rates varied from 0.1 µGy h^{-1} in the 2000s to 15 µGy h^{-1} in August 1986 (Figure 2). The result for bream was based on activity concentrations in water and on the default Kd parameter provided by the ERICA Tool, not on measured data for the sediment surface, as the only available data on activity concentrations in sediments of Lake Päijänne were from the year 1997. Therefore a more site-specific assessment for the year 1986 was prevented and the exceeding of the screening dose rate to bream could not be confirmed.

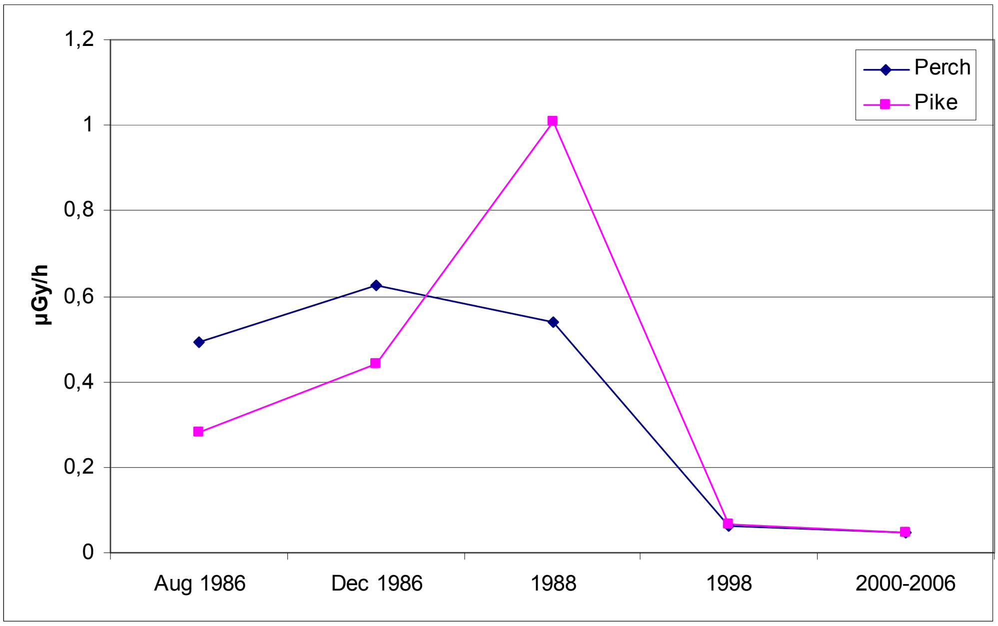

Fig. 1. Absorbed dose rate (µGy h^{-1}) from ^{137}Cs, ^{134}Cs and ^{90}Sr to perch and pike in Lake Päijänne (Assumption: Occupancy factor 1 for the water column was used for both fish species.).

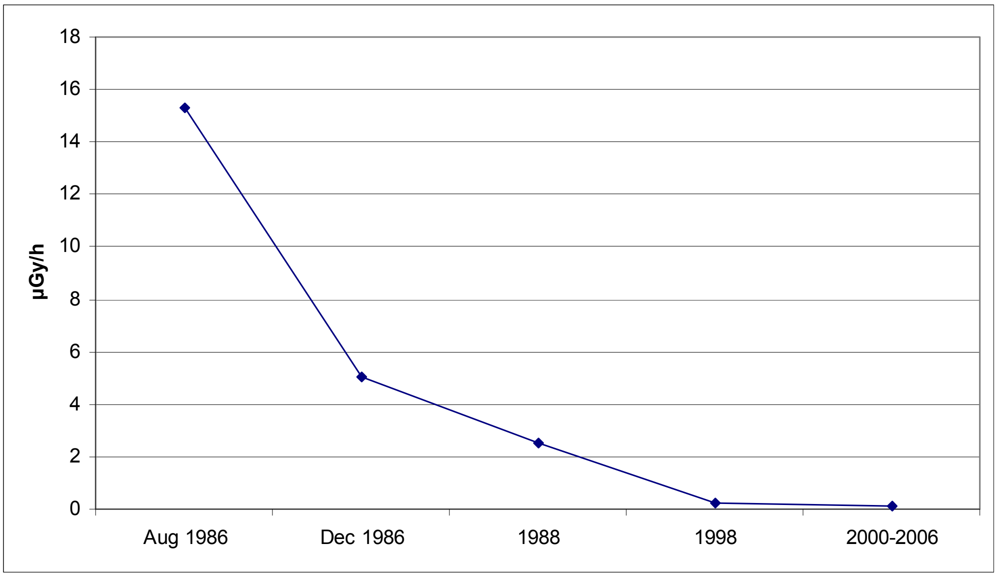

Fig. 2. Absorbed dose rate (µGy h^{-1}) from ^{137}Cs, ^{134}Cs and ^{90}Sr to bream in Lake Päijänne (Assumptions: Occupancy factor 0.8 for the water column and 0.2 for the sediment surface were used. Default values for the Kd parameter were used so that the Kd was 137 000 L kg^{-1} for Cs and 2000 L kg^{-1} for Sr.).

In the short term after the deposition, short-lived nuclides also caused a radiation dose to biota. However, this was mainly external exposure during a short period and therefore not significant for the incremental dose (Vetikko and Saxén 2010).

For perch and pike the absorbed total dose rate consisted almost entirely of the internal dose rate, whereas for bream the external dose rate was more pronounced due to exposure to radiation from the bottom sediment reflected by the parameter "occupancy factor" that for bream was assumed to have a component related to the surface sediment in addition to the water column (Table 3).

Table 3. External, internal and total dose rates (µGy h^{-1}) from ^{137}Cs, ^{134}Cs and ^{90}Sr to fish in Lake Päijänne in August and December 1986, calculated using Tier 2 of the ERICA Tool (Vetikko and Saxén 2010).

Sample	Sampling time	Occupancy factor	External dose rate	Internal dose rate	Total dose rate
Perch	August 1986	Water column = 1	1.09E-3	4.92E-1	4.93E-1
	December 1986	Water column = 1	3.32E-4	6.24E-1	6.24E-1
Pike	August 1986	Water column = 1	1.09E-3	2.80E-1	2.81E-1
	December 1986	Water column = 1	3.32E-4	4.39E-1	4.40E-1
Bream	August 1986	Water column = 0.8 Sediment surface = 0.2	1.49E1	3.94E-1	1.53E1
	December 1986	Water column = 0.8 Sediment surface = 0.2	4.54E0	5.16E-1	5.06E0

^{137}Cs accounted for 62-75% of the total dose rate to perch and pike, while 24-38% was due to ^{134}Cs (Vetikko and Saxén 2010). However, for bream ^{137}Cs accounted only for 45% in August 1986 when the contribution of ^{134}Cs to the dose was 55%. Later ^{137}Cs exceeded ^{134}Cs as a contributor to the dose. The contribution of ^{90}Sr to the dose rate of all fish species was only 0.02-0.7% (Vetikko and Saxén 2010).

Dose rate from ^{210}Po and ^{210}Pb to roach in Lake Päijänne was 0.045 µGy h^{-1} (Assumptions: Occupancy factor 1 for the water column was used.).

For Lakes Siikajärvi and Vehkajärvi, two sets of occupancy factors for fish and aquatic plants were used to provide lower and upper estimates of the dose rates (Vetikko and Saxén 2010). Dose rate from ^{137}Cs to perch in Lake Siikajärvi varied from 0.8 to 1.3 µGy h^{-1}, depending on the occupancy factor (Figure 3). For pike the dose rates were between 0.7 and 1.1 µGy h^{-1} (Figure 3). The corresponding values for perch of Lake Vehkajärvi were 0.3 and 1.6 µGy h^{-1} and those for pike 0.4 and 1.7 µGy h^{-1} (Figure 4). These dose rates were slightly higher than those for Lake Päijänne due to higher activity concentrations in fishes and water in Lakes Siikajärvi and Vehkajärvi.

The absorbed dose rate also to aquatic plants varied according to the values set for the occupancy factor (Vetikko and Saxén 2010). It should be noted that the lower values of the dose rates are based on the assumption that the whole plant is located in water, therefore excluding the exposure of roots in the sediment and resulting in unrealistically low dose rates (Figure 3, 4). The upper values of the dose rates, on the other hand, represent the maximum, whereas more realistic exposure of plants will be obtained between the two values.

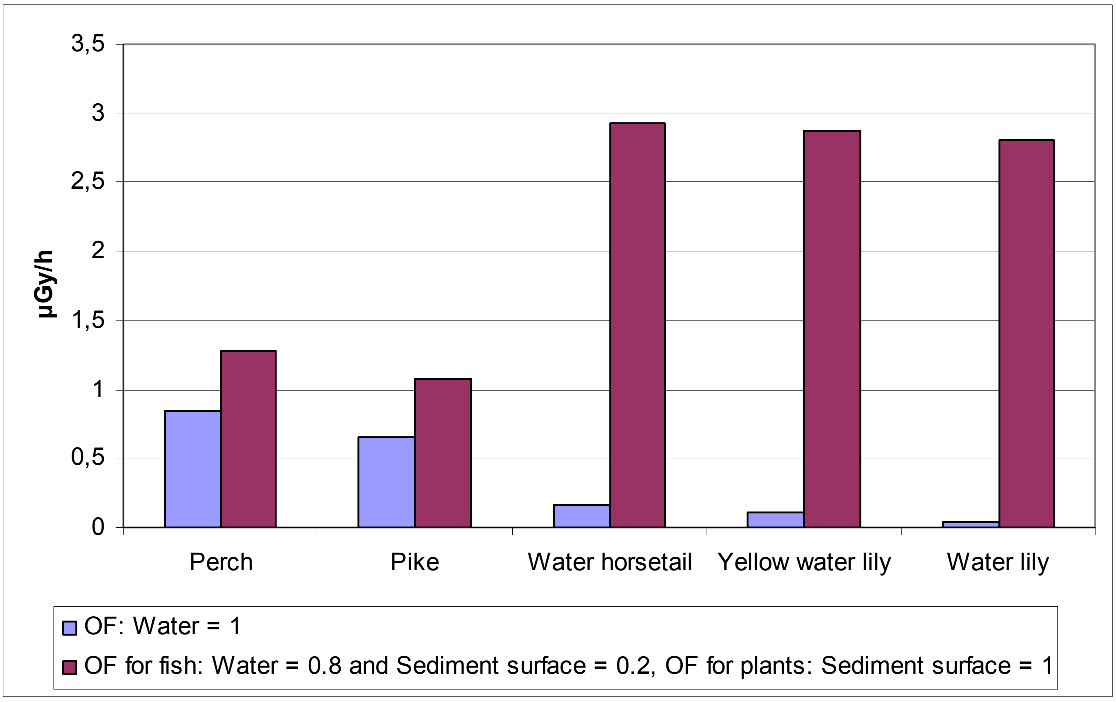

Fig. 3. Absorbed dose rate (µGy h^{-1}) from ^{137}Cs to fish and plant species in Lake Siikajärvi in 2003 (OF = occupancy factor).

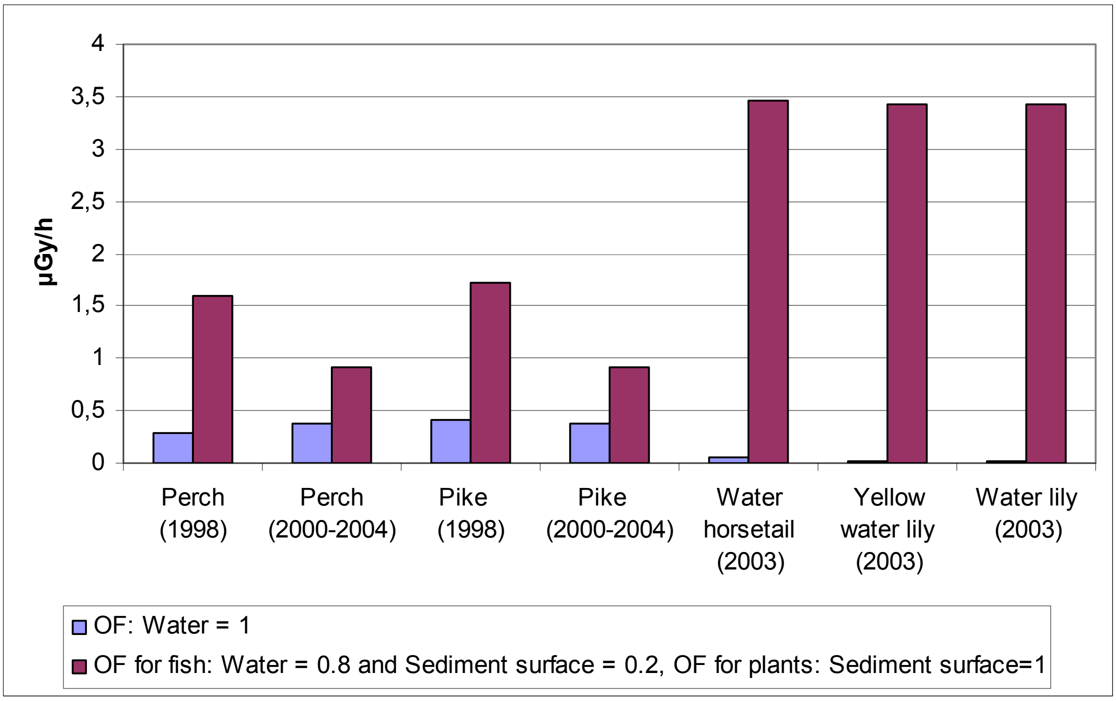

Fig. 4. Absorbed dose rate (µGy h^{-1}) from ^{137}Cs to fish and plant species in Lake Vehkajärvi (year of sampling given in brackets; OF = occupancy factor).

The roots of aquatic plants can receive higher dose rates via external exposure to contaminated sediment compared to the other plant parts located in the water column or on the water surface. For example, Nedveckaite et al. (2007) reported a ten times higher dose rate to the roots of submerged hydrophytes (0.044 μGy h^{-1}) compared to the above-sediment plant parts (0.0044 μGy h^{-1}) from ^{54}Mn, ^{60}Co, ^{137}Cs and ^{90}Sr in the cooling pond of Ignalina nuclear power plant in Lithuania.

Conclusions

The dose rates from ^{137}Cs, ^{134}Cs and ^{90}Sr to most species studied were clearly below the screening level of 10 μGy h^{-1}, indicating no significant impact of the Chernobyl fallout on these species. However, the possibility of higher dose rates to certain species living on or in the bottom sediment cannot be excluded based on this assessment.

The screening dose rate was exceeded for bream in Lake Päijänne in August 1986 due to external exposure to radiation from the sediment surface. However, the dose rate to bream did not differ from the levels of natural background radiation generally reported in the literature (see Zinger et al. 2007). This leads to the assumption that the likely risk to bream from ionising radiation in August 1986 was also minimal.

In the ERICA Tool the values set for the occupancy factor can have a considerable impact on the dose rate. The occupancy factors should be as realistic as possible with respect to the use of the habitat of the studied organisms.

Abstract
An assessment of the state of plant and animal populations inhabiting polluted territories and the analysis of mechanisms of their adaptation to adverse environmental conditions undoubtedly have general biological importance. Consequently, studies that examine biological effects on non-human biota in natural settings provide a unique opportunity for obtaining information about the potential biological hazard associated with radioactive contamination. Nevertheless, up to now there is a distinct lack of quantitative data on the real long-term biological consequences of chronic radiation exposure lasting a long period of time. Actually, few studies exist that are directly relevant to understanding the responses of plant and animal populations to radioactive substances in their natural environment. The results of long-term field experiments in the Bryansk Region affected by the Chernobyl accident and in the Semipalatinsk Test Site, Kazakhstan that have been carried out on different species of plants are discussed. Although radionuclides cause primary damage at the molecular level, there are emergent effects at the level of populations, non-predictable solely from knowledge of elementary mechanisms of the pollutants' influence. Plant populations growing in areas with relatively low levels of pollution are characterized by the increased level of both cytogenetic disturbances and genetic diversity. Radioactive contamination of the plants environment activates genetic mechanisms, changing a population's resistance to exposure. However, in different radioecological situations, genetic adaptation to extreme edaphic conditions in plant populations could be achieved with different rates.

Introduction
The majority of abiotic stress studies performed under controlled laboratory conditions does not reflect the actual situations that occur in the field. Therefore, to understand effects of contaminant exposure properly we must pay attention to what is actually going on in natural conditions. Field studies are particularly useful for assessing long-term biological effects induced by chronic low dose-rate and multi-pollutant exposure at contaminated sites. Although radionuclides and heavy metals cause primary damage at the molecular level, there are emergent effects at the level of populations that are not predictable solely from knowledge of elementary mechanisms of the pollutants'

influence. Up to now we have known little about responses of plant and animal populations to environmental pollutants in their natural environments. These data gaps imply that the protection of the environment from ionizing radiation will require more experimental data related to effects of chronic low-level exposure to radionuclides at the population level. Previously completed and ongoing field studies that have been carried out in Laboratory of Plant Ecotoxicology, RIARAE in different species of wild and agricultural plants are briefly summarized in Table 1. A wide range of radioecological situations and climatic zones have been covered in frames of this work. To illustrate the main findings, two field studies are discussed here in more detail.

Table 1. Field studies on wild and agricultural plants.

Species	Site & Time	Assay and/or endpoints
Winter rye and wheat, spring barley and oats	10-km ChNPP zone (12-454 MBq/m^2), Ukraine, 1986-1989	Morphological indices of seeds viability, cytogenetic disturbances in intercalary seedling root meristem (Geras'kin et al. 2003a)
Scots pine, couch-grass	30-km ChNPP zone (2.5-27 μGy/h), Ukraine, 1995	Cytogenetic disturbances in seedling root meristem (Geras'kin et al. 2003b)
Scots pine	Radioactive waste storage facility, Leningrad Region, Russia, 1997-2002	Cytogenetic disturbances in needle and seedling root meristems (Geras'kin et al. 2005)
Scots pine	Bryansk Region radioactively contaminated in the Chernobyl accident (0.6-3.5 μGy/h), Russia, 2003-2009	Cytogenetic disturbances in seedling root meristem, enzymatic loci polymorphism, abortive seeds (Geras'kin et al. 2008; Geras'kin et al. 2009a)
Crested hairgrass	Semipalatinsk Test Site (0.7-36 μGy/h), Kazakhstan, 2005-2008	Cytogenetic disturbances in coleoptiles of germinated seeds (Geras'kin et al. 2009b)

Material and methods

In 2005-2008 seeds of crested hairgrass (*Koeleria gracilis* Pers.) were collected from six sites of the Semipalatinsk Test Site (Kazakhstan). Radiation background at the sites and specific activity of the main dose-forming radionuclides in soil samples were measured. Doses to generative organs of crested hairgrass were calculated. Squashed slides for cytogenetic analysis were prepared of coleoptiles (2-5 mm in length) of germinated seeds. In every slide, all ana-telophase cells (4800-11900 ana-telophases in 30-90 slides) were scored to calculate frequency of aberrant cells. Detailed description of methods used is given in (Geras'kin et al. 2009b).

To study biological effects in Scots pine (*Pinus sylvestris* L.) populations experiencing chronic radiation exposure, six test sites were chosen in the Bryansk region radioactively contaminated as a result of the Chernobyl accident. Pine cones were collected in autumns of 2003-2007. Specific activities of radionuclides in soil samples were measured, and doses to the pine trees' generative organs were estimated. Aberrant cells were scored in root meristem of germinated seeds in ana-telophases of the first mitosis. The method of isozymic analysis of megagametophytes was used for an estimation of genetic variability in populations of Scots pine. Five enzymatic loci (GDH, LAP, MDH, DIA, and 6-PGD) were studied in endosperms of the seeds collected in 2005. Detailed description of materials and methods used can be found in (Geras'kin et al. 2008; Geras'kin et al. 2009a).

Results and discussion

In the Semipalatinsk Test Site (STS), 116 atmospheric and ground-surface explosions for nuclear and hydrogen bomb testing were carried out between 1949 and 1963. A study of crested hairgrass (*Koeleria gracilis* Pers.) populations, a typical wild crop for Kazakhstan, showed that the frequency of cytogenetic disturbances in coleoptiles of germinated seeds increases proportionally to the dose absorbed by plants (Fig. 1). The agreement between findings from four years of study (2005-2008), different in weather conditions, suggests the leading role of radioactive contamination in an occurrence of cytogenetic effects. Severe disturbances of single and double bridges as well as laggard chromosomes contribute mainly to the observed cytogenetic effect (Geras'kin et al. 2009b).

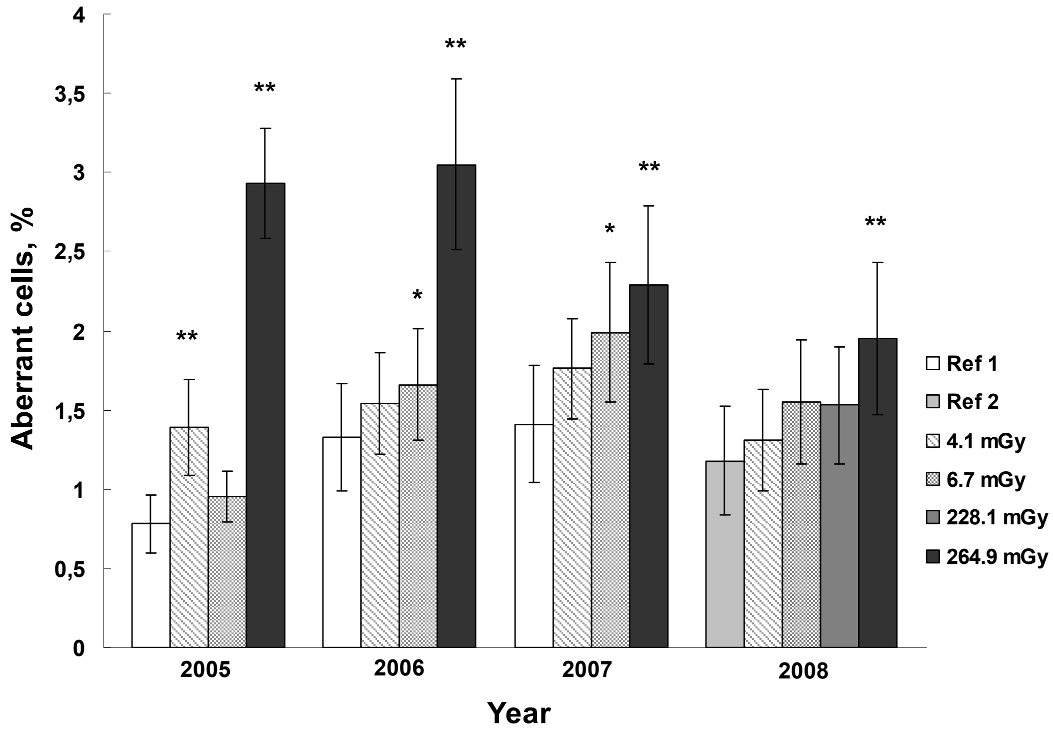

Fig. 1. Frequency of aberrant cells in coleoptiles of germinated seeds of crested hairgrass collected in the Semipalatinsk Test Site, Kazakhstan in 2005-2008 in dependence on annual dose absorbed. Ref1 and Ref2 are the reference sites in 2005-2007 and 2008, respectively. Significant difference from the corresponding reference site: * - p < 0.10; ** - p < 0.05.

Dose rate in the epicentre of nuclear tests amounts to 36 µGy/h, which is more than 3 fold of the predicted no-effect dose rate of 10 µGy/h derived in the EC ERICA project (Andersson et al. 2009). It is, however, well below the threshold for statistically significant effects (100 µGy/h) derived at the FASSET Radiation Effects Database analysis (Real et al. 2004). It is not surprising, than, that in the STS study there are found significant cytogenetic effects in crested hairgrass populations but no morphological alterations. Thus, the finding obtained are in agreement with the benchmark values proposed in the FASSET and ERICA projects to restrict radiation impact on biota.

Forest trees have gained much attention in recent years as nonclassical model eukaryotes for population, evolutionary and ecological studies (Gonzalez-Martinez et al. 2006). Because of their potential to affect many other species, any responses to selection pressures that are exerted on such keystone species as forest trees are especially important to quantify. The low domestication, large open-pollinated native populations and high sensitivity to environmental exposure make conifers almost an ideal species for the study of environmental effects of radioactive contamination.

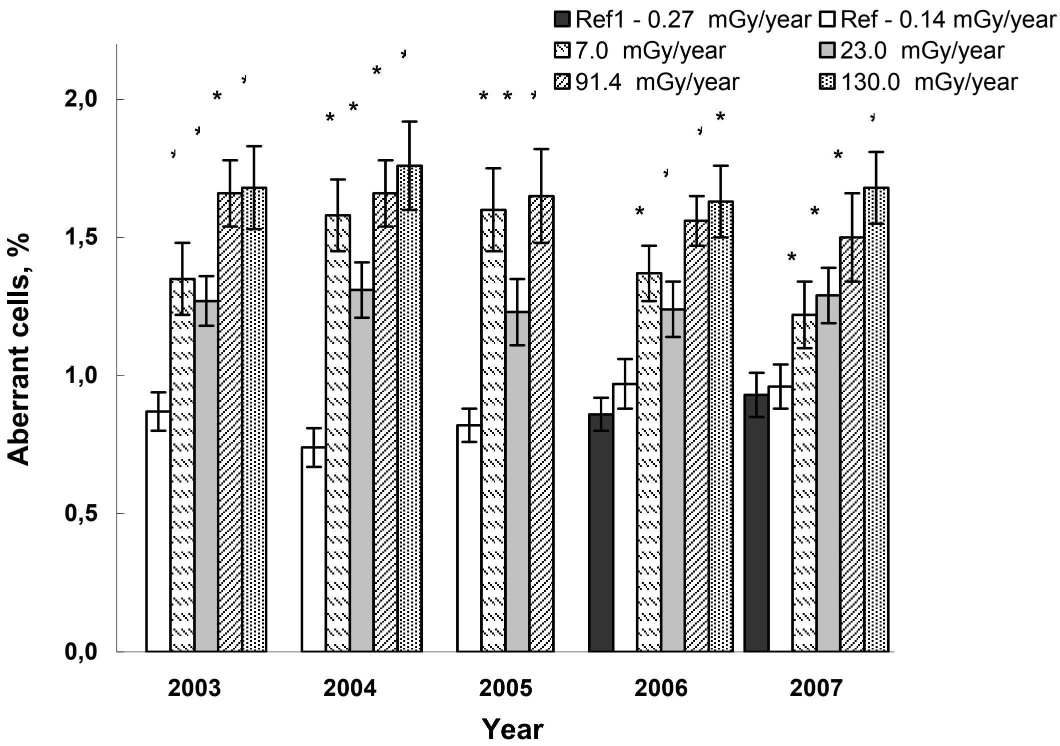

Fig. 2. Aberrant cells in root meristem of germinated seeds from Scots pine populations collected in the Bryansk Region of Russia, 2003-2007. Ref and Ref1 are the reference populations. * - significant difference from the reference populations, p < 0.05.

In Fig. 2, the 5-year results of long-term (2003-2009) study of cytogenetic effects in Scots pine populations growing in the Bryansk region radioactively contaminated as a result of the Chernobyl accident are presented. Populations under investigation have not shown any significant difference between years, so our results are robust and replicable over time. Aberrant cell frequency in root meristem of germinated seeds collected from these populations significantly exceeds reference level and shows statistically significant correlation to specific activity of ^{137}Cs, the main dose-forming radionuclide, in pine cones during all five years of study. Although there is a tendency for aberrant cells occurrence to increase with dose absorbed by the pine trees' generative organs, it is not always significant. Compiled with data from other our studies (Geras'kin et al. 2003a; Geras'kin et al. 2003b; Geras'kin et al. 2005), these findings indicate that an increased level of cytogenetic disturbances is a typical phenomenon for plant populations growing in areas with relatively low levels of pollution.

Absorbed doses in generative organs of pine trees are assessed with a dosimetric model (Fig. 2). In 22 years after the ChNPP accident, the annual doses are about thirty times below dose rate of 10 mGy/day proposed by IAEA (International… 1992) as safe for terrestrial plants. On the other hand, dose rates for two most contaminated sites are exceed the ERICA generic predicted no-effect value of 10 μGy/h (Andersson et al. 2009). From this comparison we can suppose that radiation exposure at the study sites is strong enough to induce cytogenetic but not morphologic disturbances in the exposed populations. Indeed, aberrant cell frequency in root meristem of germinated seeds collected from experimental populations significantly exceeded reference level during all five years of study (Fig. 2). It should be noted that, in the STS study, a wide range of doses from 4 to 265 mGy absorbed by the plants was studied, and dependence of cytogenetic effects on dose was revealed. On the contrary, in the Bryansk region, the range of doses absorbed by the pine trees at the study sites is much narrower; this could be the reason for an absence of statistically significant increase of biological effect with the dose absorbed in some years of observations.

It is becoming increasingly clear that cytogenetic disturbances detected in our studies might only be tip of an iceberg, reflecting global structural and functional rearrangements induced by radiation in exposed populations. An increase in mutation rate can affect the population genetic structure by producing new alleles or genotypes, and thereby has ecologically relevant effect. Alterations in the genetic make-up of populations are of primary concern because somatic changes, even if they lead to a loss of some individuals, will not be critical in populations with a large reproductive surplus. To analyze whether an exposure to radionuclides causes changes in population genetic structure, we evaluated frequencies of three different types of mutations (null allele, duplication and changing in electrophoretic mobility) of enzymatic loci in endosperm and embryos of pine trees from the studied populations. It is found that chronic radiation exposure results in the significant increase of total occurrence of enzymatic loci mutations. In particular, frequencies of mutations for loss of enzymatic activity increase with a dose absorbed by generative organs of pine trees (Fig. 3).

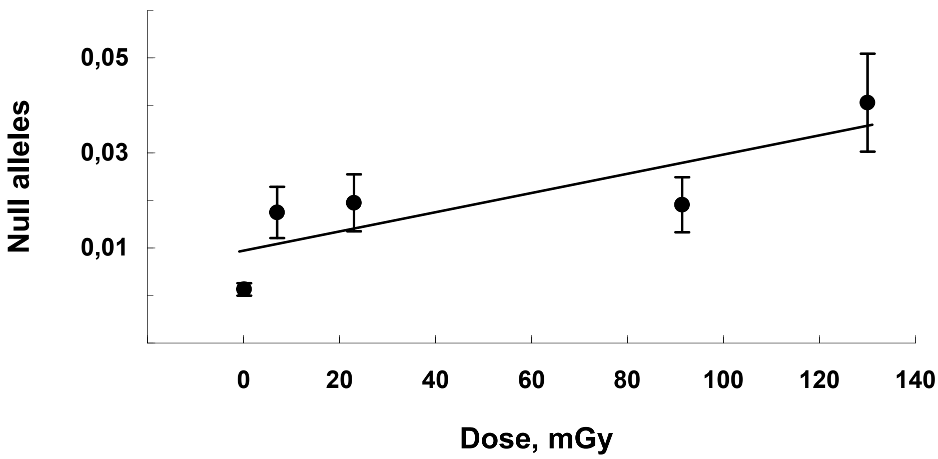

Fig. 3. Frequency of null alleles in enzymatic loci of endosperms (2005) in dependence on annual dose absorbed by generative organs of pine trees.

There are plenty of theoretical interpretations of evolution, but what is important is to see what happens in practice. Mutations in plant or animals are not necessary bad events when they do not adversely affect the population fitness. Mutation is one of the mechanisms that maintains genetic variation within a natural population and thus enables that population to cope with an adversely changing environment. Indeed, phenotypic variability in the exposed pine tree populations, estimated via Zhivotovsky index (Zhivotovsky 1980), significantly exceeds the reference level and increases with dose absorbed by generative organs of pine trees (Fig. 4).

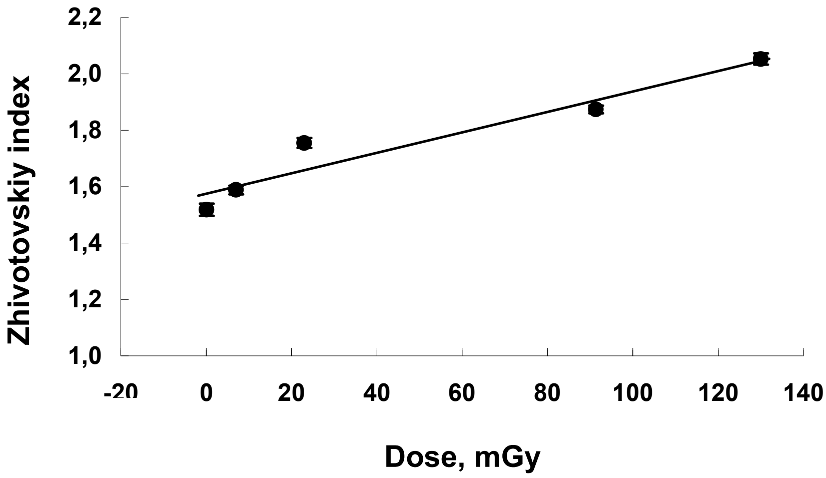

Fig. 4. Phenotypic variability estimated via the Zhivotovsky index in dependence on annual dose absorbed by generative organs of pine trees.

A decrease in heterozygosity within individuals has been associated (Theodorakis 2001) with decreased resistance to diseases, decreased growth rates, and decreased fertility. This would suggest that variations in individual heterozygosity may affect population growth and recruitment. The observed heterozygosity in pine tree populations at the radioactively contaminated sites is essentially higher then the expected one and increases with dose absorbed by generative organs of pine trees (Fig. 5).

From the data presented we can conclude that the relationship between radioactive contamination and genetic variability provides evidence of adaptation which optimizes the physiological response of a population to environmental changes. Keeping in mind all the data mentioned, it could be concluded that a high level of mutation occurrence is intrinsic for descendants of pine trees in the investigated populations, and genetic diversity in the populations is essentially conditioned by radiation exposure. So, in spite of their low values, dose rates observed can be considered as a factor able to modify genetic structure of population. Furthermore, an increased genetic diversity within the population of keystone species is likely to be positively correlated with increased species diversity of the depended community (Whitham et al. 2006).

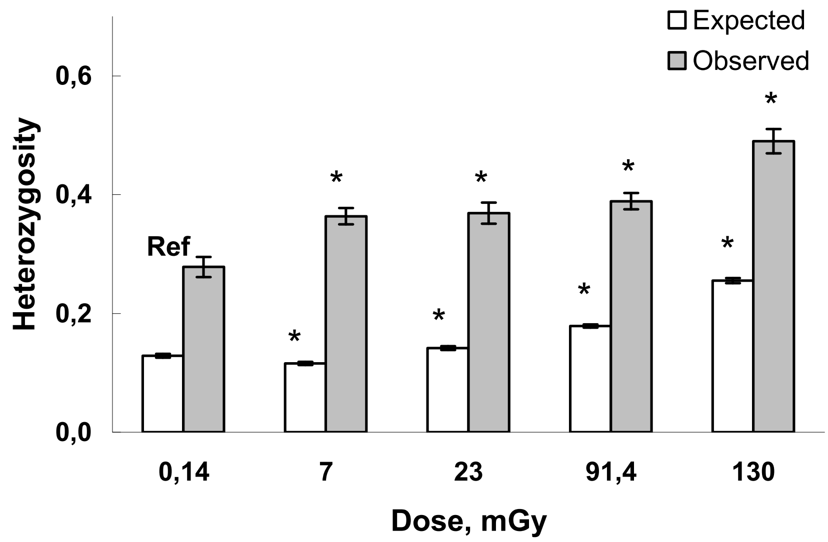

Fig. 5. Heterozygosity in endosperms of Scots pines in dependence on annual dose absorbed by generative organs of pine trees. Significant difference from the Ref population: * - p < 0.01.

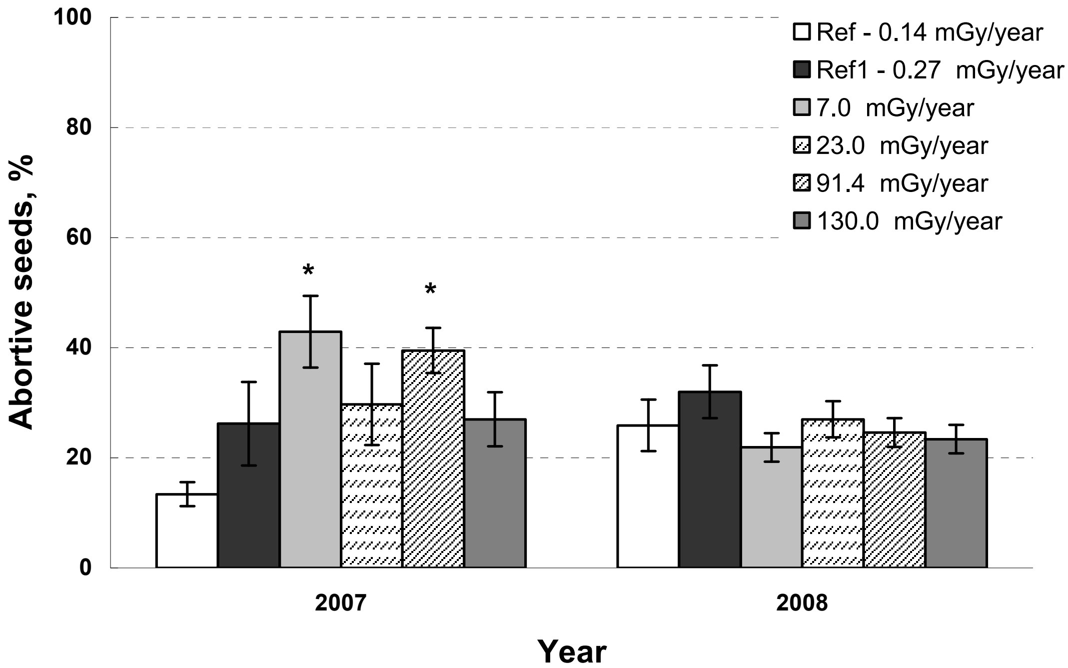

Fig. 6. Portion of abortive seeds in chronically exposed Scots pine populations. * - difference from Ref is significant, p < 0.05.

Although great progress has been made in understanding the nature of mutations, too little is yet known about the way in which mutations can lead to effects at the level of an organism and population. The effect of severe conditions on an organism is often considered to eliminate individuals. However, the alternative effect is to change the number of offspring produced by individuals without killing them. The plasticity of plants, and the fact that their reproductive organs are usually the terminal points of a branching structure, means that they tend to respond to environmental stresses by variation in reproductive rate without death. It is true that a much larger number of seeds are produced than developed into adult plants, and that the changes in frequency of the different genotypes occur due to a greater death of some genotypes than others. This is a form of response to selection, and a very powerful one (Valladares et al. 2007). From the results gathered a question arises: what could be an effect of high mutation rates revealed in our study on a reproductive potential of pine trees? From Fig. 6 it is clear that chronic exposure within the range of dose rates studied has virtually no effect on reproductive ability of pine trees from the exposed populations.

Conclusions

A basic level of concern within a newly developing system for radiological protection of the environment is a population. Of special importance in this context are studies on plant and animal populations inhabiting sites with contrasting levels and spectra of radioactive contamination. Special attention should be paid to population-level effects such as radioadaptation, changes in sexual, age and genetic structure of populations, since knowledge of elementary mechanisms of the radionuclides' impact is insufficient to predict them. Corresponding studies are likely to increase in importance as the rate at which we change the environment worldwide continues to accelerate. The findings presented here clearly indicate that plant populations growing in areas with relatively low levels of pollution are characterized by an increased level of both cytogenetic disturbances and genetic diversity. Concordant responses between changes in population genetic structure and elevated levels of cytogenetic damage provide evidence that the population genetic changes are influenced by exposure to radionuclides. Effects of contaminants on genetic diversity within a population are important because the level of genetic diversity affects a population's ability to adapt or the rate of adaptation to changes in the environment. Therefore, the amount of genetic variation within a population can influence its relative susceptibility to extinction. Finally, in spite of the wealth of information collected so far, much more still remains to be explained in order to fully understand the basis of plant populations' adaptations to a harmful environment.

Unusual damaging effects of low radiation: Model experiments with protozoa and invertebrates

Sarapultseva, E. I.[1]; Bychkovskaya, I. B.[2]

[1] Obninsk Institute for Nuclear Power Engineering of the National Research Nuclear University "MEPhI"; RUSSIAN FEDERATION

[2] Nikiforov Center of Russia World Healths, St.Petersburg, RUSSIAN FEDERATION

Abstract

The importance of peculiar disturbing effect of low radiation, observed previously by Bychkovskaya et al in protozoa and in tissues of rats (http://irbb.ucoz.ru) was studied in the model experiments on aquatic invertebrates water flea *Daphnia magna*. During these experiments we were able to show that the probability of animals' death increases even at a dose of 0.1 Gy which is a thousand times lower than predicted as lethal dose (100 Gy). The process was registered for the greater part of daphnia's lifetime. The frequency of death of irradiated animals did not increase with dose increasing from 0.1 to 20 Gy.

The negative effect of low radiation (0.01 Gy) we also observed on the aquatic unicellular ciliates *Spirostomum ambiguum*. Modal experiments of the laboratory population of *Spirostomum* showed that these protozoa are highly sensitive to gamma-irradiation by spontaneous motor activity (SMA) criterion. We observed the reliable effect of SMA decrease right after the irradiation in doses 1 sGy. It was approximately on the similar level (about 40% below control) in a broad variety of doses. These changes were mass, did not dependent on dose in a wide range and were transmitted to the descendants of irradiated cells. Changes had been inherited not only through the vegetative reproduction of organisms, but also through the sexual reproduction (water flea daphnids). Due to the fact that the cellular dose-independent effects induced by low doses were found on the different organisms (including rats), we assumed that these effects might be widespread in nature. Molecular-genetic mechanism of these changes still remains unknown; mass character and non-linear nature of these changes can not be attributed to the mutations. Generally, they can be classified as epigenetic changes which attract more and more attention.

This work is directed to the ecological problem. We have witnessed and detected the decline of the viability and functional activity of aquatic organisms in the interval of doses that are lower than considerably dangerous ones.

Introduction

In the plural studies of the subjects of various species (amoebas, ciliates, cells of different low regenerating tissue of rats) we found (Bychkovskya 1986; Bychkovskya et al 2006) the peculiar negative cellular effects of low radiation which do not fit the general concept of stochastic nature of radiation. One of the typical manifestations of these effects was the high prolonged increase of the possibility of damage and cells death compared with the control level. Unlike the widely studied genotoxic changes, these effects: i) are mass; ii) are already registered at the doses which are very low for the subjects; iii) do not increase with further increasing of radiation dose; iv) inherited; v) may be caused by exposure to the nucleus as well as the cytoplasm of cells (experiments on amoeba).

In this paper, the possibility of this unusual form of damage was confirmed in experiments conducted at new subjects – unicellular and multicellular aquatic organisms. Let's consider these materials.

Material and methods

Ciliates *Spirostomum ambiguum* Ehrbg were cultured in laboratory tubes with separated dechlarinated water at a temperature of 20±2^{0}C. The ciliates were fed nutritional yeast once a week. It is known that ciliates refer to highly radio resistant organisms. $LD_{50/30}$ is around 1000 and more of Gray (Choppin et al 1995). Spirostomum were irradiated in masscult in tubes with 6 ml of water for "Gamma-cell" radiator (Canada, ^{60}Co; 0.15 Gy/min) at doses 0.01, 0.1 and 1 Gy and "Issledovatel" radiator (Russia, ^{60}Co; 36 Gy/min) at dose 20 and 50 Gy at 28±2^{0}C as an additional negative factor. The control groups were in the same conditions as experimental, but without irradiation. The effect of irradiation was estimated by reduce the ciliates' motor activity in the experimental groups. These changes were measured immediately just after irradiation and at 2, 4 and 7 days after that. To do this, the ciliates from irradiated groups and from the control groups were placed individually in special plastic plate with holes of 5 mm in diameter and 1-2 mm in depth. Motor activity of each ciliate was observed under the microscope. At the eyepiece of the microscope were did two lines crossing each other perpendicularly. A quantitative measure of each ciliate's motor activity was the number of intersections of the lines for 1 min. It was held for 5 series of observations at each dose with coding of the samples. The effect was manifested not only in reducing the SMA of irradiated ciliates, but also in the appearance of essential disorders of motion as a function of reaction – "death prognosticators" – convulsive twitching of the body, changes in moving patterns from the normal lineal to abnormal twirling and rolling, backward movements or total body immobility. Additionally, we took in the account the number of individuals (organisms) with motion pathologies. The frequency of pathological movement forms for ciliate was measured in % of the total investigated ciliates.

In the experiments we also used aquatic invertebrates' water flea *Daphnia magna*. They were born from females of the same age and irradiated on the first day after birth. They were irradiated for 5 individuals in biological tubes with 6 ml of water for "Gamma-cell" radiator at doses 0.1 and 1 Gy and "Issledovatel" radiator at dose 20, 100, 250 and 600 Gy. Based on literature data, radiation doses around 10^2 Gy are lethal for the class Crustacea (Choppin et al 1995). Control animals were in the same conditions as experimental, but were not irradiated. Then, the control and irradiated groups were cultured in the laboratory glasses for 5 individuals per 100 ml of separated dechlarinated water at a temperature about 20±2^{0}C. Daphnia were fed algae suspension once a day at a rate of 0.1 ml (density of 600–1000 million cells per ml) per 100 ml of water. Water in the experimental and the control glasses was refreshed every week; daphnia were transferred using a plastic pipette. In these conditions daphnids' lifetime were not much longer than 3 months.

Animals' death had been checked every day for 30 days. We presented the combined data collected in the 4th (embryonic period), 14th and 30th (reproductive period) days after the irradiation. We estimated the number of surviving daphnids as % of their original number or % from control groups for the corresponding period of observations. It was held for 4 series of observations at each dose.

The reliability assessment of the experimental data was carried out by the nonparametric Fisher test.

Results and discussion

Experiments with ciliates

Consider Table 1, which demonstrated the data of ciliates' SMA in control and at various periods after γ-irradiation at doses of 0.01–50 Gy (absolute value).

Table 1. Values ciliates' SMA (in absolute value) in control and at doses of 0.01–50 Gy at various periods after γ-irradiation.

Dose, Gy \ Days	0	2	4	7
	[1]*M±m*			
0 (Control)	2.1±0.2	1.8±0.1	1.8±0.1	1.9±0.1
0.01	1.4±0.2*	1.2±0.1*	1.2±0.3*	1.3±0.1*
0.1	1.4±0.1*	1.1±0.2*	1.0±0.2*	0.8±0.2*
1	1.5±0.2*	0.9±0.2*	1.0±0.1*	1.1±0.3*
20	1.1±0.3*	1.0±0.1*	1.1±0.1*	0.9±0.1*
50	1.5±0.1*	1.0±0.1*	1.0±0.1*	0.9±0.3*

[1] In the control, in each dose and at each period studied of 60 ciliates.
*** p≤0.05**

The effect is caused by exposure to a dose of 0.01 Gy and has not run-up even with 5 thousand times dose increase. Table clearly demonstrates the detected non-linear effects of radiation and underlines the effectiveness of low doses. Figure 1 presents the data for variations in the experimental ciliates' SMA in percentage of the corresponding control with standard deviation for the percentages at various periods after irradiation.

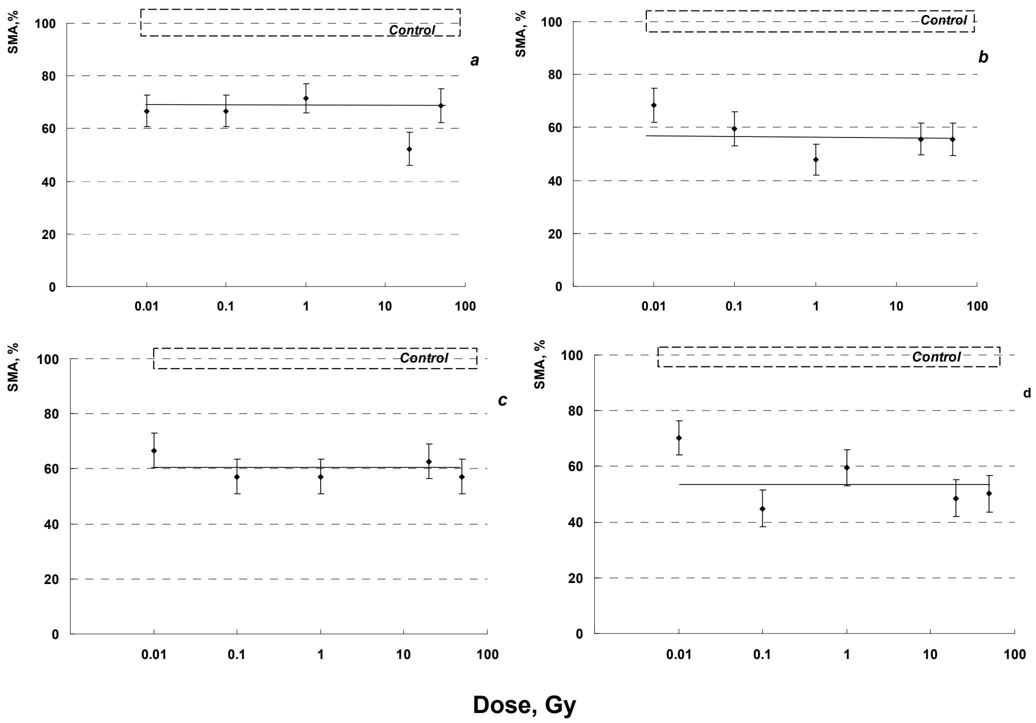

Fig. 1. The changing in ciliates' SMA (in % relative to controls) after γ-irradiation at dose of 0.01-50 Gy immediately (a) and in 2 (b), 4 (c) and 7 (d) days.

Figure 1 shows that the significant decrease ($p<0.05$) in SMA is approximately the same at all times (immediately and in distant periods after exposure) and at all doses. This effect already taken place by exposure at 0.01 Gy. The effect was recorded on the 7th days after irradiation. During that time the ciliates replaced about 3-4 generations (average length of the cell cycle was about 2 days). It follows that the effect can transmitted to descendants of irradiated cells.

The same change pattern was identified while we calculated the frequency of occurred pathological forms. Figure 2 shows these data. If in control groups pathology occurs very rarely or never recorded; but in the experiment it is expressed at each dose. It is seen that increasing the dose does not influence the degree of damage.

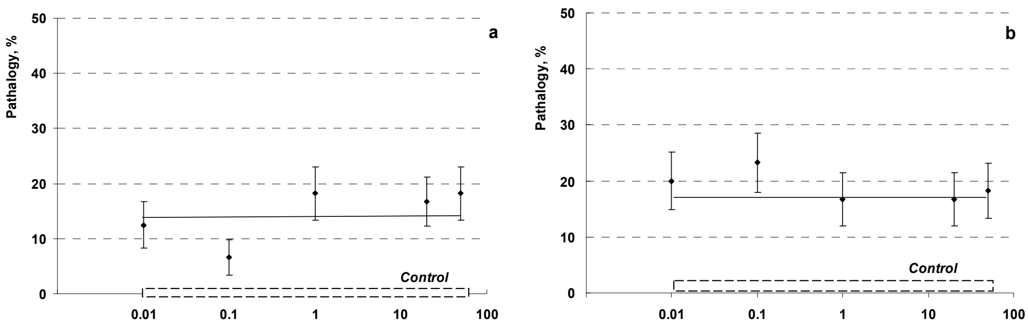

Fig. 2. The pathological forms of ciliates' movement (in %) after γ-irradiation at doses of 0.01, 0,1, 1, 20 and 50 Gy immediately (a) and in 7 (b) days.
In controls, in each dose and at each period studied for 50 ciliates.

This data shows that changes of motion function occur after low radiation and are transmitted to descendants of irradiated cells in vegetative reproduction of protozoa. We observed noticeable deviations from control group in all doses. It shows the massive nature of the changes of the described type.

Experiments with daphnids

Consider figure 3 which shows the survival of daphnia at different times in the control and after irradiation at doses from 0.1 to 600 Gy, expressed as % of the original number of animals (60 animals for each curve).

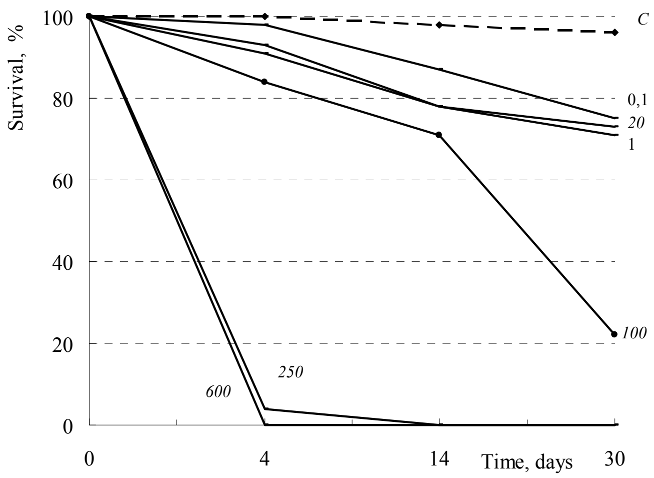

Fig. 3. Survival of daphnids during 30 days in the control (*C*) and after exposure at doses of 0.1, 1, 20, 100, 250 and 600 Gy in % of their original number (60).

There are 4 categories of curves which respectively show the evidence of the daphnids viability in the control (*C*) and after irradiation at doses from 0.1 to 20 Gy, at 100 Gy ($LD_{80/30}$) and at absolutely lethal doses – 250 and 600 Gy ($LD_{100/16}$ and $LD_{100/4}$). Fig.3 shows that even at the lowest of doses – 0.1 Gy, as well as low for subject doses of 1 and 20 Gy there is a marked deviation from control. The effect does not increase with increasing dose in this dose range and by the end of the period of observation at all doses the effect is about 20%. At the same time, unlike the actions in higher doses, there is a constant extension in the time of the death of individuals, rather than the death of the population in the relatively early time.

In the follow up experiments we studied the changes of daphnids' survival on the 30th day because the maximum differences from the control after the irradiation in relatively low doses were achieved at that time. In these experiments we discovered the possibility of inheritance of the studied forms of damage in the descendants of irradiated animal. Figure 4a shows the evaluation of survival of daphnids-parents at 30th day after the irradiation at doses of 0.1, 1 and 20 Gy.

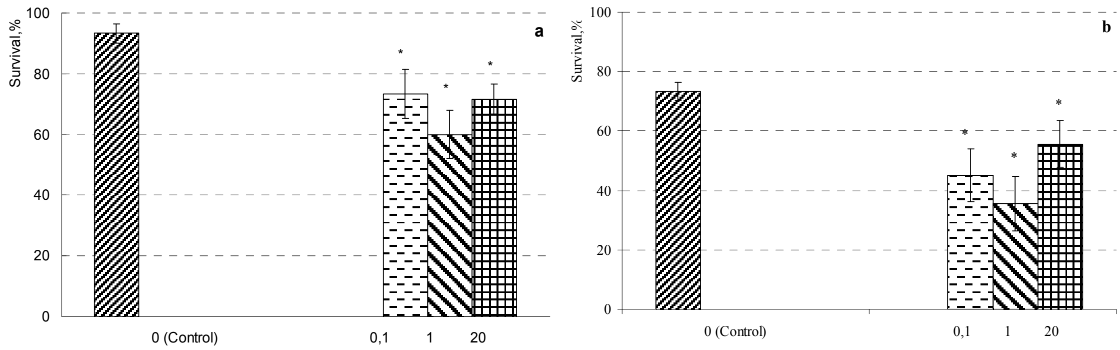

Fig. 4. The survival of daphnids-parents (a) and daphnids-descendants F_1 (b), % of the original number of the 30th day of observation with a standard error at p <0,05.
In experiments (a) up to 60 and in experiments (b) up to 45 animals in each dose and in the control.

In these experiments, we see almost the same results as in the first case (fig.3). The survival of daphnids-parents, irradiated at low for the subject doses (including 0.1 Gy), is significantly lower than in the control, and the effect does not increase even with a very large increase in radiation exposure (at 200 times).

These results enabled us to proceed to study the viability of the 1st generation offspring born from the daphnids-irradiated. The data is presented in Figure 4b. Likewise, we see that in this case the survival of experimental animals is lower than in control, and that the effect does not increase with the increasing doses.

Significant deviations from control observed for daphnids-parents and for unexposed descendants of the first generation show the mass nature of the disruption of the described type. However, we haven't seen valid deviations between control and experimental groups for second and third generations of daphnids.

Conclusions

Similar dose-independent inheritable mass damage was found in different species after low radiation. The results support the idea of the universal nature of this unusual form of reaction (Bychkovskaya 1986, Bychkovskaya I.B. et al 2006). Innovative materials are obtained showing that the phenomenon can manifest itself in violation of important physiological functions (experiments on ciliates) (Sarapultseva 2008) and on the organism level of integration (experiments on daphnids) (Sarapultseva et al 2009). In the experiments on daphnids the inheritance of the effect in F_1 confirmed previously observed effect on rats (Bychkovskaya et al 2006). It also showed the elimination of damage in subsequent generations.

The features of this effect, including unusual for radiobiology dose-independent character, cannot be related to mutations. In general this phenomenon can be related to a category of epigenomic alterations (Jablonka et al 2008).

This research can be applied to the low radiation risks' assessment.

Abstract

Arctic and boreal regions are often considered to be vulnerable to exposures from contaminants and therefore merit special attention in relation to the application of environmental impact assessment methodologies. The INTRANOR project has focussed specifically on environmental assessments for radiation exposure through application of existing methodologies and their adaptation to quantify transfer, exposure and effects in Boreal/Arctic ecosystems. Non-parametric statistical methods have been applied in order to estimate the threshold dose rates above which radiation effects can be expected in vertebrate organisms. The effects considered in the analyses include morbidity, reproduction, and life shortening and the approach has drawn upon data collations pertaining to databases on effects of chronic low-LET radiation exposure. In addition, industrial areas contaminated by uranium mill tailings and radium production wastes, in the Komi Republic, Russia, were selected as suitable study sites to study further the effects of exposure to radiation under boreal conditions. Dose–effect relationships have been established for natural *Vicia cracca L.* populations inhabiting this area. The various endpoints considered include chromosome aberration frequency in seedling root meristem, frequency of embryonic lethal mutation in legumes, germination of seeds and survival rate of sprouts of seeds. Analyses of data have allowed a benchmark to be established below which no decrease in reproductive capacity could be observed. Other work performed within the project includes the collation of data in relation to naturally occurring radionuclides and application of existing methodologies to characterise background radiation exposures. These dose-rates used in conjunction with dose rates known to have specific biological effects on individuals/populations may be a suitable means of contextualising the exposure attributable to enhanced dose-rates arising from human activities.

Introduction

At a European regional level, methodologies to assess the impact of exposure to ionising radiation on flora and fauna in European temperate and Arctic environments have been developed in two European collaborative projects "FASSET - Framework for Assessment of Environmental Impact" (Larsson et al., 2004) and "EPIC - Environmental Protection from Ionizing Contaminants in the Arctic" (Brown et al., 2003) respectively. These studies were superseded by the project "ERICA - Environmental Risk from Ionising Contaminants: Assessment and Management" wherein risk assessment methodologies have been developed and issues relevant to decision making in the context of the management of environmental impacts of radioactivity have been addressed (Larsson, 2008). Of particular relevance to the Arctic is the project EPIC which provides a number of the foundation stones that are prerequisite in the process of developing a robust assessment methodology. However, the development of the EPIC framework was curtailed at a point that did not incorporate risk characterisation or concomitant management options. With this in mind, the central rationale behind the INTRANOR project was to build upon the recent advances in environmental impact assessments, as detailed in the abovementioned research programmes, with focus on adapting the systems for Arctic/boreal environments, developing the risk characterisation component of the analysis and testing the assessments for actual situations. Some of the activities in the project are presented below.

Further development of Environmental Impact Assessment methodologies

The Environmental Impact Assessment methodologies outlined above are constructed around the concept of Reference organism, definitively specified in Larsson (2004) as '*a series of entities that provide a basis for the estimation of radiation dose rate to a range of organisms which are typical, or representative, of a contaminated environment. These estimates, in turn, would provide a basis for assessing the likelihood and degree of radiation effects'*. The approach was designed to be compatible with the methodology adopted by the International Commission on Radiological Protection, ICRP (2008) and as such some of the geometries that had been proposed for the ICRP's "Reference Animals and Plants" were used as defaults in the ERICA Approach. Reference organisms were defined and used for the derivation of geometric relationships between radiation sources and organisms, as well as for considerations of the dosimetry of both external and internal exposure (further discussed by Ulanovsky et al., 2008). The concept of reference organism also includes the consideration of transfer to the plant or animal and occupancy of the organism at locations within their habitat. With regards the former, this is achieved through the application of default concentration ratios, based on literature review or the use of suitable analogues or models, in order to derive body concentrations from media concentrations (e.g. see Hosseini et al., 2008). Occupancy factors, i.e. the time spent by an organism at a particular location within its habitat, have often been defined to maximise the dose-rate. A further intended use of reference organisms was that they could be used for pooling some of the effects data generated for a range of species. In addition, the selection of reference organisms was made with the intention of making it possible to address most protected species within Europe (and therefore be of applicability to envisaged requirements for environmental impact assessment). In view of the fact the ICRP are in the process of developing a data set that are references in the truest sense, the organism lists in EPIC and ERICA might be more appropriately referred to as representative organisms (Pentreath, 2009) which implies an application within site specific situations much in the same way as the ICRP suggest using the representative person with habits typical for those of a small number of (human) individuals who are most highly exposed within a given assessment.

Work conducted in the INTRANOR project has led to the conclusions that : Although the EPIC reference organism suite would seem to provide us with a reasonable starting point in selecting region-specific organisms for the estimation of doses and radiation impact on wildlife of the North, there are severe limitations in the existing organism suite. In particular, the fact that in many cases the reference data either do not exist, as is the case for freshwater reference organisms, or are few (much of the transfer data) means that it is a moot point whether they should be regarded as reference points at all. This of course is immediately mitigated if we consider the EPIC suite to be ‘representative’ (as oppose to ‘reference’) organisms. Several years of additional work leads to the clear observation that the transfer data in ERICA are far superior to those collated in EPIC and, in many cases, the EPIC data have been incorporated into the much larger ERICA datasets. Furthermore, ERICA allows derivation of transfer and exposure for a much broader suite of radionuclides and provides an indication of uncertainty for overall exposure estimates through the collation of detailed statistical information for concentration ratios. Additionally, with regards transfer there appears to be little justification, in most cases, for using smaller Arctic/boreal specific data sets in lieu of more comprehensive global data sets. In fact, following the arguments of Sheppard (2005), not drawing on larger generic data sets (as typified by ERICA) may be counter-productive. In the few named examples where studies have been undertaken to demonstrate a significant difference between Arctic/boreal and temperate data (see Brown et al., 2004a), then work should be done to provide these alternative values for use within an Environmental Impact Assessment. A cursory examination of the dosimetric models for ERICA also suggests that they may be suitably applied to the Arctic. This reflects the fact that the ERICA dosimetric models are based on highly generic organism categories, e.g. pelagic fish, bird etc. (Table 1) and it is therefore non-problematic to illustrate that such types of biota will be present in Arctic/boreal regions (and in most ecosystems for that matter).

For the sake of simplicity it seems reasonable to recommend, in relation to conducting environmental impact assessment in the Arctic, using the organism suite applied in the ERICA approach. This might be supplemented by a representative organism suite for application in the Arctic/boreal environment where this is deemed necessary. The system for performing an impact assessment for an Arctic site would therefore involve :

- the use of ICRP Reference Animals and Plants and guidance to allow, inter alia, site specific assessment to be more readily compared to other assessments.
- the use of the ERICA integrated approach (Larsson, 2008) supported by the ERICA Tool (Brown et al., 2008) to provide screening tools and generic

data sets to perform the assessment. The ERICA dataset might be regarded as providing data for 'representative organisms'. In this way the approach might be considered as a management tool to be applied for authorisations/compliance, for example, and as providing a pool of information to allow a more comprehensive assessment where clearer links can be made to (and relevant data derived for) actual species of interest

- If required, to collate and undertake a site specific investigation drawing on tools available in the ERICA Tool, e.g. defining site specific geometries and occupancy factors, conducting probabilistic model runs etc. Furthermore, site specific activity concentration and transfer data should be collated and for the transfer data Bayesian methods might be implemented in refining the information (e.g. see Barrera et al. 2007), i.e. allow the assessor to utilise the more comprehensive datasets available from ERICA in tandem with newly acquired site specific information.

Table 1. Boreal/Arctic Representative organisms for application in an Environmental Impact Assessment – from the ERICA Tool (Brown et al., 2008) - in italics within brackets = the corresponding ICRP Reference Animals and Plants, for which the ERICA Tool uses the proposed ICRP geometries as default.

Statistical analyses of dose-effects data

There have been recent efforts to derive predicted no effects dose-rates for wild-life based on the construction of species sensitivity distributions (SSD) that are in turn constructed from effective Dose-rate 10 % (EDR_{10}) data from individual experiments (Garnier-Laplace et al., 2008, Andersson et al., 2009). Although such methods are well established in the ecotoxicological sciences (see EC, 2003), their application within the field of radiological protection is relatively new and not without deliberation. One important limitation is the fact that the criteria used in the selection of appropriate data for construction of the SSD are extremely strict which results in the loss of a large dataset that may have great utility in informing the derivation of appropriate dose-rate benchmarks. For this reason, alternative methods for analysing dose-effects data have been explored within the INTRANOR project. Non-parametric statistical methods have been applied in order to estimate the threshold dose rates above which radiation effects can be expected in vertebrate organisms by Sazykina et al. (2009). The effects considered in the analyses include morbidity, reproduction, and life shortening and the approach has drawn upon data collations pertaining to databases on effects of chronic low-LET radiation exposure. Radiation thresholds dose-rates in vertebrate animals subjected to chronic low-LET exposure were estimated to be 2.1 x 10^{-4} Gy/day, 4.1 x 10^{-4} Gy/day and 1.1 x 10^{-3} Gy/day for the endpoints of morbidity, reproduction and life-shortening respectively. This means that that the generic screening value suggested by Andersson et al. (2009), based on SSD analysis corresponds to the lowest level for morbidity effects in mammals based on the non-parametric analyses of data proposed in INTRANOR by Sazykina et al. (2009). Further work may be required to establish whether additional uncertainty factors should be applied to generic benchmarks to account for the (perceived) greater sensitivity of Arctic systems to impacts of radioactivity.

Estimating the impacts of ionising radiation on natural plant populations

The work described above by Sazykina et al. (2009); Andersson et al. (2009) and others essentially involves an assimilation of data for dose-effects relationships for many different species of organism. In many cases of plants and animals this relationship between exposure and effects is poorly characterised or unknown. Many of the available data pertain to laboratory studies and there are few published data reporting the occurrence of biological effects in natural populations of plants and animals located within areas with enhanced concentrations of naturally occurring radionuclides, In this light, experiments have been conducted on herbaceous vegetation, Tufted vetch (*Vicia cracca)* within a boreal environment contaminated with radionuclides from ^{238}U and ^{232}Th decay chains to investigate the effects of different dose regimes (Evseeva et al., 2009). The following endpoints were selected in this study:

- chromosome aberration frequency in seedling root meristem,
- frequency of embryonic lethal mutation in legumes,
- germination of seeds and
- survival rate of sprouts of seeds.

The latter three parameters were selected as they reflect reproduction capacity in the studied organisms. A site near the Vodnyi settlement within the Komi Replublic was selected as a suitable field station. Detailed descriptions of the study area as well as results of previous radioecological investigations are presented by Geras'kin et al. (2007). The contamination of the site has been caused by storage of the uranium mill tailings and radium production wastes.

Doses to *V. cracca* plants from areas contaminated with radium production wastes, exceeded the natural background level (0.0007– 0.001 Gy) by a factor of 1.4–900. The main dose forming radionuclide was ^{226}Ra. The study of relationships between biological effects observed and weighted absorbed dose for *V. cracca* seeds showed that nonlinear models fit experimental data better than linear ones. The relationship between the frequency of the chromosome aberration in seedlings' root tip cells and the absorbed dose was found to be quadratic (Figure 1).

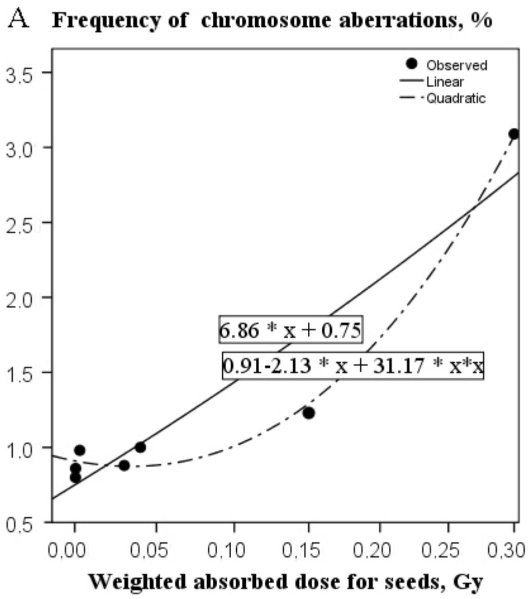

Fig. 1. Plot of models showing the relationship between chromosome aberration frequency in meristematic root tip cells of seedlings and weighted absorbed dose for seeds (From Evseeva et al., 2009).

The exponential model provided the best result in describing the empirical dependence between the absorbed dose and both the germination capacity of seeds and the survival rate of sprouts of *V. cracca*. No significant relationship (p_F>0.05) was found between the embryonic lethal mutations frequency and the absorbed dose. For *V. cracca* plants inhabiting areas contaminated with uranium mill tailings and radium production wastes, a weighted absorbed dose for the aboveground part of plants of 0.2 Gy (weighting factor for alpha particles=5) during the vegetation period (120 days) can be considered to be a level below which no increase in genetic variability and decrease in reproductive capacity is observable. Evseeva et al.(2009) essentially derive a (weighted) no observable effect dose-rate of 1.66 mGy/day (0.2 Gy over 120 days) for *V. cracca* growing over a site contaminated by enhanced levels of naturally occurring radionuclides.

Background dose rate characterisation

In helping to assess the impacts of radiation exposure on organisms, Pentreath (2002) suggested that only two reference points can be utilised in a practicable way, these being natural background dose-rates and dose-rates known to have specific biological effects on individuals/populations. Building on this, the ICRP has suggested that it would be helpful for the decision-making process if information concerning effects on biota was set out in terms of multiples of the natural background dose-rates typically experienced by each type of Reference Animals and Plants (ICRP 2008). For such a structuring of data to be made, there is clearly a requirement to provide well characterised background dose-rate estimates for the selected Reference Animals and Plants However, whilst data have been collated for terrestrial Reference Animals and

Plants (Beresford et al. 2008) information has not been collated with the express purpose of deriving background dose-rates to aquatic Reference Animals and Plants. Furthermore, there are significant limitations associated with earlier compilations of naturally occurring radionuclides in the context of deriving background dose-rates for aquatic wildlife. For example, no natural radionuclide data for European freshwater organisms were identified in the review of Brown et al. (2004b).

In light of these propositions, information on activity concentrations of naturally occurring primordial radionuclides for marine and freshwater ecosystems have been applied and appropriate dosimetry models used to derive absorbed dose-rates for Reference Animals and Plants. Although coverage of activity concentration data is comprehensive for sediment and water, few, or in some cases no, data were found for some organism groups, for most radionuclides. The activity concentrations for individual radionuclides in both organisms and their habitat often exhibit standard deviations that are substantially greater than arithmetic mean values, reflecting large variability in activity concentrations. The dominating radionuclides contributing to exposure in the Reference Animals and Plants are ^{40}K, ^{210}Po and ^{226}Ra.

The mean unweighted and weighted dose-rates for aquatic Reference Animals and Plants are in the ranges 0.07–0.39 μGy h^{-1} and 0.37–1.9 μGy h^{-1} respectively. Typical results are shown in Figure 2.

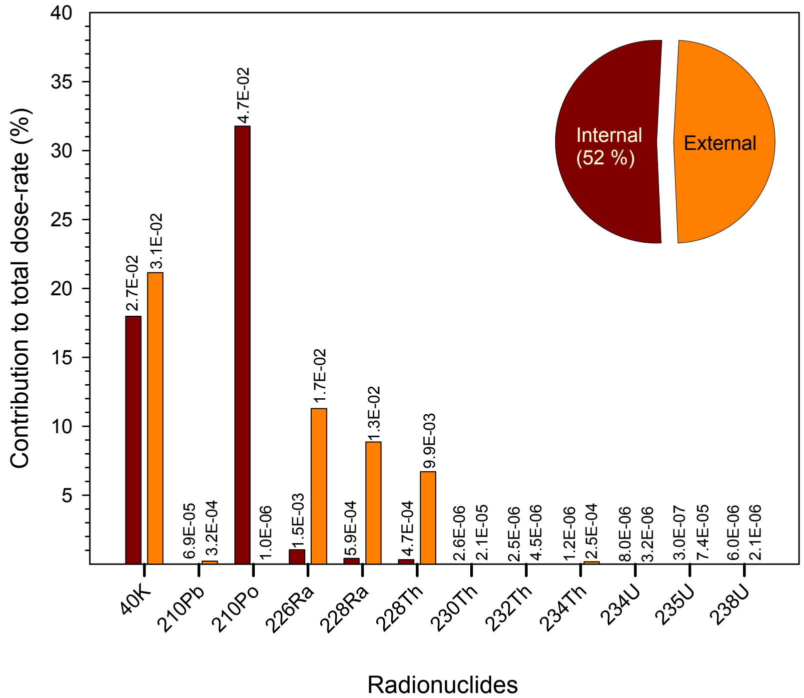

Fig. 2. Contributions of different radionuclides to internal, external and the total unweighted dose-rates for (marine) Flatfish. The vertical-orientated values are estimated internal and external dose-rates. Reproduced from Hosseini et al. (in press).

The data compiled and the dose-rates estimates in this exercise pertain to specific organism types as defined by the ICRP and are not specifically related to Arctic organisms. Further studies are required to determine the differences in exposures of boreal organisms compared to temperate organisms building on previous studies on this theme (Sazykina et al., 2003).

Conclusions

The INTRANOR project has dealt with many aspects relating to the development of a more robust methodology for assessing the impact of ionising radiation on wild-life. The general methodology itself has been reviewed with particular focus on the applicability of representative organisms in the context of boreal/Arctic systems and how these might relate to the reference animals and plants being developed by the ICRP. Dose response data from published literature has also been investigated by considering the applicability of different statistical methods in the derivation of generic benchmarks for application in protection systems. There are clearly deficiencies in relation to well characterised dose-response relationships for many organism types especially under field conditions. With this in mind, experimental studies have been conducted to investigate the dose response of herbaceous vegetation to exposures from naturally occurring radionuclides. This has allowed the shape of dose response relationship to be elucidated and information relating to no observable effects and lowest observable effects doses to be elaborated. Finally work has also been conducted in relation to the characterisation of naturally occurring radionuclides in aquatic ecosystems. By organising the data around the reference animals and plants considered by the ICRP, the data should have direct relevance as a point of reference for contextualising calculated dose-rates for any given impact assessment for ionising radiation.

Department of Environmental Science, University of Eastern Finland, Kuopio campus, P.O.Box 1627, 70211 Kuopio, FINLAND

Abstract
The use of traditional transfer factors (TF) in radioecological modelling is based on the assumption that element concentrations in plant and soil are linearly related. We tested the validity of the linearity assumption for Mo, Ni, Pb, U and Zn in boreal forest using narrow buckler fern (*Dryopteris carthusiana*) as a model plant. Higher TFs were generally found in lower soil concentrations. A non-linear function was found to explain the relationship between TF and soil concentration significantly better than the linear assumption. The use of traditional TFs may be inadequate for estimating plant concentrations, and new approaches to modelling soil-to-plant transfer are thus needed.

Introduction
In radioecological modelling, the transfer of an element from soil to plants is commonly described by an element-specific transfer factor (TF), which is defined as the plant/soil ratio of the concentration of the element (IAEA 2010). The use of these TFs is based on the assumption that soil and plant concentrations are linearly related. However, this assumption is not valid for essential elements and has also been questioned for non-essential elements (Sheppard and Sheppard 1985; Simon and Ibrahim 1987).

From experience in other fields of science, such as studies on plant nutrition and uptake of heavy metals, it s known that concentration in plants as a function of concentration in soil generally shows a steep increase at low concentrations towards a plateau at high concentrations. Several mathematical functions have been used to describe this behaviour, e.g. the Freundlich equation (Martinez-Aguirre et al. 1997; Krauss et al. 2001; Yaylah-Abanuz and Tüysüz 2009) and the Langmuir equation (Wenger et al. 2002; Han et al. 2006; Redjala et al. 2010).

In this study the soil-to-plant transfers of three essential (Mo, Ni and Zn) and two non-essential (Pb, U) elements were studied in a boreal setting using narrow buckler fern (*Dryopteris carthusiana*) as a model species. Empirical data were used investigate the relationship between plant and soil concentrations. The total element concentrations rather than radionuclide concentrations were measured in this study. Radionuclides and stable isotopes of the same element are considered to behave similarly in ecosystems, and stable isotopes can thus be used for modelling the behavior of radionuclides in the biosphere (IAEA 2010).

Material and methods

The study site was a uranium occurrence in a herb-rich forest *(Oxalis-Maianthemum* type*)* located in Nilsiä, Eastern Finland (N63°04', E27°54') (Fig 1).

Fig 1. Overall view of the study site.

The soil samples were collected from 29 systematically selected sampling points in June 2007. The topsoil was collected to the depth of 100 mm, which was considered to be the rooting depth of the understorey species, within an area of 100 mm x 100 mm. The soil samples were dried at 40 ^{o}C and sieved to diameter fractions < 2mm and > 2mm. The fraction < 2mm was used for analysis.

Plant samples were collected at the same time as soil samples. The collected plant species was narrow buckler-fern (*Dryopteris carthusiana*) which was present at 27 sampling points. The plant samples were divided into root (containing both rhizome and fine roots), petiole and leaf fractions. The plant samples were dried at 60 ^{o}C before analysis.

Inductively coupled plasma-mass spectroscopy (ICP-MS) measurements were carried out in the laboratory of Labtium Ltd. in Espoo, Finland providing pseudototal concentrations of Mo, Ni, Pb, U and Zn after nitric acid digestion (EPA 3051) in microwave oven. An estimate of mobile fraction of these elements in the soil samples was obtained by ICP-MS analyses after 1 M Ammonium acetate (NH_4Ac, buffered at pH 4.5) leach. Detection limits for Mo, Ni, Pb, U and Zn were 0.02; 0.3; 0.05; 0.01 and 0.4 mg/kg, respectively. If the concentration of an element was below detection limit the value of detection limit divided by two was used in calculations (EU 2008).

All the results were corrected to represent dry matter content (dw). TFs based on the IAEA (2010) definition for U, Mo, Ni, Pb and Zn were calculated separately for root, petiole and leaf as follows:

$TF_{t,\,p}$= concentration (dw) of Mo, Ni, Pb, U or Zn in plant part p (p= root, petiole or leaf) / total concentration (dw) of Mo, Ni, Pb, U or Zn in soil
$TF_{m,\,p}$= concentration (dw) of Mo, Ni, Pb, U or Zn in plant part p (p= root, petiole or leaf) /mobile concentration (dw) of Mo, Ni, Pb, U or Zn in soil

To investigate the relationship between TFs and soil concentrations, the data were fitted with non-linear functions. In this paper, we described results based on a Langmuir-tupe function. The Langmuir equation is of the form:

$$C_p = a\, b\, C_s / (1 + b\, C_s), \qquad (1)$$

where a and b are experimentally determined constants, C_s is the concentration in soil, and C_p is the concentration in the plant. To allow fitting with data that suggested a slowly accumulating function at high soil concentrations, we added a linear term to the Langmuir equation and got what we call the Langmuir+ equation:

$$C_p = a\, b\, C_s / (1 + b\, C_s) + c\, C_s \qquad (2)$$

To study the relationship between TF and element concentration in soil, the following equation was derived from the Langmuir+ equation:

$$TF = C_p/C_s = a\, b / (1 + b\, C_s) + c \qquad (3)$$

Results

Soil concentrations

The medians and ranges of soil total and mobile concentrations of Ni, Pb, U and Zn are shown in Table 1. For Mo the majority of measured mobile concentrations were under the detection limit and thus only the range is shown in Table 1. Zn was the most abundant of these five elements followed by Pb, Ni, U and Mo, respectively, whether soil total or mobile concentration was considered.

Table 1. Medians and ranges of total and mobile Mo, Ni, Pb, U and Zn concentrations in soil (mg kg^{-1}).

	Mo	Ni	Pb	U	Zn
Total	0.83 (0.17-32)	9.0 (4.3-26)	8.7 (5.0-120)	1.6 (0.46-110)	27 (14-74)
Mobile	<0.02-0.15	0.68 (<0.3-7.7)	2.6 (0.56-17)	0.33 (0.04-66)	3.1 (0.72-12)

Soil-to-plant transfer factors (TFs)

A trend towards higher TFs at lower soil concentrations was systematically seen in the data for both essential and non-essential elements. Data for Pb are shown as an example in Fig. 2.

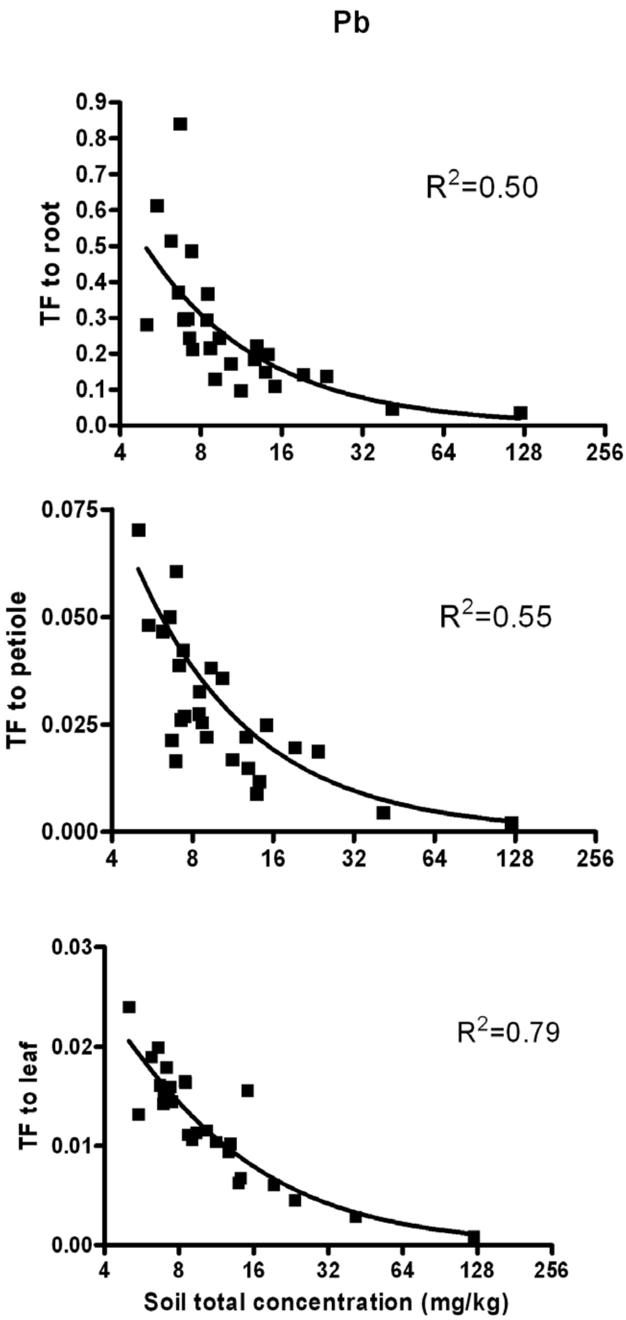

Fig. 2. TFs of Pb for different plant parts (root, petiole, leaf) as a function of soil total concentration. The line shows the fit with equation (3) (see Materials and Methods).

Non-linear and linear model

When equation (3) was fitted with the data, the goodness of fit (R^2) ranged from 7.68E-06 to 0.94 (average 0.44). The R^2-values for Pb are shown as an example in Fig. 2. In all cases the fits with the non-linear function were better than fits with linear assumption (constant TF), with produced R^2-values below 5.5E-16 (average 2.0E-17).

Discussion

Lack of linearity between soil and plant concentrations was clearly shown in this study for both essential and non-essential elements, in agreement with previous results (Sheppard & Sheppard 1985; Simon & Ibrahim 1987; Cook et al. 1994). Our results indicated that TFs are high at low soil concentrations and decrease towards a constant value at high soil concentrations. Therefore, the use of constant TFs may be justified at high soil concentrations but may lead to underestimation of plant concentrations in case of low soil concentrations (Martinez-Aguirre et al. 1997). For example, possible leaks from final disposal of spent nuclear fuel, will in all likelihood lead to low soil concentrations.

Empirically determined TFs, generally show very large variation, and published TF values therefore include a lot of uncertainty (Higley & Bytwerk 2007). Examination of the non-linear functions found in this study (Fig. 2) suggests that part of the variation (which has been traditionally assumed to be random) may in fact be systematic variation with soil concentration. Therefore, examining soil-to-plat transfer as a non-linear function might greatly improve the accuracy of predictions concerning plant concentrations.

Conclusions

The soil-to-plant transfer of both essential (Mo, Ni and Zn) and non-essential (Pb, U) elements is clearly non-linear. New approaches to model the soil-to-plant transfer are needed to improve the accuracy of model predictions.

Abstract

Posiva is implementing a deep repository for spent nuclear fuel in Olkiluoto, Finland. A site-specific safety case is being produced, and data has been acquired for the assessment models. In the dose assessment of other biota, international approaches are applied. However, determining geometry parameters for the variability of forest plants is a challenging task, not to mention coupling of the geometry to plant physiology. First, it is well known that physical dimensions of plants differ widely between plant species. Secondly, dimensions of certain plant species are dependent on growth conditions (e.g. weather, soil fertility), biological age and developmental stage of plant (e.g. many annual herbs have their highest biomass in largest extent during late summer). Furthermore, plant parts have different physiological tasks, and they should be taken into account as well (e.g. photosynthetically active green leaves compared to lignified brown stems). In this paper we illustrate problems in plant geometry using some key plant species of boreal forests and propose alternative geometries for assessment use.

Introduction

Posiva is implementing a deep repository for spent nuclear fuel in Olkiluoto, Finland. A site-specific safety case (Posiva 2008) is being produced, and data has been acquired for the assessment models (Hjerpe et al. 2010). In the dose assessment of other biota, international approaches are applied.

In all generic approaches (Copplestone et al. 2001, Brown et al. 2003, Larsson et al. 2004, Beresford et al. 2007, ICRP 2008) the basis of the dosimetric modelling is to select reference organisms that are represented by target geometry (a phantom). It has been widely acknowledged that identification of actual species or groups of species is helpful, if not even necessary, to derive the geometrical and radionuclide transport properties. However, selection of such species or group does not refer to any particular species or group of species (e.g. ICRP 2008).

Furthermore, the reference organisms can be considered to be typical of the environment "in the sense that one might expect to find them there" (ICRP 2008) or at least in the sense of being representative of the environment (Copplestone et al. 2001, Beresford et al. 2007). This is supposed to be also the meaning of the Finnish regulatory requirement to assess "typical radiation exposures" (YVL 8.4, YVL E-5).

Concerning the representatives of forest plants, roots, meristem, buds and/or seeds have been considered as the dosimetric target (Copplestone et al. 2002, Brown et al. 2003, Larsson et al. 2004), or "whole" plants have been used, as apparently in (Beresford et al. 2007). Whereas in these approaches the geometry is defined as an ellipsoid, the ICRP approach (ICRP 2008) considers pine tree as an ellipsoid for estimating the internal doses but for external doses uses a homogeneous canopy layer, and in (Larsson et al. 2004) buds and meristem of shrubs and trees are located in a canopy. Respectively ICRP also uses an ellipsoid for a spike of Wild grass, but its meristem as homogeneous layer on the ground surface. In all these approaches the organisms are assumed to be homogeneous with a density of 1 g/cm³ and in an infinite water medium (ensuring sufficient secondary photon transport). The composition of the reference organism is best described to be a four-component tissue substitute (ICRP 2008).

However, determining geometry parameters for the variability of forest plants is a challenging task, not to mention coupling of the geometry to plant physiology. First, it is well known that physical dimensions of plants differ widely between plant species. Secondly, dimensions of certain plant species are dependent on growth conditions (e.g. weather, soil moisture and fertility), biological age and developmental stage of plant (e.g. many annual herbs have their highest biomass in largest extent during late summer). Growing density and competition between plant species (or between individual species) affect also size and shape of single species. Furthermore, plant parts have different physiological tasks, and they should be taken into account as well (e.g. photosynthetically active green leaves compared to lignified brown stems).

In this paper we illustrate problems in plant geometry using some key plant species of boreal forests and propose alternative geometries for assessment use.

Material and methods

Selection of representative plants and defining their dimensions

Due to a large number of plant species and large variation in plant dimensions between different species it is impossible to cover dimensions of single plant species in dose assessment. A practical approach would be using of functional plant groups from which some typical key species are selected for detailed examination. However, two main problems still remain. First, what are the requirements and justifications for selection of key species from plant groups? Secondly, how to handle a huge variation inside plant species?

Plant species groups have been used in mapping of the nutrient status of the vegetation on Olkiluoto Island in 2005 (Tamminen et al. 2007). Plant groups were also used in determining biomass and chemical composition of the vegetation on the intensive forest monitoring plots at Olkiluoto in 2008 (Salemaa & Korpela 2009). The latter included six functional plant groups (some exemplars):

1) Evergreen dwarf shrubs (*Vaccinium vitis-idaea*)
2) Deciduous dwarf shrubs (*Vaccinium myrtillus*)
3) Lower herbs (*Maianthemum bifolium, Oxalis acetosella* and *Trientalis europaea* (shoots die annually), and *Linnaea borealis* (perennial shoots)

4) Ferns (*Equisetum sylvaticum*, *Dryopteris carthusiana*, *Gymnocarpium dryopteris*, *Pteridium aquilinum* (shoots/leaves die annually)
5) Grasses (both perennial and annual leaves, *Deschampsia flexuosa*)
6) Mosses (lower parts die gradually, *Pleurozium schreberi, Hylocomium splendens*)

In this study selection of key plant species was based on earlier vegetation inventories at Olkiluoto (Tamminen et al. 2007, Salemaa & Korpela 2009), frequency of plant species and their importance in food chains. Hence bilberry (*Vaccinium myrtillus*) was selected to represent deciduous dwarf shrubs, chickweed wintergreen (*Trientalis europaea*) lower herbs, wavy hair-grass (*Deschampsia flexuosa*) grasses and red-stemmed feather-moss (*Pleurozium schreberi*) mosses. All the selected plant species belong to a group of ten most common plant species in Southern-Finland (Reinikainen et al. 2000). Red-stemmed feather-moss also is commonly used as a bioindicator species in environmental studies. Scots pine and Norway spruce dominate forests on Olkiluoto Island (Saramäki & Korhonen 2005). Because appearance of Scots pine differs clearly from that of Norway spruce (i.e. tree crown forms separate part in the older trees), pine was selected to represent tree species in this case study.

Selection criteria for the reference organisms include ecological niche, intrinsic radiosensitivity, radioecological sensitivity, distribution (e.g. presence year-round), suitability to research and monitoring and protected status (IAEA 2010). It seems that the criteria are quite well in accordance with the key species we have selected for this study. However, intrinsic radiosensitivity of the selected species is an uncertain issue, especially regarding long-lived radionuclides characteristic to releases from deep repositories.

Determination of ellipsoid geometries was attempted to base on literature where, however, only plant heights were available. Therefore some estimates were created for plant width and length. For bilberry a demonstrative sampling was carried out. Three samples of bilberry in different developmental stages (i.e. age of plant) were subjectively collected and the dimensions measured (Fig. 2). Some results based on expert judgment during Olkiluoto Biosphere Description 2009 process (Haapanen et al. 2009) were also included. In addition, a few applications of determination ellipsoid geometries for certain plant species were proposed and discussed.

Evaluation of impacts on doses to plants

In this contribution, the effect of varying sizes of ellipsoids representing plants has been preliminary studied using the ERICA Assessment Tool (Beresford et al. 2007), version 1.0, May 2009. Default values have been used except for the organism dimensions (Table 1) and the concentration ratios, which were taken from Helin et al. (2010). The activity concentration in the soil was taken from the biosphere assessment simulations, corresponding the maximum exposure in terrestrial systems (case Sh4Q-C, dried area of Mäntykarinjärvi Lake, year 12020; Hjerpe et al. 2010). As the needed C-14 concentration in air was not easily extractable from the simulation data, it was omitted here, similarly to Pd-107 and Sn-126 not supported by the ERICA Assessment Tool. Due to the pathway, contribution of C-14 is believed not to invalidate the results below.

The contribution of the two other omitted radionuclides would be insignificantly small anyway.

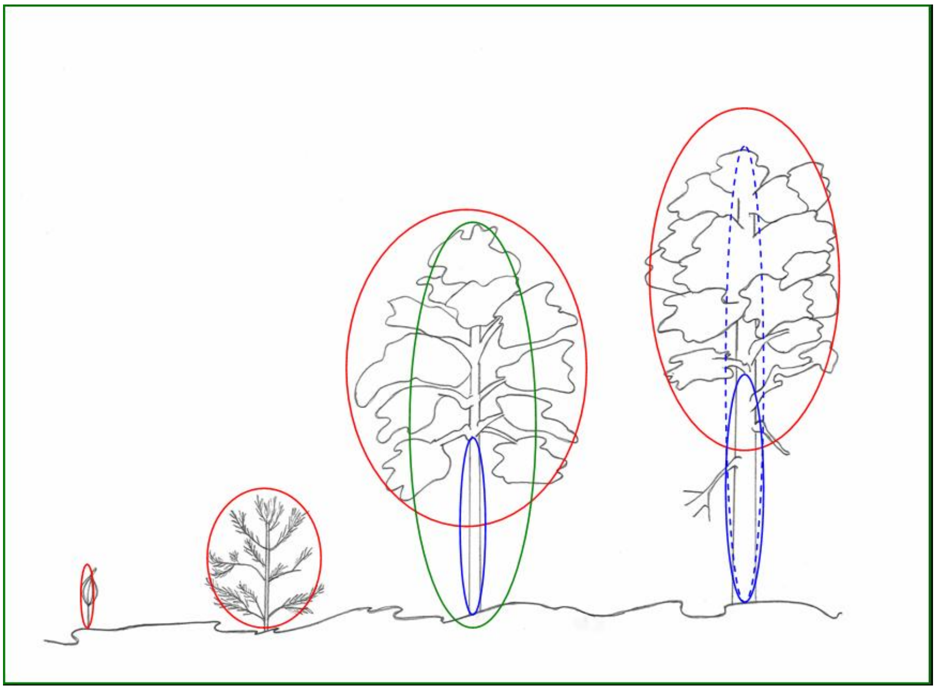

Fig. 1. Examples on Scots pine heights in different developmental stages. From left to right: young seedling (1-year-old, height 0.1 m), advanced seedling (<10 yrs, h= 5 m), mature pine tree (100-yrs-old, h= 22 m) and old mature pine tree (150-yrs-old, h= 25 m). Drawing: A. Hamari /Metla.

Fig. 2. Examples on bilberry of different developmental stages growing in mesic heath forest during winter season. Maximum dimensions (width x length x height, cm) from left to right: 18 x 10 x 25 (A), 6 x 4 x 18 (B) and 25 x 30 x 35 (C).

Results and discussion

Plant dimensions and ellipsoid geometry

A variety of plant dimensions are presented in Table 1. Typically only plant heights were found in literature. Those heights represent different growth conditions of plants, e.g. *Trientalis europaea* appears in wide range of habitats from xeric heat forests to herb-rich forests, and *Deschampsia flexuosa* and *Vaccinium myrtillus* from sub-xeric to herb-rich heat forests (Reinikainen et al. 2000). *Pleurozium schreberi* is the most common plant species in Finland and has the largest range of habitats among forest mosses (Reinikainen et al. 2000). In many cases plants reach their highest dimensions in the most fertile sites.

The age of plant (i.e. developmental stage) determines also plant size. Illustrative figures are shown for *Pinus sylvestris* and *Vaccinium myrtillus* (Table 1, Figs. 1 and 2). Some examples on determination of ellipsoids for pine are also demonstrated (Fig. 1). There are two options: consider tree crown and stem below crown separately, or consider the whole tree. ICRP (2008) also suggested that tree crown could be analysed as a one-level sheet.

Table 1. Dimensions (cm) of selected key plant species.

Species	Class/source	Width	Length	Height
Pinus sylvestris	1-year-old seedling	3[1]	3[1]	10[1]
	<10 yrs old	200[1]	200[1]	500[1]
	<100 yrs old	500[1]	500[1]	1200[1]
	150 yrs old	800[1]	800[1]	1000[1]

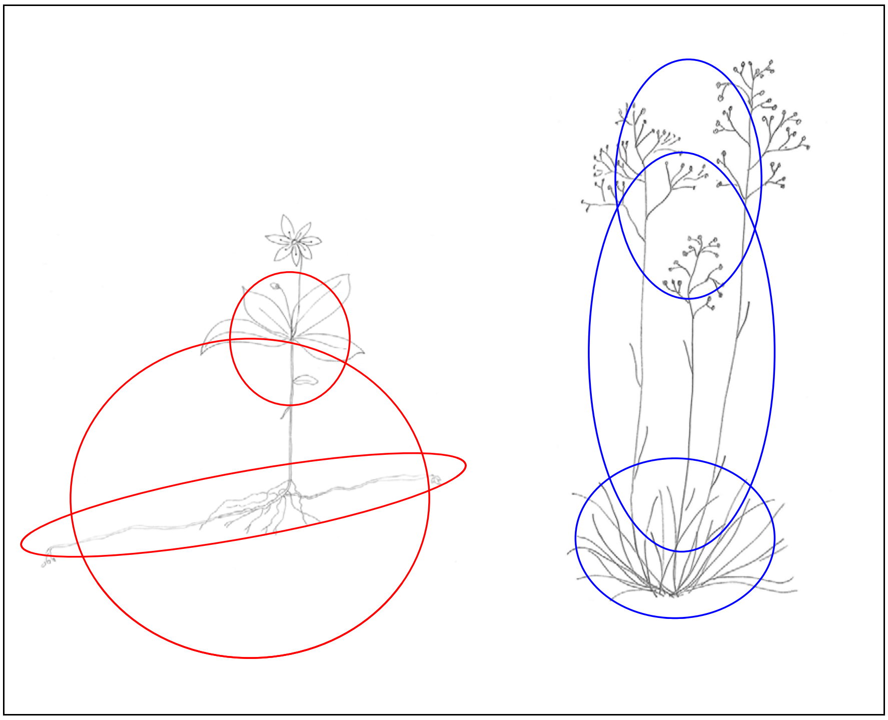

Fig. 3. Examples of ellipsoid geometry for *Trientalis europaea* (with rhizomes, on the left side) and *Deschampsia flexuosa* (perennial grass, on the right side). Drawing: A. Hamari /Metla.

Fig. 4. Red-stemmed feather-moss (*Pleurozium schreberi*) population on the left side and few individual mosses on the right side (Photos: L. Aro / Metla).

Challenges in determination geometries for species that have plant parts with distinctively features are presented in Figure 3. *Trientalis europaea* grows annually one to three superficial rhizomes which should be included in ellipsoid geometry. *Deschampsia flexuosa* is a typical example of perennial grasses with narrow leaves growing from the base and inflorescences with stems. In the case of this grass ellipsoids can be considered separately for inflorescences and leaves, or consider the whole plant which may be difficult due to the unbalanced biomass distribution in the grass.

Many plant species grow in dense populations, such as *Pleurozium schreberi* (Fig. 4). In this case ellipsoids can be determined for single moss or for a part of moss population. If the approach of single moss is used then neighbouring effect of other mosses should also be considered in dose assessment.

Implications for dose assessment

By keeping the other parameters constant and varying the size of *Vaccinium myrtillus* according to Table 1 (18·4·6, 20·15·15, 25·10·18, 35·25·30 cm), the dose conversion coefficients (DCC) for internal low beta or external radiation do not change, but those for internal beta/gamma radiation increase 0.1 to 130% from the smallest to the largest ellipsoid. For the two nuclides contributing most to the dose rate, Cl-36 and I-129, the increase is 1 and 17%, respectively.

Concerning the total absorbed dose rate to the different sizes of *Vaccinium myrtillus*, similar trend is observed but in more modest extent: compared to the smallest, the dose rate to the largest ellipsoid is 1% higher.

Similarly, for the *Pleurozium schreberi* the DCC for internal beta/gamma radiation and the total dose rate are higher for the part of the population (10·60·80 cm) compared to the ellipsoid representing an individual (2·3.5·2 cm; see also Fig. 4): The increase in the DCC is 0.4 to 190% (Cl-36 4%, I-129 27%) and the increase in the total dose rate is 4%, mostly explained by the contribution of chlorine and iodine.

It needs to be noted that these results are for the latest Posiva's assessment case producing highest exposure to the terrestrial biota (see above), and not for unit activity concentrations most commonly applied with the biosphere part decoupled from the rest of the safety assessment.

Anyway, even if the uncertainty from the organism size in the total dose rate remains much smaller than the notoriously large overall uncertainties in the biosphere assessments, there is an effect – provided that the ellipsoidal geometry assuming a phantom density of 1 g/cm³ and a substitute-material composition (ICRP 2008) is valid. For the external exposure the size does not matter, in this case, but the variation in the DCC of internal radiation infers that the geometry might have a role. At least, if the ellipsoids are used to represent also plants of varying actual shape, it appears that appropriate ellipsoid dimensions could be obtained only by careful scaling and bearing in mind the composition of the phantom and the role of the combined effect of concentration ratio and weight in the case of internal exposure. However, for screening purposes the simple ellipsoids and their casual dimensioning seem to produce robust enough results, provided that the screening limits are then set appropriately.

Conclusions

In the selection of the representative species and estimating their size should be done in the context of the site conditions. Furthermore the life stage, or age, of the plant should be taken into account. This means that ideally the sizes should be weighted with site type and plant age distributions of the area of the dose assessment, which actually is out of any reasonable resources. However, despite of large variation in plant dimensions and consequently in ellipsoids derived from them, differences in calculated doses remained quite minor in comparison with the overall uncertainties in the dose assessment. However, to improve the overall confidence to the assessment, some site-specific measurements of the selected reference species should be carried out.

It seems that the approach of using ellipsoids to represent plants in the dose assessment is reasonably robust especially for screening purposes. Still, in a graded approach to assessment, the level of conservativeness (overestimation of the doses) should decrease and realism increase with subsequent tiers. In the case of plants, there appears to be little justification for the use of the geometry – showing that size does not matter in a context of a dogmatic use of fixed geometries does not self-validate the approach; it only shows that the output is not sensitive to the dimensions. As the discussion is lacking at least from the main level documentation of the recent methodological descriptions, it is difficult to find confidence on that using an ellipsoidal geometry also for plants, of which many actually looks very different in shape, would be more conservative than a more characteristic geometry (e.g. a plate or a set of slabs). This is especially when the question comes to scaling the plant's physical dimensions to correspond the ellipsoid of uniform 1 g/cm³ matter substitute.

Even though the doses to biota are expected to remain small in the case of deep geological repositories (at maximum in the order of 10^{-3} μGy/h to terrestrial organisms in the plausible calculation cases of Posiva (Hjerpe et al. 2010), i.e. three orders of magnitude below the screening value recommended by Beresford et al. (2007)), further work on the dose assessment for plants seems useful at least to improve the conceptual basis and confidence to the approach. It is required that the assessment shall overestimate the consequences, but it shall not be overly conservative (YVL 8.4, YVL E-5); a better conception of the degree of realism of estimating doses to plants would have its use.

Assessment of critical doses for reproduction and survival of cultivated plants

Oudalova, Alla; Ulyanenko, Liliya; Geras'kin, Stanislav; Filipas, Alexander
Russian Institute of Agricultural Radiology & Agroecology, RUSSIA

Abstract

The aim of the study is to estimate radiation doses that are critical for sustainability of agrocenosis. Available information on dose dependences in such umbrella endpoints as reproductive potential, survival, morbidity, alterations in morphological and biochemical processes, genetic effects in crops, vegetables, fruit trees, etc are gathered from papers issued mainly in Russian scientific press during last 50 years. Data are maintained as database in MS Access that contains about 7000 entries; the work is ongoing. Quantitative data obtained from different sources are transformed in relative units, which makes possible analysing unified arrays referred to specific endpoints. As critical, there are considered doses producing 50% changes of biological effect at acute impact, or dose rates resulting in 10% changes at chronic exposure of plants. There are three main exposure situations for plants: acute irradiation of seeds, acute and chronic exposure of vegetating plants. Critical doses and dose rates are assessed from dose-effect dependences constructed with data sets, referred to indexes of reproduction and survival. It is found that data on survival collected so far are rather insufficient to estimate critical dose (rates) for species of cultivated plants. From the available information, the predicted no-effect doses and dose rates for agrocenosis are estimated basing on reproduction endpoint. They range within 67÷80 and 15÷17 Gy at acute exposure of the most radiosensitive species in dormant and vegetation periods, correspondingly, and 3÷10 mGy/h at chronic exposure of vegetating plants. The estimates obtained are going to be improved with further development of the database and treatment approaches.

Introduction

In recent years many efforts have been undertaken to develop a system of radiation protection for non-human biota (ICRP 2003, 2009). Agrarian ecosystems are of special concern from the viewpoint of establishing safe levels of radiation impact on the environment. On one hand, their contamination can affect human health via radionuclide uptake with food. On other hand, agroecosystems are ones of the most sensitive to a number of environmental impacts including ionising radiation (Agricultural radioecology 1991). While the existing system of radiation standards (ICRP 2007) is effective in providing radiation protection of human and restricts radionuclides content in food chains, there are no guidelines on setting any limitations to directly protect agrarian ecosystems from negative effect of radiation. The aim of this work is to develop methods for an assessment of critical doses and dose rates that can result in significant radiation-induced effects in agrocenoses. This is realized on an example of cultivated plants which are one of the main components of agroecosystems since cultured plants not only contribute essentially to food production but also fulfil an important ecological function in agrarian biocenosis.

Material and methods

Available information on radiation-induced effects in cultured plants are being gathered from papers issued mainly in Russian scientific press during last 50 years; the work is ongoing. Data are maintained as database in MS Access that now contains about 2000 records from 134 original sources. There are available about 7000 entries which are pairs of "exposure level – biological effect" data accompanied with information on experimental design, species and its life stage, exposure parameters and conditions. Most information collected concern radiation effects in crops, vegetables and roots, as well as legumes – 39%, 22% and 17% of all entries, correspondingly.

Biological responses are grouped under umbrella endpoints of reproduction, survival, morbidity, morphological changes, biochemical changes, and (cyto)genetic effects. Only data on reproduction and survival endpoints are presented here. The first group pools traits of biological productivity (seed and straw mass, dry and wet biomass, number of plants per 1 m^2, etc) and reproductive potential (portion of fertile pollen seeds, fertility/sterility, number or portion of male and female flowers, etc). The later group indexes are germination rate (in field or in laboratory), survival of germinated seeds or plants by certain time/day, etc. To stanardize the data sets, biological responses are expressed as percentages of corresponding controls, which makes possible analysing unified arrays formed of data obtained from different original sources.

Reproduction and survival data are estimated for three possible scenarios of radiation impact on cultivated plants: acute exposure of seeds, acute or chronical exposure of plants during vegetation. Following an approach proposed by (Garnier-Laplace et al 2006, 2008), the dose giving 50% change in observed effect (ED_{50}) is considered as the critical dose for acute exposure, and the critical dose rate for chronic exposure is defined as the dose rate resulting in 10% change of observed effect (EDR_{10}). Dose(rate)-response dependences are reconstructed for individual species using the linear model as the simplest approximation. An assessment of uncertainties in estimated critical doses is illustrated in Fig. 1 on an example of data on reproduction in wheat after seeds' acute exposure. The main effect is fitted with a linear dose-effect function. For every dose value, a 95% confidence interval (CI) for predicted response is calculated (Draper & Smith 1981). A CI width is not constant but increases along with shifting up or down from the median dose. Dose dependences for the upper and down margins of CIs (dotted lines in Fig. 1) are fitted with linear-quadratic model, and their intersections with the 50% effect level (dashed line in Fig. 1) are found. Thus, for the example in Fig. 1 the ED_{50} = 182.3 Gy, 95% CI – 167.3÷202.8 Gy. In several cases the linear-quadratic fit of the upper CI margin always is over the 50% effect level. Then, a linear model is used to fit the CI margins; these cases are marked below.

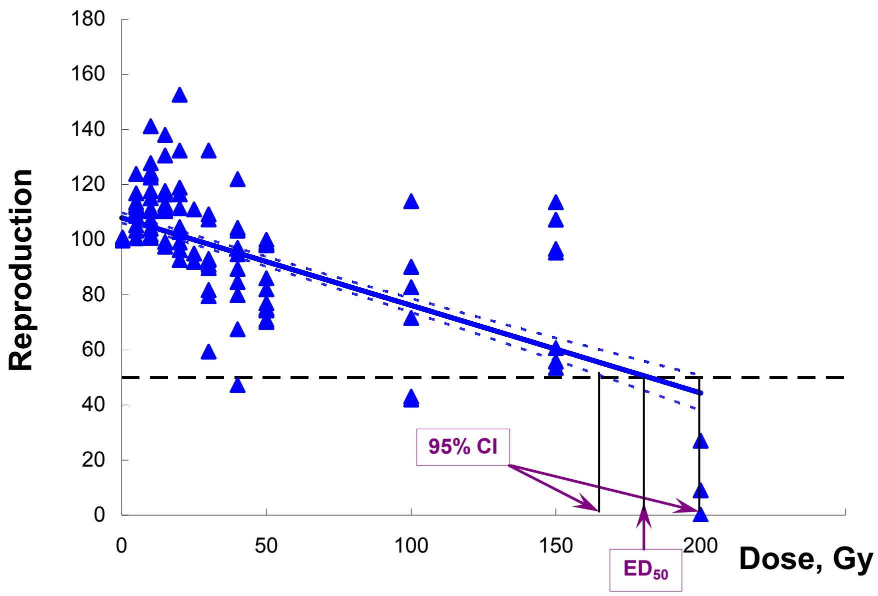

Fig. 1. Standardized data (% of control) on reproduction in wheat after seeds' acute exposure, and estimation of the ED_{50} and its uncertainty.

Results

Acute exposure of seeds

Information on acute exposure of seeds, bulbs, tubers, and other planting stock for cultivated plants is respectively well represented in Russian scientific literature because of a period of radiobiological researches when a pre-sowing irradiation was considered as a possible mean to increase harvest, resistance to diseases and other economical benefits for farming. In the database, 1124 records (4028 pair entries) refer to this exposure scenario which is about 67% of data used to reconstruct dose dependences. A short description of corresponding data collected so far including maximum dose used in original works and numbers of records and paired entries for crops, legumes, vegetables and other cultivated plant species are presented in Tables 1 for reproduction and survival endpoints. Fig. 2 illustrates data on reproduction in crops and their linear fittings. For most species, a linear model fits the data well ($p<5\%$).

On reproduction, carrot appears to be the most radioresistent (ED_{50}=1244.6 Gy). The radiosensitive species are onion and potato as an acute exposure of tubers and bulbs before germination to estimated critical doses of 33.8 Gy and 66.6 Gy, correspondingly, would result in the 50% loss of their productivity. Legumes are also quite sensitive, since bean reproduction reduces twice after 57.0 Gy of acute seeds exposure. Crops show intermediate radiosensitivity with ED_{50}=180-350 Gy.

On survival, carrot is most resistant again (ED_{50}=902.5 Gy). Cotton plants are also very resistant at seeds irradiation (ED_{50}=629.7 Gy). Wheat and corn show the level of radiosensitivity (ED_{50}=222-230 Gy) similar to that on reproduction. There are obtained the very low estimated critical doses for barley and rye (the 95% CIs are within 14÷24 Gy); it is because of very little information taken from a single paper only, and a narrow dose range studied – only up to 5 Gy, which is completely insufficient. For other cultivated plants data volumes on survival indexes are also very limited (N<10, Table 1) which often results in poor fitting (p>10%).

Table 1. Critical doses ED_{50} for reproduction and survival at acute exposure of planting stock.

D_{max} – maximum dose; N – number of records; N_p – number of entries presenting pairs of "exposure level – biological effect" data; [(l)] – a linear model is used to fit the CI margins; NE – value could not be estimated; goodness-of-fit on the Fisher test: * - p<10%, ** - p<5%, * - p<1%.**

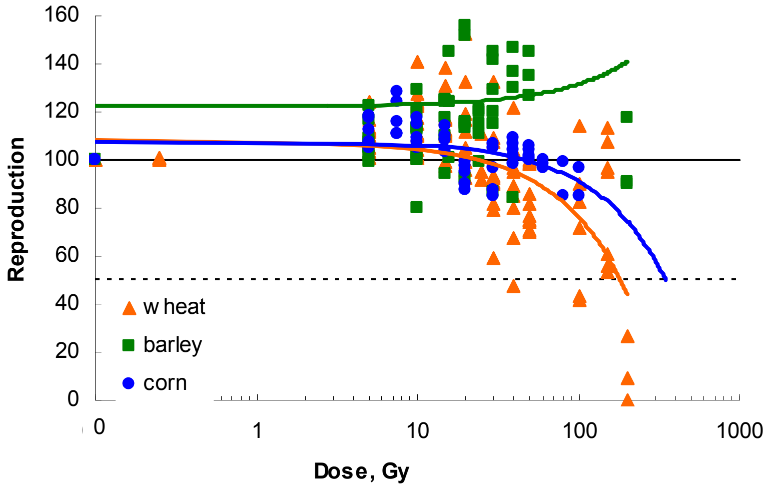

Fig. 2. Standardized data (% of control) on reproduction in crops after acute exposure of seeds and their fittings with a liner model.

For several species (barley, soya, beet, sweet pepper, and tomato at reproduction analysis, and cucumber at survival analysis) critical doses could not be estimated because of a) dose ranges of negative radiation effect are not covered in the works available, or b) large data variance and poor fittings (p>10%).

Despite respectively large in number, data on radiation effects in plants after acute exposure of seeds and other planting stock are not well suited for a purpose of a critical radiotoxicity values estimation, since original researches were mainly aimed at studying hormetic effects of radiation and often do not cover doses producing negative effects in plants. Thus, a better reproduction or lower survival in comparison to a control is shown by about 37% of the database entries refered to the scenario of seeds exposure. Stimulation could reach up to 500%. Although from the viewpoint of developing safety standards at radiation exposure of biocenoses, biological effects of low doses are of special interest, however, a correct interpretation of this kind of data is possible only when detailed information on radiation effect in the whole dose range – from stimulating to harmful – is available.

Acute exposure of plants during vegetation

Studies of radiation effects at total or partial exposure of plants during ontogenetic development are not very large in number. There are certain limitations for such researches such as an availability of special equipment at γ-fields or in greenhouse experiments, providing homogeneous radiation fields, dose and dose rate meausrements, etc. At the moment, reproduction in the database is presented by 330 pair entries that mainly refer to radiation effect in crops (Table 2); survival was studied only in one work with cherry tree cuttings' irradiation. Study design in these works was more homogeneous than at acute seeds exposure. Mostly, γ-sources are used, and dose ranges studied are similar. Radiosensitivity of plants much depends on a stage of ontogenesis at the moment of irradiation, but unfortunately, the available data are not enough to analize dose dependences for an every development stage. Radiation resulted in decreasing of reproduction and survival in all studied species excluding apple tree, where acute exposure of pollen produced a better ability of trees to set fruits and seeds.

For reproduction data, the linear fitting appears good for all species (Table 2). The less sensitive species is potato (ED_{50}=45.8 Gy) in the first and second generation after parent plants' acute exposure at different stages of ontogenesis. Cotton plants also shows high resistence with the estimated critical dose of 36.8 Gy. In crops variety, an assessment of doses leading to 50% loss of productivity gives the similar values (Fig. 3, Table 2). The most and the less radiosensitive are barley (95% CI = 14.6÷16.6 Gy) and rye (95% CI = 25.7÷37.5 Gy), respectively.

Table 2. Critical doses ED_{50} and dose rates EDR_{10} for reproduction and survival at acute and chronic exposure of vegetating plants.

DR_{max} – maximum dose rate. Other designations and marks are the same as in Table 1.

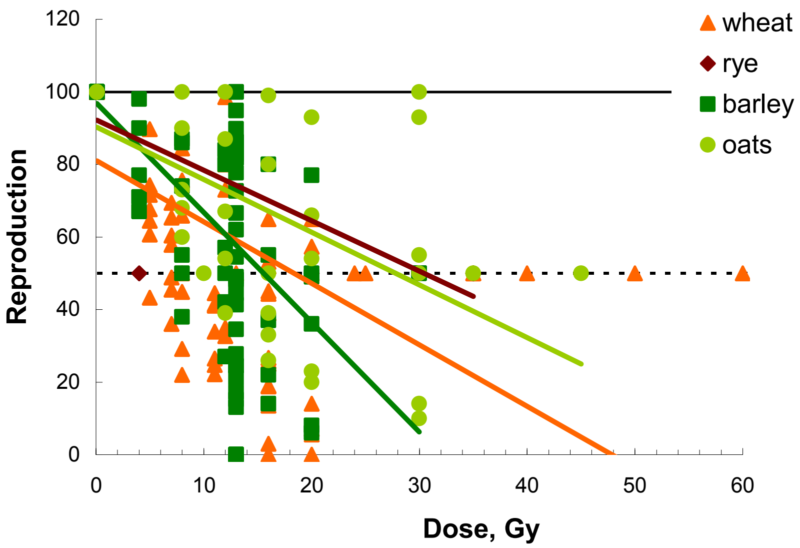

Fig. 3. Standardized data (% of control) on reproduction in crops after acute exposure of vegetating plants and their fittings with a liner model.

Chronic exposure of plants during vegetation

Works on chronic exposure of vegetating plants are the most scarce. In the database, only 63 and 7 records refer to reproduction and survival, respectively, for this exposure scenario (Table 2). Experimental design varies: plants' exposure in γ-field, soil contamination with radionuclides in controlled conditions or growing plants at territories contaminated in radiation accidents. Dose and dose rates range up to 4-5 orders of magnitude – from 10 mGy to 20 Gy, and from 1 μGy/h up to 500 mGy/h. But, the case of chronic exposure is the most interesting in terms of establishing the critical radiotoxicity values. Data on reproduction indexes gathered for cultivated plants are shown in Fig. 4. To fit dose rate – effect dependence, a linear model is used as before. The estimated critical dose rates giving the 10% decrease in biological response are presented in Table 2. In most species, chronic exposure decreases reproduction and survival (Fig. 4). Stimulating effect is observed in rye and cherry trees on reproduction, and in wheat on survival, but data volumes in these cases are limited.

For reproduction endpoint, the least value of EDR_{10}=3.2 mGy/h is obtained for grape in which the number of fruiting brunches decreased after two-year growing at γ-field. In crops, the critical dose rates for wheat (EDR_{10}=3.3÷10 mGy/h) and barley (EDR_{10}=173.3÷310.7 mGy/h) differ by a factor of 30. Possible reasons could be different study designs and incomplete dosemetric information. Thus, wheat plants were exposed in γ-field while barley data refer to both external irradiation in γ-field and mixed exposure from ^{90}Sr-contaminated soil. In the last case, internal doses were not estimated. The other species are close in radiosensitivity and the estimated critical dose rates range from 5.9 to 11.9 mGy/h (Table 4).

Survival indexes are taken from 3 papers, but neither of them gives a good example of a study on chronic radiation effect in vegetating plants. For rye, data on a germinating ability of seeds collected in August, 1986 from the 10-km zone of the Chernobyl NPP are used. The estimated critical dose rate of EDR_{10}=0.24 mGy/h is very low. To understand this data properly, it should be taken into that the parent plants not only experienced chronic radiation with dose rate dramatically changing during the whole period of vegetation, but also they were acutely irradiated in the initial period after the Chernobyl accident (May-June). At the moment of harvesting, contamination density of soils with ^{137}Cs at the study sites reached 800 MBq/m^2. So, this case should not be used to estimate derived radiation levels of chronic exposure. For peas, data are considered on the 24-day survival of seedlings after 12-hour imbibition of germinated seeds in ^{90}Sr solution, and EDR_{10}=158.6 mGy/h is obtained. However, duration of radiation impact is too short in comparison to life time to consider these data as useful for establishing critical radiotoxicity values.

In total, there is a lack of acceptable information on effects of chronic radiation in cultivated plants. The data available are few and scarce, methods and study designs are very different, dosemetric information is incomplete. A part of studies do not contain calculated and measured doses and dose rates. In some works, only data on radioactive contamination are presented (radionuclide activity in soil or plant tissues, contamination density, etc). Internal exposure is rarely taken into account at dose assessments.

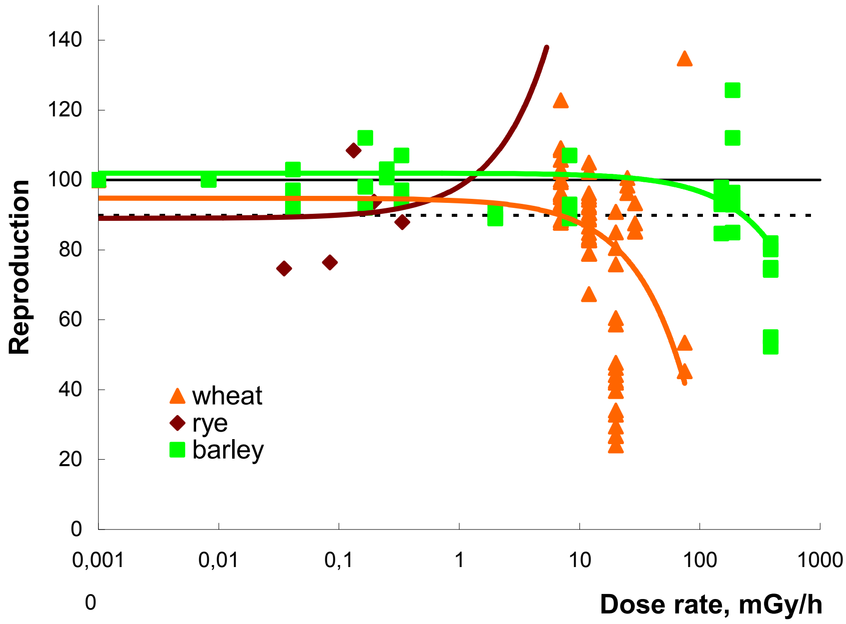

Fig. 4. Standardized data (% of control) on reproduction in crops after chronic exposure of vegetating plants and their fittings with a liner model.

Discussion

The estimated critical doses and dose rates can be used to derive the predicted no-effect dose (PNED) and dose rate (PNEDR). The lowest short-term ED_{50} and long-term EDR_{10}, which characterize radioresistance of the most sensitive species on the most affected umbrella endpoint, can be considered as the first approximation for the PNED and PNEDR in argocenosis. However, the quality and quantity of the primary data influence the safety of the estimated levels. Datasets collected from the original sources are very heterogeneous both in terms of materials and methods used and the data volumes available. To provide a certain confidence in the PNED and PNEDR values, an additional requirement of a minimal number of records N≥10 is applied to select the 'well-defined' values of ED_{50} and EDR_{10}. In Table 3 the minimal ED_{50} and EDR_{10}'s are presented that fullfill the agreed requirement for the three radiation scenarios.

Table 3. Critical doses and dose rates for the most sensitive species for different scenarios of radiation impact on cultivated plants, and the corresponding PNED and PNEDR values.

Exposure scenario	Reproduction	Survival	PNED(R)
Acute exposure of seeds	ED_{50} = 182.3 (167.3÷202.8) Gy at wheat seeds exposure ED_{50} = 66.6 (56.2÷79.9) Gy at potato tubers exposure	ED_{50} = 221.9 (205.4÷241.6) Gy at corn seeds exposure	170÷200 Gy for seeds 67÷80 Gy for other planting stock
Acute exposure of vegetating plants	ED_{50} = 15.6 (14.6÷16.6) Gy for barley	No data	15÷17 Gy
Chronic exposure of vegetating plants	EDR_{10} = 6.8 (3.3÷10.0) mGy/h for wheat	No data	3÷10 mGy/h

Minimal ED_{50} and EDR_{10} are chosen from Tables 1 and 2 following the requirement of N≥10.

From the above consideration it is obvious that data on survival collected so far are rather insufficient to estimate the critical radiotoxicity values. Radiosensitivity of two umbrella endpoints analysed (reproduction and survival) could be compared only for the case of acute seeds exposure (Table 3). According to the findings of this work, reproduction is more sensitive criteria than survival. It is well known that half-lethal doses often result in the full loss of productivity for most domesticated plants (Agricultural radioecology 1991). In terrestrial plants, the dose reducing survival by 10% is roughly equivalent to the dose reducing the yield by 50% (UNSCEAR 1996). (UNSCEAR 2008) also considers that reproductive changes are a more sensitive indicator of radiation effect than mortality. So, reproduction endpoint is used to derive PNED(R)s in this study. Consequently, at acute exposure of the most radiosensitive species in dormant and vegetation periods the PNEDs for agrocenoses amounts to 67÷80 and 15÷17 Gy, correspondingly, according to the data gathered so far. At chronic exposure, the PNEDR is within 3÷10 mGy/h.

There is a number of uncertainties that influence the estimates derived. They emerge from pooling field and laboratory based studies, different ontogenetic phases, various biological effects under one umbrella endpoints, etc. There are also some shortages in dose (rate) determination and data statistical confidence for certain datasets. Typically, the safety factors method is applied to assure a security of finally derived safe levels of radiation impact.

Authorized international organisations proposed guideline dose rates below which a population level effect in wildlife is unlikely to be induced. According to the last recommendations (UNSCEAR 2008) chronic dose rates of less than 0.1 mGy/h for terrestrial communities and acute exposure of non-human biota at doses below about 1 Gy would be unlikely to have significant effects. The PNEDR equal to 10 μGy/h was derived with the ERICA Integrated Approach (Garnier-Laplace et al. 2008). At this, mammals are regarded as the most sensitive of all non-human organisms. Taking into account that cultured plants discussed are commonly more resistant than mammals as well as the further lowering of the estimated PNED(R) due to their dividing by a safety factor, the findings of this work can be considered non-contradictory to the existing guidelines.

The estimates presented here are the first derivation of PNED(R)s for agrarian biocenoses. They are going to be improved with further development of the database and methods for data treatment. In particular, other endpoints are expected to be analysed, and different fitting models, including logistic, would be applied.

Abstract

Recently, the awareness of the vulnerability of the environment has increased and the need to protect it against industrial pollutants has been recognized. The concept of sustainable development, requires new and developing international policies for environmental protection. (Protection of the environment from the effects of ionizing radiation. IAEA-TECDOC-1091. International Atomic Energy Agency, Vienna.). As it is recommended in "Cernavoda Unit #2 NPP Environmental Impact Assessment it is Cernavoda NPP responsibility to conduct an Ecological Risk Assessment study, mainly to assess the impact of Nuclear power plant operation on terrestrial and aquatic biota. Long records from normal operation of Cernavoda Unit 1, wind pattern, meteorological conditions, and upgread source terms data were used to evaluate areas of interest for environmental impact, conducting to a circle of 20 km radius around mentioned nuclear objective. The screening campaign established tritium level (because Cernavoda NPP is a CANDU type reactor, and tritium is the most important radioisotope evacuated in the environment) in air, water, soil and vegetation, focusing the interest area on particular ecosystem. Using these primary data it was evaluated which are the monitored ecological receptors and which are the measurement endpoints. This paper presents the Ecological Risk Assessment at Cernavoda NPP technical requirements, and the preliminary results of evaluating criteria for representative ecosystem components at Cernavoda NPP.

Update of impacts of the Chernobyl accident: Assessments of the Chernobyl Forum (2003–2005) and UNSCEAR (2005–2008)

Abstract

The accident at the Chernobyl NPP in Ukraine in 1986 was the most severe in the history of the nuclear industry, causing a huge release of radionuclides over large areas of Europe. Its radiological consequences were recently revisited by the UN Chernobyl Forum (2003-2005) and UNSCEAR (2005-2008).

For the first time environmental impacts were considered in detail, including radioactive contamination of terrestrial and aquatic environments, application and effectiveness of countermeasures and effects on biota. Updated dosimetric data were presented for more than half a million of emergency and recovery operation workers, about 100 million inhabitants of the three most affected countries, Belarus, the Russian Federation and Ukraine, and for 500 million inhabitants of other European countries. The average effective dose of the emergency and recovery operation workers was estimated to be about 0.12 Sv. An exception is a cohort of several hundred emergency workers who received high radiation doses; of whom 28 persons died in 1986 due to acute radiation sickness.

The majority of the six million residents of the 'contaminated areas' in Belarus, Russia and Ukraine received relatively minor radiation doses which are comparable with the natural background levels. However, those who were children at the time and drank milk with high levels of radioactive iodine received during the first few months after the accident particularly high doses to the thyroid. Since early 1990s there was the dramatic increase in thyroid cancer incidence among those exposed to radioiodine at a young age. Also in 1990s there was some increase of leukaemia in most exposed workers.

Apart from those two health effects revealed in the two different population cohorts as the result of 20-year epidemiological observations there was, until 2007, no clearly demonstrated increase in the somatic diseases due to radiation. There was, however, an increase in psychological problems among the affected population, compounded by the social disruption that followed the break-up of the Soviet Union. In particular, the UN Chernobyl Forum concluded that after a number of years, along with

reduction of radiation levels and accumulation of humanitarian consequences, severe social and economic depression of the affected regions and associated psychological problems of the general public and the workers had become the most significant problem to be addressed by the national authorities.

Introduction

The Chernobyl accident was the most severe in the history of the world nuclear industry. At night of 26 April 1986, Unit 4 of the Chernobyl nuclear power plant, located 130 km to the north-east of Kiev, the capital of Ukraine[1], was destroyed by two powerful explosions in the reactor core. The Chernobyl NPP was equipped with four RBMK reactors with a graphite moderator, a thermal power of 3200 MW and an electrical power of 1000 MW each. The explosions were caused by gross breaches of the operating procedures by staff and technical inadequacies in the safety systems (INSAG 1993). As a result of the explosions, highly radioactive core fragments were ejected onto the site. The hot graphite exposed to air caught fire and burned for 10 days.

During that time period, radioactive substances were ejected from the burning reactor and spread by winds under changing weather conditions over Europe, principally Belarus, Ukraine and Russia. No more than 20% of the radioactive discharge spread beyond Europe (De Cort et al. 1998).

More than 400,000 emergency and recovery operation workers, including army, power plant staff, local police and fire services, were involved in containing and cleaning up the accident in 1986-1987. Later, the number of registered “liquidators” rose to about 600,000.

About six million people live in areas of Belarus, Russia and Ukraine that are ‘contaminated with radionuclides’ due to the Chernobyl accident (above 37 kBq m^{-2} or 1 Ci km^{-2} of ^{137}Cs)[2]. Amongst them, about 400,000 people lived in more contaminated areas – classified at the time by Soviet authorities as ‘areas of strict radiation control’ (above 555 kBq m^{-2} or 15 Ci km^{-2} of ^{137}Cs). Of this population, 115,000 people were evacuated in the spring and summer of 1986 from the area surrounding the Chernobyl power plant (designated the “Exclusion Zone”) to non-contaminated areas. Another 220,000 people were relocated in subsequent years (UNSCEAR 2000).

The consequences of the Chernobyl accident were widely discussed at the Kiev conference in 1988 (IAEA 1989), pursuant to the results of the IAEA Chernobyl project (IAG 1991), and at the conferences marking its 10th anniversary (Karaoglou et al. 1996; IAEA 1996). The health consequences were analysed comprehensively by UNSCEAR in its 1988 and 2000 reports (UNSCEAR 1988, 2000). In 2005-2008 UNSCEAR has undertaken further assessment of the Chernobyl environmental and health consequences and recently published the resulting report (UNSCEAR 2010).

Because of continued contradictions in the interpretation of the Chernobyl accident consequences, the IAEA initiated in early 2003 establishing the Chernobyl Forum aiming to retrospectively assess the environmental and health consequences of the accident and to advise the Governments of Belarus, Ukraine and the Russian

[1] Up until 1991, Belarus, Russia and Ukraine were parts of the USSR.

[2] In the mapping of the deposition, ^{137}Cs was chosen because it is easy to measure long-lived radionuclide, and it is of radiological significance.

Federation on future actions, such as environmental remediation and special health care as well as research activities.

The Forum participants were eight United Nations organisations (IAEA, WHO, UNDP, FAO, UN-OCHA, UNEP, UNSCEAR[3] and The World Bank) as well as the competent authorities of Belarus, Russia and Ukraine. The Forum was created as a contribution to the United Nations' ten-year strategy for Chernobyl, launched in 2002 with the publication of *Human Consequences of the Chernobyl Nuclear Accident – A Strategy for Recovery* (UNDP and UNICEF 2002). The Chernobyl Forum and subsequent conference were chaired by Dr. Burton Bennett, Radiation Effects Research Foundation, Japan.

Forum reports on environment (IAEA 2006) and health (WHO 2006) were prepared by corresponding expert working groups and approved by consensus at the last Forum meeting in April 2005. The reports were presented and discussed during the International Conference entitled "Chernobyl: Looking Back to Go Forwards" organised by the IAEA in Vienna in September 2005 (IAEA 2008).

In November 2005, the United Nations General Assembly considered a report on efforts to promote recovery in areas affected by the Chernobyl legacy and adopted a resolution A/60/L.19 (UN 2005) in which, *inter alia*, noted consensus reached among members of the Chernobyl Forum regarding assessment of the accident consequences and future actions.

This paper presents the recent findings of the Chernobyl Forum and UNSCEAR on radiological health and environmental consequences of the Chernobyl accident.

Environmental Consequences (IAEA 2006, UNSCEAR 2010)

Radionuclide release and deposition

Major releases of radionuclides from Unit 4 of the Chernobyl NPP continued for ten days following the April 26 explosion. These included radioactive gases, condensed aerosols and a large amount of fuel particles. The total release of radioactive substances was about 14 EBq, including 1.8 EBq of iodine-131, 0.085 EBq of ^{137}Cs, 0.01 EBq of ^{90}Sr and 0.003 EBq of plutonium radioisotopes. The noble gases contributed about 50% of the total release. The most up-to-date estimates of the amounts released are similar to those of the UNSCEAR 2000 Report (UNSCEAR 2000), except for the refractory elements, which are now about 50% lower (Kashparov et al 2003).

More than 200,000 square kilometres of Europe received levels of ^{137}Cs above 37 kBq m^{-2}, (De Cort et al. 1998). Over 70 percent of this area was in the three most affected countries, Belarus, Russia and Ukraine. The deposition was extremely varied, as it was enhanced in areas where it was raining when the contaminated air masses passed. Most of the strontium and plutonium radioisotopes were deposited within 100 km of the destroyed reactor due to larger particle sizes.

Many of the most significant radionuclides have decayed away. The releases of radioactive iodines caused great concern immediately after the accident. For the

[3] International Atomic Energy Agency (IAEA), World Health Organization (WHO), United Nations Development Programme (UNDP), Food and Agriculture Organization (FAO), United Nations Environment Programme (UNEP), United Nations Office for the Coordination of Humanitarian Affairs (UN-OCHA), United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR).

decades to come ^{137}Cs will continue to be of greatest importance, with secondary attention to ^{90}Sr. Over the longer term (hundreds to thousands of years) the plutonium isotopes and americium-241 will remain, although at levels that are not significant radiologically.

Environmental transfer

In the early months after the accident, the radionuclide levels of agricultural plants and plant-consuming animals was dominated by surface deposits. The deposition of iodine-131 caused the most immediate concern, but the problem was confined to the first two months after the accident because of ^{131}I decay. The radioiodine was rapidly absorbed into milk leading to significant thyroid doses to people consuming milk, especially children in Belarus, Russia and Ukraine. In the rest of Europe increased levels of ^{131}I in milk were observed in some southern areas, where dairy animals were already outdoors.

After the early phase of direct deposit, uptake of radionuclides through plant roots from soil became increasingly important. Radioisotopes of caesium (^{137}Cs and ^{134}Cs) were the nuclides which led to the largest problems. The radiocaesium content in foodstuffs was influenced not only by deposition levels but also by types of ecosystem and soil as well as by management practices. In addition, ^{90}Sr could cause problems in areas close to the reactor, but at greater distances its deposition levels were low. Other radionuclides such as plutonium isotopes and ^{241}Am did not cause real problems in agriculture, both because of low deposition levels and poor availability for root uptake from soil.

In general, there was a substantial reduction in the transfer of radionuclides to vegetation and animals in intensive agricultural systems in the first few years after deposition, as would be expected due to weathering, physical decay, migration of radionuclides down the soil, reductions in bioavailability in soil and due to countermeasures. However, in the last decade there has been little further obvious decline, by 3-7 percent per year.

Currently, ^{137}Cs activity concentrations in agricultural food products are generally below national and international action levels. However, in some limited areas with high radionuclide deposition (parts of the Gomel and Mogilev regions in Belarus and the Bryansk region in Russia) or poor organic soils (the Zhytomir and Rovno regions in Ukraine) milk may still be produced with ^{137}Cs activity concentrations that exceed national action levels of 100 Bq kg^{-1}. In these areas countermeasures and environmental remediation may still be warranted.

The uptake and retention of ^{137}Cs has generally been much higher in semi-natural ecosystems than in agricultural ecosystems, and the clearance rate from forest ecosystems is extremely slow. The highest levels in foodstuffs continue to be in mushrooms, berries, game and reindeer.

Levels of radionuclides in rivers and lakes directly after the accident fell rapidly and are now generally very low in water used for drinking and irrigation, although the radiocaesium levels in the water and fish of some closed lakes have fallen only slowly. Levels in seawater and marine fish were much lower than in freshwater systems.

The deposition in urban areas could have initially given rise to a substantial external dose. However, due to radioactive decay, wind, rain and human activities, including traffic, street washing and cleanup, surface contamination by radioactive materials and air dose rate has been reduced significantly in inhabited and recreational areas since 1986, Fig. 1.

At present, in most of the settlements subjected to radioactive contamination as a result of Chernobyl, the air dose rate above solid surfaces has returned to the background level predating the accident. But the air dose rate remains elevated above undisturbed soil in gardens and parks in some settlements of Belarus, Russia and Ukraine.

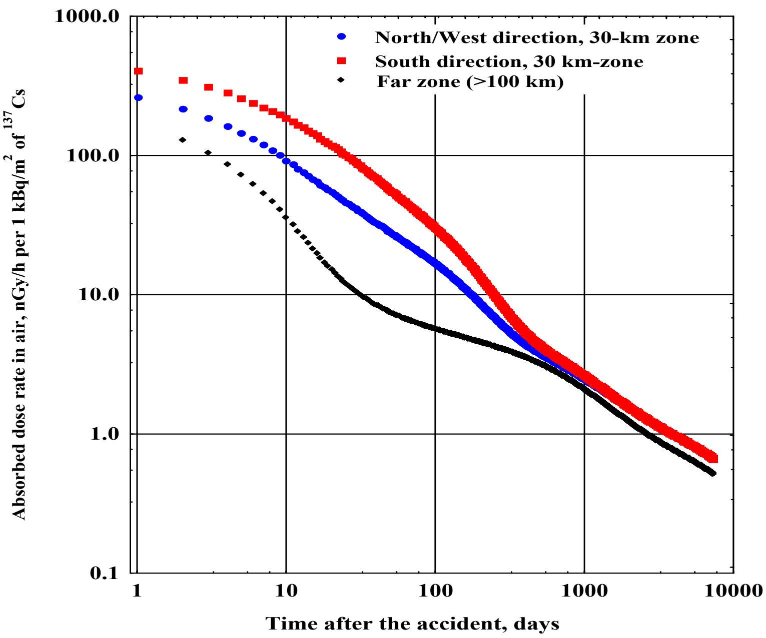

Fig. 1. Dynamics of standardised dose rate in air over undisturbed soil after the Chernobyl accident in different geographical areas (Golikov 2006).

Environmental countermeasures

The Soviet authorities introduced a wide range of short- and long-term environmental countermeasures to mitigate the accident's consequences. The countermeasures involved huge human, financial and scientific resources.

Decontamination of settlements in the affected regions of the USSR during the first years after the Chernobyl accident was successful in reducing the external dose when its implementation was preceded by proper remediation assessment. However, the decontamination has produced a disposal problem due to the considerable amount of low-level radioactive waste that was created.

In the first few weeks, management of animal fodder and milk production (including prohibiting the consumption of fresh milk) would have helped significantly to reduce the doses to the thyroid due to radioiodine. However, wide implementation of early countermeasures in the former Soviet Union was flawed, because timely advice was lacking, particularly for private farmers. Many European countries changed their agricultural practices and/or withdrew food, especially fresh milk, from the supply chain, and, in Poland, iodine prophylaxis was promptly organized; these actions generally reduced thyroid doses in those countries to negligible levels.

Over the months and years after the accident, the authorities of the former Soviet Union introduced an extensive set of agricultural countermeasures. These helped to reduce the long-term exposures from the long-lived radionuclides, notably radiocaesium. During the first few years, substantial amounts of food were removed from human consumption because of concerns about the radiocaesium levels, especially in milk and meat. In addition, pasture was treated, and clean fodder and caesium binders were provided to livestock, resulting in considerable reductions in dose.

In addition, countermeasures were instigated to reduce exposures from living and working in forests and using forest products. They included: restrictions on access; restrictions on harvesting of forest foods, such as game, berries and mushrooms; restrictions of the gathering of firewood; and alteration of hunting practices.

Early restrictions on drinking water and changing to alternative supplies reduced internal doses from aquatic pathways in the initial period. Restrictions on the consumption of freshwater fish from some lakes also proved effective in Scandinavia and Germany. Other countermeasures to reduce the transfer of radionuclides from soil to water systems were generally ineffective.

Radiation-induced effects on plants and animals

Radiation of radionuclides released from the accident caused numerous acute adverse effects on the plants and animals living in the higher exposure areas, i.e., in localized sites at distances up to about 30 kilometres from the release point. Outside this area, no acute radiation-induced effects in plants and animals have been reported.

The response of the natural environment to the accident was a complex interaction between radiation dose, radiosensitivity and recovery of the different plants and animals. Both individual and population effects caused by radiation-induced cell death have been observed in biota inside the 30-km area as follows:

- Increased mortality of coniferous plants, soil invertebrates and mammals; and
- Reproductive losses in plants and animals.

Following the natural reduction of exposure levels due to radionuclide decay and migration, biological populations have been recovering from acute radiation effects. As soon as by the next growing season following the accident, population viability of plants and animals had substantially recovered as a result of the combined effects of reparation and repopulation from less affected areas. A few years were needed for recovery from major radiation-induced adverse effects in plants and animals.

Genetic effects of radiation, in both somatic and germ cells, have been observed in plants and animals during the first few years after the Chernobyl accident. Different cytogenetic anomalies attributable to radiation continue to be reported from experimental studies. Whether the observed cytogenetic anomalies in somatic cells have any detrimental biological significance is not known.

The recovery of affected biota in the exclusion zone has been facilitated by the removal of human activities, e.g., termination of agricultural and industrial activities. As a result, populations of many plants and animals have eventually expanded, and the present environmental conditions have had a positive impact on the biota in the 30-km area. Indeed, this area has paradoxically become a unique sanctuary for biodiversity.

Radiation doses to exposed population groups (IAEA 2006, UNSCEAR 2010)

The following population categories were exposed from the Chernobyl accident:

- Emergency and recovery operation workers who worked at the Chernobyl power plant and in the exclusion zone after the accident;
- Inhabitants evacuated from abandoned areas of Belarus, Russia and Ukraine; and
- Inhabitants of areas with radioactive fallout, who were not evacuated.

With the exception of the on-site reactor personnel and the emergency workers who were present near the destroyed reactor during the time of the accident and shortly afterwards, most of recovery operation workers and people living in the contaminated territories received relatively low whole-body radiation doses, comparable to background radiation levels accumulated over the 20 year period since the accident (Table 1). For comparison, the annual average effective dose from natural background radiation is 2.4 mSv.

Table 1. Summary of updated dose estimates for the main population groups exposed from the Chernobyl fallout

Population group	Size (thousands)	Average thyroid dose in 1986 (mGy)	Average effective dose [b] in 1986-2005 (mSv)	Collective thyroid dose in 1986 (man Gy)	Collective effective dose [b] in 1986–2005 (man Sv)
Recovery operation workers (1986-1990) [a]	530	NA	117 [a]	NA	61 200
Evacuees (1986)	115	490	31	57 000	3 600
Inhabitants of areas of strict radiation control [c]	216	NA	61	NA	13 100
Inhabitants of contaminated areas [c]	6 400	102	9	650 000	58 900
Inhabitants of Belarus, Russia (19 regions) and Ukraine	98 000	16	1.3	1 600 000	125 000
Inhabitants of distant European countries [d]	500 000	1.3	0.3	660 000	130 000

NA – Data not available.

a Effective dose estimates for the workers include only the doses from external irradiation.

b Effective dose estimates are the sum of the contributions from external and internal irradiation, excluding the thyroid dose.

c The contaminated areas were defined in the former Soviet Union as areas where the ^{137}Cs levels on soil were greater than 37 kBq/m^2 and areas of strict radiation control - where the ^{137}Cs levels were greater than 555 kBq/m^2.

d All the European countries except the three republics, Turkey, countries of the Caucasus, Andorra, and San Marino.

Compared to the UNSCEAR 2000 report: (a) dose estimates have been updated for a larger number of the Belarusian, Russian, and Ukrainian recovery operation workers (510,000 instead of 380,000), and new information is presented on the Estonian, Latvian, and Lithuanian recovery operation workers; (b) thyroid dose estimates have been updated for the Belarusian and Ukrainian evacuees, and new information is presented for the Russian evacuees; (c) the estimation of thyroid and effective doses has been expanded from 5 million to 100 million inhabitants of the three republics; and (d) thyroid and effective dose estimates have been updated for the 500 million inhabitants of other European countries.

The highest doses were received by emergency workers and on-site personnel, in total less than 1,000 people, during the first days of the accident, ranging up to 20 Gy, which was fatal for some of the workers. The doses received by recovery operation workers, who worked for short periods during four years following the accident ranged from less than 10 mSv to more than 1,000 mSv, although about 85% of the recorded doses were in the range 20–500 mSv, with an average of about 117 mSv.

The collective effective dose to the 530,000 recovery operation workers is estimated to have been about 60,000 man Sv. This may, however, be an overestimate, as conservative assumptions appear to have been used in calculating some of the recorded doses.

Effective doses to the persons evacuated from the Chernobyl accident area in the spring and summer of 1986 were estimated to be about 30 mSv on average, mostly from external gamma radiation, with the highest dose of the order of several hundred mSv.

The high thyroid doses among the general population were due almost entirely to drinking fresh milk containing ^{131}I in the first few weeks following the accident. Figure 2 presents the estimated average thyroid dose to children and adolescents in 1986. The average thyroid dose to the evacuees is estimated to have been about 500 mGy (with individual values ranging from less than 50 mGy to more than 5,000 mGy). For the more than six million residents of the contaminated areas of the former Soviet Union who were not evacuated, the average thyroid dose was about 100 mGy, while for about 0.7% of them, the thyroid doses were more than 1,000 mGy. The average thyroid dose to pre-school children was some 2 to 4 times greater than the population average. For the 98 million residents of the whole Belarus and Ukraine and 19 oblasts of the Russian Federation, the average thyroid dose was much lower, about 20 mGy; most (93%) received thyroid doses of less than 50 mGy. The average thyroid dose to residents of the other European countries was about 1.3 mGy.

The collective thyroid dose to the 98 million residents of the former Soviet Union was some 1,600,000 man Gy. At the country level, the collective thyroid dose was highest in Ukraine, with 960,000 man Gy distributed over a population of 51 million people. At the regional level, the highest collective thyroid dose of about 320,000 man Gy was to the population of the Gomel oblast, corresponding to an average thyroid dose of about 200 mGy.

As far as whole body doses are concerned, the six million residents of the contaminated areas of the former Soviet Union received average effective doses for the period 1986–2005 of about 9 mSv, whereas for the 98 million people considered in the three republics, the average effective dose was 1.3 mSv, a third of which was received in 1986. This represents a minor increase over the dose due to background radiation over the same period (50 mSv). About three-quarters of the dose was due to external exposure, the rest being due to internal exposure. About 80% of the lifetime effective doses had been delivered by 2005.

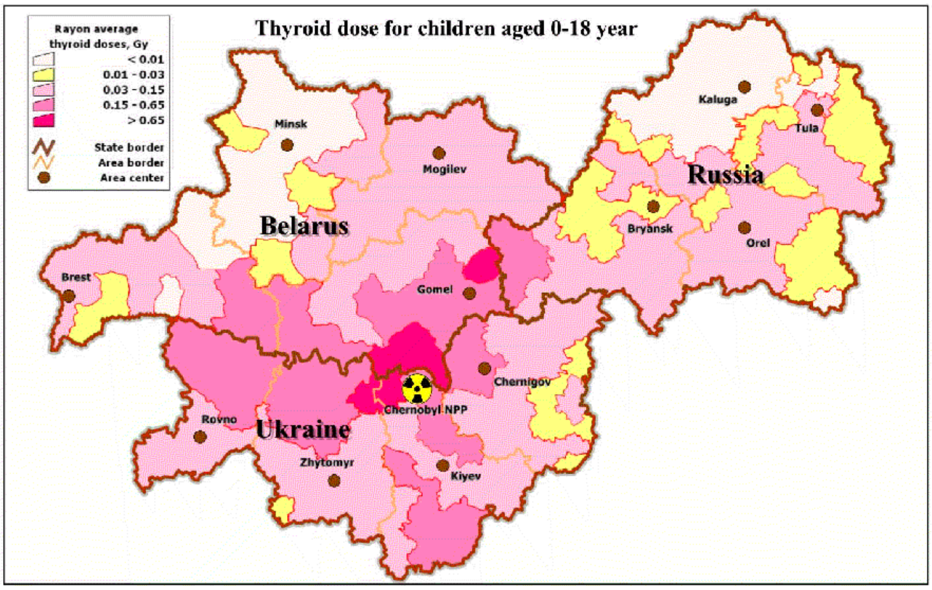

Fig. 2. The estimated district-average thyroid doses to children and adolescents living at the time of the accident in the most affected regions of Belarus, Russia and Ukraine (Russian National Medical and Dosimetric Registry 2006).

However, about 150,000 people living in the most contaminated areas received an effective dose of more than 50 mSv over the 20-year period. For the population of about 500 million in other countries of Europe, the average effective dose is estimated to have been 0.3 mSv over this period. The collective effective dose is estimated at about 125,000 man Sv to the combined populations of Belarus, Ukraine and the relevant parts of Russia, and about 130,000 man Sv to population in the rest of Europe.

Early health effects (UNSCEAR 1988, 2010)

A total of 237 emergency workers were initially examined for signs of ARS that was verified in 134 of these individuals. Of these 134 patients, 28 died within the first four months, their deaths being directly attributable to the high radiation doses.

The dominant exposures were external irradiation of the whole body at high dose rates and beta irradiation of the skin. Internal contamination was of relatively minor importance, while neutron exposure was insignificant. Underlying bone marrow failure from the external whole body irradiation was the major contributor to all the deaths during the first two months.

Each patient with bone-marrow syndrome of Grade III–IV usually also had serious radiation damage to the skin that aggravated other conditions. Skin doses exceeded bone marrow doses by a factor of 10–30, and many ARS patients received skin doses up to 500 Gy. Radiation burns to the skin were felt to be a major contributor to at least 19 of the deaths and significantly increased the severity of the ARS, especially when skin burns exceeded 50% of the body surface area and led to major infections. After 50–60 days, if the skin was not healing, a number of patients received skin graft surgery. In addition, the leg of one patient was amputated more than 200 days after the accident, gastrointestinal syndrome was seen in 15 patients and radiation pneumonitis in 8 patients.

There were no cases of ARS among the general public, either among those evacuated or those not evacuated. This is consistent with the assessment of the radiation exposures, which showed that the whole body radiation doses to members of the general public were much lower than the well-known dose thresholds for ARS.

Late health effects (UNSCEAR 2010, WHO 2006)

ARS survivors

Among the 106 patients surviving ARS, haematopoietic recovery occurred within a matter of few months. However, recovery of the immune system took at least half a year, and complete normalization several years. Cataracts, scarring and ulceration are important ongoing problems in the ARS survivors. Between 1990 and 1996, 15 ARS survivors with extensive skin injuries underwent surgery. Most ARS survivors had suffered functional sexual disorders up to 1996; however, 14 normal children were born to survivor families within the first five years of the accident.

The major health consequences from the radiation exposure of the ARS survivors remain the skin injuries and radiation-induced cataracts. The current nature and severity of the skin injuries depend on their severity during the early period. Patients who had suffered first-degree skin injuries displayed various levels of skin degeneration, ranging from slight smoothing of the skin surface to more pronounced changes. However, over longer periods, the slight changes disappeared almost completely. With third- and fourth-degree injuries, there were areas of scarring, contractures, and radiation-induced ulcers. However, since the early 1990s, microsurgery techniques have significantly reduced the problems of radiation-induced ulcers.

Many of the patients who suffered moderate or severe ARS, developed radiation-induced cataracts in the first few years after the accident, with a strong correlation between the grade of ARS and cataract prevalence.

Over the period 1987–2006, 19 ARS survivors died for various reasons. As time progressed, assignation of radiation as the cause of death has become less clear.

The follow-up of the ARS survivors indicates that: the initial haematological depression has recovered substantially in many patients; there remain significant local injuries; there has been an increase in haematological malignancies; and the increase in other diseases is probably largely due to ageing and other factors not related to radiation exposure.

Thyroid cancer

A substantial increase in thyroid cancer incidence has occurred in the three republics (the whole of Belarus and Ukraine, and the four most affected regions of Russia) since the Chernobyl accident among those exposed as children or adolescents. Amongst those under age 14 years in 1986, 5,127 cases (under age 18 years in 1986, 6,848 cases) of thyroid cancer were reported between 1991 and 2005 (Ivanov et al 2006). A substantial fraction of those cases was caused by internal exposure of thyroids of local residents with incorporated radioiodine.

Figure 3 demonstrates that in Belarus, after the Chernobyl accident in 1986, thyroid cancer incidence rates among children under age 10 years increased dramatically and subsequently declined, specifically for those born after 1986 (see 1996–2005). This pattern suggests that the dramatic increase in incidence in 1991–1995 was associated with the accident. The increase in the incidence of thyroid cancer among children and adolescents began to appear about 5 years after the accident and persisted up until 2005. The background rate of thyroid cancer among children under age 10 years is approximately 2 to 4 cases per million per year.

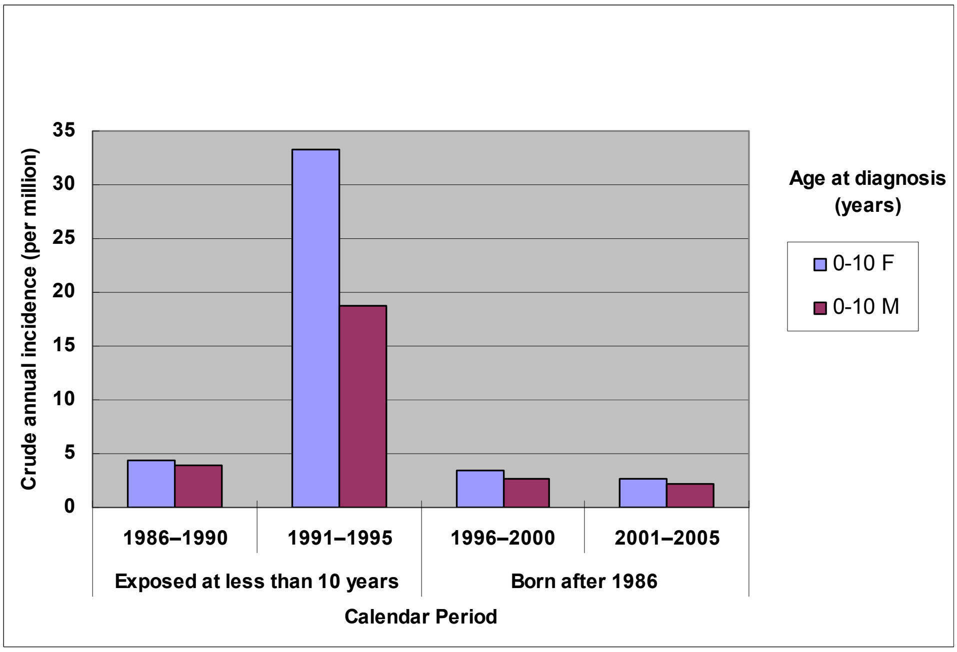

Fig. 3. Thyroid cancer incidence rate in Belarus for children under 10 years old at diagnosis.

This increase has been confirmed in several case-control and cohort studies that have related the excess incidence of thyroid cancer to the estimated individual doses due primarily to the radioiodine released during the accident. There is little suggestion of increased thyroid cancer incidence among those exposed as adults in the general population.

Evidence has also emerged since the UNSCEAR 2000 Report indicating that iodine deficiency might have influenced the risk of thyroid cancer resulting from exposure to the radioactive isotopes of iodine released during the accident (Cardis et al 2005).

Leukaemia, Solid Cancers and Circulatory Diseases

Given the level of doses received, it is likely that studies of the general population will lack statistical power to identify radiation-induced risk of leukaemia, although for higher exposed emergency and recovery operation workers an increase may be detectable. The most recent studies suggest a two-fold increase in the incidence of leukaemia between 1986 and 1996 in Russian emergency and recovery operation workers exposed to external dose of more than 150 mGy. Since the risk of radiation-induced leukaemia decreases few decades after exposure, its contribution to morbidity and mortality is likely to become less significant as time progresses.

There have been many post-Chernobyl studies of leukaemia and cancer morbidity in the populations of 'contaminated' areas in the three countries. So far, there is no convincing evidence that the incidence of leukaemia or cancer (other than thyroid) has increased in children, those exposed *in-utero*, or adult residents. It is thought, however, that for most solid cancers, the minimum latent period is of the order of 10 years or more – and it may be too early to evaluate the full radiological impact of the accident.

There appears to be some recent increase in morbidity and mortality of Russian emergency and recovery operation workers caused by circulatory system diseases. Incidence of circulatory system diseases should be interpreted with special care because of the possible indirect influence of confounding factors, such as stress and lifestyle (smoking, alcohol consumption, etc.)

Cataract

Clinically significant cataracts developed in some of the ARS survivors exposed to high radiation doses. In addition, the recently completed Ukrainian–American Chernobyl Ocular Study (Worgul et al 2007) indicates that lens opacity arising in the recovery operation workers is related to the dose received. A key finding was that the data were not compatible with a dose–effect threshold of more than 0.7 Gy, and that the lower boundary of the estimated dose threshold was close to the current dose limit for the lens of the eye, i.e. 150 mSv, although this needs to be tempered by consideration of the uncertainties in the dosimetry.

It should be noted that the main findings pertain to subclinical cataracts: 96% of observed cases were Grade I opacities. Whether or not some fraction of the radiation-associated Grade I opacities eventually progress to become more severe vision-disabling cataracts remains to be resolved.

Psychological and mental health problems (Chernobyl Forum 2006, WHO 2006)

Stress symptoms, depression, anxiety (including post-traumatic stress symptoms), and medically unexplained physical symptoms have been reported in Chernobyl-exposed populations. The studies also found that exposed populations were more likely to report subjective poor health than were unaffected control groups. In general, the social context in which the Chernobyl accident occurred makes the findings difficult to interpret because of the complicated series of events unleashed by the accident, the multiple extreme stresses and culture-specific ways of expressing distress.

In addition, individuals in the affected populations were officially categorized as "sufferers", and came to be known colloquially as "Chernobyl victims". This label, along with the extensive government benefits had the effect of encouraging individuals to think of themselves fatalistically as invalids. Thus, rather than perceiving themselves as "survivors," many of those people have come to think of themselves as helpless, weak and lacking control over their future.

Other findings of the Chernobyl Forum (Chernobyl Forum 2006, IAEA 2008)

The Chernobyl Forum also considered social and economic consequences of the Chernobyl accident that are out of scope of this paper. The Forum also elaborated practical Recommendations to the Governments of Belarus, the Russian Federation and Ukraine on health care and research, on environmental monitoring, remediation and research and those for economic and social policy that can be found elsewhere (Chernobyl Forum 2006, IAEA 2008).

Conclusions

From this paper based on 20 years of studies, it can be concluded that although those exposed to radioiodine as children or adolescents and the emergency and recovery operation workers who received high doses are at increased risk of radiation-induced effects, the vast majority of the population need not live in fear of serious health consequences from the Chernobyl accident.

Most of the workers and members of the public were exposed to low level radiation comparable to or, at most, a few times higher than the natural background levels, and exposures will continue to decrease as the deposited radionuclides decay or are further dispersed in the environment. This is true for populations of the three countries most affected by the Chernobyl accident, Belarus, the Russian Federation and Ukraine, and all the more so, for populations of other European countries. Lives have been disrupted by the Chernobyl accident, but from the radiological point of view, generally positive prospects for the future health of most individuals involved should prevail.

Abstract

On August 22, 2008, a cloud of ^{131}I was released from the Institut des Radioelements (IRE), a producer of medical isotopes located in Fleurus, Belgium. The peak of the release took place in the weekend of 23-24 August and was followed by a smaller, continuous release which lasted for several weeks.

Several measures were taken after notification of the release to the Federal Agency of Nuclear Control, the Belgian nuclear safety authority. The nuclear emergency plan was activated on a N2 level. Under this emergency plan many environmental samples were taken and analysed with the purpose of verifying whether there was no risk for the population to obtain a significant dose via the food chain. Air samples were taken to confirm that no significant persistent release of ^{131}I was still occuring. This air monitoring was performed just after notification of the release and during major replacement work of the filter systems of the isotope production plant.

The Belgian Nuclear Research Centre SCK•CEN collected and analysed many of the environmental samples, performed the air monitoring and participated in the evaluation cell of the National Crisis Centre. In the course of these activities and in the period after the immediate crisis, some points were discovered that could be improved. Most of these findings dealt with:

- acquisition and measurement capacity of environmental samples
- Public communication
- separation of different tasks in the field
- communication between experts
- availability of expert knowledge

This paper elaborates on the main aspects of the SCK•CEN participation in the emergency response of this incident and draws important lessons to dealing with similar situations in the future.

Introduction

In nuclear emergency management a relatively low number of real incidents and accidents are available for training and improving the emergency plans. Therefore nuclear emergency management relies relatively heavily on theoretical exercises, based on calculations and hypotheses. A real incident or accident may provide a strong confrontation with the existing emergency plans, not only for the technical part, but also including the high pressure from the authorities, public and press.

On August 22, 2008, a cloud of ^{131}I was released from the Institut des Radioelements (IRE), a producer of medical isotopes located in Fleurus, Belgium. The peak of the release took place in the weekend of 23-24 August and was followed by a smaller, continuous release which lasted for several weeks.

The release was followed by the activation of the Belgian nuclear emergency plan, under which e.g. many environmental samples were taken and analysed to see whether there was any radiological risk for the population.

The Belgian Nuclear Research Centre SCK•CEN collected and analysed many of these environmental samples and performed several other duties in the nuclear emergency plan. In the course of these SCK•CEN activities and in the period after the immediate crisis, several points were discovered that could be improved in the working of SCK•CEN. This will be discussed in the following chapters.

Description of the incident

The release of ^{131}I started on August 22, 2008. The total release was 45 GBq ^{131}I. The peak of the release took place in the weekend of 23-24 of August and was followed by a smaller, continuous release which went on for several weeks. The release is shown graphically in figure 1.

The cause of the release was the mixing of three different waste streams from small waste tanks (two of 50 l and one of 23 l) into one main waste tank (2700 l). This caused a chemical reaction that produced I_2 gas. The total source term in the main tank was estimated to be 37TBq. The main part was absorbed by the filters, but 0.1 % was released through the stack of the installation.

Mixing of the different waste streams was common practice. However, this time all the three small waste tanks were transferred at the same time onto the main waste tank, while normally this was done one small waste tank at a time. Furthermore the main waste tank was originally almost empty (200 l), so the remaining concentrations were higher than usual. Simulations showed that certain chemical reactions that would produce I_2 were likely to happen.

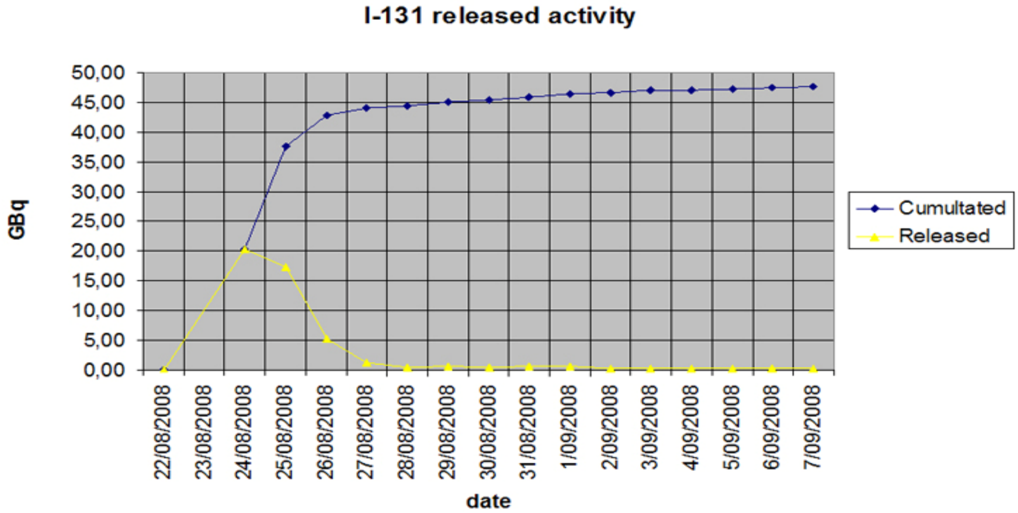

Figure 1. Released and cumulated activity of ^{131}I from the IRE incident [FANC1].

The incident remained unnoticed during the weekend of 23-24 August. It was observed on Monday 25 August by the safety engineer of IRE, who started his duty. The Belgian authorities (Federal Agency of Nuclear Control, FANC) were notified of the release at 17:30 Monday afternoon. Earlier on Monday IRE had already notified the TSO, Bel V [FANC1].

Simulations of the incident

On its own initiative SCK•CEN performed calculations with several dispersion models and decision support systems. These included Noodplan, a home-made model that is used by most Belgian nuclear facilities for emergency planning, HOTSPOT, a simple dispersion model, and RODOS, a decision support system developed with support of the EC.

The calculations with the different models showed a good agreement with each other and with the results of the measurements that were performed. Figure 2 shows just as an example results from RODOS calculations. The obtained results have not been analysed in detail and will not be further discussed in this paper.

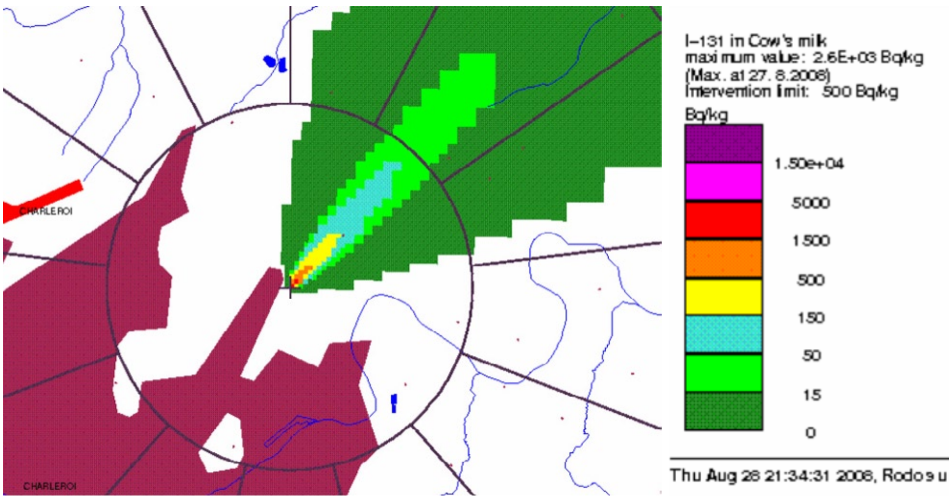

Figure 2. Results of a RODOS calculation of a release of 45 GBq ^{131}I.

The Belgian nuclear emergency plan and the role of SCK•CEN

Figure 3 shows schematically the structure of the Belgian nuclear emergency plan. The national crisis centre CGCCR consists of several cells which have their specific functions.

COFECO is chaired by the Minister of Interior Affairs or its representative and is responsible for taking decisions how an accident should be dealt with. It is supported by several cells for advise: ECOSOC for advice on social-economic consequences of countermeasures; INFOCEL for advice on communication to the public, CELEVAL for advice on radiological consequences of the accident and countermeasures. CELEVAL manages the measurement cell that performs measurements in the field and operates the TELERAD system for direct measurements of radioactivity.

By Royal Decree SCK•CEN provides a radiological expert to CELEVAL, a local measurement coordinator and a measurement team for in-situ measurements and sampling.

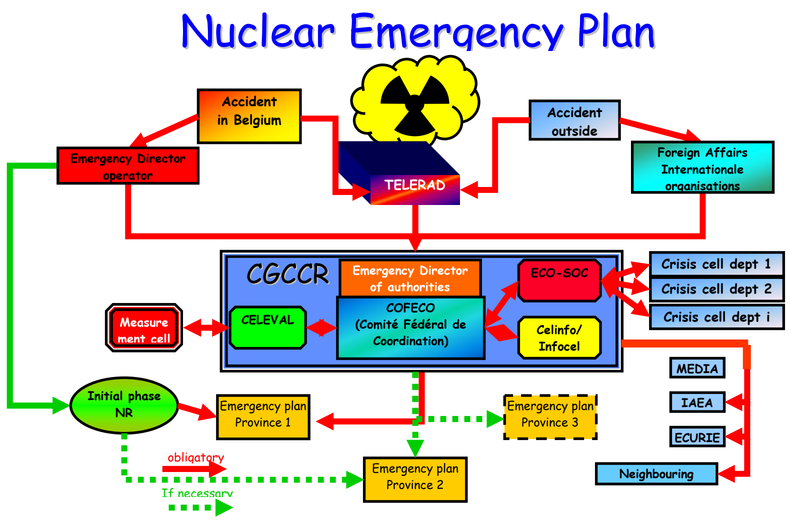

Figure 3. Structure of the Belgian nuclear emergency plan.

Measurements that were performed

On Wednesday 27 August the first three samples of grass were taken in the close vicinity of IRE by FANC. These samples were analysed at the Scientific Institute of Public Health ISP/WIV and the results were made available to the authorities on Thursday 28 August. They showed contaminations that could result in countermeasures for the food chain.

After the national nuclear emergency plan was activated on Thursday 28 August in the late afternoon, SCK•CEN was asked to prepare for the next day an intervention team for measurements and sampling. Instructions would follow the next day.

On Friday 29 August SCK•CEN sent out two teams, one for performing direct measurements and one for sampling. Two teams were sent since no instructions were received yet and it was not clear what would be asked by the authorities. Upon arrival at IRE, instructions were obtained to perform at specific locations air sampling and to perform in a quarter of a circle doserate measurements of the ground contamination. At 15:00 the coordinates were received of the locations were samples of grass or vegetables should be taken. These were five locations that were visited consecutively. In function of the availability, samples of grass, cornleaves and lettice were taken. The upper leaves of the corn were sampled to take the maximum contamination.

The samples were taken at the end of the day to SCK•CEN for sample preparation and measurement by gamma-spectrometry. Measurements were performed during the evening and night in order to provide the results to the authorities at the beginning of the next day.

Similar sampling and measurement campaigns were held at Sunday 31 August, Tuesday 2 September, Wednesday 3 September and Thursday 4 September. At the end of each day samples were taken to SCK•CEN in order to provide measurement results at the beginning of the next day. On Thursday 4 September an air sample was taken on active charcoal.

On Monday 1 September and Tuesday 2 September SCK•CEN performed, together with the University of Liège, a thyroid measurement campaign on the population of Lambusart, a village northeast of IRE. This campaign is reported in a separate paper [van der Meer et al.].

On Friday 5 September it was decided to do another air sampling campaign, since at that day an additional filter group was placed between the waste tank and the stack.

Figure 5. Sampling of vegetables in local gardens.

Countermeasures that were taken [FANC2]

As mentioned beforehand, the incident remained unnoticed during the weekend of 23-24 August. It was observed on Monday 25 August by the safety engineer of IRE, who started his duty. The Belgian authorities (Federal Agency of Nuclear Control, FANC) were notified of the release at 17:30 Monday afternoon. Earlier on Monday IRE had already notified the TSO, Bel V.

On Tuesday 26 August inspectors of FANC and Bel V visited IRE and ordered not to start any new production batch. Mobile monitoring systems were installed around the installation.

On Wednesdat 27 August FANC notified the IAEA and rated the incident on level 3 of the INES scale. FANC also collected grass samples in the close neighbourhood of the plant.

On Thursday 28 August results of the measurements became available, indicating that at certain locations the limits for countermeasures for the food chain could be passed. This triggered the activation of the national nuclear emergency plan on 17:00 on the level U2, implying no direct risk for the population but potential countermeasures for the food chain. A recommendation was issued that the population should not use vegetables or fruit from their own garden nor should use rain water in the region between 0-5 km northeast of IRE. Selling milk produced in the same region was also prohibited.

On Friday 29 August the sale of milk was again allowed, based on measurements on milk carried out on behalf of the Federal Food Agency. The other countermeasures remained in force.

On Saturday 30 August new measurement results were available. Based on the results, the affected region was reduced from 0-5 km to 0-3 km, while rainwater could be used again. The recommendation not to consume vegetables and fruit from the own garden remained.

On Saturday 6 September the remaining countermeasures were lifted, based on the results of all the measurements performed in the course of that week. Furthermore the emergency level was reduced from level 2 to level 1.

On Friday 12 September the national nuclear emergency plan was lifted.

Possible improvements

Many aspects of this incident can be used to improve the working of the nuclear emergency plan. In this paper we will mainly limit ourselves to propose improvements to the duties of SCK•CEN in the framework of the Belgian nuclear emergency plan as described above.

Separation of different tasks in the field

Before the IRE incident it was always assumed during exercises that one measurement team would be able to perform all actions in the field. Very soon it became clear that it was very cumbersome to send a team in the field with a combination of tasks. Different tasks like performing direct doserate measurements and sampling interfere quickly with each other and are best seperated, unless very little samples have to be taken. Separation of tasks also improves considerably the flexibility of the teams for answering to specific requests from the authorities.

Three different measurement teams have been defined after the incident: an intervention team responsible for direct measurements (doserate, ground contamination, air activity sampling), a sampling team for biological sampling (grass, vegetables, milk, water, ..) and an AGS team (Aereal Gamma Survey). The latter is supposed to operate from a helicopter or airplane, but at present it is operated by car.

Due to the fact that the intervention team and AGS team rely partly on the same expertise, SCK•CEN may at a certain moment not be able to provide experts for all teams in case of a protracted incident that requires measurements for e.g. several weeks.

Acquisition and measurement capacity of environmental samples

The IRE incident was a relatively small incident that contaminated only a limited area. Nevertheless it resulted in a serious demand on the capacity of the sampling team and the gamma-spectrometry measurement lab.

A larger incident in Belgium would require more resources from SCK•CEN. Both sampling and measurement capacity should be increased in that case.

A more optimized use of sampling and measurement teams seems possible. During the IRE incident the sampling locations and types were based on the collective results of the previous day resulting in a discontinuous sampling/measurement process (sampling in afternoon, measurements over night, analyses next morning + definition new sampling locations/types, new sampling in afternoon, ...). A more continuous sampling/measurement strategy in combination with the use of pure logistic teams for e.g. the transport of samples could already result in an optimization of sampling/measurement capacity.

Not all sampling teams had during the incident access in the field to software for the optimization of the route between a set of sampling locations (typical 10-20 locations). A general procedure on the transfer of measurement locations/type and measurement results was missing.

Sampling capacity was already increased by establishing a dedicated sampling team. Further expansion of the capacity is envisaged by increasing the number of sampling teams. This is only feasible in case the pool of persons that have sampling experience is increased. Expansion of this pool is envisaged by the participation of more people in the regular sampling campaigns in the framework of the surveillance of the Belgian territory. Additionally written procedures for sample taking have been developed that were lacking during the IRE incident. This will provide a better guarantee that samples will be taken in a similar way.

For several types of samples (mainly vegetation) the preparation of the samples will prove to be a bottleneck rather than a gamma-spectrometry measurement. At present preparation of samples deals with samples from the surveillance programme, that have no or very little radioactive contamination. Preparation rooms for these samples should not be used in case of contaminated or suspected samples. A dedicated room should be established. In case of the IRE incident an ad hoc solution was found by using a room with a ventilated box in a controlled area, but this room will not be sufficient for large quantities of samples.

Once prepared, samples can be measured in a rather short time since they are either sufficient active to give a good signal or will not give a significant signal from which the onclusion will be drawn that the activity is below a certain limit. However, clear measurement procedures still have to be developed for this case.

More exotic contaminations like beta or alpha contaminations will prove to be much more difficult to deal with, since the preparation time for these measurements are much longer than for gamma-spectrometry. Again specific measurement procedures have to be developed for these contaminations.

Public communication

It was inevitable that teams in the field would encounter representatives of the media. Although the communication about the incident should go exclusively via the national crisis centre, the field teams were sometimes forced to answer at least partially to specific questions. In a similar way the people whom were asked to provide their vegetables had many questions and also these questions should be answered by the teams in an adequate way in order to guarantee a continuous public support for the sampling campaign.

So although the principle of crisis communication demands one clear voice of the authorities and therefore demands a central spokesperson, the people in the field are exposed to questions from the media and should have adequate means/training to respond to these questions, either by providing clear answers or referring to a central spokesperson.

Communication between experts

Several types of communication could be distinguished:

- communication between experts for passing through information. This was mainly important for the evaluation cell of the national crisis centre. A summary of what was discussed during the day had to be given to the expert for the next day. This was done either in the form of a written report or orally by phone
- specific questions from the evaluation cell had to be dealt with by measurement experts. E.g. the request for a thyroid measurement campaign had to be supported by estimates of the detection limits of the available equipment and the amount of people that could be measured. This type of questions were handed over to a central scientist at SCK•CEN and then discussed internally with the relevant experts. An answer was provided in the form of a short note to the SCK•CEN radiological expert
- communication with the measurement team was dealt with by the measurement cell coordinator, an official function executed by SCK•CEN that takes care for the transfer of information between the federal evaluation cell and the measurement team. Coordinates of sample locations and type of samples are typical data to communicate to the measurement team.

Communication was often performed by cellular phone. This worked well, but in case of a major crisis it is envisaged that the cellular phone networks will be overloaded and cannot be used. Therefore extra phones have been purchased that function on a secure and reliable network.

Availability of expert knowledge

Both for making available an expert for the evaluation cell of the national crisis centre and for providing an expert for coordination of the measurement team, SCK•CEN has established a duty cycle. Each expert fulfills a duty of one week and hands it then over to the next expert.

It was noticed that the establisment of such a duty cycle is not a warrant that during a real crisis the expert functions can be fulfilled 24 hours per day and 7 days per week. The duty cycle is only a warrant that SCK•CEN will be able to provide an expert the moment an emergency call comes in for the next 8-12 hours. An expert shift had not been established.

During the incident SCK•CEN provided an expert for each evaluation cell meeting, based on the availability within the pool of experts at SCK•CEN. The decision who would participate in a meeting was normally taken one or two days before that meeting took place, but it cannot be denied that this method of working implied a certain form of improvisation.

The same was true for the establishment of the measurement teams. This was done on a daily basis and subject to the demand from the national crisis centre. Since only the coordinator of the measurement team is in a duty cycle, but not the team members themselves, here the level of improvisation tended to be higher than for the evaluation cell expert.

It has been recognised that the number of available experts should be enlarged in several domains: radiological experts, sampling team members, measurement analysts and experts (both for in the field and at the labs). However, in view of the limited resources available for this enlargement it should also be recognised that a certain level of improvisation will always be present.

Conclusions

The IRE incident did not cause any radiological harm to the general public. It is an interesting case to provide some lessons learnt for the emergency preparedness organisations in Belgium and possibly abroad.

The tasks that had to be executed in the field required one person (or team) for one job. Too many different tasks divide the attention people can devote the these tasks and imply a risk for making mistakes.

Sampling procedures have to be improved in order to be able to take more samples in a uniform way. Dedicated rooms for active samples should be present where many samples can be processed.

Gamma-spectrometry will not provide a bottleneck in measuring samples. However, due to the long preparation time alpha and beta measurements may require dedicated measurement procedures for large numbers of active samples.

Public communication is an important tool to provide the necessary support of the public for the measurement campaigns and countermeasures. During the sampling campaign SCK•CEN encountered full support of the public to provide samples from gardens.

Communication between the experts was satisfactory, but should be performed in a more standardised way by e.g. providing meeting reports after each day.

Availability of sufficient experts remains a difficult problem for relatively small organisations in a small country. Improving procedures will solve this partly, but a certain reliance on improvisation will remain.

Abstract

The EURANOS (European Approach to Nuclear and Radiological Emergency Management and Rehabilitation Strategies) project aimed to increase the coherence and effectiveness of nuclear and radiological emergency management in Europe including the rehabilitation of contaminated areas. Basis of this project was the establishment of an effective working platform of emergency management institutions, Research and Technological Development (RTD) institutes, end-users and other stakeholders. Within the EURANOS project, 17 different demonstrations were conducted. The objective of these demonstrations was to apply a certain product in the operational environment of an emergency centre and to check its performance either in particular exercises or in their daily use. As a result of a demonstration feedback to the development team was provided, highlighting requirements for the further development of the product – if necessary. A second key pillar in the project was the intensive involvement of the RODOS Users Group (RUG) in the research activities. In particular all work packages related to the further improvement of the RODOS system have been observed by the RUG. In some of the work packages, the RUG was involved from the beginning and participated even in the design documents for the software development. Both mechanisms, the demonstrations and user involvement, guaranteed that the end user's perspective was considered throughout all phases of the EURANOS project.

Introduction

Since the Chernobyl accident, considerable effort has been made in improving emergency management in Europe following nuclear incidents or accidents. However, many of these methods and information technology (IT) tools developed either nationally or under the EC's 4th and 5th Framework Programme are still not fully operational or not disseminated all over Europe. As a consequence, the EURANOS (European Approach to Nuclear and Radiological Emergency Management and Rehabilitation Strategies) project was initiated to increase the coherence and effectiveness of nuclear and radiological emergency management in Europe including the rehabilitation of contaminated areas. From the beginning it was obvious that such a task can only be accomplished successfully when Research and Technological Development (RTD) institutes, end-users and other stakeholders work together focusing on methods and tools that could be used operationally all over Europe.

The overall goal of the project was the enhancement of the technical, methodological and strategic approaches for national and cross-border emergency management and rehabilitation in Europe, what could progressively lead to the establishment of a European Platform for emergency management and rehabilitation strategies.

This could only be achieved with a large number of partners and when those responsible for nuclear or radiological emergency management and rehabilitation strategies within their countries and the Research Institutes developing methods, IT tools and strategies work closely together. Within the EURANOS project, 50 partners (17 national emergency management organisations and 33 research organisations) from 22 countries established a comprehensive working platform that covered all parts of Europe (see Figure 1).

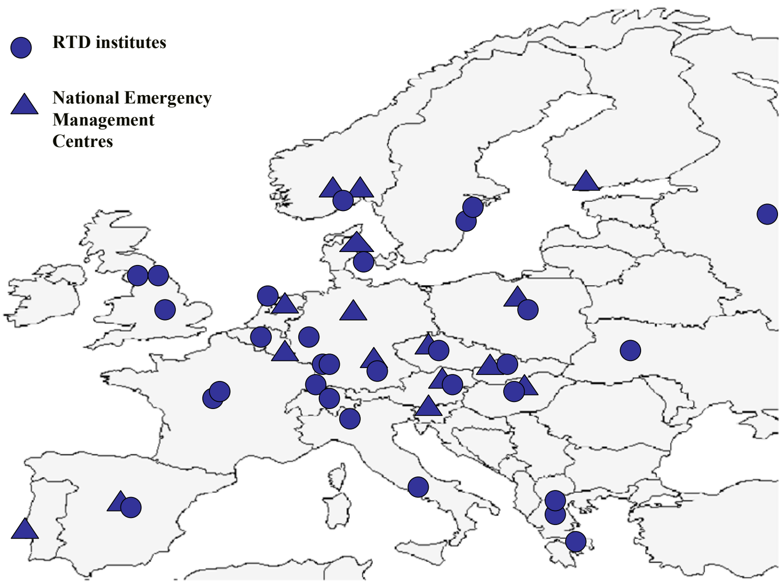

Fig.1. European coverage of the EURANOS project.

The work program of the EURANOS projects was structured in such a way that end products of research activities were continuously demonstrated by the operational community. This provided immediate feedback on the operation and usefulness of new methods, IT tools strategies and guidance (see Fig. 2).

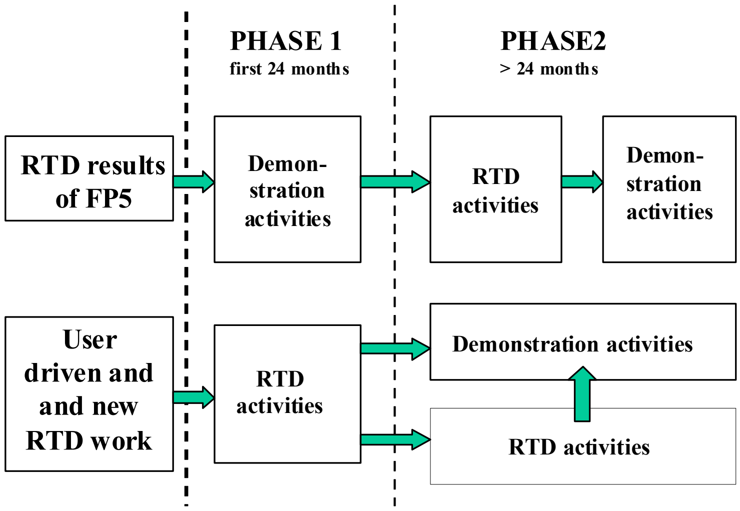

Fig. 2. Structure of the interaction between RTD and demonstration activities within phases 1 and 2 of EURANOS.

The objective of the demonstrations was to - using the feedback from expected future users - identify which of the tools, methods and approaches need further development and refinement. The scope of the demonstration activities in the EURANOS project encompasses activities in the various RTD work packages. In each of these work packages, the tools (in some cases specific elements of the tools), methods and approaches have been demonstrated under conditions which reflected as close as possible future operational uses of the tools demonstrated.

As one of the aims of EURANOS was to improve the operational use of the RODOS (Real-time On-line Decisions Support) decision support system (Ehrhardt, 2000), the RODOS Users Group (RUG) has been established as a discussion and interaction forum for co-ordinating and managing activities related to the demonstration and enhancement of the RODOS system and for providing essential feedback to the developers.

This combination of the user interaction via the demonstration projects and via the RUG as forum was one of the pre-conditions for the success of the EURANOS project.

Demonstration Projects

Demonstration activities were subdivided into two phases. In the first two years of the project (phase 1), either products from former research programs were demonstrated or products that were accomplished in the beginning of the various RTD activities of EURANOS. In the second phase, demonstrations focused on those produced realised within the EURANOS project only.

The demonstrations carried out within Phase 1 focused on the RODOS system. In particular the rather complex user interaction with the system was criticised in light of the continuously decreasing manpower and resources in emergency centres. Therefore, the use of the system has to be guaranteed also with a limited number of operators not deeply familiar with the RODOS system.

In the second phase, demonstrations focused on the usability of the decision aiding component of the RODOS software, small scale exercises dealing with releases other than from a nuclear power plant and the two handbooks on assisting in the management of contaminated food production systems and contaminated areas, which have been developed within the EURANOS project. In these two demonstrations of the generic handbooks not only the final product was exercised but also the process how to establish the best environment for the usage of these handbooks. This comprised the set-up of stakeholder panels which are an integral part of the successful application of the handbooks following a nuclear or radiological emergency. The two handbook demonstrations provided valuable feedback for the further improvement of the final documents available by the end of the EURANOS project. The final demonstration was devoted to the re-engineered RODOS system. The following list provides an overview on the seventeen demonstrations carried out.

Title	Objective of the Demonstration
Probabilistic Estimation of Source Terms from in plant data (SPRINT)	To demonstrate the use of SPRINT within the emergency organisation (plant or site-level as well as national level) to determine the feasibility of this tool for early prediction of the source term and to resolve related issues. To determine the appropriateness and related conditions for operational use of SPRINT To collect feedback from plant operators, TSC staff and decision makers (a/o authorities) in order to produce recommendations on further refinements or enhancements needed.
Networking and processing of on-line data in decision support systems	To verify the operability of the systems and including the compatibility of the formats to enable RODOS system to adopt the data and use it in its predictions: Specifically, the aims of the demonstration are to verify: • Transmission of on-line radiological and meteorological data from monitoring systems • Request and transmission of meteorological forecasts from national weather services • Further processing and adoption of both types of data within RODOS, in particular in the different operating modes.
Visualisation and evaluation of on-line data in decision support systems (RtGraph)	To evaluate RtGraph, RODOS' data visualisation tool for its usefulness and possible uses by emergency support organisations. To provide specialized user's perspective feedback to the development of the RtGraph on possible needs and ways to enhance and optimise the products to achieve the functionality needed.
User interfaces of decision support systems 1 – UI provided with patch 6.0	To assess the adequacy and usefulness of the RODOS user interface that was delivered within the RODOS patch #6.
User interfaces of decision support systems 2 – RODOS Lite	To assess the adequacy, usefulness and robustness of the new RODOS Lite user interface.
Adequacy of the system results and their forms of presentation within the decision making process	To establish to which extent RODOS (or another DSS) fulfils the needs of an emergency centre in providing the information that is needed for the support the decision making during various phases of nuclear emergencies.
Operation of decision support systems in a cluster environment with remote users of different access rights within one country	To demonstrate the use of the RODOS system with a central installation of the system in a national cluster with several external (i.e. remote from the central installation) RODOS users with different roles and rights.

Title	Objective of the Demonstration
Shared use of and data exchange between decision support systems installed in neighbouring countries	To demonstrate the use of the MODEM server for the exchange of information between countries using decision support systems, RODOS and ARGOS in this case. To investigate the benefits and possibilities to enhance the decision support while continuously (i.e. discretely, but in relatively short intervals) obtaining the data for a country where an accident occurred, and using those within RODOS.
Evaluation of the appropriateness of the ASTRID system for source term estimations based on in-plant data	To evaluate if the ASTRID system answers to potential end-users needs in emergency situation.
Small projects	To demonstrate the usability and usefulness of RODOS to support the decision making related with releases other than major NPP accidents.
Testing atmospheric capabilities of RODOS system installations through ENSEMBLE atmospheric dispersion exercises	To explore in RUG or elsewhere the interest in the emergency management community for having access to results for food concentrations, intervention levels, etc, of a similar form to those in ENSEMBLE for air concentration and deposition and second to attract all emergency management organisations to make use of the ENSEMBLE facility and to test the implementation and use of the MATCH model (inside RODOS) in the various countries
Demonstration of the usefulness and usability of the evaluation techniques in RODOS - Web-HIPRE	To demonstrate the usefulness and usability of the Web-HIPRE (Hierarchical PREference analysis in the World Wide Web) Java applet for decision analytic problem structuring, multi-criteria evaluation and prioritisation as part of the RODOS system for the later phase problems
Application of the MOIRA DSS to evaluate rehabilitation strategies for contaminated freshwater bodies at the local or regional levels	Testing the applicability of the MOIRA system for the definition and analysis of a variety of appropriate strategies for the long-term management of contaminated freshwater bodies, for both lakes (local scale) and rivers (regional scale). Testing the validity of the MOIRA system as a tool in the decision making process able to incorporate inputs from different ranges of stakeholders.
Demonstration of the usefulness and suitability of the hydrological dispersion module (HDM)	To assess whether the use of hydrological dispersion model (rivers) is of interest for emergency preparedness and how such a model would enable faster and better decision making at emergency centres. This was exercised with the help of a Polish case study
Generic Handbook for assisting in the management of contaminated food production systems in Europe	The first part of the demonstration aimed at testing the usefulness of the Handbook for developing a management strategy for one or more scenarios involving contamination of the foodchain. The objective of the second part of this demonstration was to assess the value of engaging stakeholders in applying the Handbook.
Generic Handbook for assisting in the management of contaminated inhabited areas in Europe	To test the usefulness of the Handbook for developing a management strategy for one or more scenarios involving contamination of an inhabited area
Basic Evaluation of JRODOS	To evaluate the reengineered RODOS system software, from the perspective of its usability and its robustness. Further to corroborate that the RUG requirements for the reengineered RODOS software are adequately addressed.

A demonstration project consisted of three main steps. First, the demonstration notebook was created which defines the main tasks to be carried out during the demonstrations and identifies the evaluation criteria. The second step was the demonstration itself which was performed either by individual organisations or in clusters of countries (which was the case for the demonstration of data exchange between decision support systems installed in neighbouring countries). Finally, the findings were summarised and evaluated resulting in recommendations from the operational user community how to proceed further with the tool demonstrated.

Key demonstrations related to RODOS were devoted to the revised user interface (RODOS-Lite) and the re-engineering of the RODOS system.

RODOS-Lite

In the first phase, the demonstration of the user interface resulted in a complete restructuring and improvement of the design, layout and IT-basis of the interface. From the beginning, even in the design phase, the RUG was heavily involved and interlinked with the research team. The RUG provided guidance in all aspects related to the operational use of such input forms. They also defined used cases describing the functional specifications needed for their operational application in their emergency centres. The demonstration thus focused on the fact to which extent the requirements set up by the end users had been realised in the final product. This final product, named RODOS-Lite user interface, was and is an integrated part of the RODOS system in all its realisations, either on HP, Linux or, with the re-engineered system, also Windows operating system.

Most of the RODOS users participated in the demonstration. At the end 12 organisations from 9 countries delivered individual reports with detailed information on the demonstration and findings that were forwarded to the software developers for further improvement of the product. In general it was concluded, that the RODOS-Lite user interface met the objectives defined at the start of the development pahse. Furthermore, it is applicable also for those users with little RODOS knowledge or even for fully untrained users.

JRODOS

With the ongoing EURANOS project, the RUG decided to request a fully re-engineering of the RODOS system. This was partly caused by the success of the RODOS-Lite interface demonstrating the capabilities when using state of the art IT technologies and modern design aspects. Therefore, two years before the end of the project, re-engineering of RODOS started focusing on a complete restructuring of the operating system but aiming to leave the simulation models unchanged. The new version should be JAVA based and thus applicable under the Linux and the Microsoft WINDOWS operating systems. The new version was named JRODOS. As RODOS was an important part of EURANOS, the success of the re-engineering of the RODOS system was important for the success of EURANOS in general. To demonstrate and evaluate the re-engineered RODOS system, four months before the end of the project, a demonstration was scheduled with the aim to assess the installation, overall performance and robustness of the new version and to test all functionalities by applying it to exercises or test runs. The assessment was expected to be done also in comparison to existing HP-UX/Linux installations of RODOS.

The number of participants was the highest among all demonstration projects. 15 organisations participated and issued either individual or combined reports with their main findings. There was a clear positive outcome of this demonstration project. Most of the participants concluded that JRODOS would be the version of RODOS that will be used in future in their emergency centres. However, some recommendations should still be considered. In this way, this demonstration highlighted the positive feedback of the users' involvement from the beginning of the RTD project and via the demonstration up to the final product.

RODOS Users Group (RUG)

When starting the EURANOS project, the Management Committee realised quite soon the importance of the end users' integration into the feedback loop – via the demonstrations – but also into the software development projects themselves. Therefore an imitative was started to create the RODOS Users Group in the first year of the EURANOS project. Furthermore, the chair person of the RUG became a member of the EURANOS Management Committee. This assured that feedback from this side was always represented at the highest level of management of the project.

The objective of the RUG during the EURANOS project was to provide RODOS system users with assurances that their experience and their demands was adequately considered. The aim was also to assure that there is a long lasting commitment of the RODOS developers to ensure proper operation and maintenance of the system for the future. To stimulate the feedback expected from the RUG, a strong interaction with the demonstration activities within EURANOS project had been established.

Specific aims of the RUG included:

- To provide a platform through which the members of the RUG can communicate their views, needs and comments and exchange their experience related with all elements of the RODOS system and its use, in particular provide response and guidance on refinements to make the system more user friendly and for any future developments of RODOS.
- To contribute to, to discuss and to approve the evaluation reports of the individual demonstration projects.
- To establish reports on RODOS users' requirements and views to the EURANOS Management Committee, and to provide advice on specific questions of the Management Committee, such as on planned directions for improvements / development.
- To share experience gained while integrating RODOS in the national emergency management arrangements, and to enable RUG members to enhance their own arrangements.
- To identify best practices, to share technical know-how and organisational solutions, software developments and data bases and their implementation, and to provide mutual support, particularly on a regional basis.
- To share practice and solutions related with use of RODOS for training and in exercises.
- To provide a forum through which the members of the RUG can network with each other, independent of the RUG's activities.
- To establish contacts to the User Groups of other decision support systems within Europe (ARGOS and RECASS) and overseas and/or to emergency management organisations not involved in the EURANOS project.
- Strive at reaching compatibility of the RODOS system with other decision support systems.

- To ensure sustainability of the RODOS decision support system after the end of the EURANOS project through the establishment of maintenance procedures and sustainable arrangements between the users and the developers.
- Promote the use of RODOS in Europe.

Members of the RUG participated in all demonstrations related to the RODOS systems. From the beginning, the user interaction with the system was of highest concern for the RUG. In a first step the RUG participated in the development of the RODOS-Lite user interface promoting state of the art IT technologies with its implementation in JAVA (object oriented programming language). The RUG requested functionalities for a direct error management of the user's input and consequent guidance of the user through a series of easy to understand input frames. In a second step, the RUG laid down their requirements for the re-engineering of the RODOS system in a long "wish list", in which priorities for the various requirements were provided, general demands were listed and more detailed requests were developed for a list of 16 use cases, which described typical applications of the system in an emergency centre. Especially important for the RUG were the following topics to be considered in the re-engineering:

- User friendly and intuitive graphical user interface with low training requirements and easy, consistent and neatly arranged user input forms
- Graphical representation of results that meets user requirements (e.g. integration of GIS functionalities, multi-lingual, annotated, etc.)
- Easy system administration and low maintenance costs
- Technical support including hot-line, web page (properly managed, supervised and kept actual, with notification on news etc.) for download both updates, patches, new versions etc. and guides and manuals, FAQ section
- Easy way of integrating external simulation modules in a framework with clearly defined interfaces

The RUG also requested that intermediate prototypes should be released for immediate testing. With this prototyping the RUG assured that new features introduced in one prototype could be immediately tested and feedback from the tests could be used in the development of the next prototype. This feedback loop via the numerous prototypes released within the two years of the re-engineering guaranteed that the development followed the requests and recommendations of the operational end users.

Due to the successful cooperation within the RUG and in between RUG and the RODOS developers it was decided among the RUG members to keep this group alive even beyond the end of the EURANOS project. For the future it is planned that the RUG becomes a part of the emerging European Platform NERIS (see further down).

Conclusions

When evaluating the results of the EURANOS project, one can conclude that the project successfully accomplished most of the objectives defined in its working program. This success is clearly the result of the demonstration projects as focal point for the application oriented RTD activities and the intensive interaction with the end-users organised in the RUG. Both have led to significant modifications of the working programme from the beginning of the project. They initiated in particular the development of the user friendly input interface RODOS-Lite and the complete re-engineering of the RODOS system focusing on modern IT-technology and enhancing the system to be used as an information platform for tools related to emergency management and rehabilitation. In this way, the new concept of involving end users from the beginning in a research project has been the key of success of the EURANOS project and will build a perfect basis for any further development of decision support systems. This success can be also seen in the emerging European Platform on Preparedness for Nuclear and Radiological Emergency Response and Recovery (NERIS) that will be established as part of the IRPA 2010 congress. In NERIS, for the first time research and operational community will form a sustainable platform aiming to sustain the current high achievements and further improve emergency management and response in Europe.

Acknowledgment

This work has received partial financial support from the European Commission Sixth Framework Programme (Nuclear Fission/Radiation Protection) under the EURANOS integrated project: European approach to nuclear and radiological emergency management and rehabilitation strategies (Contract No: FI6R-CT-2004-508843).

Abstract

Large scale activities aimed at decommissioning of a great number of Naval radiation-hazardous facilities are being implemented in Northwest Russia throughout the last decade. One of the key elements of safe decommissioning is preparedness to response to possible radiological accidents. Therefore, a modern emergency response system in the Murmansk and Arkhangelsk Regions are an obligatory element ensuring protection of population and territories in case of radiological accidents at facilities connected to nuclear submarine decommissioning, spent nuclear fuel (SNF) and radioactive waste (RW) management.

The paper describes the basic results of the international project "Enhancement of the Radiation Monitoring and Emergency Response System in the Murmansk region" implemented in 2005-2008 by the Energy Safety Analysis Centre of IBRAE RAS. The Project was funded by the Northern Dimension Environmental Partnership Support Fund - Nuclear Window. The Government of the Murmansk Region was the customer and beneficiary of this activity. The same project was started in Arkhangelsk region in mart 2009.

Introduction

The key objective of the Project is the cardinal improvement of the Radiation Monitoring and Emergency Response System in case of accidents at radiation hazardous facilities related to NPS dismantlement and RW, SNF management. The project is directed to the increase of emergency response forces and techniques preparedness, the minimization of possible radiation accidents effect, the increase of efficiency of decision-making and the implementation of actions related to population and environment protection. Radiation-hazardous facilities integrated into the radiation monitoring and emergency response system of the Murmansk region are given in Fig. 1.

[1] Presenting author, E-mail:kis@ibrae.ac.ru

Fig. 1. Radiation-hazardous facilities integrated into the radiation monitoring and emergency response system of the Murmansk region.

The Project Objective are:

– creation of Regional Crisis Center(RCC) in Murmansk region and Crisis Center of FSUE SevRAO;
– creation of program and technical system of operative expert support to make decision concerning the personnel, population and areas protection;
– development of existing and creation of new automated radiation monitoring systems (ARMS) at the areas of the enterprise and facility including the mobile systems of radiation survey;
– creation of communication systems and lines for data transfer, collection, processing, storage and representation for emergency response participants at facility, regional and federal levels and creation of operative expert support system of RCC of Murmansk region and FSUE SevRAO on the basis of Technical Crisis Centre(TCC) of IBRAE RAS.

Functional Diagram of Emergency Response System in Murmansk Region is given in Fig. 2. The main activities in the Project framework included the modernization of the existing and creating ARMS for facilities and territories, including mobile radiation surveillance laboratories; establishment of the RCC of the Murmansk region and the Crisis Centre of the FSUE SevRAO; setting up communication systems for transfer, acquisition, processing, storage and presentation of data for participants of emergency response at the facility, regional and federal levels; development of software and hardware systems for expert support of decision-making on personnel, population and environment protection; and establishment of a system for expert support of the created centres by the TCC of IBRAE RAS.

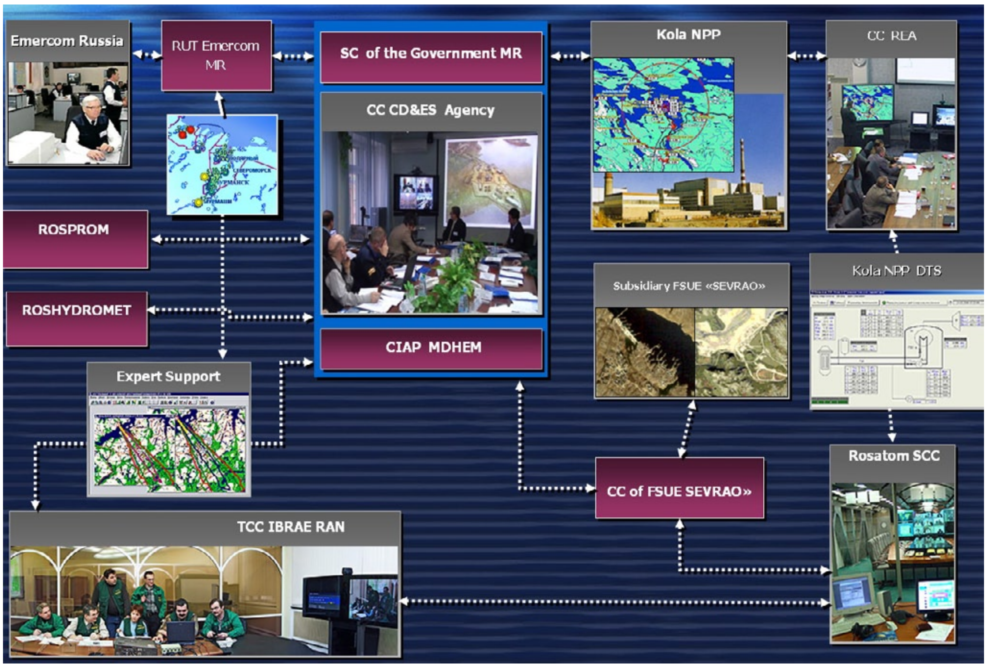

Fig. 2. Functional diagram of emergency response system of the Murmansk Region.

The Regional Crisis Centre(RCC)

The Regional Crisis Centre is created for the information and technical support of the Regional Administration, expert groups and commissions responsible for development and decision making for population and area protection in case of emergency at the nuclear and radiation hazardous facilities. In routine activity RCC carries out the operative monitoring of radiation environment at the local area, planning and control of measures for emergency situation prevention, trials and exercises. RCC includes the Contingency Center of the Government of Murmansk area, Crisis Center of Civil Defense, Emergency and Fire Protection Agency, Data Collection and Processing Center of Murmansk Agency of the Federal Hydrometeorology and Environmental Monitoring Service.

All parts of RCC are equipped with modern equipment and communication channels to organize the information interaction with local enterprises, regional and federal structures of the executive power.

The key tasks of the RCC:

- The information and technical support of the regional administration
- Agencies responsible for decision making under the minimization and elimination of the radiation accident effects;
- Planning and control of measures aimed against the accidents for the region as a whole;
- Current monitoring of key parameters of radiation situation at the overall area of the region;
- Provision of the interaction between participants of emergency response system at local, regional and federal levels;

The key tasks of the Contingency Center:

- Operative information provision about current situation in emergency area to the regional administration, operative cooperation with the Commission on emergency situation in the region, regional and federal executive bodies and enterprises;
- Daily information provision about emergency situation prevention measures to the regional administration, control of potentially dangerous facilities and environment of the region;
- Public information.

The key tasks of the Crisis Center of Civil Defense, Emergency Situations and Fire Protection Agency:

- Information and technical support of the regional commission on emergency situations and the Government of Murmansk area in daily and emergency modes;
- Planning and control of commission and execution of actions against the emergency situations for the region as a whole;
- Operative monitoring of key parameters of radiation situation at overall region including mobile laboratories of radiation survey;
- Support and development of information and program technical resources, provision of communication facilities operation and data exchange.

The Major Tasks of Data Collection and Processing Center:

- Collection, accumulation, processing, analysis, submission and transfer of the radiation situation data of local ARMS;
- Processing of current data about meteorological situation in the region and prognosis
- Provision (in case of the radiation situation); technical support and development of local ARMS; assessment and prognosis of air and water radionuclides transfer including Tran boundary one (together with Information Analytical Center of Rosgidromet).

Crisis Center of SevRAO

Crisis Center of SevRAO is intended for support and information reaction at the level of radiation hazardous facilities located at the area of the enterprise engaged in nuclear fleet decommission, RW and SNF management and the infrastructure facilities remediation. There are three branches in SevRAO, i.e. the former coastal technical bases of the Navy in Andreeva Bay and Gremikha and reactor compartment storage facility in Saida Bay. Crisis Center of SevRAO is formed on the basis of the enterprise in administration in Murmansk. The key tasks of the Center:

- Operative monitoring of main parameters of the radiation situation at the area of the enterprise branches;
- Planning and control of measures against the emergency situations at the branches of the enterprise;
- Assessment of situation, elaboration of recommendations and technical support of Commissions on Emergency Situations of SevRAO and branches in emergency situations;
- Information coordination with Rosatom;

- Information interchange between participants of emergency response system including the interaction with Regional Center of Murmansk area, Contingency Crisis Center of Rosatom and TCC of IBRAE RAS.

Information and Technical Complex of Crisis Centers

Information and Technical Complex of Crisis Centers includes:

– software: data bases, informational systems of radiation hazardous facilities condition, scenario of possible accidents, plans of the personnel and population protection, electronic maps, design simulated systems of prediction and assessment of the radiation situation with radioactive waste release in the atmosphere, water pollution assessment system (coastal water), engineering application programming of radiation dose and contamination assessment, display facilities of radiation monitoring system data;
– hardware: videoconference system, audio video presentation equipment, modern automated working places for the personnel, server and communication equipment, no break power system;
– communication facilities: office automatic exchange, automated warning system, fiberoptic communication lines between Crisis Centers; communication facilities with centers of the Federal level; satellite network for Rosatom data transfer; duplicated communication lines.

The certain set of the program and information facilities are used in the Crisis Centers depending on specific features of work. For example, the systems of assessment and prediction of radiation accident effects to the personnel, coastal sites and controlled areas are installed in the Crisis Centre of SevRAO. Centralized Information Exchange System of Murmansk Hydrometeorology and Environment Monitoring Agency provides the opportunity of operative processing of data concerning the radiation monitoring and prediction of air, water transboundary radioactive waste transfer.

In the Crisis Centre of Civil Defense, Emergency Situations and Fire Protection Agency it is possible to carry out the preparation of recommendations, concerning the population and areas protection measures with help of computer systems.

Murmansk Territorial ARMS

Murmansk Territorial ARMS are designed for online data collection about the radiation situation in Murmansk region, information of the regional and the Federal executive bodies and population. Murmansk Hydrometeorology and Environment Monitoring Agency is assigned by the corresponding legislative acts as the center of operational data accumulation, storage and the primary analysis. Within the framework of the project the works on Murmansk territorial ARMS elaboration including the development of new and updating the existing software of the system, the installation of 23 new automaticdose-rate measuring points at area of the region, the installation of 9 automatic meteorological stations, the installation of modern computer and communication equipment in Murmansk administration of the Federal Hydrometeorology and Environmental Monitoring Service have been carried out.

Location of monitoring stations of the Murmansk Regional Radiation Monitoring System is given in Fig. 3.

Under the initiative of Rosenergoatom Concern the integration of the existing ARMS of the supervised area of the Kola atomic power station in the territorial system of Murmansk region is provided. Simultaneously the staff of the local Crisis centre of the Kola NPP has got the access to the measurement data of the territorial ARMS of Murmansk area.

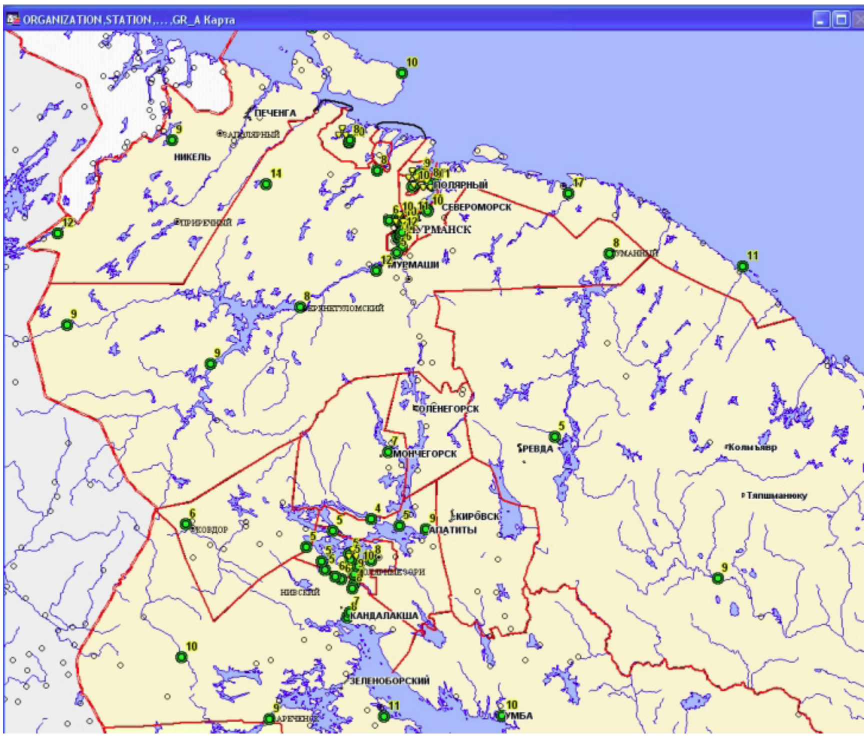

Fig. 3. Location of monitoring stations of the Murmansk Regional Radiation Monitoring System.

Mobile radiation surveillance Laboratories(MRL)

Four mobile radiation surveillance laboratories (MRL) are designed for operative radiation surveillance duties in case of radiological emergencies.

Capabilities: detection and localization of radioactivity sources and contamination; sampling and express-analysis of soil, air and water samples; determination of the characteristics of contamination; mapping of the boundaries of contaminated areas; transmission of measurement data to crisis centers in a real-time mode.(fig.4).

MRL equipment includes: measurement equipment stationary and portable gamma-spectrometer installations, dosimeters, alpha-, beta-, and gamma radiometers, sampling equipment; computer and communication equipment Inmarsat satellite terminal, cellular telephone communications, VHF radio station, GPS satellite navigation system, industrial computer and an auxiliary laptop, photo and video equipment; specialized software; auxiliary equipment vehicle power supply system, including petrol generator, and adaptation of the equipment to climatic conditions; working clothes and deactivation equipment.

Fig. 4. Location Mobile Radiation Laboratory(MRL). A fragment of data transferred from MRL System.

System of scientific and technical expert support

Now the Technical Crisis Centre of IBRAE RAS carries out the scientific and technical, expert support of Contingency Crisis Center of Rosatom, National Emergencies Management Center of the Ministry of Emergencies of Russia, the Crisis Centre of Rosenergoatom Concern, Information Analysis Center of Rostehnadzor, the enterprises, the regional bodies of the emergency situation prevention and elimination

The basic functions of Technical Crisis Centre at the Northwest of Russia are:

– Expert support of the Crisis Centers personnel and development of recommendations on minimization of emergency situation radiation effects for the personnel, population and areas of the region; Scientific, methodical and technical support of actions on forces and emergency response equipment readiness in the course of the exercises and trials included; Scientific, information, methodical and technical support for creation, development and introduction of new hardware and software systems for the support of administrative decisions concerning the protection of the personnel, population and areas in case of emergency situation.

The development of the territorial ARMS is carried out in Murmansk, Arkhangelsk, Kursk, Tver, Kaluga regions and Moscow in the framework of Rosatom, EMERCOM, Rosgidromet and IBRAE RAS cooperation as well as with Russian Federation Subjects agreements. There is a public site (Radiation Situation at Rosatom Enterprises) (www.russianatom.ru) created by Rosatom and IBRAE RAS. (fig 5).

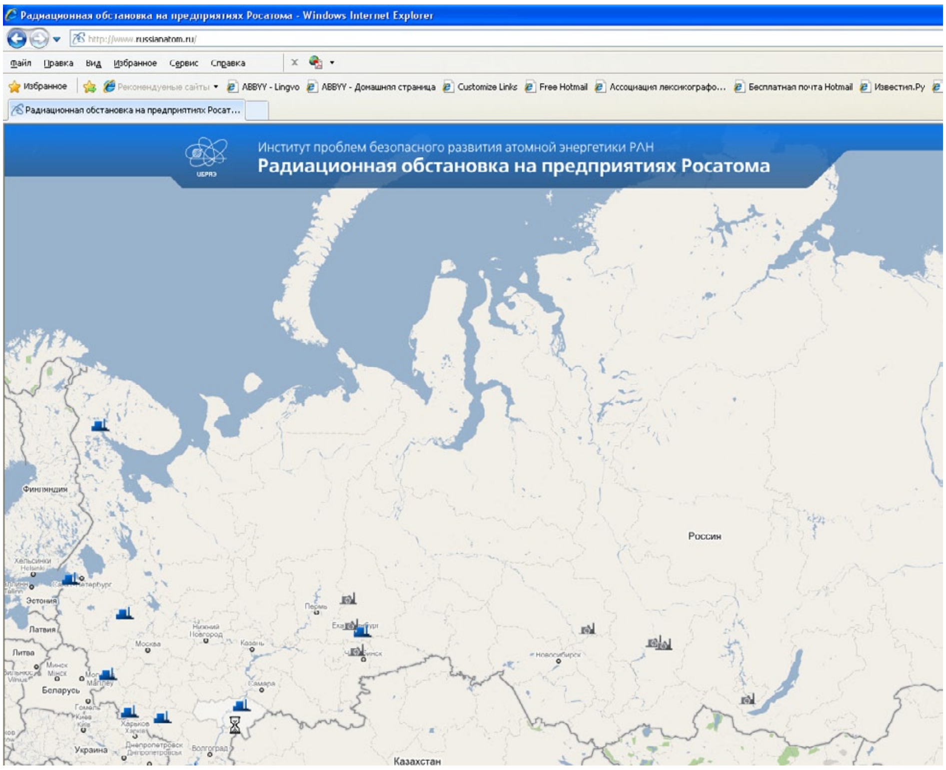

Fig. 5 The Internet Site Screen (Radiation Situation at Rosatom Enterprises).

Command staff exercise Zapolyarie 2007

Exercise "Zapolyarie-2007" in October 2007 demonstrated operability of all created elements and interaction of all participants of emergency response in the Murmansk Region.

All stated objectives of Zapolyarie 2007 Exercise have been reached. The interaction of emergency response system elements of Murmansk region and Murmansk territorial subsystem of the Unified State System of Emergency Situation Prevention and Elimination has been fulfilled. The exercise showed the steady work of all automated systems, communication lines under working in various modes. Data of current situation were operatively transferred to the exercise control body and all participants of the exercise (data from exercise area : branch No.1 of SevRAO, local and territorial ARMS, mobile laboratories). The interaction of all parts of emergency response system of Murmansk region and Murmansk territorial subsystem of the Unified State System of Emergency Situation Prevention and Elimination was completed.

The exercise was acknowledged as very successful by the management of the Murmansk Region and observers of IAEA mission. An IAEA mission, while assessing the emergency response status in the Murmansk region, confirmed a high level of preparedness and recommended the system established for further expansion.

Radiation Monitoring and Emergency Response System Upgrading in Arkhangelsk Region

In March 2009 the Agreement of the similar project implementation in Arkhangelsk region was signed with EBRD. There are some radiation dangerous facilities where works with Spent Nuclear Fuel (SNF) and Radioactive Waste (RW) are carried out. The key facilities are in Severodvinsk, Russia. Such facilities are: Zvezdochka Shipyard, Sevmash Shipyard, and Mironova Gora (radioactive waste storage facility).

Safety measures in the radiation emergency situation of the regional scale are taken at the local level in accordance with the Federal Law No. 68_ФЗ dated December 21,1994 and regulatory documents (the RF Government Decree No. 794 dated December 30, 2003). In case of emergency situation at the radiation dangerous facilities the Administration of Arkhangelsk region is to solve the problems of population protection, information delivery and intercommunication at the interregional level with the Administration of the neighboring Russian Federation Subjects, Authorities of the Federal Districts and Federal structures of the executive bodies. The Emergency Response Commission of Arkhangelsk region renders the decision on counter measures Implementation The system will comply with requirements of the Russian legislation and the international practice of the radiation monitoring and emergency response system organization.

One more key objective of the Project is the provision of the total radiation situation information to the population and public authorities at Arkhangelsk region and the transfer it to the neighboring states in accordance with the international obligations. The Project implementation will allow carrying out the sustained radiation environmental monitoring, the measurements for the short time radiation dangerous works execution period at the enterprises and obtaining data about the radiation doses at the areas contaminated as the result of the radiation accident.

In the framework of the emergency response system development the creation of the local and two site ARMS, the delivery of the MRL is of the highest priority. These systems are the important parts of the modern early warning and emergency response system for the enterprises and the Russian Federation subject. The system is to be integrated with similar system of Murmansk region.

The main scope of Project works will be completed for 20–24 months. It gives six months more for trial operation of subsystems, operators training and systems upgrading. Throughout 30 months the system is to be ready for operation as a whole. The system operation is to be carried out by owner.

Conclusions

NDEP-003 project is incomparable in Russia in terms of the covered territory, the number of radiation hazardous facilities and facilities participating in the international and Russian programs aimed at NS decommissioning and management of SNF and RW. The implementation of the Project provides the Murmansk Region with modern systems of radiation monitoring, informational, analytical and operative expert support of regional authorities in planning and executing activities on protection of the population in case of radiation accidents.

By considering the successful experience in Murmansk region the State Corporation Rosatom management included the works concerning the creation of similar systems in the regions of nuclear and radiation dangerous facilities location in the Federal Target Program (Nuclear and Radiation Safety in 2008 and to 2015).

Nordic Emergency Preparedness (NEP) – A regional concept for emergency planning

Husin, Stig
Swedish Radiation Safety Authority, Radiation Protection, SWEDEN

Abstract
The Chernobyl accident 1986 lead to number concrete steps that were taken worldwide aiming at enhancing the preparedness for Nuclear and Radiological Emergencies. One of these steps was the establishments of bilateral agreements and associated practical arrangements between Denmark, Norway, Finland and Sweden on Early Notification and Information Exchange. This in turn lead to an understanding of the feasibility of setting up an organised form of cooperation between the Nordic nuclear and radiation safety authorities on emergency preparedness matters. This cooperation was formally established in the year 1993 and has over the years rendered a regime for regular communication tests, good cross boarder knowledge and understating of the set-up in our countries, detailed arrangements for the practical implementation of the bilateral agreements and a lot more. The presentation will describe the historical background of NEP, show its present agenda, work process and highlight some of results achieved. The overall objective of the presentation is to, by using the NEP cooperation as an example, show the value a good and structured regional cooperation on an institutional level could add to existing international agreements and arrangements.

Incident and Emergency Centre of the IAEA

Stern, Warren; Buglova, Elena; Baciu, Florian

International Atomic Energy Agency, Incident and Emergency Centre, Department of Nuclear Safety and Security, AUSTRIA

Abstract

The Incident and Emergency Centre of the International Atomic Emergency Agency is the global focal point for preparedness, event reporting and response to nuclear and radiological incidents and emergencies irrespective of their cause.

The Centre continuously works to develop standards and guidance for strengthening Member States' preparedness; practical tools and training programs to assist Member States in promptly applying the standards and guidance; and organizes a variety of training events and exercises. Lessons learned from response to past emergencies form the basis for developing such standards, guidance and tools. Together with the experts from the Member States and the ICRP the IEC made efforts to develop the generic and operational criteria for application in preparedness for and response to a nuclear and radiological emergency. A rigorous examination of the response to past emergencies has shown that there is a need for international guidance on taking protective and other response actions and for placing a guidance in a context that is both comprehensive for the decision makers and can be explained to the public. So the criteria developed are accompanied by the plain language explanation. In addition these generic criteria are developed in the way that there application will ensure consistency with the concept of reference levels presented in the ICRP 103.

The Centre evaluates national plans and assists in their development; facilitates effective communication between countries; develops response procedures; and supports national exercises. The Centre provides access to multiple information resources; assess trends that may influence crisis and consequence management plans and response; and develops and continuously enhances methodology for identifying conditions needed for early warning and response. The Centre provides around-the-clock assistance to Member States in dealing with nuclear and radiological events, including security related events through timely and efficient services and the provision of a coordinated international response to such emergencies.

TMT Handbook – Triage, Monitoring and Treatment of people exposed to ionising radiation following a malevolent act

Muikku, Maarit[1]; Rahola, Tua[1]; Liland, Astrid[2]; Jaworska, Alicja[2]; Jerstad, Ane[2]; Rojas-Palma, Carlos[3]; van der Meer, Klaas[3]; Kruse, Phil[4]; Smith, Karen[4]; Etherington, George[5]; del Rosario Pérez, Maria[6]; Carr, Zhanat[6], Smagala, Genowefa[7]

[6] WHO – World Health Organization
[7] CLOR Central Laboratory for Radiological Protection, POLAND

Abstract
In the aftermath of the Chernobyl accident European national emergency response plans were focused on dealing with accidents at nuclear power plants. The perception of the increased threat has shifted the focus to being prepared also for malevolent use of ionising radiation. The European Commission through the Euratom Sixth Framework Programme was co-sponsoring a specific targeted research project aimed at producing a practicable handbook for an adequate response to such incidents (TMT Handbook). The handbook gives advice on how to prepare the response for such incidents and how to handle the situation both at the scene of the incident and at the hospitals. Advice on public health interventions including criteria for the long term follow up are also described.

1 Introduction
Until recently European national emergency response plans focused on accidents at nuclear power plants. Several terrorist acts carried out by disaffected groups have shifted the focus to being prepared also for malevolent use of ionising radiation aimed at creating disruption and panic in the society. The casualties of these kinds of acts will most likely be members of the public. The radiation exposure can range from very low to substantial and it could be combined with conventional injuries. It might also be the case that the magnitude of the incident is such that the national response capability is overwhelmed, calling for international assistance.

The European Commission through the Euratom Sixth Framework Programme was co-sponsoring the specific targeted research project TMT handbook. The main objective of this project was to produce a practicable handbook for the effective and timely triage, monitoring and treatment of people exposed to radiation following a malevolent act. The TMT handbook project started with the collection of already published material to identify useful practices and provide a basis on which to develop clear guidance that was consistent with the current knowledge and experience in this field. There are a number of recent publications that address some of the issues raised in responding to malevolent use of radiation. For example, ICRP Publication 96: Protecting people against radiation in the event of a radiological attack [1] focuses on protection criteria for responders and the public. US NCRP [2] provides a review of the consequences and management of terrorist events involving radioactive material. A number of international publications [3-9] including the advice for first responders [10] and for medical response [11] provide useful guidance on the early response and generic treatment options available. In addition to the published articles in journals [12, 13, 14] there are some national guidance and protocols available. However, the information on triage, monitoring and treatment of people is scattered in several documents, especially with regard to a malevolent event scenario. As no single reference source existed on dealing with these issues, the need for TMT handbook was apparent.

In order to produce the TMT Handbook a project consortium was drawn together including the Belgian Nuclear Research Centre (the project coordinator), the Norwegian Radiation Protection Authority, Radiation and Nuclear Safety Authority of Finland, the UK Health Protection Agency, the Central Laboratory for Radiological Protection of Poland and the World Health Organization. Enviros Consulting was acting as the technical secretariat for the project. The TMT handbook was drafted by the consortium members with input from subject-matter experts and circulated for feedback to European emergency response institutions that would play a part in the handling of malevolent acts using radioactive material. These institutions were given a consultation time with encouragement to test and evaluate the handbook content through national emergency response exercises and stakeholder consultations. A workshop was held in December 2008 in Lillehammer, Norway to obtain feedback from the end users on the content, structure and usefulness of the handbook before the final version was produced. The received comments and suggestions helped in improving and harmonising the handbook for the use in European countries.

The TMT handbook contains both general information and detailed recommended actions to be taken at the scene of the incident and in hospitals by specialised response teams in radiation protection, monitoring, dosimetry and medical management. It gives advice on how to plan the response for such incidents and how to handle the situation starting at the scene of the incident going through the response at hospital level and further to public health interventions including criteria for the long term follow up. It also provides guidance on public information and communication strategies. The TMT Handbook is also a useful tool for training purposes. The aim of this paper is to give an overview of the contents of the TMT handbook.

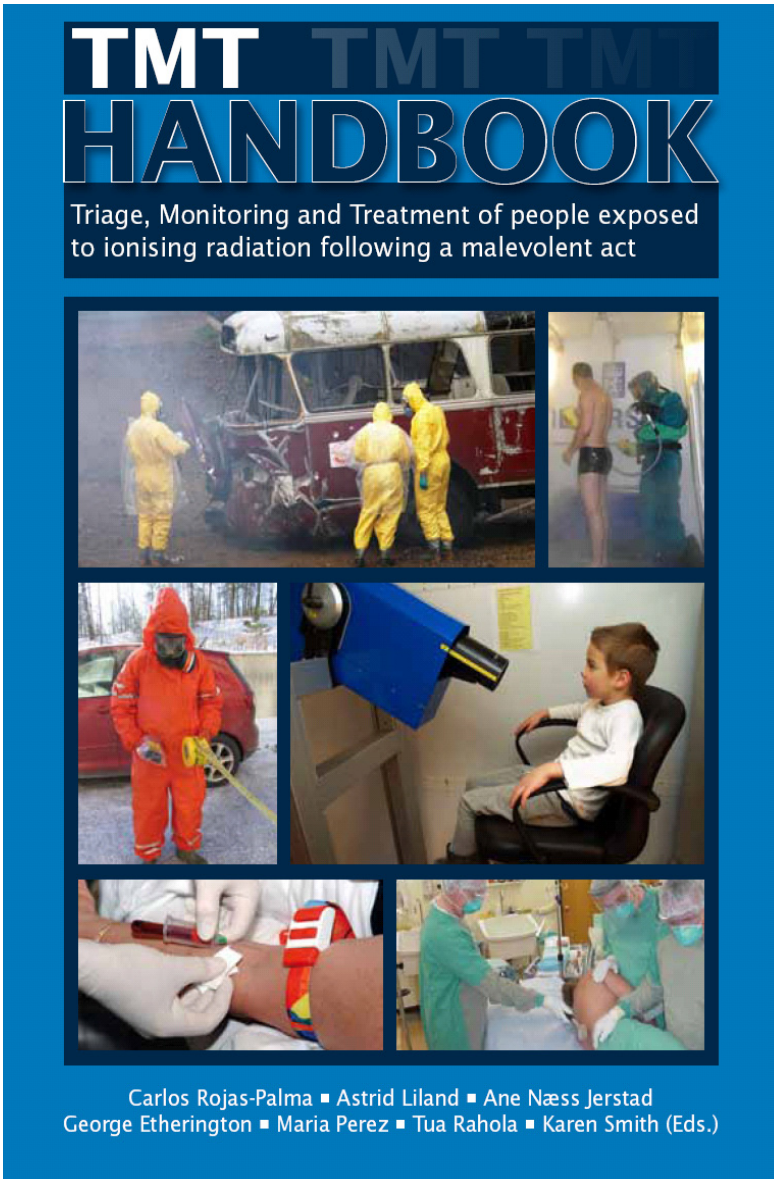

Figure 1. The cover of the TMT handbook.

2 Contents of the TMT Handbook

The content focuses on topics specifically related to the triage, monitoring and treatment necessary to respond to a malevolent act, while ensuring the appropriate protection of responding personnel. It is not intended as a complete check list for first responders, but instructions are given for actions and it can be used in the training of such personnel. Nor is the handbook intended to include exhaustive descriptions of medical treatment of conventional injuries since hospital staff is already trained for this. The handbook includes twelve color-coded chapters, annexes, references and a glossary.

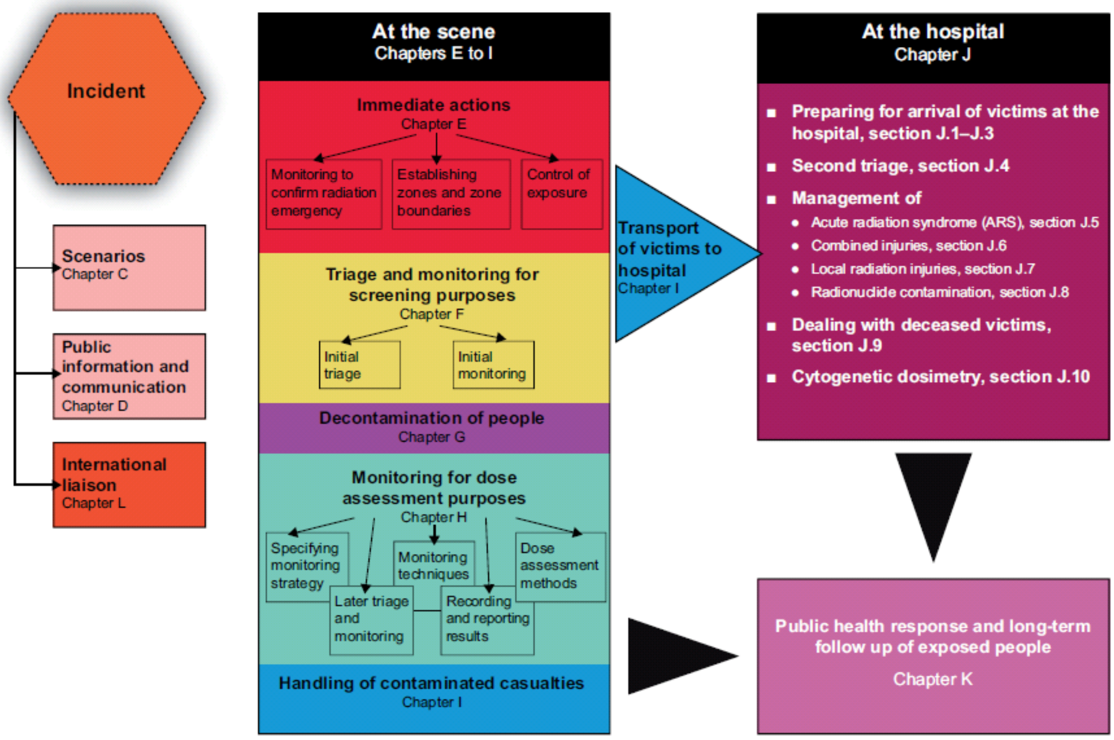

Figure 2. The content of the TMT handbook.

Chapter A introduces the handbook.

Chapter B gives an explanation on the handbook structure and guidance on how to use it. It is recommended to read this carefully before proceeding to chapters E to J. Chapters E-J give practical guidance for incidental and accidental situations. The structure of the handbook is such that the numbered instructions to be used by the incident responders are presented on the left hand pages, linked to relevant supportive information that is presented on the right hand pages.

Chapter C gives a short summary of possible malevolent scenarios. The chapter does not include detailed descriptions of scenarios in order not to facilitate malevolent acts by disaffected groups. The scenarios are not meant to indicate the probability or possibility of any such event actually occurring. Neither should it be assumed that the scenarios described are an exhaustive list of the possible incidents that could occur. It is the responsibility of each country to carry out its own threat assessments as a basis for developing national radiation emergency and response plans.

Chapter D gives general guidelines on public information and communication strategies. Public communication should be considered a key function in any response involving the malevolent use of radiation. For public communication to be credible and trustworthy, the organisation providing it must be seen as open and transparent. To be effective, public information response should be planned in advance. These plans will need to be integrated within the overall planning for managing malevolent acts and should detail the roles and responsibilities to be carried out during the response. It should also be recognised that there exist cultural differences between countries and therefore similar means and techniques for communication may not be effective in all countries, any approach would need to be tailored to the specific situation and location.

Chapter E describes immediate actions specific to the radiological emergencies to be taken at the scene mainly during the first hours after notification or discovery of an incident. These actions include monitoring to confirm a radiation emergency, establishing zones and controlling the exposure situation. In the initial stages of the response, there will be little time to carry out detailed planning of the response, and minimal information on which to base such plans. The actions given in this chapter may be implemented automatically without the need to develop plans that are specific to the incident. It is advised, however, to be familiarised with the handbook content before using it in the field.

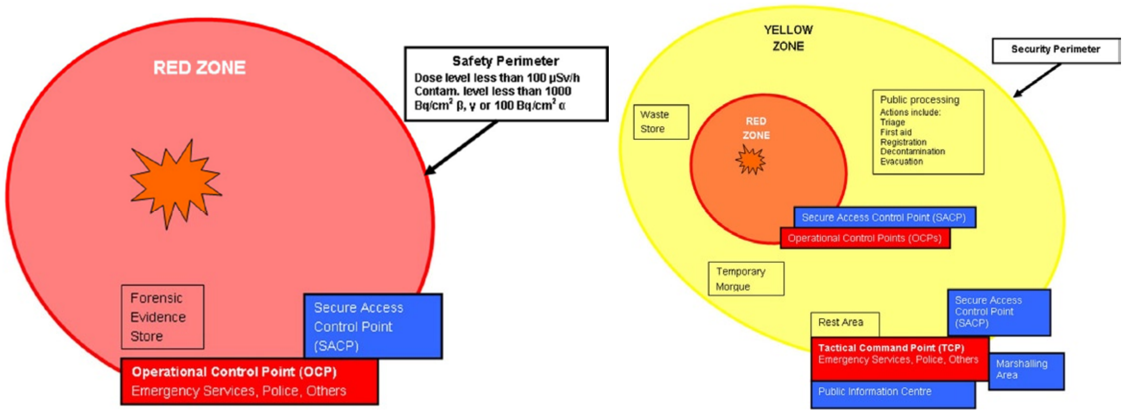

Figure 3. Generic layout of the red and yeallow zones.

Chapter F is dedicated to the best practice for triage and monitoring of people for the purpose of screening. "Triage" is the use of simple procedures for rapidly sorting people into groups based on (a) their degree of physical injury and (b) on actual or potential radiation effects on health, and the allocation of care to these people so as to expedite treatment and maximise the effective use of resources. Conventional trauma triage may be required following incidents involving the malevolent use of radiation or radioactive material in a public place. However, the scope of triage is broader for such incidents and includes a group of actions that can be termed "*radiological triage*". These actions are intended to sort people rapidly into groups depending on actual or potential effects on their health resulting from radiation exposure. In the handbook the objectives of the triage process are presented. The term "*monitoring*" describes the measurement of radiation dose or contamination for reasons related to the assessment or control of exposure to ionising radiation or radioactive material, and the interpretation of the results.

Figure 4. Left: "Lap geometry" for whole body measurement with portable gamma spectrometer. Right: Measurement of ^{131}I in the thyroid. These photographs illustrate the method, but when responding to an incident, additional measures would need to be employed, i.e. the detector would be wrapped in plastic film, and the subject would wear disposable gloves. Photos: STUK.

Chapter G gives practical advice on decontamination of people in the field. In this chapter only the removal of radioactive contamination is considered. People who have only been externally irradiated do not require decontamination. Decontamination should be carried out as soon as possible but does not require the same immediacy as chemical or biological contamination, except in extreme circumstances where the contamination is sufficient to cause deterministic effects. People involved in an incident where radioactive material is present in the environment will be prioritised for decontamination using the procedures detailed in chapter F. Decontamination of injured people will take place either in hospital or adjacent to the incident, depending on the severity of injuries.

Figure 5. Demonstration of decontamination of people who need assistance. Photos: HPA.

Chapter H provides instructions for monitoring of ionising radiation for dose assessment purposes. The TMT Handbook is mainly concerned with individual monitoring, but the other forms of monitoring (e.g. source monitoring, environmental monitoring) also come within the scope of the handbook. Individual monitoring is monitoring using measurements of quantities of radioactive material in or on the body of the individual, or measurements made by dosimeters worn by individual workers. It includes the assessment of radiation doses from the results of such measurements. The main objectives of monitoring are: to quantify absorbed doses to organs and tissues for people exposed to radiation at a level high enough to potentially give rise to deterministic health effects, to provide the dosimetric information that would allow urgent decisions to be made to remove individuals from a source of external exposure, or to remove or reduce contamination on or in the body, to quantify committed effective doses for people with lower levels of internal contamination that could result in an elevated risk of stochastic health effects, to provide dosimetric information that could be used when making decisions on medical treatment and to quantify committed effective doses for people whose exposures are very unlikely to have an effect on health.

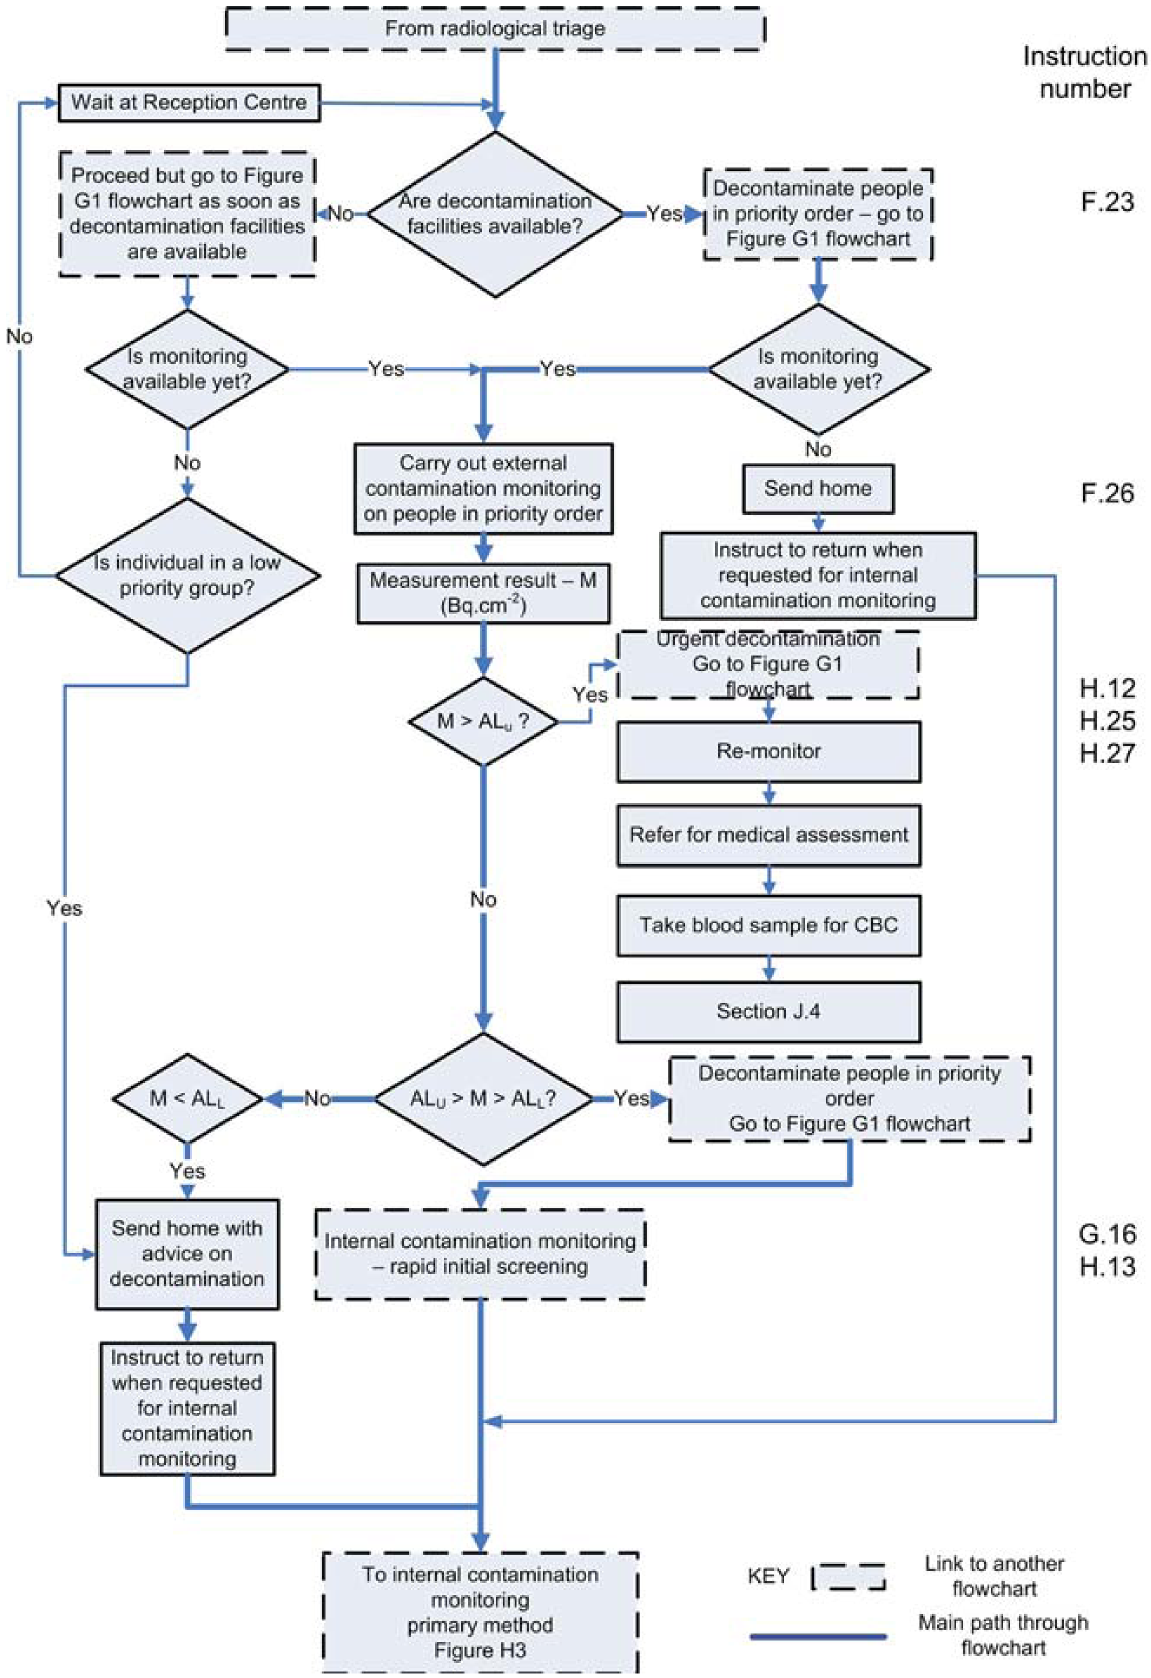

Figure 6. An example of the flowcharts in the handbook. This flowchart shows radiological triage based on results of external contamination monitoring.

Chapter I gives advice on handling of contaminated casualties and transport to hospital.

Chapter J is addressed at medical doctors, nurses and other health-care workers who may have to manage people affected by events involving the malevolent use of radioactive sources and would be responsible for actions to be taken at the first referral hospital level concerning diagnosis, prognosis and treatment and health-care facilities management. The chapter includes the information on management of acute radiation syndrome (ARS), local radiation injuries, combined injuries and internal contamination including management of contaminated patients and decorporation techniques. The chapter highlights the critical links between pre-hospital and hospital response.

Figure 7. While conservative treatment may be indicated for superficial lesions, painful deep ulcerations and necrosis require surgical treatment. These photos show the evolution of tissue necrosis after surgical treatment including artificial skin graft. Photos: courtesy of Percy Hospital and IRSN. For artificial skin graft photo, permission also provided by the IAEA.

Chapter K provides guidance on public health response, including the role of health authorities during the emergency, initial actions to be taken, management of outbreaks of unusual disease attributable to radiation exposure, and criteria for long-term follow-up. During radiation emergencies resulting from malevolent use of radioactive sources, health authorities should make provisions for dealing with a large number of people who may self-report experiencing symptoms or even as asymptomatic patients. Some people may be concerned about consequences of possible exposure to radiation, even if not actually exposed (“worried well”). Prevention and management of psychosocial effects are also addressed in this chapter. Psychosocial impact is one of the terrorism’s chief aims.

Chapter L provides information on existing arrangements based on the international conventions for early notification and assistance in case of radiological and nuclear emergencies. The proper handling of serious incidents or situations where prompt response is warranted in order to mitigate the effects of a perceived hazard, may require resources that challenge the capabilities of a single country. It is therefore important for countries to co-operate in order to better respond to such emergencies. The international assistance arrangements are set up through formal mechanisms such as the IAEA's Emergency Conventions, the WHO's International Health Regulations. These mechanisms provide for coordination of international arrangements, while not necessarily eliminating the need for bilateral or multilateral agreements between countries relating to the information exchange or assistance.

Annexes 1-14 contain a lot of supplementary information and practicable look-up tables for both the planning and the response phase:

Annex 1: Required facilities
Annex 2: Equipment required for radiological triage and monitoring purposes
Annex 3: Forms, questionnaires and information leaflets
Annex 4: Allocation of roles
Annex 5: Interpretation of clinical signs and symptoms
Annex 6: Specifying a monitoring strategy for internal contamination
Annex 7: Later triage and monitoring
Annex 8: Monitoring techniques
Annex 9: Biodosimetry
Annex 10: Action Levels
Annex 11: Sampling of excreta and blood
Annex 12: Management of internal contamination
Annex 13: Look-up tables for the assessment of internal doses
Annex 14: Methodology applied by WHO for developing guidance on health interventions for Chapters J and K of this Handbook

3 Dissemination of the TMT Handbook

At the start of the TMT Handbook project, an information leaflet was sent to all European emergency response organisations with specific functions to plan, coordinate and execute mitigating actions in response to malevolent acts involving ionising radiation. The leaflet informed about the project and encouraged organisations to join as end user. The role of the end users was to give feedback on a draft version of the handbook and, if possible, test the handbook in national emergency response exercises. End users from 16 countries participated in the project and gave valuable input to the draft both by correspondence and by participation at a feedback workshop arranged in Norway after a consultation period of about 6 months. This gave valuable input for adjusting the layout and content for the final, printed version.

A training course based on the TMT Handbook was held in February 2009. The training was directed primarily to representatives of national emergency response organisations with responsibility for first response in emergency situations, hospitals and wider health-care infrastructure, such as public health authorities. The aim of this course was to enable participants to better understand the principles of management of malevolent events involving exposure to radiation, to strengthen national capabilities for planning and response to such events and to encourage participants to promote the incorporation of the TMT Handbook into exercise and training programmes in their countries. The course also provided a platform to identify common challenges and discuss opportunities for harmonised and coherent response strategies within the European Union.

The TMT Handbook was published in April 2009. The electronic version is available on the project's web page: www.tmthandbook.org upon registration. More than one thousand users from 57 countries on five continents have downloaded the handbook and nearly two thousand hard copies have been distributed by the summer 2010.

The TMT handbook will contribute to a harmonisation across Europe of the approaches to triage, monitoring and treatment of people exposed to radiation following a malevolent act. It will be also a tool to build capacity in the region as well as beyond Europe to be incorporated into training programmes at national, regional and global level.

Acknowledgements

This work was partially supported by the Norwegian Research Council and the European Commission Euratom Sixth Framework Programme through grant number FP6- 036497. We are grateful to all European emergency response organisations that agreed to test and evaluate the handbook as end users.

Norwegian assessment of current national nuclear and radiological preparedness

Selnæs, Øyvind Gjølme; Holo, Eldri Naadland; Eliassen, Karl Emil
Norwegian Radiation Protection Authority, NORWAY

Summary

In 2004, the Norwegian Crisis Committee for Nuclear and Radiological Preparedness initiated a project to assess the current level of national preparedness regarding nuclear and radiological emergencies. The purpose of the initiative was to make recommendations on how to further develop preparedness within the Norwegian nuclear and radiological preparedness organisation and to improve current national emergency response planning. The project is expected to be completed during the summer of 2010.

The first phase of this project was finalised in the autumn of 2008 and constitutes a comprehensive hazard assessment. The second phase of the project will address two issues. Firstly, based on foreseen scenarios and relevant consequences from the study in phase one, it will study management of nuclear and radiological emergencies. It will also review the roles and responsibilities of different regional and national authorities and explore the practical implementation of different mitigation efforts. Secondly, resource requirements within the nuclear and radiological preparedness organisation will be addressed.

Phase 1: Assessment of nuclear and radiological hazards

The first phase of the project points out changes in the Norwegian perception of nuclear and radiological hazards over the last few years. It provides an overview of possible nuclear or radiological events which may affect Norway or Norwegian interests abroad, as well as relevant consequences for public health, the environment and other public interests.

The assessment of nuclear and radiological hazards was published in the autumn of 2008 as NRPA Report 2008:11 (in Norwegian).

Phase 2: Adequate management of nuclear and radiological emergencies and resource requirements

Roles and responsibilities

Norwegian preparedness for nuclear and radiological emergencies differs from most other national emergency preparedness systems in Norway. In order to ensure an efficient, rapid and competent management of the early phase of a nuclear event, a national Crisis Committee for Nuclear Preparedness has been appointed. The Committee is authorised to make decisions and order implementation of specific countermeasures in the early phase and ensures good coordination on a sub-strategic level (directorate level).

Phase 2 of the project reviews and clarifies the roles and responsibilities of the governmental bodies involved in the nuclear emergency organisation and addresses the relationship between them.

Dimensioning of Norwegian nuclear and radiological preparedness and crisis management

There is an evident need for a common understanding of the basis for choices made regarding emergency preparedness development. Phase 2 of the project establishes a set of six general dimensioning scenarios qualitatively describing the consequences of a nuclear or radiological incident. These scenarios enable a better prioritising of current needs and have been approved by Norwegian political authorities.

Emergency management timeline and nuclear emergency phases

Current Norwegian nuclear and radiological emergency management adheres to the “acute” and “late” categorisation of emergency phases. These phases are poorly defined in existing emergency plans and the transition between the phases is poorly developed. The police and medical services in particular have a different intuitive understanding of the term “acute” than other governmental bodies involved in nuclear emergency preparedness. A more thorough description of the emergency timeline is therefore recommended.

Necessary management

Phase 2 of the project reviews necessary management of nuclear and radiological emergencies and examines mitigation strategies. Different actions are defined and categorised and practical implementation of different mitigation efforts is explored.

Resource requirements

In the last few years, there has been a positive development concerning warning routines and measurement capabilities. Phase 2 of the project recommends that future preparedness development has emphasis on competence, organisation, plans and exercises.

[2] Finnish Meteorological Institute, FINLAND

Abstract

A lot of expertise and teamwork is needed to understand an evolving nuclear accident, to assess its off-site consequences, and to make optimal recommendations. The working of the various groups involved relies on information exchange and on adequate computer support. In Finland we have been developing a Web platform that makes it easier to exchange information and for all users to be kept up-to-date with the development of the situation. The platform bridges the spatial remoteness of expertise (incl. hardware and software) and provides a consistent user interface to tools that could be used before only with special training. In addition, it provides the different users with their views of the situation and supports the process from source term input, over dispersion and dose assessment, up to the approval of various reports. Although still developed, the platform has been in use in the Radiation and Nuclear Safety Authority of Finland (STUK) and the Finnish Meteorological Institute (FMI) for roughly two years. So far we have received mainly positive feedback.

Introduction

Emergency management of nuclear accidents is a collaborative effort: one team assesses the plant status and makes an assessment of the likelihood and magnitude of a release; another team is in charge of making dispersion calculations with the given release assessment; their results are given to yet another team so that they can plan suitable measurement campaigns; still another team assesses possible health effects and the need for interventions by taking into account the most likely dispersion situation and already available measurement results; and there is a need for coordinating all this effort and communicating to the public, which in turn can only be done successfully if first hand and timely information about the current state of affairs and about likely future developments are readily at hand. Of course collaboration does not stop here but this does roughly picture the collaboration that is needed at STUK and FMI to cope with an event.

Collaboration, however, is not something that happens spontaneously during an event. It has to be planned for and arrangements have to be in place. STUK and FMI have developed therefore a Web application that allows them to manage, view and share the results of dispersion and dose calculations and other information related to nuclear or radiation accidents (Lahtinen et al. 2008, Ammann et al. 2008). The application helps them to produce timely reports of the radiological situation and to plan protective actions. In addition, it keeps record of all relevant user activities and allows the simulation of measurement data.

Ketale collaborative software

The main purpose of the Ketale system is to support the management of nuclear or radiological emergencies at STUK and FMI. The use cases of Table 1 are typical in this context.

Table 1. Typical uses cases of the Ketale system during emergency management.

1.	The duty officer creates an event ID.
2.	FMI issues weather bulletins and recommends the most appropriate numerical weather prediction dataset to be used in subsequent dispersion calculations. FMI also provides weather radar images, met tower measurement readings, and other weather related products.
3.	The radiological consequence assessment group requests trajectories.
4.	The accident assessment group makes a release assessment.
5.	The radiological consequence assessment group requests dispersion and dose calculations for the given release assessment. The group compiles a report with various forecasts of the radiological situation.
6.	The recommendation planning group plans protective actions and compiles a recommendation report.
7.	The management group views and evaluates the various reports.

STUK and FMI work together in this process. FMI operates numerical weather prediction models, provides access to their long-range atmospheric dispersion model and offers other weather related products. STUK, on the other hand, keeps contact to the accident site, makes release assessments, compiles all data into various reports and recommends protective actions. Within these institutes the work is further distributed over different groups, most importantly for our purposes an accident assessment group for release assessments, a radiological consequence assessment group for dispersion calculations, and a recommendation planning group for the planning of protective actions.

Next to the human aspect of collaboration there is a software and hardware aspect as well. Experts use all sort of tools (source term assessment codes, dispersion models, environmental transfer models, dose models, etc.) when making their assessments. Some of these tools work only on particular operation systems and on dedicated hardware. For example the long-range dispersion code runs on a supercomputer at FMI, and the dose model is a traditional single-user Windows program. Users need various communication software (e.g. FTP, email) to transfer results between tools and other users; and they need office tools, GIS, image processing software, and other productivity software for various purposes. An additional complication is the need for authorization and authentication in order to gain access to the various resources. In practice, it can be therefore quite challenging to timely produce the high-quality reports that are required.

In summary the following observations can be made:

- Emergency management is a collaborative effort. An easily accessible and constantly updated audit trail of all activities such as model requests or communications is needed.
- Modelling applications and expertise are distributed (weather forecasts and dispersion predictions by FMI, source term and dose assessments by STUK) and have are integrated.
- Modelling applications run on different hardware and software and often have scientifically motivated user interfaces. The users, however, should not have to care about these peculiarities.
- Modelling applications often produce static images that are hardly suitable for all users in all cases.

The Ketale system was created to streamline the data and information exchange between the various groups involved in the process. The goal was to create an application that integrates the distributed modelling applications and facilitates collaboration and sharing of information. It is a Web application that complies with the following user requirements (Lahtinen et al. 2008):

- Collaboratively multi-user: users work together on a single case and need access to remote resources;
- Ease-of-use: there should be only very few client side requirements; the system should not require any special or advanced computer skills; different users need different views of the system;
- Multi-purpose: emergencies, exercises, training, measurement simulation, comparison exercises, source detection should all be supported; the system should have at least European wide coverage;
- Multi-lingual: Finnish, Swedish, and English should be supported at least as far as products and reports are concerned;
- Reliable: the system should be fit for operational use in emergency centres; this must be assured by constant quality control;
- Open: data import and export should be easy; the system should integrate well with other systems;

Operational experience

Feedback from emergency exercises is the main vehicle to constantly improve the system and make it more apt to the actual process of how emergencies are handled. The most recent operational experience comes from the Loviisa preparedness exercise held in March 2010. This exercise demonstrated quite well the important role that Ketale has today in the emergency arrangements of STUK and FMI. During this exercise 11 Ketale users collaborated in the production of 31 different reports, and many more participants used Ketale to keep track of the accumulation of information. The system was used to exchange 7 different release assumptions, which subsequently were fed into both far-range and near-range dispersion and dose models. The results of these model runs were again available to all Ketale users.

Expectedly, model results changed with new release assumptions; but they also changed according to the chosen numerical weather prediction model or dispersion model. During and after the exercise the contamination pattern that was estimated by the long-range dispersion model was compared with those of three different near-range dispersion models (all calculations were basically done with the same release assumptions and numerical weather prediction dataset) and they all differed to various extents. This raised the problem of how to choose the most suitable weather prediction and dispersion models, or how to unify such disparate results and communicate the underlying uncertainties to other users. Currently Ketale does not offer a solution to this problem.

Although positive in its general tenor, user feedback pointed out several other areas of improvements. Most notably the rather new features of planning protective actions, on-line report editing and the integration of measurement data seem to need additional attention. For the first time the simulation of measurements was available during the exercise. A Ketale user kept all her activities private and feed simulated measurements into STUK's monitoring software, from which it was available to other Ketale users as well. This feature was widely appreciated as it allowed testing the use and usability of monitoring data.

Discussion

In several exercises before the introduction of Ketale it was recognized that the handling of dose and dispersion calculations was quite unsatisfactory and that it took far too long to produce reports that were needed to brief decision makers or their senior advisors.

First of all, most of the modelling applications were not very user-friendly. Models were difficult to use and they often required special operation systems (e.g. UNIX). Their graphical results were mostly static maps with poor geographic details and lacking annotation. The maps also varied with colour, projection, grid size, etc., which made it difficult to compare results from different programs.

Secondly, the modelling applications did not interoperate well or not at all and it was difficult and time consuming to produce reports of the radiological situation. It took typically over an hour to produce a first report with a map of the area of risk and relevant weather descriptions, which was considered too long a time.

Information exchange between FMI and STUK happened mainly by telephone request and FTP transfer of the results. Telephone requests, however, had major drawbacks as lists of phone numbers had to be maintained, messages could be easily misunderstood, and the process worked only if there was a counterpart present on the other side. Luckily FMI operated a 24/7 person-on-duty service, though. In addition there was the problem of how to convey the content of the telephone conversation to other participants.

There were no technical arrangements in place to communicate source terms – that is, data on the amount and nuclide composition of the release – to different dispersion models. Each model had its own ways (and limitations) of dealing with source terms so that the procedures of providing source terms to these models were rather cumbersome to follow.

Another issue that was not sufficiently supported was the planning of countermeasures. It relied on generic GIS software, which was not linked well with other software. For example, though desirable, it was not possible to display model results as a backdrop map when planning intervention areas. Furthermore, manual cut & paste procedures had to be followed in order to get the resulting images into a report.

Eventually, modelling data and reports were not stored in one place but instead were distributed in several places. After the exercise it was difficult therefore to analyze the case.

On the whole, the reliability of the whole process was unknown. Major exercises are arranged quite rarely (about once a year) and accidents can happen at any moment. That is why it is important to regularly check the availability of all tools. Routine tests of such non-automated procedures are quite time-consuming to perform, however, so that they were not often enough made. This left the users often in the awkward situation that they did not know whether their tools will work or not.

Many of the just mentioned shortcomings could be remedied. A trajectory model and a long-range dispersion model, both from FMI, are coupled to the Ketale system as is a dose model from STUK. Results from these models can now be transparently requested by filling in and submitting Ketale forms, the results can be displayed interactively, and suitable portrayals can be added effortlessly to summary reports. The requests appear on a notification page and are accessible to all observers.

The major advantage compared with the situation before the introduction of Ketale is the significant improvement in the time it takes to create reports. It takes now less than 10 minutes to create a summary report containing for example a map of the dispersion area and a textual weather description. Also the quality of graphical outputs is improved. These improvements were achieved by automating some steps that previously had to be done by hand with word processors and image manipulation programs. Ketale’s translation feature is another major benefit. By changing the language settings of the web page it is very easy now to create reports in English in addition to reports in Finnish.

Conclusions

Information exchange between STUK and FMI has mostly been automated. It is now documented and constantly tested. Testing does not only allow increasing the reliability of the preparedness tools and communication channels, but also allows putting a reliability index on the availability of the system. This is useful for quality assurance purposes.

Ketale was found to be very useful in the exercises held so far. The time needed to produce reports for senior advisors or decision makers has decreased significantly, and their quality and consistency has improved substantially. The countermeasure planning page was highly appreciated by the recommendation group.

But Ketale was not only found to be useful, it had also a considerable effect on the emergency preparedness organization and on how the process could be conducted. Prior to the introduction of Ketale, far too much expertise had to be diverted from producing assessments and recommendations to the technical details of the process (how to get data from here to there, how to produce maps, etc.). Formerly STUK needed to maintain trained personnel for the various modelling applications, now this demand has almost vanished. Ketale provides a consistent user interface to the modelling applications and hides all technical peculiarities. Questions like: Where is program X installed? What is the user account? How do I get the results into the report?, do not have to be asked anymore.

The application supports the process from source term input up to the issue of reports. In doing so it preserves a complete audit trail. Data and information exchange is streamlined, transparent, traceable, and routinely tested. Reports are produced much faster than before, they are standardized and better deliberated, and data portrayals are tailored to the needs of the users. Although still developed, the application has been in use in STUK and FMI since 2008. So far we have received mainly positive feedback.

Acknowledgements
There were many more people involved in the project than could be accommodated in the list of authors. We thank the project members K. Alm-Lytz, L. Pöllänen, and H. Lemmelä from STUK and J. Vira, J. Korhonen, M. Visa, M. Aalto from FMI for their valuable contributions. We thank the members of the steering group H. Aaltonen, S. Salomaa, R. Mustonen, and H. Toivonen from STUK and H. Juntti, J. Korhonen, and T. Tourula from FMI.

Abstract

The paper presents several aspects believed to be relevant for the integration into the decision support systems for the management of radiological emergencies, of assessment tools addressing surface water contamination. A few exemplary cases are discussed, relating to domestic and international alert exercises and including, in the major league, tools like RODOS and MOIRA, both developed by multinational consortia; and, in the domestic league, solutions trading off scientific appropriateness in grasping the complex phenomenology involved, with computational practicality, mainly revolving around a radiological assessment toolkit, developed as an open-ended software that assemblies requisite source term evaluation, environmental transport, dosimetric diagnose and countermeasure projections. Tools complementarity and synergy; model streamlining; and interfaces comprehensible and palatable for the stakeholders appear to be the key factors paving the way of the aquatic path into the emergency response business.

Introduction

The National Institute of Physics and Nuclear Engineering (IFIN-HH) in Bucharest was the Romanian partner of election for the European consortium that has developed RODOS (Real-time, Online DecisiOn Support System for the management of nuclear emergencies in Europe); In so doing, institute's underlying strategy has rested on:

(i) pursuing a substantive participation in the development and promotion of a reference, mutually agreed upon, and thereby credible and internationally-credited decision support systems in the case in point RODOS and MOIRA (A MOdel-based computerised system for management support to Identify optimal remedial strategies for Restoring radionuclide contaminated Aquatic ecosystems and drainage areas);

(ii) developing, parallelly, domestic knowledge and data bases as well and innovative tools - methods and software, in order to emulate, at various levels of complexity, and get familiar with, the functions embedded in the reference tools; and ensure a meaningful participation in hypothetic incident analysis and periodic national and international drills.

Two decades of tool development and applications have left many practitioners with the feeling that, while the atmospheric path of environmental and human radioactive contamination is confidently marked, the aquatic path is, comparatively, approached with reluctance and treated in much more idiosyncratic ways. The fact may be attributable, at least in part, to the modelling complexities of the transport and dispersion of pollutants in water, called to account for sensitivities to volumes, boundaries, shapes, flows, injection mechanisms, space and time scale of events etc., and the reservations of the emergency responders to confront such complexities. Indeed, the comparative look at the essentials in the surface water dispersion models may result in quite a list of input variables that may be compiled from the variety of minimal problems that challenge the analysis. A typical (yet non-exhaustive) set of problems may read as follows:

(1) A single port of cross-sectional area A_o (m^2) discharges a liquid pollutant of density ρ (kg/m^3) at a volumetric flow rate Q_o (m^3/s) at, or close to, the surface of a water body of depth H (m), density ρ_o (kg/m^3), and featuring a crosscurrent of speed U_a (m/s).

(2) A single port of cross-sectional area A_o (m^2) discharges a liquid pollutant of density ρ (kg/m^3) at a volumetric flow rate Q_o (m^3/s), under an angle θ (deg. of angle) from the horizontal, deep below the surface of a water body of depth H (m) and density ρ_o (kg/m^3). Determine the concentration field.

(3) A multiple port of length L_d (m), consisting of n identical ports, spaced at l metres from each other, each port d metres in diameter, discharges a liquid pollutant of density ρ (kg/m^3) at a volumetric flow rate Q_o (m^3/s), under an angle θ (deg. of angle) from the horizontal, deep below the surface of an ambient water of density ρ_o (kg/m^3), depth H (m), crossflow velocity U_a (m/s), L_r cross-length, and flow rate Q_r (m^3/s). Determine the downstream concentration field.

(4) Determine the steady-state bidimensional concentration field $C(x,y)$ (kg/m^3) resulting from an initial (representative near-field) source concentration C_i (kg/m^3) of a pollutant released at Q_o (m^3/s), of decay constant λ (1/s), in a river with uniform depth H (m), ambient velocity U (m/s), and slope s, knowing that, by virtue of either plume narrowness or river's wide channel, there is no significant plume/bank interaction.

(5) Determine the steady-state bidimensional concentration field $C(x,y)$ (kg/m^3) resulting from an initial (representative near-field) source concentration C_i (kg/m^3) of a pollutant released at a rate of Q_o (m^3/s), of decay constant λ (1/s), occupying a transverse river expanse between y_1 (m) and y_2 (m), in a river with uniform depth H (m), uniform width W (m), ambient velocity U (m/s), cross-current velocity U_a (m/s), and slope s, knowing that, by virtue of either plume's wide aperture or river's narrow channel, there is a significant plume/bank interaction.

(6) Determine the steady-state concentration field $C(x)$ (kg/m^3) resulting from an initial source concentration C_o (kg/m^3) of a pollutant released at a rate of Q_o (m^3/s), of decay constant λ (1/s), in a river with uniform depth H (m),

uniform width W (m), ambient velocity U (m/s), and slope s, knowing that the pollutant is short-lived and/or the conditions are highly unsteady (e.g. in case of an accidental spill, of an important river shear flow or cross-sectional turbulent mixing).

(7) Determine the time-evolving concentration field $C(x,t)$ (kg/m^3) resulting from an instantaneous discharge of M_o (kg) pollutant of decay constant λ (1/s), in a river with uniform depth H (m), uniform width W (m), ambient velocity U (m/s), and slope s.

(8) Determine the steady concentration field $C(x)$ (kg/m^3) resulting from a discharge of initial concentration C_o (kg/m^3) and flow rate Q_o (kg/m^3) pollutant of decay constant λ (1/s), in a marine (tide-featuring) estuary with uniform depth H (m), uniform width W (m), ambient freshwater velocity U_f (m/s), and slope s.

(9) Determine the concentration, assumed to be uniform, C (kg/m^3) resulting from a recirculated discharge of initial concentration C_o (kg/m^3) and flow rate q_o (kg/m^3) pollutant of decay constant λ (1/s), in a small lake, pond or reservoir of volume V (m^3), with a throughput flow rate q (m^3/s).

(10) Determine the time-evolving concentration field, $C(x,y,z;t)$ (kg/m^3), with z measured from the water surface, resulting from a discharge of initial concentration C_o (kg/m^3), flow rate Q_o (m^3/s) and pollutant decay constant λ (1/s), into an open sea advective current of velocity U (m/s).

(11) Determine the time-evolving concentration field, $C(x,y;t)$ (kg/m^3), valid within a water colomn of depth H (m), resulting from an instantaneous discharge of a mass M_o (kg), of pollutant with a decay constant λ (1/s), into an open sea.

Fig.1 presents some accidental releases to surface water as model output examples like: river release, weak interaction with banks; river release, strong interaction with banks; open sea, instantaneous release; estuary, continuous release. The DSS software employed is AIDRAM (Gheorghe and Vamanu, 2003; 2005).

Drills and tools

An international exercise targeting the response to a virtual (simulated) abnormal event with offsite consequences at the nuclear power plant Cernavoda, ConvEX-3 aimed at, essentially, comparing national capabilities to conjointly and consistently address the same occurence in the nuclear emergency business. On the domestic side, Oltenia 07 has tested near-site response capabilities in the case of a transborder accidental release at the Kozloduy NPP, on the Danube river in nearby Bulgaria. Again looking at Cernavoda, Axiopolis 09 challenged, under international monitoring, local authority capabilities to mount countermeasures to an abnormal release, in the order of a limited evacuation of the population. The impact assessment of the (virtual) radioactive release on the hydrological network, especially on the Danube river were looked at as obviously less familiar than the atmospheric release (Vamanu et al., 2010), and so were also the decision support tools called upon to assist in the process.

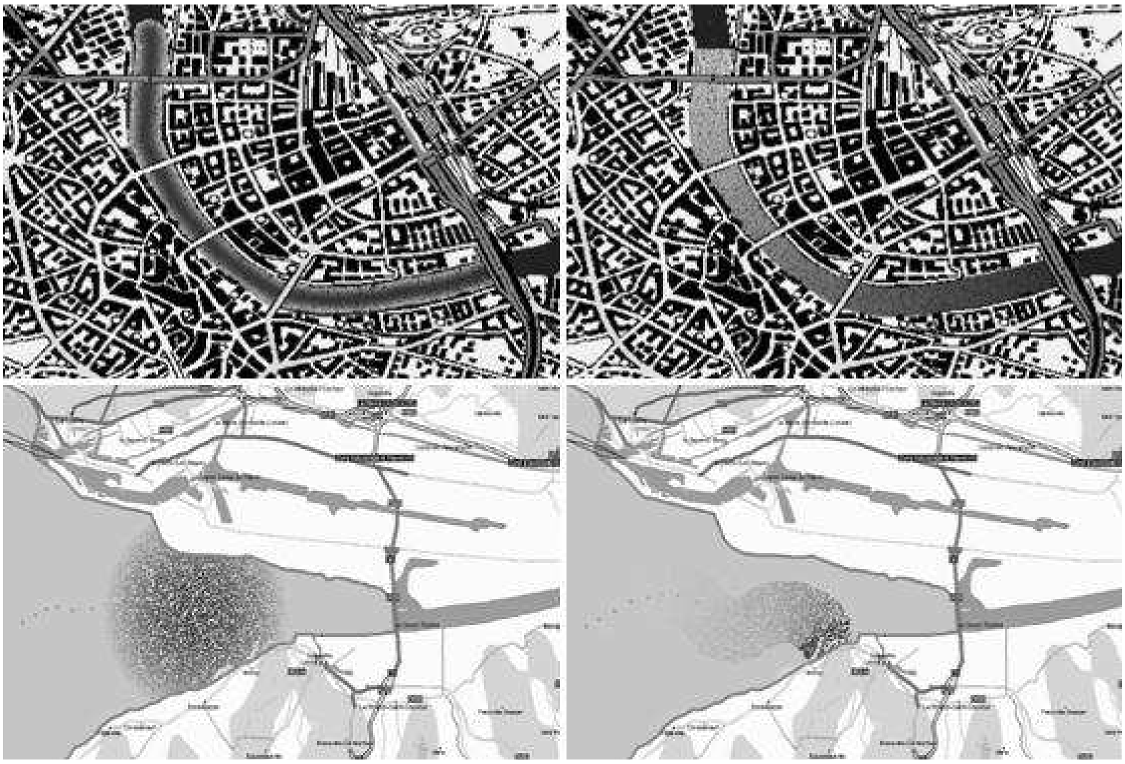

Fig. 1. Accidental releases to surface water as model output examples like: river release, weak interaction with banks; river release, strong interaction with banks; open sea, instantaneous release; estuary, continuous release.

A comprehensive software package developed by a consortium of European research institutions and promoted by EC as a reference DSS, RODOS (Vamanu et al., 2006; Rafat et al., 2006; Raskob and Ehrhardt, 2000) covers the early (1-7 days) as well as the intermediate and long (ingestion) phases (months, years) in the development of an accidental radioactive release, with the health-, environmental- and economic issues properly considered. The RODOS system includes a specialist module known as HDM, covering the relevant transfer processes in the hydrosphere. The HDM facility relies on the Saint-Venant equations for water flow modelling, assuming the flow as one dimensional. MOIRA (Magan and Gallego, 2006), on the other hand, is a management-oriented model to identify optimal strategies for restoring radionuclide contaminated aquatic ecosystems and drainage areas. The system is able to screen and evaluate a variety of strategies for the long-term management of contaminated freshwater bodies. MOIRA models the water transport process by the assessment of the input/output balance of water flowing to and from each reach, subdividing the river in 20 reaches. Both RODOS (RODOS Working Group, 2005) and MOIRA simulate processes of migration of radionuclides to sediment, resuspension and to biota. RODOS was customised by the Romanian (IFIN-HH) team in charge with its implementation only to Cernavoda conditions and was used in ConvEX-3 and Oltenia 07 exercises, whereas MOIRA was customised for all Romanian segments of the Danube and used throughout the entire series of exercises.

The first information requested by the decision makers concerned the estimated time of arrival of the radioactivity peak from ^{137}Cs due to deposition of the radionuclide on and near the Danube river, along with an assessment as to whether or not the concentration in water is harmful. In consideration of this, the assessment was designed in two steps:

(a) The determination of the radioactive peak arrival times, following the deposition of radioactivity carriers on water surface, at several cities along the Danube river. The computation was conducted using the RODOS – HDM (hydrological module) and emphasized the early time estimation of concentration in water for the isotopes ^{137}Cs and ^{90}Sr.

(b) The evaluation of the activity concentration in fish and water in the long run (months, years) due to the deposition and radionuclide migration from the catchment – this deed performed by the MOIRA system.

For the sake of illustration, figures 2 reproduce RODOS-HDM results over ConvEX-3 and Axiopolis 09 drills, regarding the concentration and peak arrival for ^{137}Cs and ^{131}I, respectively, at several major cities downstream the Danube.

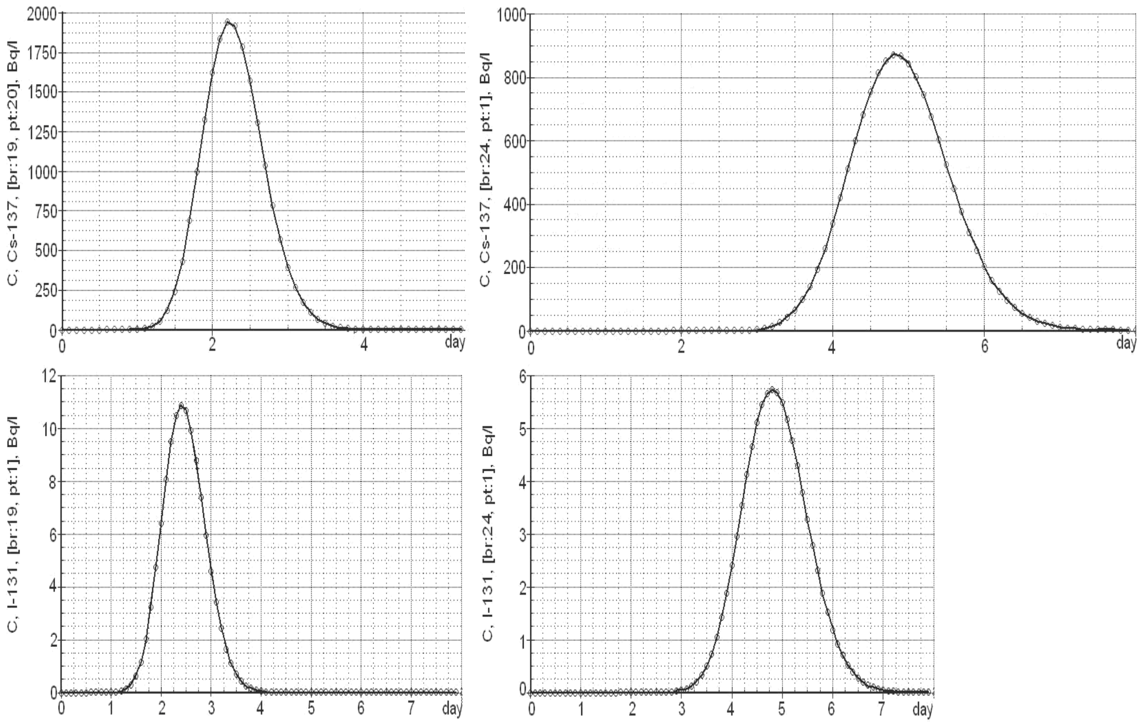

Fig. 2. CONVEX-3 and AXIOPOLIS 09. Peak arrival at several major cities downstream the Danube.

Figure 3 renders findings from MOIRA system runs, concerning ^{137}Cs concentration in water, prey and predatory fish in the first 20 and 40 months after deposition, due to migration of the radionuclide through river catchment and in the absence of any countermeasure. The results are obtained on the Danube segment near the Cernavoda – 20 months; and Kozloduy – 40 months, respectively. Another important result – coming from RODOS - concerned the evaluation of the radiological impact of Tritium – a nuclide expected to abound in releases from CANDU reactors like the one at Cernavoda.

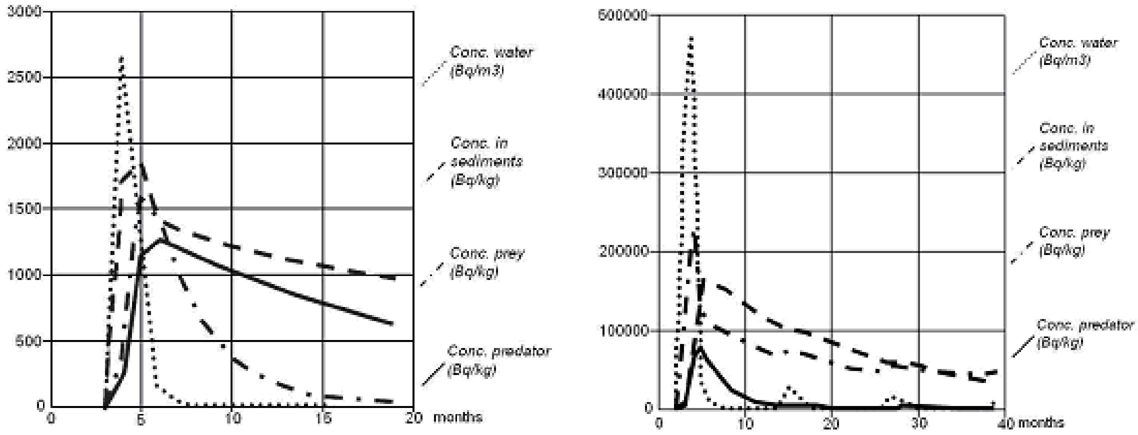

Fig. 3. CONVEX-3 ^{137}Cs concentration – left and, OLTENIA-07 ^{137}Cs concentration - right

Beyond the numbers and graphs however, what the response operatives seemed to appreciate even more during the exercises were the 'verbose' recommendations such as: "Proceed to banning the river water use, yet allow locally-catched fish consumption" – in the case on Conv-EX-3; or "Proceed to banning the river water use and locally-catched fish consumption" – in the case of Oltenia 07.

Such lessons on 'how-relevant-is-what, for whom', resulting from the assistants-operatives interaction added up into the folkore collection of rules of thumb in the emergency support ergonomics, currently open and indeed taken seriously at IFIN-HH.

Conclusions

Drill debriefings have consolidated a number of lessons, conducive towards a correct assessment of the current status and, in principle, to improving the effectiveness of the decision support in nuclear emergencies. Thus, attention was drawn to:

- the effective role and weight that tends to be retained, in actual practice, by Civil Defence and regulatory authorities for decision support systems in the response to abnormal nuclear events; and, in the context, the importance of listening to stakeholders and speaking their tongue;
- the complementarity and productive synergy of various systems - including RODOS, MOIRA and others, developed and customised for national compatibility;
- the merits of employing expert systems to overcome stress and psychological pressure, and avoid confusion or ill-fated decisions, in the early phase as well as in the aftermath of emergencies.

It also becomes increasingly evident that the proper implementation of DSS systems requires considerable volumes of custom environmental and socio-economic data be collected. The operational use may require that data be prepared ahead and updated. In fact, many views nowadays converge on *seeing a DSS as a tripolar, integrated simulation and visualization platform resting on three resources: the models; the data libraries; and the geographic information system (GIS) – all dynamically exchanging information at runtime in both inputing and outputing modes*. And, looming over horizons are the prospects for full 'webification' of the decision support tools.

While the importance of the internationally-accepted reference DSSs – a status to which RODOS aspires and was designed for – cannot and should never be underplayed, *the reality of national authorities and scientific establishments lending a confident ear to their own analytic tools should also be properly recognized*, and indeed be valued as a consolidating, rather than a dissipative, factor.

Concerning, specifically, the value of pursuing water contamination assessments as a consubstantial part of nuclear emergency preparedness and response management the following may stand out for consideration: the operation is definitely necessary, particularly in view of (i) the stealthy character of both environmental nuclide migration and exposure, on the aquatic paths; (ii) the remarkably long time spans involved; (iii) the proclivity of the paths for internal – that is aggravating, exposure. Given the complexities of the modeling, simulation and visualization techniques involved, the key success factor seems however to stay with the advent of a new kind of developer: one who is able to think like a scientist – yet speak like a stakeholder.

Aknowledgments

This work was supported by the National Agency for Science, Technology and Innovation, [PNCDI-2, 32-117 and PN 09 37 03 01] projects.

Istituto Superiore di Sanità (ISS) – Italian National Institute of Health – Technology and Health Department, Rome. ITALY

Abstract

AGMS (Airborne Gamma Monitoring System), equipped with passive detectors, are used in many countries to face nuclear or radiological accident that results in a release of radioactive plume; however the AGMS is able to provide quantitative assessment on the radiological situation (land surface contamination level) only when the air contamination due to the passage of the travelling plume has become negligible.

To overcome this limitation, the Italian Institute of Health has developed and implemented a multi purpose air sampling system based on a fixed wing aircraft, for time-effective, large areas radiological surveillance (to face radiological emergency and to support homeland security).

A fixed wing aircraft (Sky Arrow 650) with the front part of the fuselage properly adapted to house the detection equipment has been equipped with a compact air sampling line where the isokinetic sampling is dynamically maintained. Aerosol is collected on a Teflon filter positioned along the line and hosted on a rotating 4-filters disk. A system of detectors allows radionuclide identification in the collected aerosol samples. The correlated analysis of the detectors data provides a quantitative measurement of air as well as ground surface concentration of gamma emitting radioisotopes. Environmental sensors and a GPS receiver logs the sampling conditions and the temporal and geographical location of the acquired data. Acquisition and control system based on compact electronics and real time software that operate the sampling line actuators, guarantee the dynamical isokinetic condition, and acquire the detectors and sensor data. The system is also equipped with additional sampling lines to provide information on concentrations of other chemical pollutants.

Operative flights have been carried out in the last years, performances and results are presented.

Introduction

Main motivations for the research program launched some years ago stem from our experience gained during the Chernobyl accident. Detailed information on what we have learned in that occasion has been already reported elsewhere [Castelluccio et al. 2006,] here we summarize only what is needed to understand the inputs to our program.

Flying during the period beginning of May – mid June 1986 with an AGMS, mounted in an Agusta-Bell 412 helicopter and developed in the follow up of the COSMOS 954 event [Gummer et al. 1980] by Italian Civil Defence (VVFF) and Italian National Institute of Health (ISS), three different situations were found.

Till approximately May the 7th, measurements taken at the same place but at different heights could not match the scale behaviour expected if only contamination at ground were present. Moreover as the helicopter moved along its flight path a continuous increase of the counting rate was detected, showing a clear accumulation of radioactivity on the helicopter fuselage. After each flight this contamination was easily removed through a normal procedure of external washing of the vehicle, subsequent controls shown no residual contamination.

From May the 7th till approximately May the 17th, measurements still did not scale in a proper way at different heights but there was not any more the accumulation of radioactivity on the helicopter fuselage. This could be understood as a result of a still persisting air contamination, but only with fine and ultra-fine radioactive aerosol that due to its mobile Brownian-like nature was not fitted to be accumulated by any surface. Instead the more gross type aerosol, being dragged off with an essentially gravity-like mechanism, did not represent at that time a significant source of air contamination.

Starting from May the 19th (25 days since the beginning of the Chernobyl accident and 20 days since the arrival of radioactive plume in Italy), measurements at different heights scaled as expected and only at that time it was possible to have quantitative measurements of (ground) contamination with the required accuracy.

The lack of quantitative measurements and the ensuing uncertainty in forecasting the propagation of radioactive contamination do not help the emergency management in the most critical phase, i.e. when countermeasures have to be taken in a preventive way and some risk of negative effects is inevitably linked to their enforcement.

Computer based management tools for nuclear emergency (developed since the Chernobyl accident) like RODOS [Raskob et al 2005] and ARGOS [Hoe et al. 2005], support integration of AGMSs but the provided information are of relative use during the plume phase of an accident. On the other hand the measurement of γ emitters concentration in air, extension of the plume, in situ environmental and meteorological parameters would be an invaluable help to forecast transport and dispersion of the plume and ground contamination levels.

During the last years research and development of the SNIFFER system, a new aerial platform instrumented for in-plume contamination measurements have been carried on; the SNIFFER aims to characterize the extension, composition and concentration of the radioactive mixture in the plume, as well as to measure in situ meteorological parameters [Cisbani et al. 1996, Frullani et al. 2004, Castelluccio et al. 2005, Castelluccio et al. 2006, Frullani et al 2008]. Here we report the main features of the SNIFFER system and the results obtained.

Material and methods

SNIFFER payload allows the atmospheric and ground radioactive contaminants and air pollution monitoring on large areas in relatively short time.

The system is mounted on board of a fixed wings aircraft (shown in Fig. 1) and consists of the following main components: a) aerial platform; b) isokinetic sampling unit (probe, suction line and filters subsystem); c) radiation measuring equipments (BGO, Geiger, HPGe and NaI detectors and relative electronics); d) VOC - PAH (Volatile Organic Compounds - Polycyclic Aromatic Hydrocarbons) sampling unit – developed for a program on environmental control on traffic pollutants – not discussed in this paper; e) control and data acquisition subsystem (electronic cards, actuators and sensors).

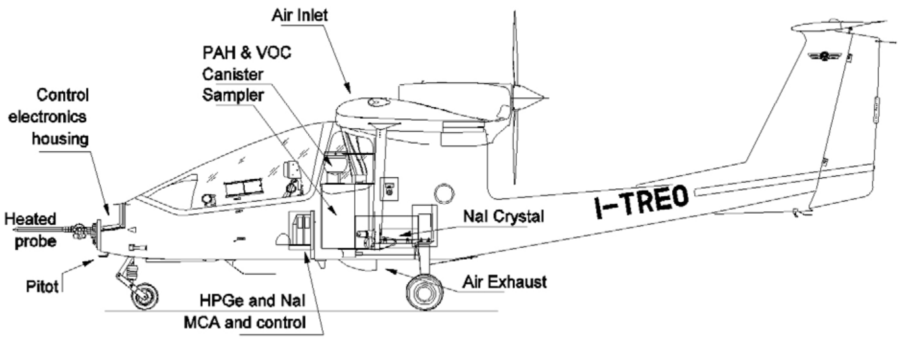

Fig. 1. Installation of the SNIFFER in the Sky Arrow.

The aerial platform complies with the constraints demanded by sampling methodology and operative conditions. The sampling probe is located in a place where aerodynamic perturbation induced by the movement of the platform is negligible. The profile of the front cap of the airplane has been modified to allocate the sampling unit. Safety conditions for the flights are satisfied at an altitude range from some tens of meters to a few kilometres while take off and landing operations are possible in a grass type airstrip of a few hundreds meters (Short Take Off and Landing – STOL type aircraft).

To guarantee the representative and significance of the gathered data, the sampling has to ensure isokinetic conditions, i.e. the inlet walls of the sampler have to be parallel to the gas streamlines and the gas velocity entering the probe has to be identical to the free stream velocity entering the inlet. This is equivalent to the absence of any stream lines deformation in the neighbourhood of the inlet. A failure in the isokinetic sampling may result in a distortion of the size distribution and a misrepresentation of the concentration. To fulfil the isokinetic condition, the sampling line is then provided with a flow regulator (through a valve) operated by an automated control unit that, by means of sensors measuring the relevant environmental parameters, can assure isokinetic sampling. The control software regulates the suction of the air and computes the needed sampled air volume in the current and nominal (STP, Standard Temperature and Pressure) conditions.

The sampling line is essentially a controlled suction line with filters to collect aerosol samples and radiation detectors; its most important subcomponents are (Fig. 2): a) the probe; b) the Shutter (a controlled valve that opens or shuts the line); c) the sampling filters and the filter-case disk; d) the Holder (a small movable box containing a small BGO detector and a Geiger counter); e) the needle valve that permits to maintain the active isokinetic sampling; f) two radiation detectors (BGO and Geiger); g) the Venturi flow meter (not shown in the figure).

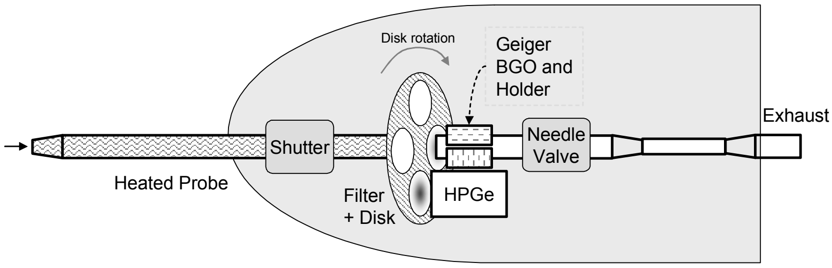

Figure 2. Scheme of the sampling line unit with its components and radiation detectors.

To keep isokinetic sampling condition, the velocity of the entering stream must be adapted to that of the external air (relative speed of the aircraft respect to the air) through a continuous regulation of the inlet flow rate according to the operative and environmental parameters (aircraft speed, pressure and temperature).

The sampling line is therefore operated by the control system that assures isokinetic sampling by means of sensors measuring the relevant environmental parameters. The control software regulates the suction (through the needle valve) according to what the environmental sensors measure.

The radiation measuring system includes four detectors that, under the supervision of the acquisition and control system, allows the quantitative estimation of the radionuclide activities and the determination of the environmental contamination.

A small Geiger detector, having 10 mm external diameter, is mounted inside the Holder box with the entrance mica window in front of the in-line filter. It is powered by the acquisition and control boards and the generated signals are sent to a pulse counter whose contents is periodically read and stored.

A small in-line gamma detector is made of (1 cm^3) BGO crystal, a photodiode and a signal preamplifier. It is located inside the Holder box, next to the Geiger counter, with the sensible window in front of the filter. It provides online information on the presence of radioactive contaminants on the exposed filter (and therefore on the sampled air) but, due to its very small size, it does not have enough energy resolution to permit the identification of the radioactive isotopes.

A high resolution HPGe (High Purity Germanium) detector allows radionuclide identification in the sample collected on the filters. It has been designed in collaboration with Camberra Semiconductor, taking into accounts the constrains imposed by the sampling unit and its aerial platform. The system cooling is assured by a dewar filled up of liquid Nitrogen, providing the proper cooling for up to four hours, compatible with the aircraft autonomy. Due to the crystal size, the detector is not inserted into the sampling line, but is located in such manner that with a 90° rotation of the filter disk it can face the last exposed filter. The dewar is flanged to aircraft fuselage but installed externally to it to minimize its influence on penetration efficiency of the aircraft and to facilitate Nitrogen refilling.

External to the sampling unit, a large volume high sensitivity NaI(Tl) detector ($400 \times 100 \times 100$ mm^3, 17.5 kg in weight), is installed in the rear part of the aircraft, behind the shoulders of the pilot, in correspondence of an opening hole on the bottom of the fuselage.

Environmental contamination in its airborne (particulate) and ground contaminations can be deduced from measurements. Air contamination through the direct measurement of aerosol activity deposited on filter and ground contamination as derived by the large volume high sensitivity detector measurements, taking into account the measured air contamination and a suitable model of the influence of the air contamination and possibly other background contributions on the NaI measurements.

A management unit is dedicated to the control of the devices of the SNIFFER (detectors, sensor and transducers) and to the acquisition of signals coming from them.

This sub-system is made of: 1) two 386-compatible CPU boards (Mesa 4C60 and Mesa 4C28) in PC104 and PC104 Plus standard. The two boards communicate by the respective parallel ports (laplink protocol) in a master-slave scheme. The use of the PC104 offers a reliable operation in a very compact solution, fitting the strong constraints on the available room for the electronics; 2) a PC104 card equipped with a series of Digital to Analog Converters to handle the flow regulation valve; 3) a standard PC104 card (Mesa 4I22) to manage the digital TTL input/output signals of the Shutter, Holder, filter Disk, Canister and Sampler sensors and to drive the regulation of the Geiger high voltage; 4) a custom board consisting mainly of voltage regulators to provide the proper power supplies to several devices; 5) a custom board for signal conversion (sensor specific to TTL and vice versa).

The initialization and final phases are serialized on the two CPUs. Main control is delegated to the 4C60. During the acquisition the 4C60 receives messages from the 4C28 and handle the commands from operator by means of the 3 keys keyboard. Periodically it reads GPS stream data and store them on the on-board flash card. On the other hand, the 4C28 is responsible of the regulation of the flow (via the regulation valve) in order to keep the isokinetic conditions and periodically reads the Geiger's counter. Besides it stops the acquisitions, read data acquired and save them on files at fixed times (defined during the mission plan); eventually it changes the filter (by operator action or at planned intervals).

The interface with the operator (the pilot) consists of a monitor and a small keyboard, these two devices allow to the operator to interact in real time with the acquisition and control system. The operator screen connected to the 4C60 VGA interface is virtually split into two windows: the upper one displays information about the status of the devices; on the lower window scrolling log messages are shown. The verbosity of the visualized messages can be controlled at configuration time. The operator keyboard allows three simple commands: i) start of the acquisition; ii) stop of the acquisition and end of the flight program; iii) change of the filter before the pre-programmed time if an anomalous level of radioactivity has been found.

Results

The instrumented aircraft has got the provisional authorization to flight and after devoted test flights obtained the full certification to perform environmental campaigns, fulfilling the full set of criteria of the Italian Airworthiness Authority. The system obtained also the permission to fly over the Rome urban area in October 2007, in connexion with a campaign devoted also, with different instrumentation, to assess the levels, at height, of some pollutants connected with vehicle traffic.

During these tests, the instrumentation performed quite in agreement with the design specifications. At the end of every flight mission measurement data stored in flash memories were retrieved, analyzed and compared with expectations according to the flight operations for what regards aircraft speed patterns, static pressure differences, flow variations respect to the controlling valve aperture, isokinetic condition automatic regulation, pressure and temperature sensors performances.

The different detectors have been tested and calibrated, using mainly calibrated sealed sources of ^{60}Co and of ^{137}Cs. These sources have been also located very close to the filter position in the suction line to simulate a contaminated filter. Tests were done to check gain stability of the different detectors and connected electronics before and after the flights.

Fig. 3 shows the GPS data during one of the missions. Two heights have been planned on each height, the aircraft has 4 run speeds (60, 70,80, 90 knots aircraft-air relative speed), moving forth and back on a fixed direction.

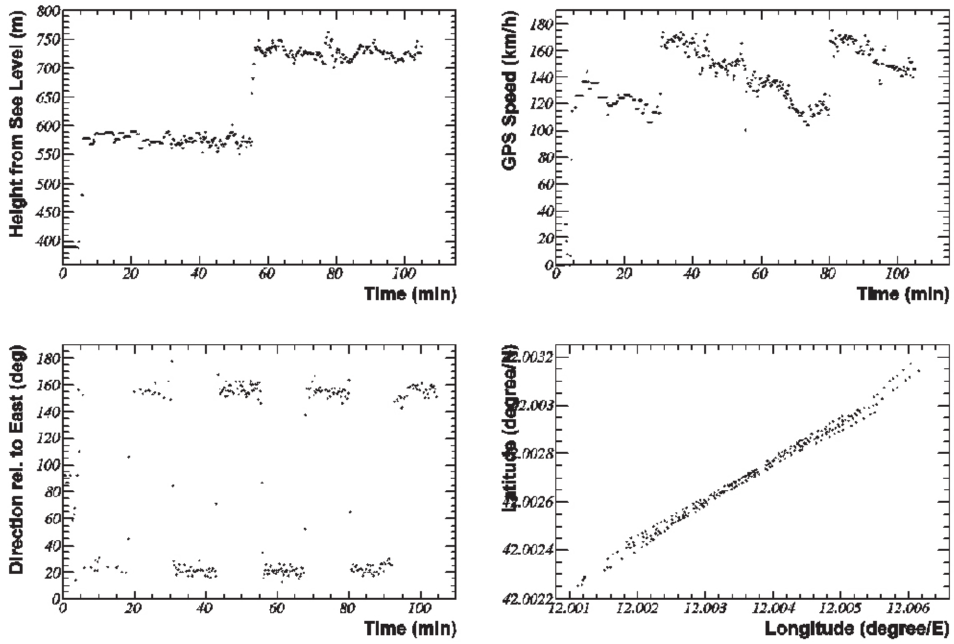

Fig. 3. GPS information from mission 07091415.39, (two heights respect to ground with about 150m variation and four different aircraft speed) that reflects a more complex trend of the air-ground speed registered by GPS module depending on the aircraft flight direction and wind speed.

Fig. 4 shows aerodynamic data from the same mission. Note as static pressure follows aircraft altitude variation during the flight, while dynamic pressure variation reproduces the four different aircraft-air speeds for the two altitude reached during the flight. Comparison with the certified aircraft instrumentation allowed to obtain the proper calibration of the data.

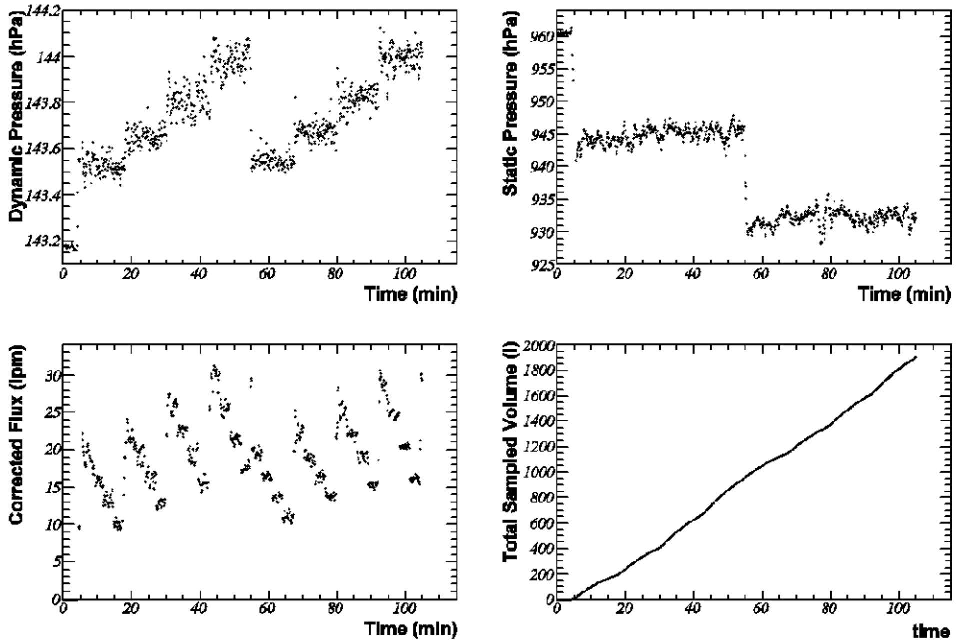

Fig. 4. Static and Dynamic pressures, sampled air flux and total sampled air in mission 07091415.39, see Fig. 3 for a comparison with the correlated GPS data.

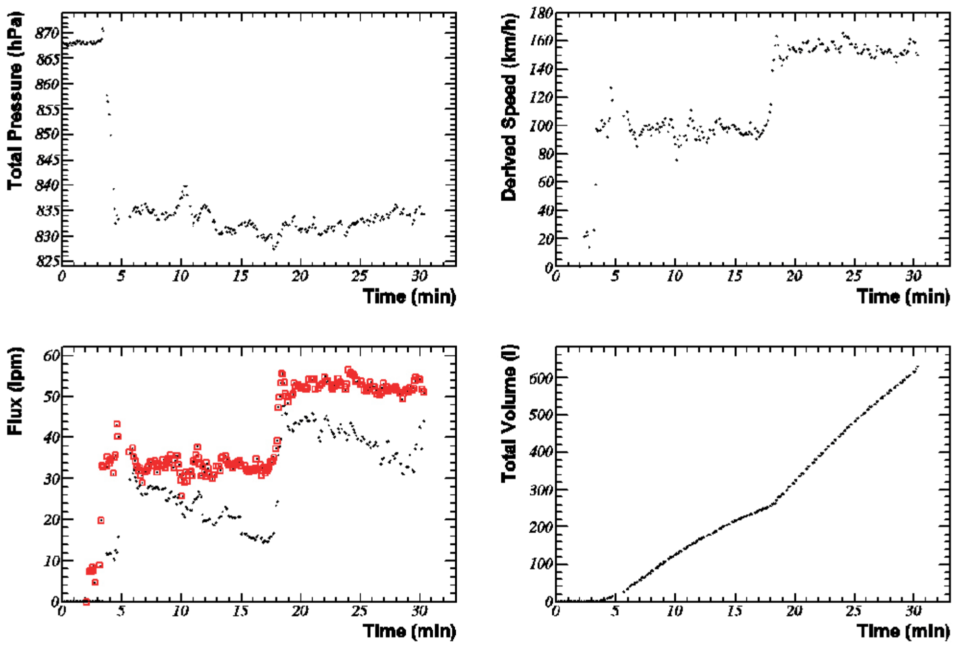

Fig. 5. Calibrated parameters of mission 07100416.52. Data taken at two different speeds at fixed height. Upper-right plot: speed derive from the on-board certified Pitot-Prandtl device; bottom-left plot: the inlet flow isokinetic values (red squares) derived from pressure and temperature sensors are compared to the measured flux (small black cross). The difference shows an uncompensated output impedance.

Data in Fig. 5 have been obtained during a single flight mission at one flight altitude and two different aircraft-air speed. The dynamic pressure data are calculated from calibrated static and total pressure data. The bottom-left plot shows the difference

– due to uncompensated impedance, between the isokinetic optimal flux (used to regulate the needle valve) and the measured one. This difference has been eliminated with a more effective ejector at the end of the line with the result to lower the line impedence

While the filter γ activity characterization is made during the mission, characterizations of the aerosol collected on the filters can be done at the end of the flight mission through detailed offline-analysis.

Different kind of analysis can be carried out, in particular as routine analysis we can mention: 1) gravimetric analysis to evaluate the particle mass collected; 2) SEM (Scanning Electron Microscope) analysis to characterize the morphology and the composition of the particulate; 3) ICP - MS (Inductively Coupled Plasma – Mass Spectroscopy) analysis to characterize metallic-like components in aerosols.

As an example, in Fig 6 a 2000x SEM picture of a filter exposed during a flight along the border of the high traffic ring road encircling Rome is shown. Two different aerosol size distributions (fine and coarse) are clearly visible, as also is shown by the quantitative analysis made and reported in Fig 7.

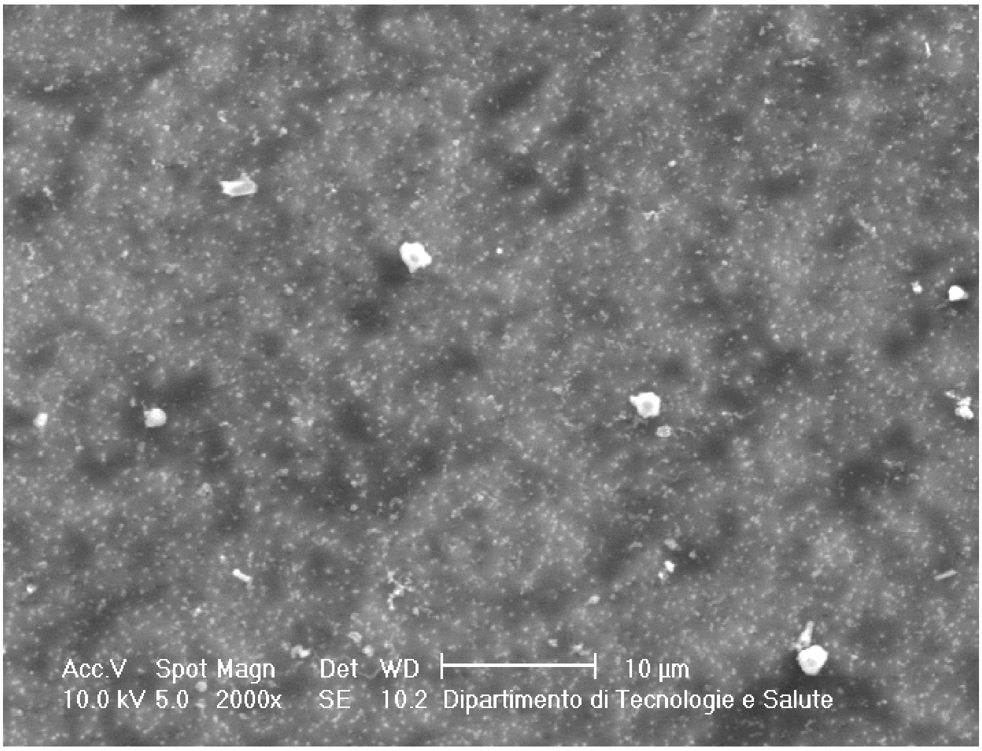

Fig. 6 High enlargement (2000x) SEM picture of an exposed filter during an environmental campaign with SNIFFER. Two different aerosol size distributions can be seen, as demonstrated by the quantitative analysis of Fig 7.

The analysis can be pushed further determining the spectrum of aerosol elemental composition that, in the case discussed, shows a high carbon content in the fine size population while there is a high concentration of silicates in the coarse size population.

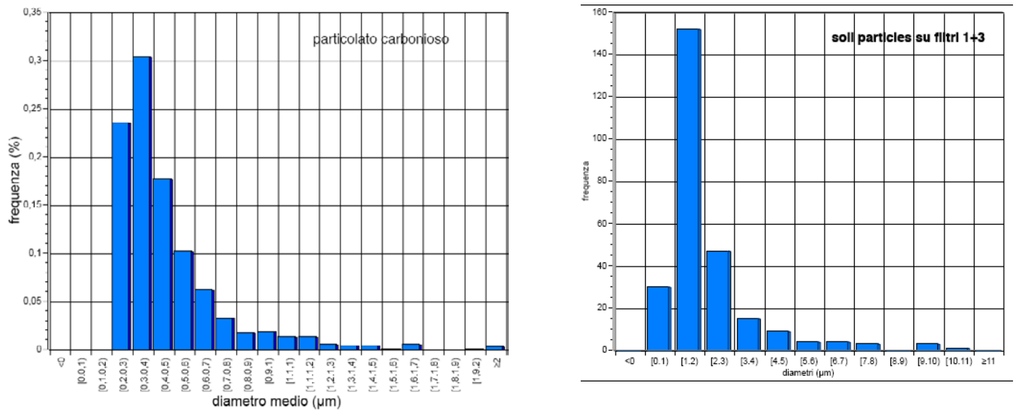

Fig 7. Two populations of aerosol size distribution (fine and coarse) present on an exposed filter, probably attesting different (antropic and natural) mechanisms for their production.

Both such analysis, size distribution and elemental composition, can be a precious element of knowledge in case of an accident to better known the kind of pollutants and the possible pathways for radioactivity transport and migration.

Conclusions and Outlook

A new type of Airborne Gamma Monitoring System has been demonstrated viable, combining a traditional system based on passive (NaI or HPGe) detectors with an active sampling system able to collect air sample and measure their γ emitters composition in real-time.

In this way, the main limitation of the traditional AGMS, that is the inability to provide quantitative measurements on the radioactive contamination during the early phase of an accident, when the plume or its residual fine aerosol content result in contamination dispersed in air, can be overcome. A precious tool for the quantitative radiological assessment can then be available for the emergency management since the early phase of an accident.

The feasibility has been proved for a manned airplane, then useful only in a far field situation. The instrumentation used, for its weight and power requirement can be easily adapted in an UAV (Unmanned Air Vehicle), suitable then to be used even in near field situations. A network of equipped UAVs can give a substantial support in the management even of a severe accident.

The promotion, within an International Cooperative Program, of a project to develop new measurement platforms with the above discussed (and demonstrated) characteristics and performances, represents an important opportunity for research, industry, safety and security.

Abstract

The Italian Institute of Health in collaboration with the Ministry of Environment developed and implemented a multi purpose air sampling system based on a fixed wing aircraft, for time-effective, large areas radiological surveillance (to face radiological emergency and to support homeland security) and air pollution monitoring.

The system design has mainly originated from the experience gained during the emergency management of the Chernobyl nuclear power accident (1986).

In order to provide quantitative information on ground as well as atmospheric radioactive contamination (and permit, e.g., reliable plume behavior forecast), the SNIFFER consists of a fixed wings aircraft (Sky Arrow 650 by 3I) properly adapted to house a relatively compact payload equipped with a sampling line that works in isokinetic regime. The line serves the β and γ atmospheric radiation detection system made of: one small BGO scintillator and one Geiger counter providing a near real time information on the air sampled radiation excess and one high energy resolution hyper-pure germanium for radionuclides quantitative identification.

A large NaI scintillator detects the ground and atmospheric radiations; The combination of the information from the above 4 detectors permits the quantitative estimation of both atmospheric and ground contamination.

Two sampling devices devoted to polycyclic aromatic hydrocarbons and volatile organic compounds air quality monitoring are also integrated into the SNIFFER.

A fully automated acquisition and control system actively manage all the payload components.

The whole acquired data are integrated by environmental (temperature, pressure and air density) and geolocation information for a complete characterization of the sampling conditions and their temporal and geographical location.

The system and the results of the first aerial mission will be presented at the conference.

BALTRAD – An advanced weather radar network for the Baltic Sea Region meteorological institutes and authorities

Abstract
Accurate and timely weather forecasts provide essential information for the authorities by warning them of hazardous conditions (e.g. snow storms or floods). Weather radar systems are one of the tools producing such information because they are capable of monitoring rain, snow, hail, and wind over large geographical areas with high resolution in both time and space. Radiation protection authorities are amongst the potential end-user organizations because radar data can be utilized in making forecasts of the precipitation scavenging of radioactive particles to the ground. The objective of the BALTRAD project is to create a state-of-the-art real-time weather radar network for the Baltic Sea Region that facilitates the harmonised production, exchange and use of radar data. The project (2009–2012) is partially funded by the European Union's Baltic Sea Region Programme 2007–2013. An integral part of the project includes so-called pilots that will demonstrate the value of BALTRAD for end users in the fields of e.g. hydrology, aviation and radiation safety.

Introduction
The objective of the BALTRAD (An advanced weather radar network for the Baltic Sea Region: BALTRAD) project is to create a state-of-the-art real-time weather radar network for the Baltic Sea Region, the so-called BALTRAD system. When completed, the system will facilitate the harmonised production, exchange and use of real-time weather radar data, and contribute to the production of accurate and timely weather forecasts that provide essential information for the authorities by warning them of

hazardous conditions (e.g. snow storms or floods). Generally, BALTRAD delivers value-added precipitation information to improve short-term weather forecasts.

The project, headed by SMHI, was officially started in February 2009 and continues until the end of January 2012. The source of funding is the EU's Baltic Sea Region Programme 2007–2013. The Partnership comprises eight national organizations from seven countries (Sweden, Finland, Poland, Latvia, Denmark, Belarus, Estonia). In addition, there are associated organizations in Denmark, Latvia and Poland which will be contributing in various ways. The project contains a few pilot applications that will demonstrate the value of BALTRAD for end users in the fields of e.g. flood protection, aviation and crisis management (including nuclear accidents).

The technology developed by and for BALTRAD will be proposed as the standard for exchanging weather radar data in the World Meteorological Organization Information System (WIS).

In the following we first describe briefly the project and project's organizational structure. After that we discuss possible uses of the final system from an end-user point of view, the emphasis being on applications related to radiation monitoring and management of nuclear or major radiological emergencies.

BALTRAD project

BALTRAD represents the first dedicated international weather radar networking project funded by the EU. However, the concept being followed has already been proven once before in the NORDRAD network (involving the radars from Norway, Finland and Sweden) some 20 years ago. The original NORDRAD technology is becoming obsolete and it is time to go further. Within BALTRAD it is hoped to create:

– real-time exchange of radar data among all members;
– a common production framework containing harmonized algorithms;
– consistent end-to-end management of quality information;
– an Open Source software system.

The goal is to achieve cutting-edge distributed radar networking (see Fig. 1 for the radars planned to be in the network), i.e. a network where data is exchanged on equal terms and where each institute processes the data according to its local needs.

The work is organized into seven work packages (leader organization given in parentheses):

1. Management and administration (SMHI).
2. Communications (FMI). This work package is dedicated to both internal and external communications.
3. Core network (IMGW). This work includes creating the real-time networking functionality. It is foreseen that it will be based on secure HTTP-based mechanisms with subscription services. The long-term goal is to contribute such mechanisms to WIS for Europe.
4. Data catalogue (EMHI). This work involves managing all data to be exchanged and processed and focuses on creating a database for all metadata and systematic methods for storing data files.
5. Production framework (FMI). This work package deals with developing, collecting, and harmonizing numerous algorithms for improving the quality of raw data and creating products from them.

6. Deployment (SMHI). This involves integrating the outputs of work packages 3-5 into a real-time system suitable for operational deployment. Regular releases will be installed at all Partners. A case log will be prepared containing cases relevant to air traffic, flash flooding, urban hydrology and nuclear or radiological accident scenarios.
7. Pilots (IMGW). This work serves to make the BALTRAD system and its radar-based information available to test pilots and to collect the pilots' feedback to integrate new and improved software and products. In this way the value achieved in a true end-to-end radar network will be demonstrated.

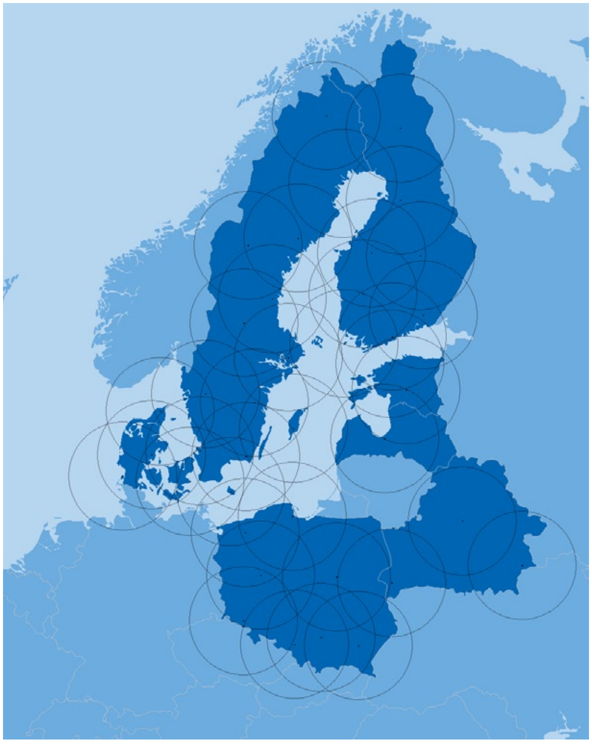

Fig. 1. BALTRAD radars. Radar radius is typically 200 kilometers.

Importance of weather radar data for end-users

Weather radar systems are capable of producing information on rain, snow, hail, and wind over large geographical areas with high resolution in both time and space. This information is of great value for the authorities especially in the context of various disasters, such as accidents involving releases of chemical or radioactive substances to the atmosphere, or in case of severe weather conditions (heavy rain, tornadoes, very stormy wind, air pollution situations…) that may affect the normal functions of the society and people’s everyday life. However, accurate and timely weather data are needed also during normal situation. In aviation, for example, weather radar is the most important tool for monitoring weather for flight planning and air traffic control. The most hazardous phenomena in this context are thunderstorms, heavy rain and hails, and strong wind shear. Generally, precipitation intensity and accumulation, precipitation type, wind velocity and direction are amongst the data that various authorities need to have access to both in emergencies and in routine conditions.

As already mentioned, the BALTRAD project includes a work package (WP7) which is dedicated to end-user views and pilot applications. Radiation protection authorities are amongst the potential end-user organizations because rain, for example, increases deposition and consequently dose rates at the ground level (see Fig. 2). Rain information can be used in planning and directing emergency measurement activities and in interpreting exceptionally high radiation levels during routine conditions, and numerical data (precipitation rates, accumulated precipitation) can be input to consequence assessment models. Heavy rain or otherwise severe meteorological conditions (e.g. very strong wind) may also prevent performing certain types of radiation measurements, such as measurements using airborne platforms (airplanes, helicopters, unmanned aerial vehicles).

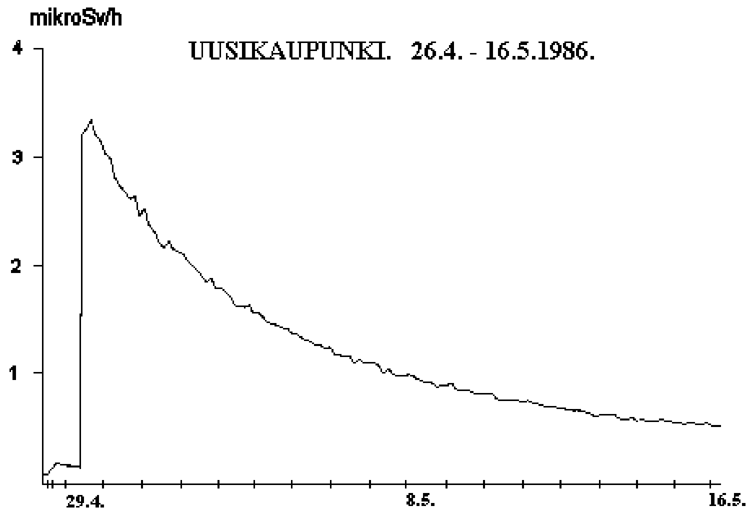

Fig. 2. Effect of rain occurrence on measured dose rates at ground-level during the Chernobyl accident. Uusikaupunki is located on the western coast of Finland.

End-user applications of the Finnish radiation protection authority

Currently STUK utilizes radar data from FMI in two basic ways:

1. The radiation information system (USVA) controlling the national automatic dose-rate monitoring network (ULJAS) receives observation data (given as echo strengths) every ten minutes. These data can be used in routine conditions to help to interpret the increases of dose rate levels caused by natural radioactive substances brought down close to the ground by precipitation.
2. STUK and FMI have developed a system known as KETALE (Fig.3; Amman et al. 2010) for the overall management of meteorological data and dispersion and dose calculation results in radiation emergencies. Radar images – such as the one shown in Fig. 4 – can be downloaded from FMI's systems and included in the situational analysis reports prepared with KETALE but flexible comparison with calculation results (mainly deposited activities or ground exposures) is currently not easy.

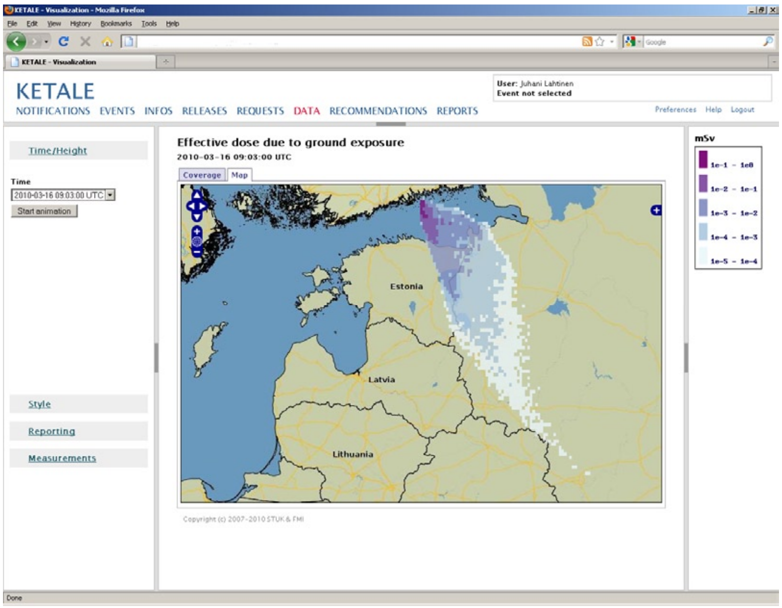

Fig. 3. Example of KETALE output on screen (hypothetical scenario). Radar images available in a proper format could be compared with calculational results using the same map. This would help to assess and interpret the overall situation and to plan further measurement activities.

Fig. 4. Example of radar images accessible to STUK at FMI's restricted web site.

After the completion of the BALTRAD project, STUK would appreciate having access to a flexible, reliable and user-friendly system that could provide both high-quality radar images and numeric data. STUK and many other authorities are interested primarily in precipitation-related ground data (precipitation rate, accumulated precipitation, precipitation type…), although certain other available quantities may be of use in some situations. All data should be given in user-friendly quantities – not as echo intensities in desibels but as e.g. rain intensities in millimeters per hour – and include some index of uncertainty or inaccuracy.

On one hand, numeric data, such as average rain intensities in spatial grid cells, can be utilized in emergencies to correct or estimate so-called precipitation scavenging coefficients (washout coefficients) used in model calculations (see e.g. Ilvonen 2002). On the other hand, graphical images generated from numeric data by e.g. a Web Map Service can be used in KETALE to visually compare the observed spatial rain distributions with the calculated spatial radionuclide-concentration and dose distributions. This kind of comparison helps to assess the overall situation and to plan further measurement activities. As mentioned above, in the USVA system radar data can be used in interpreting observed measurement results.

Conclusions

Weather radars provide meteorological institutes and many other authorities with essential data that can be used both in normal situation and during hazardous conditions, including various accidents and other events involving releases of dangerous substances to the atmosphere. The BALTRAD project aims at creating a state-of-the-art real-time weather radar network for the Baltic Sea Region.

Various end users play an important role in the project by developing pilot applications. Radiation protection authorities are amongst the potential end-user organizations because precipitation, for example, increases deposition of airborne radioactive particles. As an official partner in the project, STUK is responsible for creating applications related to emergency activities and radiation monitoring. It is foreseen that these applications will have close interfaces with the Finnish ULJAS/USVA and KETALE systems, the first being the nation-wide dose-rate monitoring system and the latter being the national platform designed to manage the assessment of environmental consequences of major radiation emergencies.

Belgian Nuclear Research Centre (SCK•CEN), BELGIUM

Abstract

Over the past decades SCK•CEN has developed a set of models –called the NOODPLAN models– for consequence analysis of atmospheric releases during the early phase of a nuclear emergency. All these models use segmented bi-Gaussian plume dispersion algorithms based on the Bultynck-Malet scheme and are limited to a local scale (50 km from the release point).

The different NOODPLAN models are largely customised to the needs of several external users. Customisation includes e.g. source term determination from stack monitoring, connection to on-site meteorological masts, graphic display of countermeasure areas corresponding to intervention guidelines, special modules with standard accident scenarios and specific calculations at the location of detector points (e.g. corresponding to monitoring network). These models have been primarily designed for the Belgian nuclear power plants, the results being used by the radiological evaluation cell of the Federal Crisis Centre, within the framework of the Belgian nuclear and radiological emergency plan. Additional users include research reactors and other nuclear facilities.

The NOODPLAN models perform real time calculations based on variable on-site measured meteorological data, as well as prognostic evaluations. Following a brief description of the different functionalities of the models, this paper will focus on the evaluation of the different NOODPLAN models. This evaluation will draw on our experiences with the NOODPLAN models from regular emergency exercises and will include an inter-model comparison study with state-of-the-art atmospheric dispersion models integrated into the European decision support system RODOS. The results of this evaluation highlight possible future development required to ensure a fast and reliable decision making during the early phase of a nuclear emergency.

Introduction

In a nuclear or radiological emergency the release of radionuclides in the atmosphere can lead to the external and internal exposure of the surrounding population and the contamination of land and water including food products. To estimate the radiological consequences and to initiate the essential countermeasures during an incidental release historically many organisations have developed their own emergency models or systems. Such models combine an atmospheric dispersion part for the calculation of air concentrations and deposition values with a dose model to evaluate the dose from different pathways. Depending on the complexity of the model, the dose from contributions like cloud shine, inhalation, ground shine, ingestion, re-suspension … is calculated.

The NOODPLAN models are a set of models developed for the radiological evaluation of an incidental or accidental atmospheric releases from specific nuclear sites in Belgium. Off-site radiological evaluations up to a few tens of kilometres from the release point by the nuclear operators are a legal requirement in Belgium. The results of the radiological evaluations are sent to the Federal Crisis Centre for further evaluations and decisions on e.g. countermeasures and measurement strategy. Although the NOODPLAN models are historically well established, a regular evaluation and confrontation with the latest developments in the field of nuclear emergency modelling is required. Over the past decade advanced decision support systems with state-of-the-art atmospheric dispersion and dose models have been developed and are increasingly being installed for operational use in national emergency centres. Examples of the main decision support systems for nuclear emergency management used in Europe are ARGOS (Information Management and Decision-Support System for Radiological-Nuclear Hazard Preparedness and Response) and RODOS (Real-time On-line DecisiOn Support system for off-site nuclear emergency management). The evaluation and confrontation of historical models developed for specific sites like the NOODPLAN models with new and generally applicable models can highlight interesting aspects such as the use of specific required model input, model differences and uncertainties (under specific conditions) and possible requirements on future developments for fast and reliable radiological evaluations.

Description of the models

The NOODPLAN models are based on the historical work of Bultynck-Malet [Bultynck H, Malet L, 1969]. During an extensive measurement campaign in the period 1966-1968 using the meteorological mast at the Belgian Nuclear Research Centre (SCK•CEN) an atmospheric turbulence typing scheme with seven stability categories E1-E7 was developed. This so-called Bultynck-Malet categorization is essentially based on the ratio between the vertical gradient of the potential temperature (8m -114m) and the square of the measured mean wind speed at an intermediate level (69m). During the same measurement campaign the appropriate dispersion parameters for each of the stability classes E1-E7 were experimentally determined from wind vector fluctuations in three dimensions measured by means of an anemometer at a height of 69 m. Based on these measurements the dispersion parameters in respectively the horizontal and vertical direction are analytically expressed in function of the distance (x) as $\sigma_y=Ax^a$ and $\sigma_z=Bx^b$ with A, a, B and b depending on the stability category E1 to E7. E1 corresponds to very stable, E3 to neutral and E6 to very unstable atmospheric conditions. E7 is a special neutral category for high wind speed (≥ 11.5 m/s at a height of 69 m). Bultynck-Malet completed these atmospheric dispersion investigations with tracer experiments. In total 15 experiments were executed in which 5 to 6 kg of fluorescent material/experiment was released by an aerosol generator (aerosol dimensions < 4 μm) from the meteorological mast at a height of 69 m and during a release period of ~50 minutes. Air samples were taken at 3 to 7 different locations/experiment at distances ranging from 100 m to 15 km. These experiments showed no significantly nor systematically difference from the calculated values. In addition Bultynck-Malet compared their atmospheric dispersion results with extensive field experiments executed by Brookhaven National Laboratory in better experimental conditions and for a release height near ground level and at 110 m. Due to the better experimental conditions they found even better agreement with these experimental data. More recently the model was confronted with additional limited tracer experiments for ground releases [Govaerts et al., 1988] and stack releases [Rojas Palma et al., 2004]. In both studies the Bultynck-Malet based model performed as good as Lagrangian models.

It can be summarized that the Bultynck-Malet scheme was experimentally well established for hourly values and varying release heights in regions with a rather high surface roughness of 1 to 3 m, applicable in large parts of Belgium and Europe and from distances of a few hundred meters to a few tens of kilometers from the release point.

Based on the Bultynck-Malet formalism different bi-Gaussian plume and even tri-Gaussian puff [Govaerts et al., 1988] models were developed. The formalism was used as well for the development of short duration discharge models for the evaluation of the consequences of accidental releases in nuclear facilities as well as for long duration discharge models for the assessment of routine discharges. The latter evolved to the Immersion Frequency Distribution Model (IFDM) under current development by VITO (The Flemish Institute for Technological Research) which is widely used to calculate the impact of routine releases from industrial facilities [Cosemans et al., 2000]. The Bultynck-Malet (sometimes also called Mol) parameterization is also part of the different parameterization schemes used in the RODOS system.

To overcome the stationary and homogenous situation inherent to Gaussian plume models the NOODPLAN models discussed here make use of the segmented bi-Gaussian plume approach. This makes it possible to treat time-varying releases and transport conditions and especially changes in wind directions. In this approach the plume is broken up into plume segments corresponding to fixed time periods of 10-minutes. To take into account the difference between the original Bultynck-Malet sampling time (30-60 minutes) and the 10-minute periods used in NOODPLAN a correction factor to the dispersion parameters is applied.

The difference between the different NOODPLAN models is the specific customization for the origin of the release. Because the models were developed historically at different moments in time also some –in general minor- differences exist in the modeling aspects. Currently three versions are existing corresponding to a version specific for the Nuclear Power Plants (NPP's) at Doel, at Tihange and the nuclear facilities in the surrounding of Mol (SCK•CEN, Belgoprocess …). All models have the same structure and comprise an input, calculation and reporting module. The input module is highly customized and allows the selection of a specific release pathway (different stacks, steam generator incidents, releases with fire, ground release …) and determines the relative isotopic composition of the different release groups (noble gases, iodine, βγ-aerosols, α-aerosols, tritium) based on the time of release after reactor shutdown. For some of the models automated import of source term data (directly converted from e.g. stack monitoring as well as ventilation rates) and meteorological data is possible. The calculation module allows for the Doel and Tihange systems to add 3 user defined periods with prognostic data. The output module allows printing and visualizing numerical and graphical results. Direct selection of a color scale for the graphical results corresponding to the intervention limits in Belgium is possible. The Doel and Tihange models have in addition a standard scenario module. This is a simple (non-segmented) bi-Gaussian plume model coupled to a database of over 100 standard accident scenarios/reactor. When, based on the technical information available, the best fitting accident scenario is determined this standard scenario module allows doing a first full assessment in less than 1 minute with on-site meteorological data. The models are used by the operators and the results (scenario files) are sent to the Federal Crisis Centre in case of an emergency (or during exercises).

A polar spatial grid is used with a calculation point every 5° on concentric circles with distances from the release point determined by the arithmetic progression with a ratio of $2^{1/8}$ (for Doel and Tihange) and $2^{1/4}$ (for Mol) starting from 200 m up to ~50 km. This gives a very high calculation resolution near the release point while the total number of calculation points is limited resulting in a very short calculation time. Several hundreds additional calculation points can be defined and stored in a database by the users (e.g. detector points corresponding to the environmental monitoring network and points on pre-defined measurement routes) without increasing the calculation time noticeable.

Results

The models are regularly –in general at least two times a year - used during emergency exercises resulting in an important experience in using the models and interpreting the results. Based on the SCK•CEN experience (as utility and operator of the model at the evaluation cell of the Federal Crisis Centre) the following shortcomings can be identified:

- The restriction of the calculation area to around 50 km on several occasions caused problems and confusion regarding intervention limits especially in the case of an important release of I-131. Easy export of all input data available in the NOODPLAN models to a model with an extended range would be interesting.
- The transfer of calculation results from the operator to the Federal Crisis Centre is slow because old technology is used. For this reason the evolution of an emergency –which can easily be calculated with the NOODPLAN models by adding 10-minute periods without the requirement for performing the original calculations again- cannot always be followed continuously. This problem will be solved by using fast data connections in the future.

- Although the definition of additional (detector) points is possible, a direct and fast relation with measurement predictions or results (e.g. combination of dose rate from cloud and ground shine) is missing.
- Although the interface is rather simple, some specific actions of the user are necessary (e.g. specific action for selection and validation of input). This implies the necessity of a regular training (a limited yearly training session seems sufficient) for adequate knowledge of the software.

Further, an evaluation was made by executing an inter-model comparison with state-of-the-art models. Inter-model comparisons are an excellent tool for the assessment of model differences and the uncertainties related to these differences as shown in [Kok et al., 2005]. In this inter-model comparison the Noodplan results are compared with RODOS (ATSTEP) and RIMPUFF results (RIMPUFF within RODOS or a RIMPUFF stand alone version). ATSTEP is a tri-Gaussian puff model with time integrated elongated puffs and employs modified Karlsruhe-Jülich/Mol dispersion parameters applicable for different types of land-use up to a distance of about 100 km from the release point [Pässler-Sauer, 2007]. RIMPUFF is a Lagrangian mesoscale atmospheric tri-Gaussian dispersion puff model developed by Risø (RIsø Mesoscale PUFF model). For RIMPUFF within RODOS the Carruthers sigma-parameters for near range (similarity scaling), and a sigma parameterisation for medium range calculations are used. For the standalone version of RIMPUFF different parameterization schemes can be used but for the calculations performed here similarity-scaling of atmospheric turbulence and diffusion is used in which the calculation of plume spread is based on the basic physical parameters that governs the atmospheric boundary layer turbulence [Thykier-Nielsen et al., 2004].

Both basic scenarios and full realistic scenarios are included in this study. The basic scenarios assume a constant release and constant meteorological conditions for the duration of the plume passage. Nine basic scenarios are defined, starting from a release condition very close to the tracer experiment conditions of Bultynck-Malet, investigating the effect of release height and atmospheric stability under dry conditions. An additional (tenth) basic scenario is defined to evaluate the effect of rain. The scenarios are defined in Table 1. For the RODOS calculations a Cartesian variable grid is selected up to 40 km from the release point with near the release point a grid resolution of 500 m.

Table 1. Definition of the basic scenarios for the inter-model comparison. As well the Pasquill as Bultynck-Malet stability class is specified.

Basic Scenario	Variable parameters			Common parameters
	H_{eff} (m)	Stability	Rain (mm/h)	
1	72	D/E3	0	Release duration: 60 minutes
2-3	1/160	D/E3	0	Released nuclide: I-131 (100% elemental)
4-6	1/74/160	C/E5	0	Total released activity: 6.10^{14} Bq
7-9	1/74/160	F/E1	0	Wind speed= 5 m/s at 72 m
10	72	D/E3	3	No plume rise, no building effects

The complex or realistic scenarios comprise a calculation of a stack release for the Doel site and a release with fire from the Tihange site. Both scenarios consist of a release of 35 periods of 10 minutes, with variable release rates (noble gases, iodine and aerosols) and real meteorological data as typically available on-site (measurements from mast) including periods with rain as well as important changes in all other meteorological parameters. For this study in addition to the NOODPLAN calculations RODOS (ATSTEP) calculations are performed on a variable Cartesian grid with an extension of 80 km from the release point and for the RIMPUFF stand alone calculations with a constant Cartesian grid of 364x364 points with an extension of ~50 km from the release. The models are used at their full complexity for both the basic and complex scenarios. This means that standard land use and topography data are taken into account for the RODOS and/or RIMPUFF calculations. Also the NOODPLAN models are used in the way they are operationally used (i.e. topography used for the Tihange site, not for the Doel site, differences due to different land use is not taking into account in the NOODPLAN models).

The basic results (Time integrated concentration near ground level) for scenario 1 are displayed in Fig. 1. For this scenario the Noodplan results on the plume axis as a function of distance from the release point are compared with RODOS results (ATSTEP as well as RIMPUFF). Clearly visible is the effect of the polar grid with high resolution near the release point of the 'Noodplan' models resulting in a higher value at the position of the maximum. For the other basic scenarios a comparison of 'Noodplan' with RODOS (ATSTEP) is only made at specific distances corresponding with typical distances used for the implementation of countermeasures like sheltering, iodine prophylaxis or evacuation (at position of maximum, 5, 10 and 20 km from the release point). Results for the time integrated concentration as well as the total effective dose are shown in Fig. 2. The total effective dose includes only cloud shine, inhalation and ground shine integrated for 1 week. For the Noodplan models the ground shine for 1 week is calculated based on the value for 24h and 2 weeks (1 week integration time is not a standard output). In general the agreement between the models is very good (in general within a factor 2). For the value at the position of the maximum, the Noodplan results are nearly always higher compared to the RODOS values. This can again be attributed to a difference in spatial resolution near the release point of the two models. The variation of the ratio of the results seems to be somewhat higher for the location at 20 km, compared to 5 or 10 km. The total effective dose is mainly determined by the inhalation dose. The NOODPLAN results are in general higher. If individual exposure pathways are studied the difference is mainly due to a higher contribution from ground shine by the NOODPLAN models.

Results on dry and wet deposition based on scenario 1 and 10 are summarized in Table 2. The difference between the models for deposition (as well dry as wet deposition) is larger then the differences for the air concentration and total effective dose. Differences of a factor 3 to 4 are found here. The Noodplan models show higher deposition values which is explained by a difference in deposition velocities used by the models.

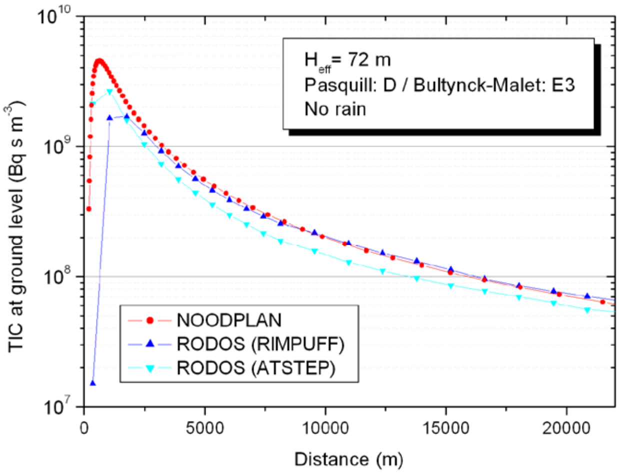

Fig. 1. The Time Integrated Concentration (TIC) near ground level for scenario 1 as a function of distance under the plume axis for the NOODPLAN model compared with the atmospheric dispersion models ATSTEP and RIMPUFF within RODOS.

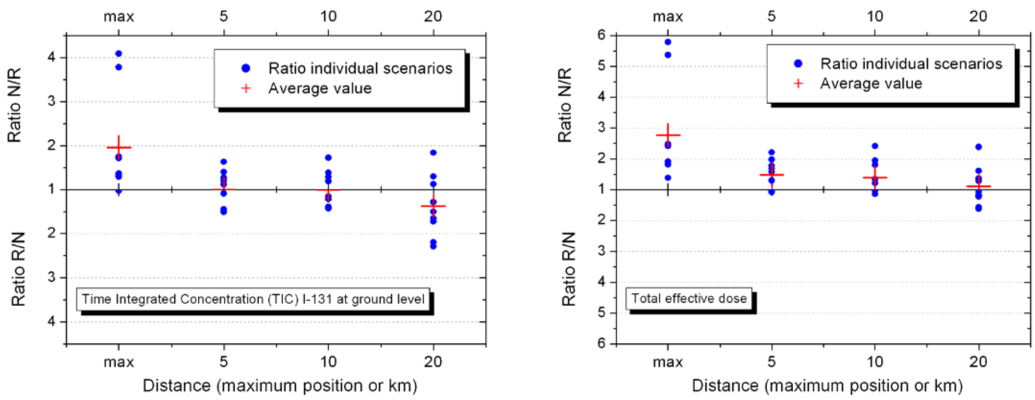

Fig. 2. Results of the inter-model comparison between NOODPLAN (N) and RODOS/ATSTEP (R) for the basic scenarios 1 to 9. On the left site the results of the Time Integrated Concentration are shown, on the right side the results for the total effective dose.

Table 2. Inter-model comparison between NOODPLAN (N) and RODOS/ATSTEP (R) based on scenario 1 and 10 for dry and/or wet deposition of elemental I-131. The dry deposition velocities are derived from the ratio of the deposition to the Time Integrated Concentration at every location. For NOODPLAN this deposition velocity is a constant, for RODOS the value can be dependent on the land use. The difference between the NOODPLAN and RODOS results for the ground contamination is mainly determined by a difference in the deposition velocity (a factor 3).

Distance (max or km)	Dry deposition			Dry+wet deposition
	Ratio N/R	$v_{d,Noodplan}$ (m/s)	$v_{d, Rodos}$ (m/s)	Ratio N/R
max	5.07	1.00E-02	3.39E-03	4.99
5	3.61	1.00E-02	3.51E-03	3.00
10	3.94	1.00E-02	3.52E-03	3.28
20	3.27	1.00E-02	3.97E-03	3.22

For the complex scenarios only a qualitative comparison could be made due to differences in the calculation grids used by the models. For the NOODPLAN results a transformation could be made from the standard polar grid to the Cartesian grid selected for the RIMPUFF calculations by a nearest neighbour algorithm. The results for NOODPLAN and RIMPUFF for the most complex scenario with fire and in a complex region (Tihange site in valley of river Meuse) are shown as an example in Fig. 3. The RODOS (ATSTEP) results look very similar. The results for the Doel scenario (stack release, flat terrain) match even somewhat better.

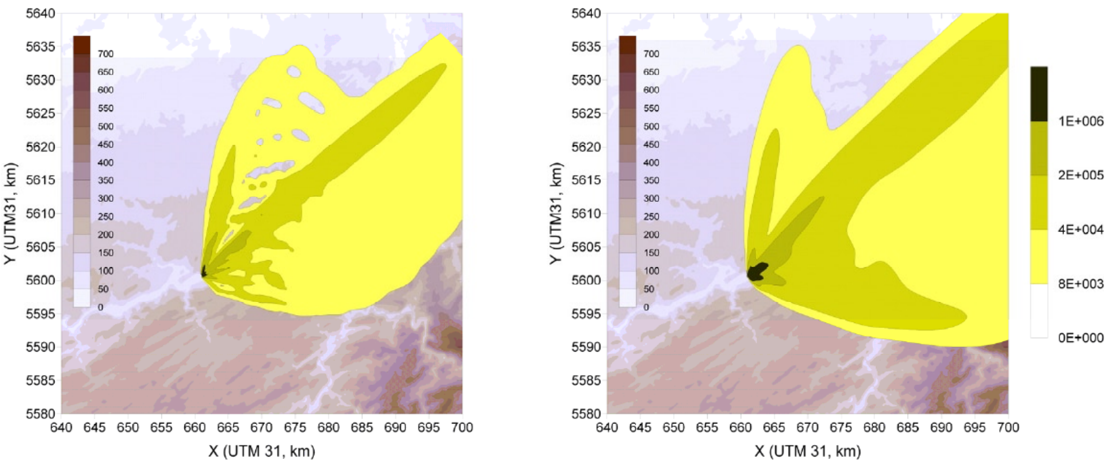

Fig. 3. Time Integrated Concentration (TIC) near ground level of Cs-137 for a release scenario for the Tihange site with fire (35 periods of 10 minutes) for NOODPLAN (left) and RIMPUFF (right) on top of a map showing the topography (height above sea level in meters). The same (color) scale scale for the TIC is used expressed in Bq·s/m^3 in both graphs.

Discussion

Although a good agreement of results in an inter-model comparison is not a guarantee for accurate results due to e.g. common simplifications and assumptions, the execution of inter-model comparisons can identify differences and give confidence in the typical uncertainties present in atmospheric dispersion modelling. Based on this study several interesting observations can be made which highlight possible future developments.

During emergency exercises often the maximal dose or contamination values calculated by the models are used as a starting point for a discussion on the advice of countermeasures. This study clearly illustrates that the maximal value can be strongly connected to grid resolution around this maximum position. A polar grid as used by the Noodplan models has a very high resolution near the release point without having a large number of total grid points. In many scenarios, in which the maximum is within a few kilometres from the release point, this can be seen as an important advantage. However, for specific scenarios with the maximum at several kilometres from the release point the resolution near this maximum will also be limited for the Noodplan models. Most models have fixed grids (or has to be fixed by the user as part of the input data) leading to results in a calculation area and with a resolution which is not always optimal for the interpretation of the scenario under study. The development of routines with flexible and (automated) guidance on grids based on available input and required output seems interesting in this context.

Although the differences in the inter-model comparison in this study for the basic model output (the time integrated concentrations) are small, differences increase clearly for derived parameters like e.g. the ground contamination by dry and/or wet deposition. This increase in difference is only due to the use of different deposition velocities. This shows clearly that good knowledge of basic parameters (such as the deposition velocity) is crucial. Apart from effort in better and more accurate atmospheric dispersion modelling (especially for specific situations like e.g. influence of buildings, urban areas …) a better quantification of basic parameters like deposition velocities seems important. In this respect the confrontation of model results for routine releases with measurements from these discharges in specific regions can be helpful.

Executing inter-model comparisons confronts the user of the models with differences in the required input. The NOODPLAN models are highly customized in a way that all input required by the models is directly related to physical (measured) parameters operationally available on-site. For performing calculations with other models conversions of some parameters have to be done to be able to run these models such as e.g. the parameters for the calculation of the plume rise (specifically for a release with fire). Because the NOODPLAN models are only applicable for the early phase and local scale of a nuclear incident it is interesting to have all input data available for other models. In the new versions of the NOODPLAN models an XML-file with all input data is generated. Concerning the output, a specific module is foreseen to transfer the output files to CSV files for export to a Geographical Information System (GIS).

Although, it is possible in the NOODPLAN models to define a large number of specific calculation points (e.g. detector points) and to display all calculated output for a specific calculation point, fast prediction of or comparison with measurement results is difficult. The development of (scenario preparation) tools for e.g. direct calculation of measurement results in a large number of points (e.g. dose rates, surface contamination, air concentrations) for a number of operationally used detectors would be very interesting.

Simple but highly customized models used by different operators like the NOODPLAN models are under constant evaluation by as well the users (operators), inspectors of the nuclear facilities, and developers. The models are often also used as part of the licensing procedures for the nuclear activities as well as for investigations of routine releases and their impact. In this respect such models are fully complementary to the decision support systems introduced in many European countries the last decade. However, results should be in line and/or differences should be well understood.

Conclusions

This review and evaluation of the NOODPLAN models used as a fast tool to perform radiological impact assessments for the early phase of an accidental atmospheric release from specific nuclear sites in Belgium shows that the results of these models are in line with state-of-the-art nuclear emergency decision support systems installed nowadays by different countries in their emergency centres. The differences found in the inter-model comparison for the basic atmospheric dispersion parameters like air concentrations at ground level are typical smaller than a factor 2-3 even for complex scenarios in large areas of the calculation grid. Derived values such as deposition and dose values differ in general more. This underlines the importance of a good knowledge of the parameters used for the determination of these derived quantities because they determine in a large group of scenarios the main difference between the different models studied here. In addition the polar grid used in the NOODPLAN models showed that the determination of the maximum value of a quantity is less dependent on the gird compared to the grids used for the other models when the location of the maximum is within a few kilometres from the release point. Optimization of grid format, extension and spacing in function of scenario can in this respect be identified as an interesting topic for model developers. The high degree of customization of the NOODPLAN models in combination with (partly automated) input of source and meteorological data validated by the operators during an emergency guarantees the use of as complete and correct as possible data for performing the radiological impact calculations. Because the NOODPLAN models are limited in e.g. range (50 km) and scope (early phase) the export of all input data in a common file structure for use by other models has been identified as an important topic for future development.

Abstract

Following an atmospheric release of radioactive material during e.g. a nuclear or radiological incident, it is well known that local precipitation can have a large impact on the deposition pattern. Atmospheric dispersion and deposition models use different approaches to take precipitation into account. Moreover, often only limited precipitation information is available. Although rain-radar data are less accurate than rain intensities that are measured directly, they ensure a more detailed coverage of the potentially affected region, which can, in turn, affect the decisions on management options and measurement strategies.

Data from a C-band Doppler rain-radar located at Wideumont and operated by the Royal Meteorological Institute of Belgium were converted to be used with the Risø Mesoscale puff model (Rimpuff). This model was then used to execute several calculations concerning a possible nuclear event with different rain input data ranging from single station to rain-radar data. Results obtained for different parameters, such as deposition and cloud-shine, corresponding to precipitation measurements from weather stations on the one hand, and from rain-radar data on the other hand, are compared.

This paper assesses the importance of the rain-radar data in the early phase of a nuclear or radiological emergency. The resolution and the uncertainties associated with the different available rain data are discussed. Also, a quantitative analysis is presented of the results obtained when different rain input data are used. Finally, to strengthen our conclusion on the added value of rain-radar data in the early phase, a survey on the opinion of several radiological experts on the use of rain-radar data based on a case study with calculated examples will be discussed.

Is one set of intervention levels for radiation emergency planning enough?

Abstract

A common set of intervention levels is still missing for introducing early (sheltering, evacuation) and late (relocation, resettlement, returning to evacuated areas) protective actions in radiation emergencies. A two-step method has been suggested to derive a consistent set of intervention levels. In the first step, the projected effective doses are calculated for different accidental release scenarios for three defined time periods which corresponds with integration times for sheltering and relocation and the corresponding dose ratios estimated. In the second step, it is necessary to adopt a reference dose level for a certain time period. The relationships between the projected effective doses and the agreed reference level are used to derive a consistent set of intervention levels for early and late protective actions. In this contribution the recommendation of ICRP to limit the annual dose to the public to 100 mSv in the first year is adopted. Based on this reference level, the intervention levels for the early and late protective actions are derived for a variety of scenarios. The influence of different parameters on the variation of results is analysed and discussed with respect to establish appropriate intervention levels. Based on the results, it is further discussed whether it is of advantage to have only one set of intervention levels which covers even unfavourable conditions, or, whether it might be more appropriate to derive more than one set of intervention levels for different scenarios, which enable decision makers for a flexible response according to the accidental situation.

Introduction

An international agreed set of intervention levels is still missing for introducing early (sheltering, evacuation) and late protective actions (relocation and returning to evacuated areas) in radiation emergency preparedness. International organizations (ICRP 2007; IAEA 2009) recommend a reference level between 20 and 100 mSv per year but they do not give guidance how to split this level into discrete values for sheltering, evacuation and returning, which is of greatest importance for practical decisions. For implementing best radiation protection to the affected population, decision makers have to decide on sheltering and evacuation in an event even before radionuclides are released, and on relocation immediately after the passage of a cloud. As there is not much time for consideration of protective actions, intervention levels for each countermeasure have to be agreed in the planning phase. In this paper sets of intervention levels for early and late protective actions are derived, which are in line with each other. It is discussed whether one set of intervention level is sufficient to deal properly with all kind of radiation emergencies or whether few sets of intervention levels might be more appropriate to cover different scenarios.

Material and methods

The recommendation of ICRP to limit the maximum annual dose to the public to 100 mSv in the first year after the accident occurance is adopted. The time dependent curve of the projected effective doses within the first year is analysed for different scenarios. It is assumed that the integration time for early protective actions will be 2 days and for relocation 30 days and 1 year. Accordingly, effective doses are calculated for the three time periods separately: from the beginning of the release until the end of the 2nd day, from 3rd day until the 30th day and from the 31st day until first year. Then, the ratios of the doses for the three time periods are calculated. When a set of dose ratios is adopted for one scenario, the recommended annual dose of 100 mSv/a is split according to the dose ratios to obtain a consistent set of intervention levels for sheltering and relocation. The variation of the dose ratios leads to different sets of intervention levels for sheltering and relocation, dependent on each scenario considered.

Three different kinds of source terms have been defined:

- two complex source terms for accidental releases from a NPP,
- Iodine-131 release, as example for short lived β- and γ radionuclides, and
- Cs-137 release, as example for long lived β- and γ radionuclides.

Six different weather conditions have been assumed: Pasquill stability class B, with wind speed of 3 m/s; Pasquill stability D, with wind speed 6 m/s; and Pasquill stability F, with wind speed 2 m/s. Both dry and rainy conditions have been assumed. When rain has been considered, a wash-out coefficient of 3.5E-04 s^{-1} has been used for calculations. The emission characteristics are: heigh 50 m, duration 2 hours. The dose calculations have been carried out with the Romanian RO-CODE and the German version of RODOS.

The Romanian RO-CODE is software specifically developed by the representative of Regulatory Authority in Romania as an in-house tool for the assessment of possible radiological consequences of nuclear accidents at Cernavoda NPP (Baciu 2004). The computer code uses the Gaussian plume model to simulate the dispersion and the transport of the radionuclides at different distances from the source. The dose coefficients are taken from Eckerman and Ryman (1993). The RODOS code is described in literature (Ehrhardt and Weis 2000; Ehrhardt et al. 2007).

Results

The results indicate that the amount of doses in the first period (the first two days after the accident occurrence) depends significantly on the weather condition. The projected effective doses vary with the stability class and the kind of deposition – dry or wet. But the dose ratios show a different picture: The ratios of the doses in the three periods are fairly independent from the stability class but differ significantly for wet and dry deposition. The results of both models, presented in Table 1, are in a fairly good agreement.

Table 1. Projected effective doses *E* (mSv) and dose ratios P_n/P_2 (n = 1, 2, 3) calculated with RO-CODE and RODOS for the time periods P_1 to P_3, in 5 km distance assuming different atmospheric stability classes (B, D, and F) as well as dry and wet conditions, for all source terms considered.

Conditions	RO-CODE			RODOS

To derive sets of intervention levels, the annual reference dose of 100 mSv has been split according to the dose ratios obtained for the different scenaris (table 2)

Table 2. Derived sets of intervention levels for sheltering and relocation, for all source terms considered (source term, Cs-137 and I-131, in dry and wet conditions.

Conditions	Sheltering (mSv, 2 days)	Relocation (mSv, 1st month)	Relocation/ Resettlement (mSv, 1st year)
Dry deposition			
Complex source term for NPP			
Intervention level	50 mSv/2 days	65 mSv/1st month	100 mSv/1st year
Dose ratio	4	1	2
Cs-137 release			
Intervention level	22 mSv/2 days	30 mSv/1st month	100 mSv/1st year
Dose ratio	3	1	10
I-131 release			
Intervention level	75 mSv/2 days	100 mSv/1st month	100 mSv/1st year
Dose ratio	3	1	0.1
Wet deposition			
Complex source term for NPP			
Intervention level	12,5 mSv/2 days	37.5 mSv/1st month	100 mSv/1st year
Dose ratio	0,5	1	2.5
Cs-137 release			
Intervention level	1 mSv/2 days	10 mSv/1st month	100 mSv/1st year
Dose ratio	0.1	1	10
I-131 release			
Intervention level	30 mSv/2 days	100 mSv/1st month	100 mSv/1st year
Dose ratio	0.3	1	0.15

Concerning the source term of a NPP and assuming dry deposition, about half of the annual dose is received during the first 2 days when the radioactive cloud passes. Concerning wet conditions, the dose in first 2 days is only about one eighth of the annual total dose. What does this mean with respect to emergency management? Many countries have settled an intervention level for sheltering of 10 mSv integrated over 2 days. This means when the dose of 10 mSv is exceed in the first two days and it is raining, then it has to be assumed that also reference dose of 100 mSv for one year might be exceeded and relocation have to be taken into account directly after the cloud´s passage. But a completely different picture is given when it does not rain during the cloud´s passage. The projected dose integrated over 2 days could be significantly higher than 10 mSv but relocation must not be considered because the annual dose of 100 mSv will be not be exceeded.

It is obvious that the results strongly depend on assumption on the radionuclide composition. To get an idea on dose ratios for the different time periods, calculation were carried out for I-131 as representative of a short lived β- and γ radionuclide and for Cs-137 as representative for long lived β- and γ radionuclide. Concerning I-131 about 70 % of the dose is received during the passage of a cloud in the absence of precipitations. Under wet conditions, the dose ratios are vice versa. About 30 % of the dose is received in the first 2 days but about 70 % in the next 28 days.

Opposite results are obtained for Cs-137. About 25% of the annual dose is received in the first 2 days assuming dry deposition which means that inhalation plays a significant role during the passage of the cloud. In the later periods, when direct deposition is the dominant pathway, the monthly exposure declines slowly. Concerning wet deposition, the dose from inhalation is becoming of minor importance. The dominant pathway is direct radiation in each period. Consequenty only about 1/100 of the total annual dose is received in the first 2 days during the passage of the cloud. But when the doses are fairly constant over 1 year, late countermeasures become more relevant than short term ones.

Conclusions

First analysis show that sets of intervention levels vary significantly with the fraction of long-lived and short-lived radionuclide in the source term and with dry or wet deposition. But the dose ratios and consequently the derived intervention levels are fairly independent from the stability class.

Concerning dry deposition, an intervention level for sheltering of 10 mSv per 2 days would make sure that the annual dose of 100 mSv per year will not be exceeded in all examples. The annual dose will even stay below 50 mSv in these cases. This means when the intervention level for sheltering is not met, also relocation must not be recommended too. The derived values are in line with each other.

A different picture has been received for wet deposition. The contribution of the dose received during the passage of a cloud to the total annual dose is significant lower for all sources considered. For I-131, the intervention level of 30 mSv during the first 2 days corresponds with an annual dose of 100 mSv. Concerning releases from NPPs, an annual dose of 100 mSv can be expected when the dose within the first period is expected to be a little more than 10 mSv for wet deposition. But concerning Cs-137, a dose of only 1 mSv during the first 2 days corresponds with an annual dose of 100 mSv. This means that the dose reduction by implementing sheltering will be insignificant in comparison to the annual dose. Consequently, when the dose is below 1 mSv in the first 2 days, then neither sheltering not relocation have to be considered. Above 1 mSv per 2 days, countermeasures to reduce direct radiation have to be taken into account immediately. Otherwise evacuation has directly to be taken into account as protective action for population.

Coming back to the question whether one set of intervention level is sufficient for emergency planning: The answer is complex: a distinction between wet and dry deposition seems to be appropriate due to the differences in results. But on the other hand fast and common decisions can rather be expected when only one set of intervention has been settled. Based on these calculations, it is would be possible to take into account the intervention levels derived for a release at a NPP under wet conditions. It covers all situation analysed, excepting the very special situations when only long lived β- and γ emitting radionuclides are released under wet conditions. In this special situation, evacuation, respectively relocation has to be considered directly.

The objective of this contribution is to address the problem of setting up intervention levels which are in line with each other. It is obvious that additional scenarios and assumptions, like different radionuclide compositions, different deposition rates and washout coefficients have to be analysed to create a good basis for a final conclusion whether one set of intervention levels is appropriate in radiation emergency preparedness.

Technical considerations for protective action strategy in nuclear emergency using probabilistic accident consequence assessment model

Kimura, Masanori; Takahara, Shogo; Homma, Toshimitsu
Japan Atomic Energy Agency, JAPAN

Abstract

If an accident occurred at nuclear power plant and any plume of radioactive materials was released into the environment, country and local government immediately have to implement protective actions for people around the plant to reduce exposed dose. In order to efficiently implement protective actions, it is important to preliminarily develop the good planning for emergency preparedness and response to a nuclear accident. In particular, it is important to provide the technical guidance for the development of urgent protective actions (e.g. evacuation, sheltering and iodine prophylaxis), based upon a comprehensive threat assessment that takes into account the full range of postulated events for nuclear accidents. The most effective response strategy in nuclear emergency will involve a combination of these protective actions. The ICRP recommends focusing on optimization with respect to the overall strategy, rather than the individual protective action in the ICRP new recommendation, Publication 103. To develop a generic response strategy, probabilistic accident consequence assessment models can be very useful for providing a quantitative basis on discussing the effective emergency plan. Our study shows results of the technical considerations for the overall strategy of implementing protective actions in emergency exposure situation using a probabilistic accident consequence assessment model by Japan Atomic Energy Agency. For postulated accidents with source terms derived from a generic level 2 PSA of the reference plant in Japan, residual doses are calculated in case of implementing combination of these protective actions and then optimization process being guided by reference levels is applied. The preliminary results will provide the insights of technical guidance for the development of these protective actions.

System for the prognosis of the population doses due to emergency atmospheric release from nuclear power plants

Bonchuk, Iurii[1]; Talerko, Nikolai[2]

[1] Radiation Protection Institute, Kyiv, UKRAINE

[2] Institute for Safety Problems of Nuclear Power Plants, Kyiv, UKRAINE

Abstract

A description of the structure and capabilities of the system used for assessment and prediction of the effects of radioactive releases from Rivne Nuclear Power Plant (RNPP) is given. The system includes models for calculation of the atmospheric transport, external and internal doses, as well as module for justification assessment of emergency and urgent countermeasures. The calculations of possible impact of beyond design basis accident for the population within RNPP's supervised area were performed. It is shown that an increase in efficiency of iodine prophylaxis by using the prediction results of the radiation situation can provide a significant reduction of avertable dose to thyroid.

Introduction

In 2007 Ukrainian state enterprise National Nuclear Energy Generating Company (NNEGC) "Energoatom" adopted the concept of a computer decision support system (DSS) in the event of radiation accidents at Nuclear Power Plant (NPP), according to which DSS must have a two-level structure, consisting of two subsystems:

– site (plant) subsystem which placed at each NPP in Ukraine;
– central subsystem which placed in the Crisis Centre of NNEGC "Energoatom".

The main element of the DSS is site subsystem that efficiently should perform decision-making support at an early phase of the accident according to requirements of the Typical emergency plan for NPP in Ukraine.

System of operative analysis of radiation situation due to accidents at NPP in Ukraine (SOARS) was established by the Radiation Protection Institute (Kyiv) for dose calculation and support decisions about countermeasures. SOARS is used at Rivne NPP from 2003, it fully complies with the requirements of Radiation Safety Standards of Ukraine. The paper is devoted to a brief description of its capabilities and prospects for its further improvement.

The generic structure of SOARS

System of operative analysis of radiation situation is intended for calculation the consequences of atmospheric releases from NPP within its supervised area at an early stage of the accident. It includes following main modules:

- module for calculation of atmospheric transport and fallout to the ground surface;
- module for calculation of external doses from radioactive clouds;
- module for calculation of external doses from fallout to the ground surface;
- module for calculation of internal doses due to inhalation;
- module for calculation of internal doses due to ingestion of contaminated food (pilot module);
- module for countermeasures.

Fig. 1 shows the appearance of the main window of the system and a fragment of one of the auxiliary window with summary results of dose calculations and countermeasures for settlements in NPP supervised area.

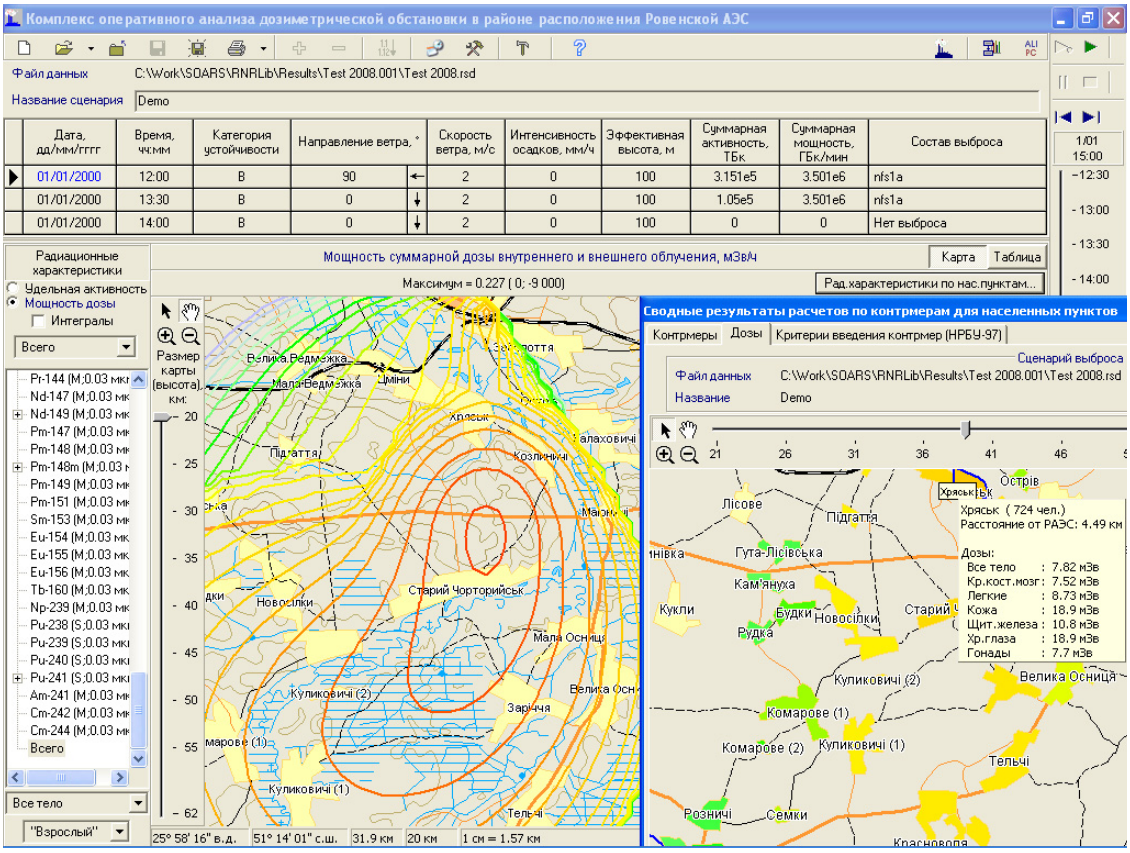

Fig. 1. The main window of SOARS and a fragment of *Summary results* window.

Atmospheric transport module

The module calculates the field of volume specific activities of radionuclides in the surface air and surface specific activities of radionuclides in the fallout to the ground surface. It is based on time-dependent model of atmospheric dispersion that is used to calculate the possible consequences of accidental releases at distances up to 30 km. In contrast to the standard Gaussian model of atmospheric dispersion (IAEA 1980), time-dependent atmospheric transport models can be applied in situations characterized by rapidly changing trend of release and in conditions with changing of meteorological fields during the time of pollutant transport (essentially, speed and direction of wind). Prolonged non-stationary release of radionuclides from the source is modelled by a sequence of discrete releases ("puffs") emitted from the source through some (sufficiently small) intervals. The detailed model applied in the SOARS for the calculation of the volume specific activity of radionuclide in the air is given in (Talerko 2005). This approach allows to increase the range of applicability of the model for the transport distances (within the supervised area of NPP) in comparison with the common Gaussian model, which (according to (IAEA 1980)) is recommended for use only at distances up to 10 km from the source. Discussion of features and limitations for the applicability of these models is given in (Talerko 2009).

The source data for calculations consist of release parameters and meteorological data (variable with time): release rate (activities of separate radionuclides), duration of release, release height, stability class, wind speed, wind direction, precipitation rate.

Module for calculation of external doses

The module calculates the effective dose and equivalent dose to organs (tissues), formed by external exposure from radionuclides in the plume and radionuclides in the fallout to the ground surface.

The module contains two models for calculation the external dose from the plume:

a) model of a semi-infinite spatially homogeneous source (IAEA 1980);

b) integrated model of the plume (Talerko 2005).

The homogeneous semi-infinite source model can lead to large errors in dose assessment from radioactive plume on conditions of high spatial gradients of radionuclide activity at small distances from the source of releases. Therefore integral model is used in substantially heterogeneous and rapidly changing fields of activity of radionuclides in the surface air. The model allows clarifying the dose assessment substantially, especially at distances comparable with the release height.

Calculation of effective dose of external exposure from fallout to the ground surface is based on the model of source, uniformly distributed on the infinite surface. Values of external dose rates per unit of surface specific activity of radionuclides on the ground surface are given according to (Eckerman, Leggett 1996).

Module for calculation of internal doses

The module calculates the effective dose and equivalent dose to organs (tissues), formed by internal exposure of radionuclides. The calculation is performed for each radionuclide in release composition and its progeny produced during radioactive decay.

Inhalation. The projected effective dose (for reference age τ), formed by inhalation intake of radionuclide i at time t, calculated as follows:

$$E_{\tau,i}^{inhal}(t)=\int_0^t \dot{E}_{\tau,i}^{inhal}(\theta)\,d\theta\,. \tag{1}$$

Internal dose rate due to inhalation intake ($\dot{E}_{\tau,i}^{inhal}(\theta)$, mSv·h^{-1}) is determined by the formula

$$\dot{E}_{\tau,i}^{inhal}(\theta) = A_{V,i}(x, y, 0, \theta)\dot{g}_{\tau,i}^{inhal}, \tag{2}$$

where $A_{V,i}(x, y, 0, \theta)$ is a volume specific activity of the radionuclide i in the surface air at the time θ (Bq·m^{-3}) for settlement with the coordinates (x, y); $\dot{g}_{\tau,i}^{inhal}$ is an effective internal dose rate due to inhalation for reference age τ per unit volume specific activity of radionuclide i in air, mSv·Bq^{-1}·m^{3}·h^{-1}.

The calculation of $\dot{g}_{\tau,i}^{inhal}$ is based on biokinetic and dosimetry models of the International Commission on Radiological Protection (ICRP). These values are pre-calculated using the IDSS software (Internal Dosimetry Support System), developed by the Ukrainian Radiation Protection Institute (Berkovski et al. 1998). The calculated coefficients are stored in the internal database, which contains data for more than 700 radionuclides (for six reference ages). IDSS demonstrated good correspondence of calculation results with the values of doses per unit intake published by ICRP. Calculation of equivalent dose to organs (tissues) is similar to the calculation of effective doses. For this purpose the corresponding values $\dot{g}_{\tau,i}^{inhal}$ are also stored in SOARS database.

Ingestion. Module for calculation of internal dose due to ingestion intake is a pilot module (under development and testing) which is not included in the SOARS, currently operated in RNPP. The projected effective dose, formed by ingestion of radionuclide i at time t, is calculated in this module as

$$E_{\tau,i}^{ingest}(t) = \sum_{\Theta} E_{\tau,i}^{ingest}(\Theta), \tag{3}$$

where $E_{\tau,i}^{ingest}(\Theta)$ is a projected effective dose for the reference age τ formed by ingestion of radionuclide i during the calendar date Θ.

The summation in the formula is performed on all calendar dates from the beginning of an emergency release to the date corresponding to time t. Effective internal dose for the calendar date Θ is determined by the formula

$$E_{\tau,i}^{ingest}(\Theta) = I_{\tau,i}^{ingest}(\Theta) \cdot e_{\tau,i}^{ingest}, \tag{4}$$

where $I_{\tau,i}^{ingest}(\Theta)$ is an ingestion intake of radionuclide i for calendar date Θ for the reference age τ, Bq; $e_{\tau,i}^{ingest}$ is an effective dose per unit of ingestion of radionuclide i for the reference age τ, Sv·Bq^{-1}.

An ECOSYS model (Muller, Prohl 1993) is the basis of assessment of ingestion intake, however typical Ukrainian food consumption levels are used in the module. A set of pre-calculated daily intakes (for the reference ages), formed by a fallout in every single day of the year, is used for dose calculation. The database of doses per unit intake created by IDSS software (as well as inhalational intake) is also used (Berkovski et al. 1998).

Module for countermeasures

Accordingly to Ukrainian legislation predicted and avertable doses to the population of settlements in supervised area are estimated (RSSU 1997). Predicted absorbed doses to organs (tissues) are calculated for 2 days after emergency release (for decision-making about emergency countermeasures). Avertable doses to whole body, thyroid and skin are calculated for 2 weeks after accident (for decision-making about urgent countermeasures). Avertable doses depend on efficiency and duration of one or several countermeasures (sheltering, evacuation, iodine prophylaxis, outdoor restriction). Scheme of calculation of avertable doses is described below as an example for effective doses.

For external exposure and internal exposure due to inhalation, the effective dose $E_{cm,\tau}$, avertable at time t (for the radionuclide i and for the reference age τ), is calculated as follows:

$$E^{p}_{cm,\tau,i}(t)=\int_0^t\left(1-\frac{1}{k^{p}_{cm,\tau,i}(\theta)}\right)\dot{E}^{p}_{\tau,i}(\theta)\,d\theta\,, \tag{5}$$

where $k^{p}_{cm,\tau,i}$ is a reduction function for the effective dose for reference age τ, radionuclide i, and pathway of dose formation p due to applying of countermeasures ($k^{p}_{cm,\tau,i}(\theta)\geq 1$ for each θ; $k^{p}_{cm,\tau,i}(\theta)\equiv 1$ if countermeasures are not applied or they are not effective); $\dot{E}^{p}_{\tau,i}(\theta)$ is an effective dose rate at time θ for radionuclide i and pathway p.

The effective dose due to ingestion for reference age τ, avertable during time t, is determined by the formula:

$$E^{ingest}_{cm,\tau,i}(t)=\sum_{\Theta}\left(1-\frac{1}{k^{ingest}_{cm,\tau,i}(\Theta)}\right)E^{ingest}_{\tau,i}(\Theta), \tag{6}$$

where $k^{ingest}_{cm,\tau,i}$ is a reduction factor for the effective dose from ingestion of radionuclide i during application of countermeasures in the calendar date Θ; $E^{ingest}_{\tau,i}(\Theta)$ is a projected effective dose from ingestion of radionuclide i during the calendar date Θ.

It is necessary to draw attention to 'behaviour mode' term, for which the following numerical characteristics are specified: for rural population – 0.29, for population of urban villages – 0.2, and for urban population – 0.13 (Likhtariov et al. 1996). The behaviour mode in several times (from 3.4 to 7.7) reduces the estimated value of external dose due to fallout to the ground surface.

For the calculation of avertable doses, SOARS uses charts of countermeasure application, which allows specifying the beginning, duration and efficiency (reduction factor for each pathway). As far as countermeasures can be applied with some delay, their application cannot avert a projected dose completely, but only reduce it (sometimes substantially). Therefore, some countermeasures for settlements may not be justified, despite significant accident doses.

Auxiliary modules

Auxiliary modules SOARS include: module with radionuclides data, reference information module, and geographic information module.

Module with radionuclides data provides detailed radionuclide data (radioactive decay constants, decay chains, spectral characteristics), necessary to perform the calculation of dosimetry situation.

Reference information module performs the displaying of data stored in the module with radionuclides data.

Geographic information module contains cartographic information about Rivne and Volyn regions within a radius of 50 km from RNPP and includes basic map layers (boundaries of the regions and districts, topography, vegetation, water bodies, settlements, roads and railways).

Application SOARS for impact assessments of emergency releases

The application of SOARS for the analysis of the impact of beyond design state accident (BDSA) on the power unit VVER-1000 on RNPP is considered below (NNEGC "Energoatom" 1999). Example demonstrates the possibility of SOARS for decision-making support on countermeasures. The release duration is limited to two hours (for simplifying the analysis), the release indicated in the Table 1.

Table 1. The composition of the release of radionuclides in the BDSA on VVER-1000.

Radionuclide		Release, TBq	
		0 – 1 hour	1 – 2 hrs
Inert radioactive gases	^{85m}Kr	1000	200
	^{87}Kr	2400	200
	^{88}Kr	3700	700
	^{133}Xe	19000	2000
	^{135}Xe	1100	200
Molecular iodine	^{131}I	810	40
	^{132}I	560	30
	^{133}I	560	–
	^{134}I	410	–
	^{135}I	370	40
Organic compounds of iodine (CH_3I)	^{131}I	96	14
	^{132}I	63	7
	^{133}I	67	7
	^{134}I	37	4
	^{135}I	44	4
Caesium	^{134}Cs	25	–
	^{137}Cs	13	–

Calculations were performed for the following meteorological characteristics: atmospheric stability class is E, wind speed is 2 $m \cdot s^{-1}$, wind direction is toward Kuznetsovsk. Calculations were performed for two effective heights of release: 40 m (outflow from the containment) and 120 m (release from the stack). The calculations did not take into account the ingestion intake of radionuclides with contaminated food. This component is essential for the formation of the dose, but it is more delayed in time than other pathways. This paper focuses on the first few hours after the release.

The results of the calculations (projected doses to population of settlements) are presented in Table 2. Since the criteria for urgent countermeasures are not achieved, and criteria for the introduction of urgent countermeasures are exceeded only lower bounds on the justification, specified for the doses to the skin, Table 2 shows only the values of doses to the whole body and thyroid. In the columns "Children" shows the values of doses are the highest among all reference ages, except for reference age "Adult". Mode behaviour in Table 2 is not taken into account.

Table 2. Projected dose exposure of various settlements in supervised area of RNPP (indicating the distance from the RNPP).

Release height	Organ (tissue)	Time	Kuznetsovsk (2,9 km)		Berezina (18,6 km)		Serkhiv (24,9 km)		Kolodii (7,1 km)	
			Children	Adults	Children	Adults	Children	Adults	Children	Adults
40 m	Whole body, mSv	Plume*	56	32	4.7	2.7	3.4	1.9	0.8	0.5
		2 days	65	41	5.3	3.3	3.8	2.3	1.0	0.6
		14 days	81	57	6.5	4.5	4.7	3.2	1.2	0.8
	Thyroid, mGy	Plume*	1000	510	84	43	61	31	15	7.5
		2 days	1010	520	85	43	62	32	15	7.6
		14 days	1030	530	86	45	63	33	15	7.9
120 m	Whole body, mSv	Plume*	37	21	5.8	3.3	4.2	2.4	0.9	0.5
		2 days	43	27	6.6	4.1	4.7	2.9	1.0	0.6
		14 days	54	38	8.3	5.8	5.9	4.1	1.3	0.9
	Thyroid, mGy	Plume*	670	340	110	54	77	39	16	8.2
		2 days	670	340	110	55	78	40	16	8.3
		14 days	680	350	110	57	79	41	17	8.6

* Doses which will be received during the plume passing above settlement are specified.

The main dose formation factor is the inhalation intake of iodine. Its contribution to the total effective dose (for the population of Kuznetsovsk) ranges from 80% (for release height 40 m) to 82% (120 m). Approximately 70% of these values formed by ^{131}I, and up to 8% formed by ^{133}I. The external exposure formed by radioactive inert gases is the following by importance. Its contribution ranges from 9% (for the release height 120 m) to 11% (40 m) of the total dose (most of which goes to ^{88}Kr). The contribution of other ways of the dose formation is considerably less: an external exposure from fallout to the ground surface gives about 4%, and inhalation intake of caesium radionuclides gives about 2%.

The above mentioned fractions are related to the duration of exposure during the plume passage. In considering the longer time intervals (2 and 14 days) for which countermeasures are applied, the growth of the fraction of external exposure from fallout will be observed. As shown in Table 2, the increase may reach 30% for 2 days and 80% for 14 days (for the effective dose). However, for such time intervals a mode of behaviour should be taken into account. Using of it will reduce the specified growth of doses at least in three times. On the other hand, the dose assessment may increase substantially, taking into account the ingestion intake.

Concerning doses to thyroid, it is obvious that they are almost entirely (~99%) are formed by inhalation intake of iodine radionuclides (~85% by ^{131}I, ~12% by ^{133}I) and almost did not increase after the passage of the plume release.

According to Table 2, levels of unconditional justification for outdoor restriction can be exceeded for the population of Kuznetsovsk (for both release heights).

The levels of unconditional justification of iodine prophylaxis may be exceeded for both release heights for children, and for the release height 40 m for adults (lower justification limits may be exceeded only for adults for the release height 120 m). Exceeding of levels for urgent countermeasures intentionally mentioned as possibilities, but it is not obligatory, because it is required to prove (for their justification) the exceeding of avertable (not projected) doses.

Depending of avertable doses from the operability of countermeasures introduction is described below. Since this dependence for the outdoor restriction is more obvious, it focuses on the iodine prophylaxis.

Dependence of the effectiveness of iodine prophylaxis on the time of stable iodine consumption after intake of radionuclide was adopted in accordance with (Prister et al. 2007). Results of calculation of avertable doses are given in Table 3.

Table 3. Dependence of avertable doses from the beginning of iodine prophylaxis.

Release height	Age	Organ/tissue	Projected dose	Avertable dose (depending on the time of the introduction of iodine prophylaxis after the release)				
				1 hour	2 hrs	3 hrs	4 hrs	5 hrs
40 m	Children	Whole body, mSv	56	47	45	37	27	24
		Thyroid, mGy	1000	940	880	740	530	480
	Adults	Whole body, mSv	32	24	23	19	14	12
		Thyroid, mGy	510	470	440	370	270	240
120 m	Children	Whole body, mSv	37	32	30	25	18	16
		Thyroid, mGy	670	630	590	490	350	320
	Adults	Whole body, mSv	21	16	15	13	9.1	8.1
		Thyroid, mGy	340	320	300	250	180	160

The results presented in Table 3, demonstrate a significant reduction of avertable doses (to thyroid) with increasing of delay of iodine prophylaxis introduction. Although the justification of iodine prophylaxis introduction (for a given release scenario) is remained even after 5 hrs after the accident, the fraction of dose that can be averted is reduced (compared to 1 h) almost two times (from 9 to 48%). The doses that will not be averted due to the late introduction of countermeasures, respectively, exceed half of the estimated doses to thyroid. The value of non-avertable effective dose (to the population) may even exceed the dose limit for the personal (category A). This example demonstrates the necessity for earliest possible introduction of iodine prophylaxis in the event of the considered BDSA.

Conclusions

SOARS is installed at RNPP (4 units) for the decision support in case of accidental releases of RNPP. SOARS was operated since 2003 and was commended by experts from the International Atomic Energy Agency during the OSART (Operational Safety Review Team) mission and by experts of the three missions of WANO (World Association of Nuclear Operators plants). The latest comprehensive emergency training, during which SOARS has been successfully used, were performed by NNEGC "Energoatom" in September 2008.

The further development and improvement of SOARS are planned:

1. Formation of the release scenario database at different accidents at NPP with VVER reactors.
2. Development and improvement of the atmospheric transport module to taking into account physical and geographical peculiarities of the supervised area of the NPP (complex relief, presence of large water bodies, and irregularities of the underlying surface).
3. Inclusion of ingestion intake of radionuclides to the module for dose calculation.
4. Automatic input of meteorological information for real-time of system operation.
5. Ability to assimilate the radiation monitoring data from the supervised zone of NPP to clarify the characteristics of radioactive contamination and the parameters of release sources (inverse problem of atmospheric dispersion and dosimetry).

Taking into account the prospects for above listed expanding of functionality, NNEGC "Energoatom" spreads SOARS for all 4 operating Ukrainian NPPs (15 units). Works on adaptation of SOARS for use at Khmelnitsky NPP (2 units) are carrying out now.

Dose assessment for population in case of a beyound design basis accident at NPP

Kliaus, Viktoryia
Republican Scientific-Practical Centre of Hygiene, BELARUS

Abstract

Radiation protection of the population in case of a reactor accident utilizes reference levels and generic criteria which are based on dose values. Therefore adequate provisions for effective and timely dose assessment for population in case of beyond design basis accident (BDBA) at NPP are important. Developing the background for such provisions is the objective of this study. In the result of our calculations and their analysis versus international recommendations it was found that after the BDBA at NPP with a PWR reactor there is no need for evacuation or providing sheltering for the public because the total effective dose will not reach currently recommended generic criteria (100 mSv in the first 7 days). However, emergency plans should be made to: a) recommend to the public to avoid eating potentially contaminated food or milk; b) perform an environmental monitoring and monitoring of food, water and fodder within 25 km from the NPP; c) provide food monitoring on the territory about 300 km round the NPP. The results of the study could be used for emergency planning purposes.

Introduction

One of the most important aspects of managing a nuclear emergency is the ability to promptly and adequately estimate the consequences of an accident. Because of the need for protective actions to be initiated promptly in order to be effective, nuclear accident assessment must take account of all information that is available to on-site and off-site organizations.

Radioecological modeling is used widely to assess the consequences of potential or ongoing releases at NPPs within the NPP country and beyond the national borders.

Models usually require information that might be available during an emergency. The data required are accident location, either an assessment of plant conditions or an estimated source term, and basic meteorological information.

All these models have been developed carefully according to the present state of science in the field of radioecology. Nevertheless, radioecological models are approximations of reality and hence deviations from real accident conditions may occur. The bases of all existing models is the principles of radioecological prognosis which take into account such parameters as source term, release path, meteorological data, breathing rate, the type of dwelling (e.g. shielding characteristics), dietary habits (e.g. special foodstuffs and amounts consumed), domestic habits (e.g. time spent indoors, frequency of personal washing, and laundering of clothes), etc.

Analysis of the consequences of beyond design basis accidents (BDBA) for the purposes of emergency preparedness and response are usually made for determination of sizes of emergency zones for threat category I and II facilities. Radiation protection of the population in case of a reactor accident utilizes reference levels and generic criteria which are based on dose values [1]. Therefore adequate provisions for effective and timely dose assessment for population in case of BDBA at NPP are important.

Material and methods

Radiological consequences for the beyond design basis accident at NPP with a PWR reactor (or WWER in case of a Russian design) were studied.

Beyond design basis accident is defined in the IAEA Safety Glossary as accident conditions more severe than as design basis accident (accident conditions against which a facility is designed according to established design criteria, and for which the damage to the fuel and the release of radioactive material are kept within authorized limits) [2].

Release out of primary system through the containment to the atmosphere was included in the considered scenario.

A gap release assumes that the core is damaged and all fuel pins have failed, releasing the gaseous fission products contained in the fuel pin gap. For each release route, the mechanisms that will substantially reduce the release are considered (e.g., containment sprays). The effectiveness of the reduction mechanism used is representative for a range of assumptions. In the case of this study it is a release from the containment. It assumes a release into the containment which leaks to the atmosphere. It is reduced it the release from the fuel passes through some process (e.g., sprays, filters) on the way to the atmosphere that will remove a large fraction of the iodine and particulate. It is assumed that an atmospheric release route is not reduced. The release is not reduced for large or wet releases because filters may clog and fail. Normally it is assumed that the release is not reduced if the filters are in containment because a large release may clog them. Hold up time (average time radioactive material released from core remains in containment before release) assumed to be zero.

The release rate will be very difficult if not impossible to determine early in an accident and yet it is the single most important factor in determining off-site consequences. Therefore it is important to bound the release rates by selecting the rate closest to best estimate and a reasonable worst case scenario. Most of the release from the core were chosen to be released within 2,5 hours.

Release from the containment assumed as a ground-level release, not isolated release location. In this case building wake effects need to be considered. If the wind speed was zero the release would be considered as a release from the definite height [4].

Parameters of the model used for calculations are presented in the Table 1.

Table 1. Plant conditions.

Parameter	Value
Power of reactor PWR-1000	3000 MW (th)
Level of core damage	10-50 % core melt (rapid release of volatile fission products)
Leak rate	0,02 %/hour
Release condition	Not reduced (no spray or pool, filters are assumed to blow out)
Hold up time	any
Release height	0 m
Containment volume	71040 m^3
Containment surface space	53250 m^2

Real meteorological data which typical for winter and summer seasons in Belarus accordingly were used for calculations (see Table 2).

All plant-specific and meteorological data have been selected for the purpose of the assessment of the worst case scenario of beyond design basis accident.

Table 2. Meteorological data for "winter" and "summer" scenarios of beyond design basis accident.

Parameter	Value	
	summer	winter
Wind direction	south-west	west, south-west
Surface wind speed	6,4 – 6,7 m/s	5,5 -11 m/s
Atmospheric pressure	993,7 GPa	1008,0 GPa
Air temperature	20 °C	-2,5 - -1,5 °C at night and in the morning 3,7-1,8 °C – in the day time
Cloudiness	100 %	0 %
Precipitation rate	No rain	1-4 mm/hour, snow 1-1.5 cm height
Mixing layer height	0,6 км	1,2 - 1,5 km at night 0,5 - 0,3 km in the day time and at evening
Stability class	D	F

Building shielding factor assumed to be zero, i.e. population spent 100 % of the time outdoors (conservative assessment).

Source term estimation in case of BDBA:

$$SourceTerm_i = FPI_i \cdot CRF_i \cdot \prod_{j=1}^{N} RDF_{(i.j)} \cdot EF_i \, , \qquad (1)$$

FPI_i – Isotope inventory;

CRF_i – Amount of isotope i released out of core/core inventory of isotope i;

RDF_i – Fraction of the isotope i activity available for release following reduction mechanism j;

EF – Fraction of activity available for release that is released [3].

Activity of radionuclides and doses for the public in case of the BDBA were calculated using The International Radiological Assessment System (InterRAS) software, which was developed for use by personnel who responds to a nuclear l emergencies. The InterRAS is a set of personal computer-based tools. InterRAS Version 1 is based on the U.S. NRC's RASCAL Version 2.1 code (NRC94) but was modified to allow assessment a greater range of accidents and to conform to the guidance in the IAEA Basic Safety Standard (IAEA96) [4, 5].

The “Source Term to Dose” (ST-DOSE) model was used. This model contains tools to estimate the distance at which urgent protective actions may be needed based on nuclear power plant conditions or release rates. The ST-Dose model will first generate a time-dependent “source term”, the release rate for each radionuclide from the facility as a function of time. The time-dependent release rate (the “source term”) than provides the input to an atmospheric dispersion and transport model.

The atmospheric dispersion and transport model estimates radionuclide concentrations to downwind, both in the air and in the ground deposition. The calculated concentrations than are used to estimate projected doses. The dose pathways are: cloudshine from the plume, inhalation from the plume, and groundshine from deposited radionuclides (assuming 4 days of exposure to groundshine).

Radionuclide concentrations downwind from the NPP and projected doses due to the accident were estimated at distances of 1, 2, 5, 25 and 50 km from the site.

Results

Results of calculation of total activity of the accidental release in case of BDBA at NPP with a PWR reactor are presented in the Table 3.

Table 3. Activity of radionuclides released to the atmosphere, Bq.

Nuclide	Activity, Bq	Nuclide	Activity, Bq	Nuclide	Activity, Bq
Kr-85	1,00E+13	Kr-85m	4,2E+14	Kr-87	8,4E+14
Kr-88	1,2E+15	Sr-89	3,9E+13	Sr-90	1,5E+12
Sr-91	4,60E+13	Y-91	3,30E+12	Mo-99	1,80E+13
Tc-99m	1,80E+13	Ru-103	1,20E+13	Ru-106	2,70E+12
Sb-127	1,2E+13	Sb-129	6,9E+13	Te-129m	1,1E+13
Te-131m	2,5E+13	Te-132	2,5E+14	I-131	4,1E+14
I-132	5,8E+14	I-133	8,3E+14	I-134	9,2E+14
I-135	7,3E+14	Xe-131m	1,7E+13	Xe-133	3,0E+15
Xe-133m	1,1E+14	Xe-135	5,8E+14	Xe-138	3,0E+15
Cs-134	2,6E+13	Cs-136	1,0E+13	Cs-137	1,70E+13
Ba-140	8,8E+13	La-140	4,40E+12	Ce-144	1,2E+13
Np-239	2,3E+14	Rb-88	1,2E+15	Rh-106	2,7E+12
Te-129	1,10E+13	Xe-135m	1,2E+14	Ba-137m	1,70E+13
Pr-144	1,2E+13	–	–	–	–

Total activity of the accidental release was $1{,}50 \times 10^{16}$ Bq for all the scenarios of BDBA.

The dose values obtained using the InterRAS in case of "winter" and "summer" scenario of beyond design basis accident are presented in tables 4-5.

Table 4. Maximum early doses for population in case of "winter" scenario of beyond design basis accident

Distance from site, km	Cloud shine dose, mSv	Ground shine dose, mSv	Effective inhalation dose, mSv
1	3,50	11,0	79,0
2	2,40	6,30	47,0
5	1,10	2,90	22,0
25	0,14	0,18	1,30
50	0,11	0,13	1,00

Table 5. Maximum early doses for population in case of "summer" scenario of beyond design basis accident

Distance from site, km	Cloud shine dose, mSv	Ground shine dose, mSv	Effective inhalation dose, mSv
1	2,10	5,40	40,0
2	0,97	2,30	17,0
5	0,44	0,66	5,00
25	0,05	0,05	0,37
50	0,01	0,02	0,14

The total effective dose values in the figures 1-4 were obtained by running InterRAS and interpreting the results of calculations for near and far zones of NPP in case of "winter" and "summer" scenario.

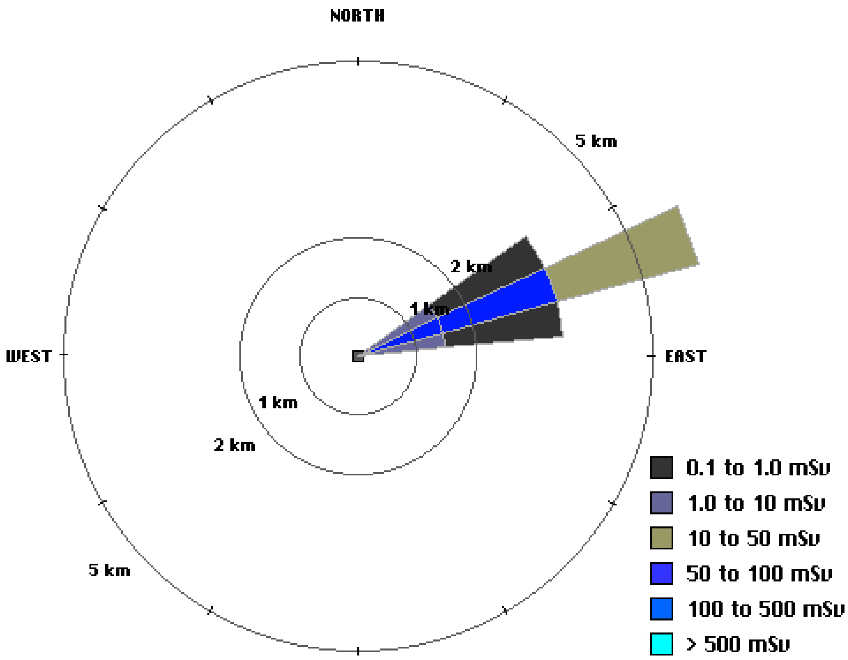

Fig. 1. Total effective dose in the near zone of NPP in case of "winter" scenario of BDBA, mSv.

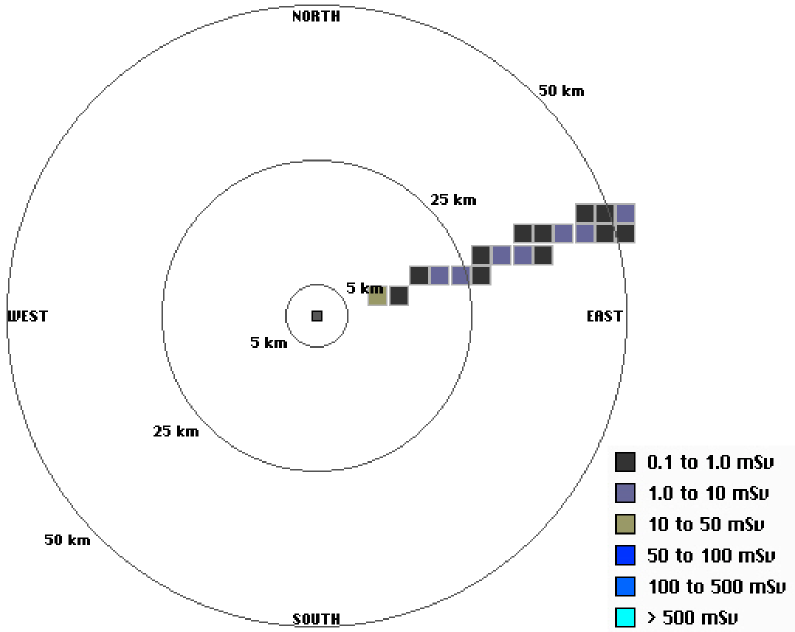

Fig. 2. Total effective dose in the far zone of NPP in case of "winter" scenario of BDBA, mSv.

In case of "winter" scenario the highest value of total effective dose for population living in the near zone was 94 mSv, bearing 70° (south-west) at a distance of 1 km from the site (see figure 1), the highest value for the population living in the far zone was 1 mSv, at a distance of 10,5 km, bearing 72°(see figure 2). The total effective dose at a distance of 50 km was 1,24 mSv.

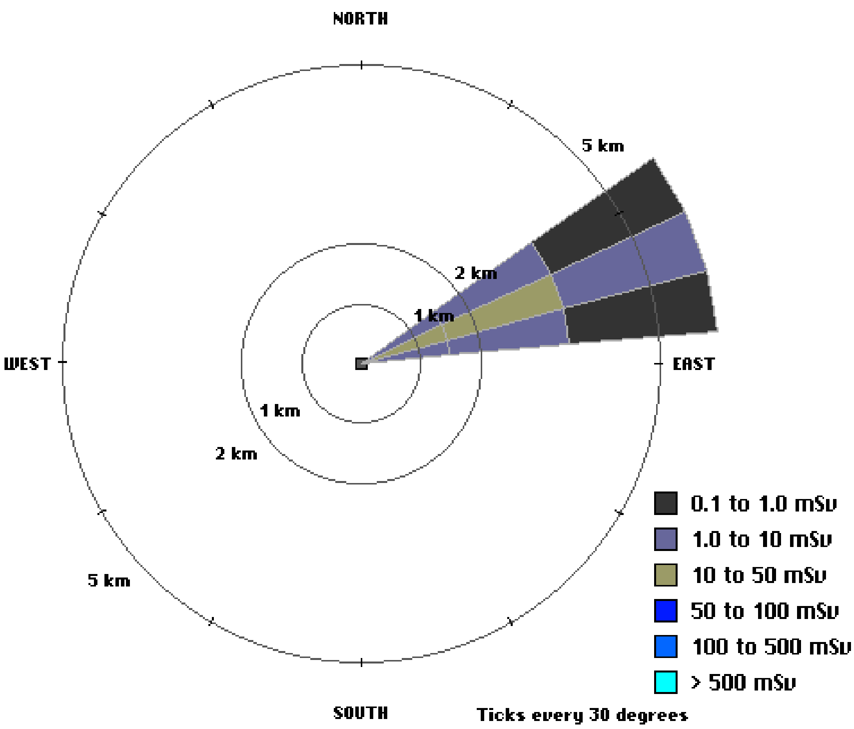

Fig. 3. Total effective dose in the near zone of NPP in case of "summer" scenario of BDBA, mSv.

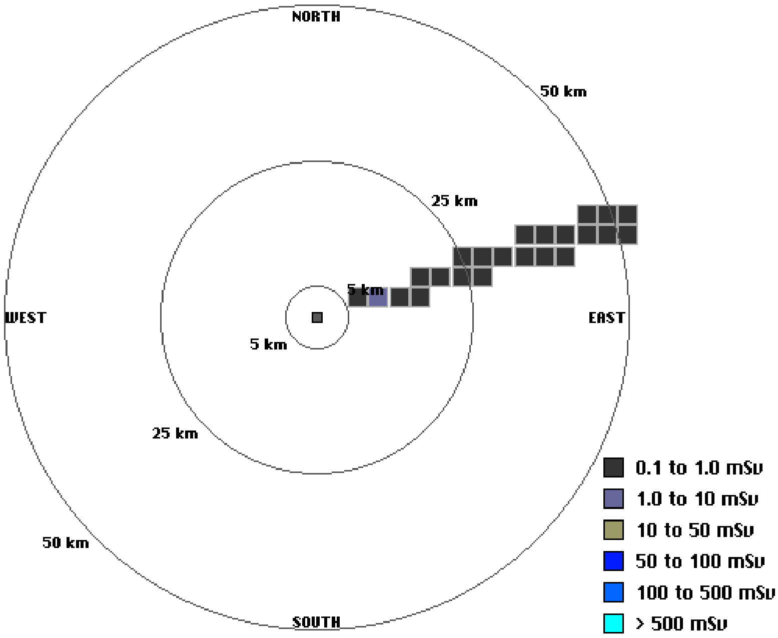

Fig. 4. Total effective dose in the far zone of NPP in case of "summer" scenario of BDBA, mSv.

In case of "summer" scenario the highest value of total effective dose for population living in the near zone was 47,5 mSv, bearing 70° (south-west) at a distance of 1 km from the site (see figure 3). The highest value for the population living in the far zone was 3 mSv, at a distance of 10,5 km at the same direction (see figure 4). At a distance of 50 km the total effective dose was 0,17 mSv.

Dose decreases with distance as shown in the formulas (1/R — for no rain and $1/R^2$ — with rain) [3]. It means that total effective dose decreases with increasing of the distance from the site (see figure 5). During Chernobyl accident this was a reasonable assumption if all the deposition is averaged, but is not valid for local contamination (hot spots).

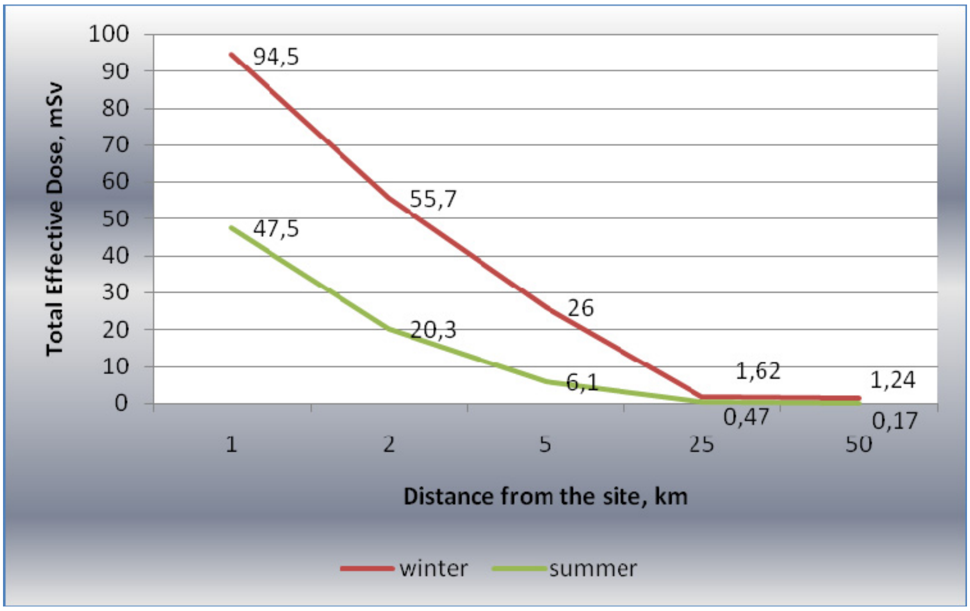

Fig. 5. Decreasing of total effective dose with increasing of the distance from the site.

Discussion

Class stability F ("winter" scenario) is the most unfavorable for radioactive release dispersion, as in this case the highest doses were observed (see Table 4). But dose reduction factors (e.g., building shielding factor) were not taken into account in calculations. In real situation doses for public in winter period would be much less that calculated numbers. Contrary to that, if the accident would happen in summer period, the doses for public could increase due to consumption of locally produced food which will appear to be contaminated.

The primary objectives for protection are to prevent the occurrence of deterministic effects in individuals by keeping doses below the relevant threshold and to ensure that all reasonable steps are taken to reduce the occurrence of stochastic effects in the population.

For facilities in threat category I (e.g., NPP) arrangements shall be made for effectively making and implementing decisions on urgent protective actions off the site [6]. These arrangements shall include the specification of off-site emergency zones for which arrangements shall be made for taking urgent protective action. These emergency zones shall be contiguous across national borders, where appropriate, and shall include:

(i) A precautionary action zone (3-5 km), for which arrangements shall be made with the goal of taking precautionary urgent protective action before a release of radioactive material occurs or shortly after a release of radioactive material begins, on the basis of conditions at the facility (such as the emergency classification) in order to reduce substantially the risk of severe deterministic health effects.

(ii) An urgent protective action planning zone (25 km), for which arrangements shall be made for urgent protective action to be taken promptly, in order to avert doses off the site in accordance with international standards.

(iii) Food restriction planning radius (300 km) – this is the area where preparations for effective implementation of protective actions to reduce the risk of stochastic health effects from the ingestion of locally grown food should be developed in advance.

In general, protective actions such as relocation, food restriction and agricultural countermeasures will be based on environmental monitoring and food sampling.

The sizes are shown in terms of a radius of a circle centered at the source of the potential release or criticality. However, the actual boundary of the zones should not be a circle but should be established to conform the geographical features such as roads, rivers or political boundaries [7].

Conclusions

In the result of our calculations and their analysis versus international recommendations it was found that after the BDBA at NPP with a PWR reactor there is no need for evacuation or providing sheltering for the public because the total effective dose will not achieve currently recommended generic criteria (100 mSv in the first 7 days) [8]. However, plans should be made to:

a) recommend to the public to avoid eating potentially contaminated food or milk;
b) perform an environmental monitoring and monitoring of food, water and fodder within 25 km from the NPP;

c) provide food monitoring on the territory about 300 km around the NPP.

The need for these actions may be than revised based on prevailing accidental conditions, environmental measurements and actual dose values promoted and/or received in an emergency. The results of the study could be used for emergency planning purposes.

Prognosis of thyroid doses in case of an accident at a nuclear power plant

Kouts, Katerina
Republican Scientific Practical Centre of Hygiene, BELARUS

Abstract

Despite all the precautions that are taken at the design stage and during the operation of nuclear power plants (NPP), there remains a possibility that failures of any of the systems or of the equipment may lead to a nuclear emergency with a release of radioactive materials into the environment that may require emergency response actions.

The purpose of this study was to make prognosis of thyroid doses in case of an accident at a NPP. In order to achieve this the following was done:

–assessment of thyroid doses caused by beyond design basis accident (BDBA) at NPP with water-water reactor (at different distances from the station);

–estimation of the length of the territories at which dose exposure may exceed the current international generic criteria for protective and other actions in case of the BDBA (PWR).

For modelling of the accident scenario geographic location and technical characteristics of the station and weather conditions were taken into account.

Simulation and evaluation of the potential nuclear emergency were performed using the software (InterRAS, RASCAL) which takes into account all the above-listed parameters.

The calculations also took into account the contribution of internal thyroid dose due to consumption of contaminated foodstuff into formation of the thyroid dose.

This study allowed estimating the thyroid doses, as well as the necessity of protective and other actions in case of the BDBA.

Results of prognosis using the international models have demonstrated that:

–there is a need in thyroid blocking for population at a distance up to 25 km from the station;

–the possibility of restrictions of consumption for potentially contaminated by iodine-131 food, milk and other products should be preplanned;

The results of modelling performed in this study form a basis for developing national arrangements for response to a BDBA at considered NPP.

Introduction

Today, the priority in nuclear energy development is improvement of the safety of existing nuclear power plants and development of the nuclear power reactors of new generation with advanced security features. High security level is achieved due to improvement of active and introducing passive protective and localizing systems, as well as due to the consequent implementation of the inherent safety concept[1]. Development of modern reactors with the feature of self-protectability can provide the resistance to equipment failures and mistakes of staff, limit radioactive consequences of the most severe accidents, exclude the need in evacuation of population.

However, despite the high security of a new type of nuclear power plants and low probability of occurrence of any possible failures, the probability still exists, and therefore there is no absolute guarantee that the radioactive release due to an accident will not happen (IAEA Safety Standards Series №GS-R-2, 2002.). Among the possible causes of the accident can be a degraded control of nuclear chain reaction in the reactor core, the formation of local criticality while refuelling, transportation and storage of nuclear fuel, degraded heat removing from the fuel elements, etc.

A nuclear accident, which accompanied by release of radioactive materials outside the station, can lead to environmental pollution and exposure of population.

The following categories of initiating events are considered within the safety justification process: design and beyond design basis accidents. Beyond design basis accident is an accident caused by not accounted for the design basis accident initiating events, or which is accompanied in comparison with design basis accident by additional failures of safety systems, the implementation of staff's mistaken decisions, which can lead to serious injuries or to core melt. Reducing of consequences is achieved by severe accident management and / or implementation of emergency plans to protect workers and the public.

As a result of the Chernobyl accident currently there is a significant increase of thyroid cancer incidences among inhabitants of Russia, Ukraine and Belarus (Kenigsberg J. et al 2004). Taking into account the possibility of such increase in case of an accident at a NPP and in order to make prognosis of possible consequences of severe accident at a nuclear installation the following was carried out:

– estimation of thyroid doses at different distances from the station;
– assessment of length of the territories on which the irradiation doses to population may exceed the current international generic criteria for protective actions and other response actions in emergency exposure situations;
– suggestion of measures to respond to such accidents.

Material and methods

Simulation and estimation of consequences of potential nuclear emergency is possible using the software which takes into consideration such significant parameters as geographical location and technical characteristics of NPP, weather conditions during the potential accident and accident plant conditions. InterRAS (The International

[1] Inherent safety concept – is a new level of quality at which the deviation of certain parameters of the NPP from the norm is adjusted automatically without operator or, in case of emergency situation, the reactor is blocked automatically.

Radiological Assessment System) is a set of personal computer-based tools developed for use by personnel who conduct an independent assessment of radiological accidents and protective actions and allows to carry out estimations of the release and doses to the public. Software models are used by specialists of leading organizations in radiation safety area – IAEA's and U.S. NRC's specialists (IAEA-TECDOC-955, 1997).

The model «ST-DOSE» (Source Term To Dose) was used for dose estimation. It allows calculating activities of released radionuclides, to estimate the distance at which the urgent protective actions may be needed and to assess integrated radiation doses which form due to accident release of radioactive material into the atmosphere. The model enables to estimate consequences of potential or actual release and requires only information that might be available during an emergency. The data required are accident location, either an assessment of plant conditions or an estimated source term, and basic meteorological information.

In this study a water-water energy reactor (WWER) accident with dry containment leakage was considered as beyond design basic accident. The scenario assumes releases from the core that are typical of cladding failure or core melt. At the beginning of the accident reactor power was 3200 MWt, 10-50% of core melted (rapid release of volatile fission products).

It was also assumed that the release passed by a dry route through the primary system into the containment atmosphere without passing through any systems (e.g., the suppression poll) that would remove iodine or particulate. Iodine or particulate airborne in the containment can be reduced by factors to account for the actions of sprays, filters or natural processes before release into the atmosphere. This removal is a function of the hold-up time. In this study the hold-up time was set equal to zero, it means that the release into the environment started immediately.

Leak rate of radioactive material is 0.02 % per hour.

Containment sprays and air discharge purification system are off. The release is ground level, the effect of building wake, which leads to the greater spreading of radionuclides around the station, are taken into account.

All above mentioned conditions were chosen like that to consider the worst scenario of the BDBA.

The duration of the radionuclides release into the environment due to the leakage through the containment was set equal to 2.5 hour.

Various real possible weather scenarios were considered to simulate transfer of radionuclides in atmosphere. The worst meteorological conditions, which lead to the highest doses to population, are presented in Tables 1-2. The data correspond to "winter" and "summer" seasons, respectively.

Table 1. Site meteorological data («winter» scenario of BDBA).

Parameter	Parameter value
Wind Direction	western turning into south-western
Wind Speed	5.5 – 11 m/s
Air Pressure	1008.0 hPa

Table 1. Continued.

Parameter	Parameter value
Air Temperature	-2.5 – -1.5 at night and in the morning 3.7 – 1.8 in the afternoon and in the evening
Cloudiness	0 %
Mixing layer height	1200 – 1500m at night 500 – 300m in the afternoon and in the evening
Stability Class	F
Intensity of Precipitation	from 1 to 4 mm/h
Snow cover height	from 0.01 to 0.15 m

Table 2. Site meteorological data («summer» scenario of BDBA).

Parameter	Parameter value
Wind Direction	south-western
Wind Speed	6.4 – 6.7 m/s
Air Pressure	993.7 hPa
Air Temperature	20 °C
Cloudiness	100 %
Mixing layer height	600 m
Stability Class	D
Intensity of Precipitation	None
Snow cover	None

Review of “summer” variant of weather conditions allows taking into account considerable contribution of internal dose caused by the consumption of contaminated foodstuff into total thyroid dose.

Thyroid dose consists of dose due to the inhalation of iodine-131 and dose due to the consumption of contaminated products, generally milk and leafy vegetables. The first constituent that is thyroid dose to adult person while he/she is performing an easy activity was calculated using the InterRAS model. Dose due to the alimentary intake of iodine-131 was calculated by hand to six age groups on the basis of iodine-131 concentration in food (milk, leafy vegetables).

Realise of iodine to the environment caused by the accident at nuclear installation can be estimated using the formula below:

$$Source\ Term_i = FPI_i \cdot CRF_i \cdot \prod_{j=1}^{N} RDF_{(i.j)} \cdot EF_i\ , \tag{1}$$

where: FPI_i – isotope inventory;

CRF_i – amount of isotope i released out of core/core inventory of isotope i;

$RDF_{(i,j)}$ – fraction of the isotope i activity available for release following reduction mechanism j;

EF_i – fraction of activity available for release that is released.

Results

Total release of radionuclides into the environment in case of the above described accident scenario regardless of weather conditions amounted to $1.5 \cdot 10^{16}$ Bq. Activities of emitted iodine isotopes are represented in Table 3.

Table 3. Activity of iodine isotopes released into the environment due to BDBA, Bq.

Radionuclide	Activity, Bq
I-131	4.10E+14
I-132	5.80E+14
I-133	8.30E+14
I-134	9.20E+14
I-135	7.30E+14
TOTAL	3.47E+15

Iodine emission is 23.1 % of the total radioactive material released into the environment as a result of nuclear accident. This value is in a good agreement with mean estimate of the iodine fraction usually released during accidents (IAEA-TECDOC-955, 1997).

Calculated thyroid doses caused by inhalation of iodine for "winter" scenario of BDBA are presented in Figures 1 – 2.

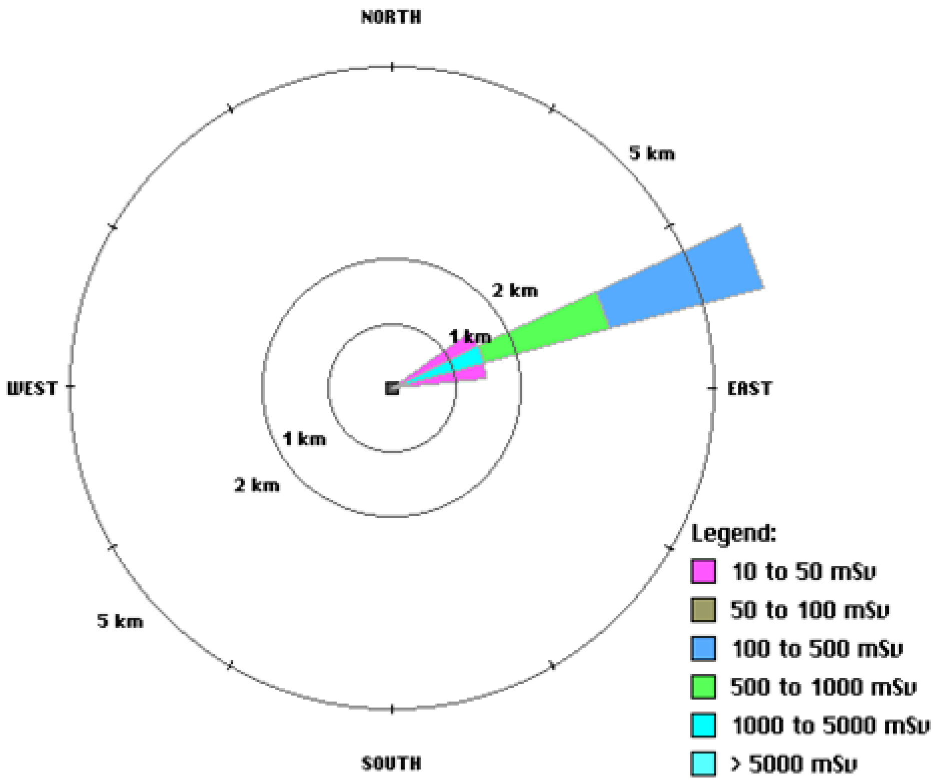

Fig. 1. Thyroid dose at a short distance from the NPP, mGy.

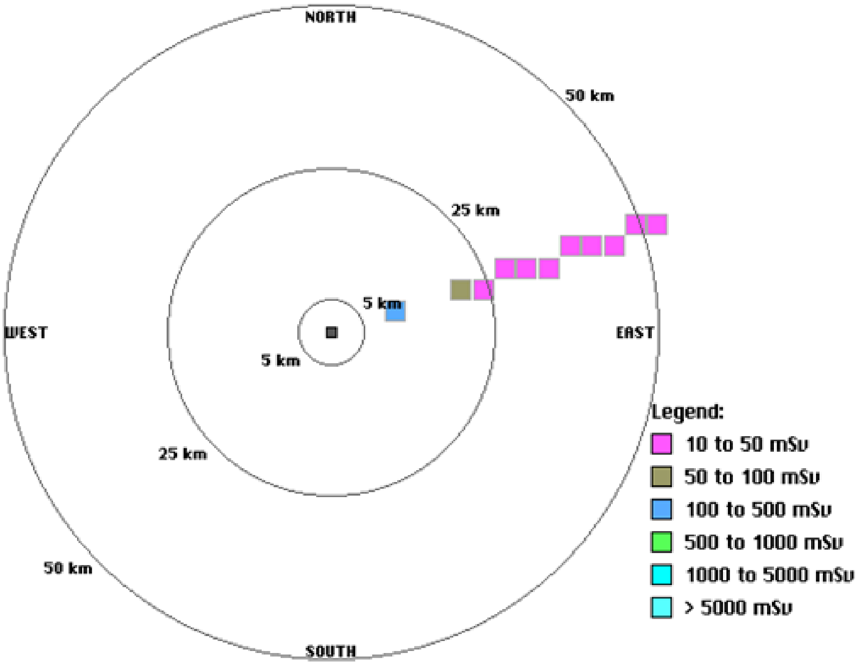

Fig. 2. Thyroid dose at a long distance from the NPP, mGy.

The maximum thyroid dose value for “winter” scenario is observed downwind 1 km away from the station and equals to $1.5 \cdot 10^3$ mGy. At a distance of 10.5 km in the same direction dose to the thyroid may reach $1.7 \cdot 10^2$ mGy.

Estimated doses to thyroid gland caused by inhalation of iodine for “summer” accident scenario are presented in Table 4.

Table 4. – Early doses at different distances from the NPP in case of «summer» scenario of BDBA.

Distance, km	Thyroid dose*, mGy
1	770
2	330
5	95
25	7.1
50	2.6
* Thyroid dose includes iodine only.	

In the “winter” version of the accident the weather corresponds to the atmospheric stability class F (moderately stable condition), which is most unfavourable for the dispersion of the radioactive release, and, consequently, leads to higher doses.

Internal exposure due to consumption of contaminated food contributes significantly to the total thyroid dose in the case of “summer” scenario. If the radioactive fallout occurred in the pasture period, the radionuclides rapidly incorporate into the trophic migration chains through consumption of contaminated pasture vegetation by animals, and then through the chain of pasture - animal - milk get into the human body and deposit at the thyroid gland.

Figures 3 – 4 show the calculated thyroid doses to six age groups caused by consumption of milk and leafy vegetables contaminated by iodine in the case of BDBA.

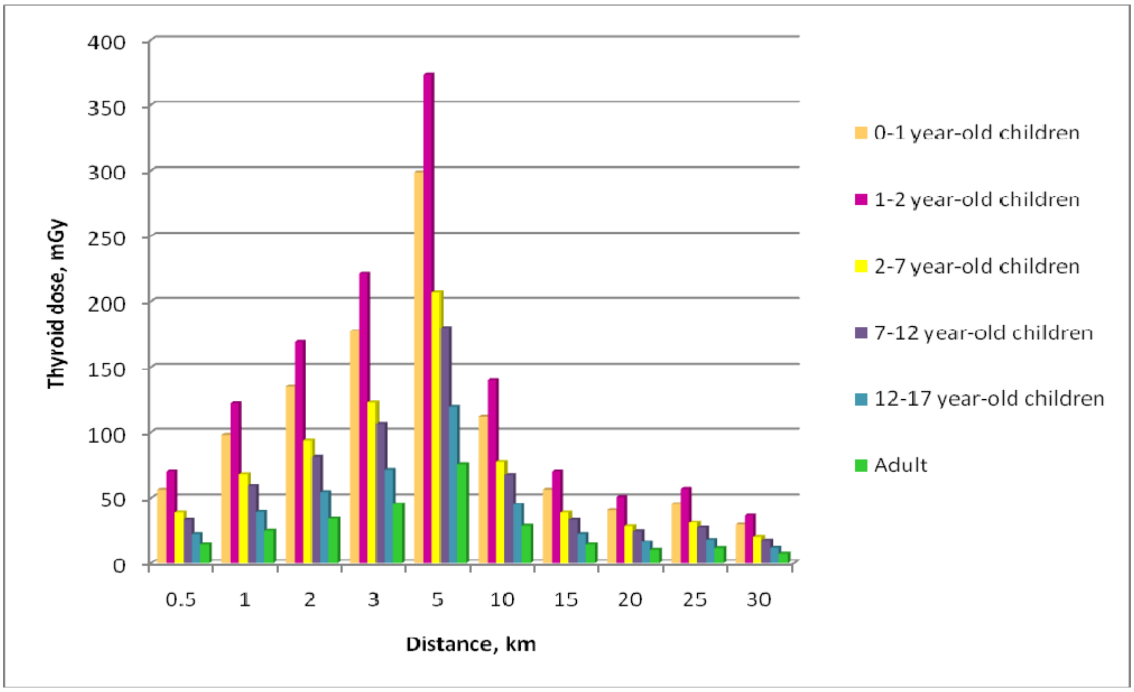

Fig.3. Thyroid dose to six age groups in 30 days after BDBA caused by their consumption of milk contaminated by iodine-131, mGy.

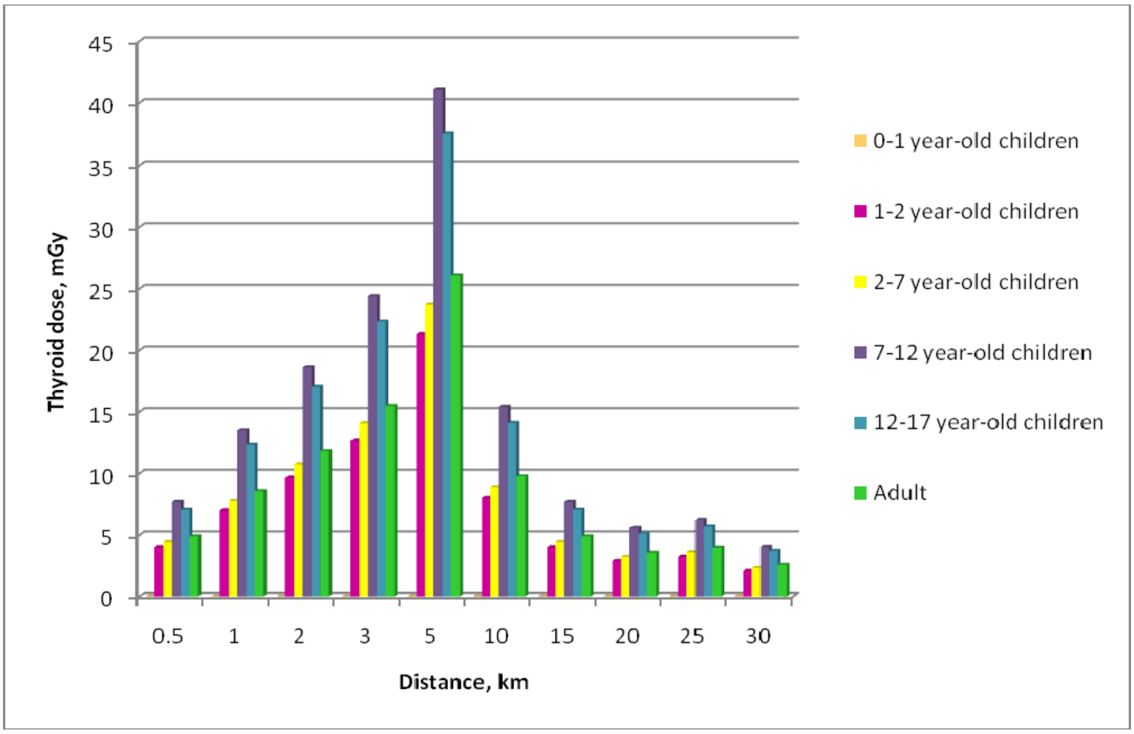

Fig.4. Thyroid dose to six age groups in 30 days after BDBA caused by their consumption of leafy vegetables contaminated by iodine-131, mGy.

The highest thyroid doses due to the intake of contaminated milk and leafy vegetables are observed at a distance of 5 km away from the station, which can be explained by the transition of radioactive cloud by air stream.

Differences in the consumption of considered products are the reason of that thyroid doses caused by the consumption of contaminated milk is much higher than the dose due to the consumption of leafy vegetables. Sex, age, and hence physiological differences lead to the fact that the largest dose because of consumption of contaminated by iodine-131 milk were observed in children that are not older than two years.

Conclusion

One of the most important aspects of managing a nuclear emergency is the ability to promptly and adequately estimate the consequences of an accident. This will help to make a quick justified decision about necessity of protective actions and other response actions and consequently will allow to avoid or to minimize different deterministic and stochastic health effects.

Thyroid dose estimation in case of BDBA showed that maximum doses due to the iodine inhalation are 1500 and 770 mGy under “winter” or “summer” accident conditions, respectively; radiation dose due to the consumption of milk contaminated by iodine-131 is 373 mGy, leafy vegetables – 41 mGy. Total exposure doses exceed generic criteria for protective actions and other response actions in emergency exposure situations – 50 mGy in the first 7 days after accident (IAEA-TECDOC-1432, 2004) – in both considered BDBA scenarios. The results demonstrated that there is a need in thyroid blocking for population at a distance up to 25 km from the station at the early phase of the accident. The possibility of restriction of consumption for potentially contaminated by iodine-131 food, milk and other products should be pre-planned as well. In addition the possibility of urgent environmental monitoring, monitoring of foodstuff and fodder at a distance of not less than 30 km from the station should be ensured, too.

The results of modelling performed in this study form a basis for developing national arrangements for response to a BDBA at considered NPP.

Dose response of sugar and sweeteners for EPR retrospective dosimetry using sweets and chewing gum carried by victims at nuclear emergencies

Israelsson, Axel; Gustafsson, Håkan; Pettersson, Håkan; Lund, Eva

Department of Medical and Health Sciences, Radiation Physics, Linköping University, SWEDEN

Abstract

After a nuclear accident it is important to reconstruct the individual doses for planning the medical treatment. Another task is to establish moderate or small dose levels, in order to inform people about expected radiation risk. Electron paramagnetic resonance (EPR) spectroscopy provides a mean to measure absorbed doses by quantification of free radicals induced in materials by ionizing radiation. Since people normally do not wear personal dosimeters, it is of interest to investigate radiation induced radicals in materials that are often carried by people with the intent to measure absorbed doses. The objective of this study is to investigate sugars and sweeteners for the possibilities of using sweets and chewing gum for retrospective dosimetry.

Sucrose, sorbitol and xylitol are investigated by means of EPR spectroscopy regarding the dosimetric properties; radical stability, dose response and dependence on environmental factors. The knowledge obtained is applied to one common type of chewing gum by determination of the dose response, obtained accuracy and lowest detectable dose for that specific material.

The sweeteners are sensitive to daylight and the EPR spectrum shows a complicated evolution with time. This is not a problem if the chewing gum is kept in dark and if the signal evolution with time is carefully mapped since the time between exposure and analysis is well known. The EPR spectrum of the irradiated chewing gum is mainly composed by the spectra from sorbitol and xylitol. By identifying the components of the dosimetric signal, the absorbed dose in the chewing gum can be determined and thus make an estimation of the effective dose to exposed individuals possible. With a new ultra sensitive EPR spectrometer, under installation, we expect the lowest detectable dose to be 50 mSv and the uncertainty in dose determinations less than 50 mSv.

Introduction

If a radiation accident occurs, it is of great importance to estimate the radiation dose to exposed individuals as soon as possible. If the absorbed doses are high (>1Gy) dose information may help optimize the medical treatment. At lower doses the information is important for risk assessment and epidemiological studies of long term effects of radiation.

Since people usually do not carry personal dosimeters there is a need to make retrospective dose assessments after the exposure. If several dose assessments are obtained from different locations at the site of exposure, a dose reconstruction map can be drawn. Surveillance cameras at the site of exposure can serve as a source of information on time and location of the individuals.

Electron Paramagnetic Resonance (EPR) is a well established method used for retrospective dosimetry. A recent review study (Trompier et al 2009) evaluates the materials that can be analyzed with EPR. It includes sugar, plastics, glass, cotton, wool, nails, hair, bones and tooth enamel. The most suitable materials for retrospective dose determinations are the ones best fulfilling the following requirements: High radiation induced signal specificity, low background signal, low UV-induced signal, low Minimum Detectable Dose (MDD), linearity at low doses, high signal stability and ubiquity. Sugar was reported well suited regarding radiation sensitivity and signal stability while the ubiquity was mentioned as a drawback.

Sugar has been used several times for retrospective dose reconstructions after real accidents (Hutt et al 1996; Nakajima 1994; Sagstuen et al 1983; Shiraishi 2002). The presence of sugar in confectionery and chewing gums nowadays are not as important, as sweeteners are widely used. A few studies on sweeteners have been performed (Hervé 2006; Hervé et al 2006). Using aspartame doses <1 Gy can be measured (Maghraby & Salama 2010). There is a need to further investigate irradiated sweetening in order to understand the complexity of the EPR spectra. With increased understanding, more accurate dose determinations can be performed. The aim of this work was to characterize and analyze the dose response signals in sweeteners for the possibilities of using chewing gum for retrospective dosimetry.

Material and methods

EPR-dosimetry is based on the quantification of radiation induced free radicals in a sample. This is done by obtaining the magnetization produced by the unpaired electrons of the radicals. When exposing the sample to microwaves while applying and sweeping a magnetic field over it, resonance will occur for the magnetic field values creating electron spin energy levels that match the energy of the microwaves (Weil 2007). Each kind of radical has its own magnetic properties. The radiation induced radicals in sucrose are well characterized (De Cooman et al 2008) but in sweeteners to a lesser degree. Radical studies have been performed on single crystals of xylitol and sorbitol irradiated and measured at low temperatures ≈ 4K (Budzinski et al 1980), where radiation induced radicals are very stable. At higher temperatures radicals are less stable and the EPR spectra changes with time and possibly also with exposure to UV-light.

Since different types of radicals often are saturated at different microwave power, power saturation measurements may help separate signals from different radical types in the EPR spectrum.

The following investigations were performed: Time dependence, Power saturation, Light sensitivity, Sample variation and Dose response. Each experiment followed the same scheme of sample preparation, irradiation, EPR measurement and data analysis. A standard method to perform each phase is described below. Deviations from the standard are then described in the sections of the specific experiments.

Sample preparation

Xylitol[1] and D-sorbitol[2] were purchased from Sigma-Aldrich and chewing gums "dental V6 + white fresh fruit[3]", "dental V6 + strong teeth spearmint[4]" and granulated sugar (sucrose) were bought in Swedish grocery stores. The sweetening of the chewing gum is mainly located in the coating while the inner substance is a gum base mixture. The coating was carefully separated from the rest of the chewing gum. A manual pellet press[5] was used for all sample materials, except sucrose, to form cylindrical tablets . No binding material was needed to form robust tablets. The tablets had masses of 200±5 mg which correspond to dimensions of 10 mm height and 5 mm diameter. Between irradiation and analyses the tablets were stored in light proof containers.

Irradiation

The irradiations were performed at room temperature with a Varian Clinac 600 C/D accelerator using a 6 MV photon beam. During irradiation the samples were placed in a PMMA phantom of height 17 cm and area of 20x20 cm^2 at depth 4 cm. Source to surface distance was 100 cm and the radiation field 10x10 cm^2. The absorbed doses were approximated as dose in water based on the gantry detectors recordings. The samples were irradiated at mean dose rate of 6 Gy/min.

EPR measurement

All measurements were performed with a BRUKER EleXsys E580 EPR spectrometer operating at X-band equipped with an ER 4102ST standard cavity. The tablets were placed in a quartz sample tube inserted in the cavity during measurements. A plastic pedestal containing a Mn^{2+}/MgO reference sample was placed inside the cavity to assure that the sample was centered in the cavity and that the position of the sample tube was kept constant between measurements.

Data analysis

Data analysis was performed in MatLab. The spectra were corrected for having base line slopes by subtraction of a linearly fitted base line. The Mn^{2+} line at g = 2.034 served as reference line as the spectra were normalized to its magnetic field value. For

[1] Xylitol Crystallin, minimum 99%, Sigma-Aldrich Sweden AB®
[2] D-Sorbitol, minimum 98%, Sigma-Aldrich Sweden AB®
[3] Dental V6 +white fresh fruit®, Cadbury Sweden AB
[4] Dental V6 +strong teeth spearmint®, Cadbury Sweden AB
[5] Manual pellet press®, Parr instrument company

the purpose of noise reduction the spectra were thereafter smoothed. The dose response signals were then determined from peak-to-peak signals of the spectrum.

Time dependence measurement

One pressed tablet of each Xylitol, sorbitol and V6[6] were irradiated to 50 Gy. The EPR measurements were performed with 80 sweeps for each tablet and were carried out 6 times from 24 hours after irradiation to 84 days after irradiation. Spectrometer settings were: 1 mW microwave power, 0.2 mT modulation amplitude, 100Hz modulation frequency, 1024 measurement points, 20 s sweep time, 10 ms time constant and the field sweep of width 10 mT was centered between the third and fourth line of the Mn^{2+} reference signal. The obtained EPR spectra were not normalized to the Mn^{2+} line intensity. The background was subtracted from all spectra.

Power saturation measurement

One pressed tablet of each xylitol, sorbitol and V6[6] were irradiated to 50 Gy. The EPR measurements were performed with 8 sweeps of 10 different microwave effects ramped exponentially from 0.2 mW to 100 mW. This was done 1, 16 and 84 days after irradiation. Spectrometer settings were: 0.2 mT modulation amplitude, 100Hz modulation frequency, 1024 measurement points, 20 s sweep time, 10 ms time constant and the field sweep of width 10 mT was centered between the third and fourth line of the Mn^{2+} reference signal.

Light exposure experiment

The samples sensitivity to light exposure was tested by within 15 minutes after a 10 Gy irradiation placing three tablets of each xylitol and sorbitol in a lightproof container while three other tablets of each material were placed exposed to daylight. All tablets were stored for 69 days and then measured with the spectrometer settings: Spectrometer settings were: 100 mW and 63 mW microwave power for sorbitol and xylitol respectively, 0.1 mT modulation amplitude, 100Hz modulation frequency, 1024 measurement points, 10 sweeps of 20 s, 1.28 ms time constant and the field sweep of width 10 mT was centered between the third and fourth line of the Mn^{2+} reference signal.

Measurement of variation between chewing gums

Seven V6 chewing gums[7] from different batches were investigated. Each was irradiated to 1.8 Gy and the coating was then pressed into a tablet. The tablet masses were 102±5 mg. EPR measurements were then performed three days after irradiation. Each tablet was measured once and one of them was chosen to be measured 7 times. The single measurements of the 7 tablets were then compared with the seven measurements of one tablet. Spectrometer settings were: 1 mW microwave power, 0.2 mT modulation amplitude, 100Hz modulation frequency, 1024 measurement points, 80 sweeps of 20 s, 10 ms time constant and the field sweep of width 10 mT was centered between the third and fourth line of the Mn^{2+} reference signal. The spectra were normalized to the

[6] Dental V6 +white fresh fruit
[7] Dental V6 +strong teeth spearmint

intensity of the Mn^{2+} line at g = 2.034. Smoothing of the spectra were also performed so that each point in the EPR-spectrum was an average of the nearest 10 points.

Dose response measurement of V6

V6 chewing gums[8] were irradiated at depth 8.5 cm in a PMMA phantom of surface area 20 cm * 20 cm. 20 cm of PMMA was also placed behind the samples to assure full backscatter. The Source Sample Distance (SSD) was 100 cm and the field size was 12 cm * 12 cm. For accurate dose determinations an NE 2571 ionization chamber traceable to the Swedish secondary standard laboratory was placed at the same depth and distance from field centre to simultaneously determine the absorbed dose in water. Two chewing gums received doses of 2.04 Gy, two 4.07 Gy, two 6.11 Gy and another two were irradiated to a dose unknown to the investigator. Two days after irradiation tablets were pressed of the chewing gums to masses of 100 ± 2mg. The tablets were read out in the spectrometer after one additional day with settings: 20 mW microwave power, 0.5 mT modulation amplitude, 100Hz modulation frequency, 1024 measurement points, 25 sweeps of 20 s, 10 ms time constant and the field sweep of width 10 mT was centered between the third and fourth line of the Mn^{2+} reference signal. A smoothing of N = 5 was performed on each spectra.

Dose response measurement of sucrose

After irradiation to doses from 1 to 14 Gy 400 mg of granulated sugar was filled into tubes of quartz and measured in a JEOL FR30EX Free radical monitor 4 days after irradiation. The settings used were: 4 mW microwave power, 2 mT modulation amplitude, 4096 measurement points, 4 sweeps of 4 s, and the field sweep of width 10 mT was centred between the third and fourth line of the Mn^{2+} reference signal.

Statistics and uncertainty analysis

To obtain the regression parameters A and B in the relation $f(x) = Ax + B$, where $f(x)$ is the EPR peak-to-peak signal and x is the absorbed dose, a least square fit was obtained from the measured peak-to-peak signals, $f(x_i)$. The least square fit was performed with the uncertainty of $f(x_i)$ given as

$\sigma_{f(x_i)} = \sqrt{\frac{1}{N-2}\sum_{i=1}^{N}(f(x_i) - B - Ax_i)^2}$. The uncertainty of the regression curve was calculated from $\sigma_{f(x)} = \sqrt{\left(\frac{df}{dA}\right)^2 \cdot \sigma_A{}^2 + \left(\frac{df}{dB}\right)^2 \sigma_B{}^2 + \left(\frac{df}{dx}\right)^2 \sigma_x{}^2 + 2 \cdot x \cdot cov(A,B)}$. The uncertainty of the dose σ_x was given by the ionization chamber measurement and σ_A, σ_B and $cov(A,B)$ were acquired from the least square fit function.

The dose of the unknown chewing gum was estimated by calculating the mean of the measured unknown dose peak-to-peak values and inserting it in the regression equation, $= \frac{f(x)-B}{A}$. The uncertainty of the unknown dose, σ_{x_u}, was then obtained by adding the equivalent uncertainties of the peak-to-peak value, $\frac{\sigma_{f(x_i=x_u)}}{A}$, and the regression uncertainty at the estimated dose, $\frac{\sigma_{f(x=x_u)}}{A}$, resulting in

[8] Dental V6 +strong teeth spearmint

$$\sigma_{x_u} = \sqrt{\left(\frac{\sigma_{f(x_i=x_u)}}{A}\right)^2 + \left(\frac{\sigma_{f(x=x_u)}}{A}\right)^2}.$$

Results and discussion

The spectra from the time dependence measurements are shown in figures 1 and 2. The spectra of V6 were found to be very similar to those of xylitol, which indicate that the content of xylitol in the chewing gum coating is large compared to the content of sorbitol. The xylitol spectrum was found to change considerably from 1 day after exposure to 84 days after exposure. At one day after exposure peaks, X_1 at 341.5 mT and X_2 at 343.6 are pronounced (see figure 1). The X_1 peak is decreasing after 1 day while the X_2 peak is slightly increasing with time up to 16 days, thereafter the peak is decreasing. A peak X_3 at 342.5 mT appears at 36 days and is increased till 84 days after irradiation. A negative peak X_4 at 345.1 mT was initially increasing until 16 days after exposure after which it decreased. This behavior is similar to the X_2 peak.

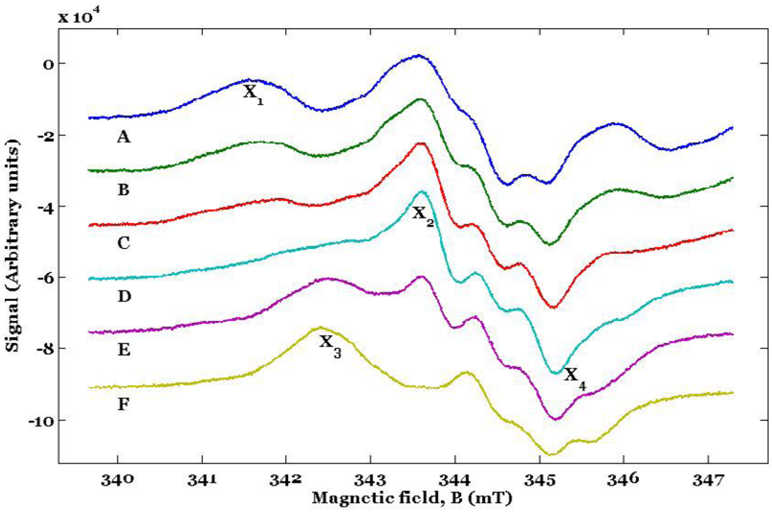

Figure 1. EPR spectra of xylitol irradiated to 50 Gy measured 'A' = 1, 'B' = 4, 'C' = 8, 'D' = 16, 'E' = 36, 'F' = 84 days after irradiation. Microwave power used was 1 mW. The peaks X_1 at 341.5 mT, X_2 at 343.6 mT, X_3 at 342.5 mT and X_4 at 345.1 mT were used for saturation measurements.

The sorbitol spectrum changed less than xylitol with time after irradiation (see figure 2). One peak, S1 at 342.6 mT was found rather stable through all measurements while S2 at 344.2 increased up to 36 days. A third negative peak S3 at 345.5 mT decreased gradually with time after exposure. These measurements indicate that S1 is the most stable signal and therefore best suited for dose response determinations.

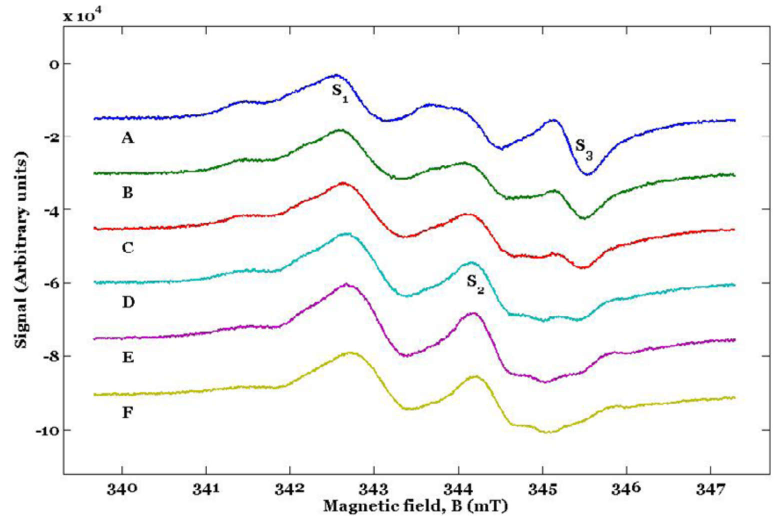

Figure 2. EPR spectra of sorbitol irradiated to 50 Gy measured 'A' = 1, 'B' = 4, 'C' = 8, 'D' = 16, 'E' = 36, 'F' = 84 days after irradiation. Microwave power used was 1 mW. The peaks S_1 at 342.6 mT, S_2 at 344.2 and S_3 at 345.5 mT were used for saturation measurements.

Power saturation measurement

The saturation curves were obtained from peaks in the EPR spectra at 10 different values of microwave power, see figure 3. The xylitol peaks were measured at magnetic field values X_1 at 341.5 mT, X_2 at 343.6 mT, X_3 at 342.5 and X_4 at 345.1 mT, see figure 1. The X_2 and X_4 peaks show similar behavior while the X_1 and X_3 peaks saturate at different power. The high magnitude of the X_2 and X_4 signals at high microwave powers suggest that these peaks might be most suitable for dose assessments.

The corresponding saturation curves for sorbitol showed that the signals of S_1 and S_3 were saturated at a microwave power of about 20 mW, while S_2 was saturated at about 3 mW.

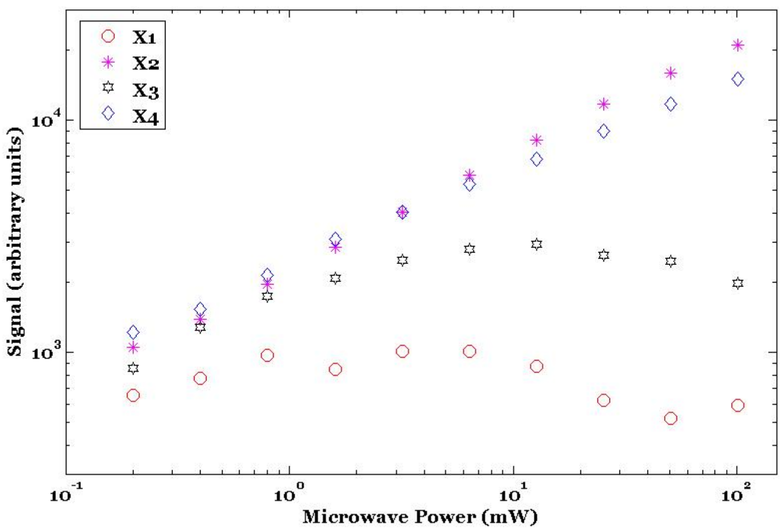

Figure 3. Saturation curves of xylitol at magnetic field values X_1 at 341.5 mT, X_2 at 342.5 mT, X_3 at 343.6 and X_4 at 345.1 mT.

Investigation of the variation between chewing gums

Peak to peak values were obtained from the EPR spectra at the magnetic field values of X_2 and X_4 and plotted for the background, single tablet measurement, one tablet measured 7 times and multi tablet measurement, 7 tablets measured one time. The peak-to-peak values of the single tablet show less scatter than those of the multi tablets. The scatter is about 3 times larger for the multi tablet measurement, which shows that the contribution of uncertainty from the tablet composition variation is large.

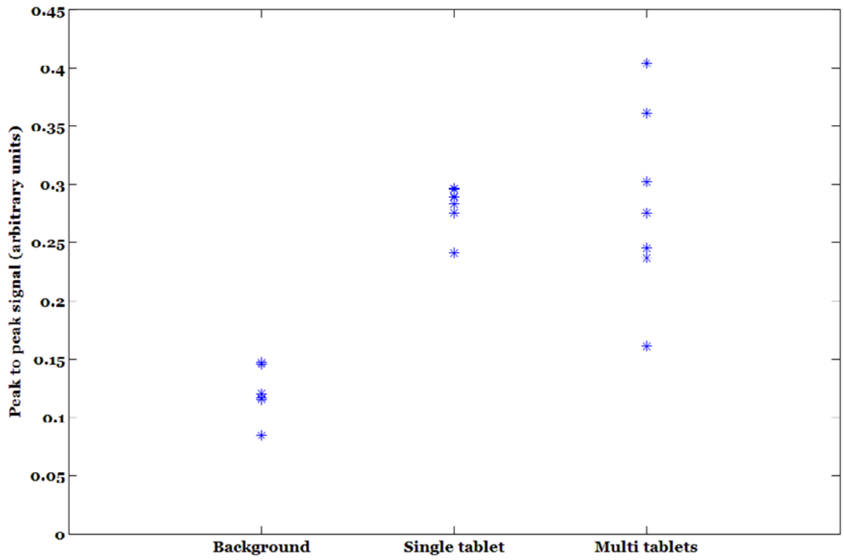

Figure 4. Peak-to-peak values obtained from EPR spectra of background and irradiated 1.8 Gy irradiated chewing gums. The background values correspond to two tablets measured 3 times each. The single tablet values correspond to one tablet measured 7 times and the multi tablets values correspond to seven tablets each measured once.

Dose response measurements

The dose response determinations of the chewing gum was performed for the peaks X_2 and X_4, see figure 1. The result is displayed in figure 5 showing the regression line with ± 1 Standard Deviation (SD) uncertainty indicated. To the right in figure 5 the dose determination of the unknown dose is inserted. The vertical error bar corresponds to one SD of the peak-to-peak signal of the chewing gum of unknown dose. Its corresponding uncertainty in dose is shown as the horizontal dotted line. This uncertainty was added to the uncertainty of the regression curve to obtain the combined uncertainty of the dose determination for the unknown dose. This dose was determined to be 3.76 ± 0.18 Gy (1 SD), which well agree with the given "unknown" dose of 3.56 Gy, indicated as a star in figure 5.

The sucrose dose response curve is showed in figure 6.

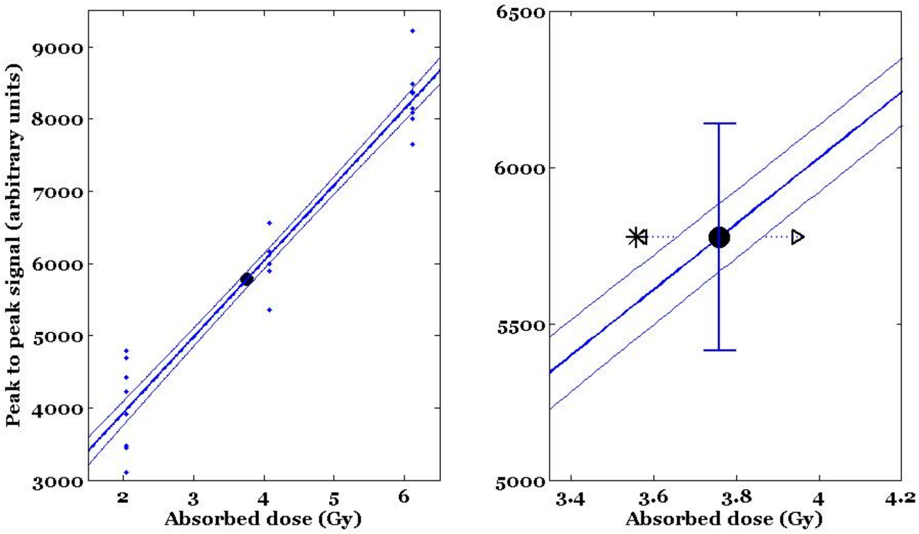

Figure 5. The figures show the dose response of V6 chewing gum. To the left the regression curve with the ± 1 SD uncertainty lines. The regression was obtained from two tablets irradiated with 2 Gy and measured 4 times, 2 tablets irradiated with 4 Gy measured 3 times and 2 tablets given 6 Gy measured 4 times. To the right the dose determination of the unknown dose is displayed. The vertical error bar corresponds to the uncertainty (± 1 SD) of the peak-to-peak signal points of the unknown dose chewing gum. Its corresponding uncertainty in dose is shown as the horizontal dotted line. The unknown dose was determined to be 3.76 ± 0.18 Gy (1 SD). The dose given was 3.56 Gy, indicated as a star.

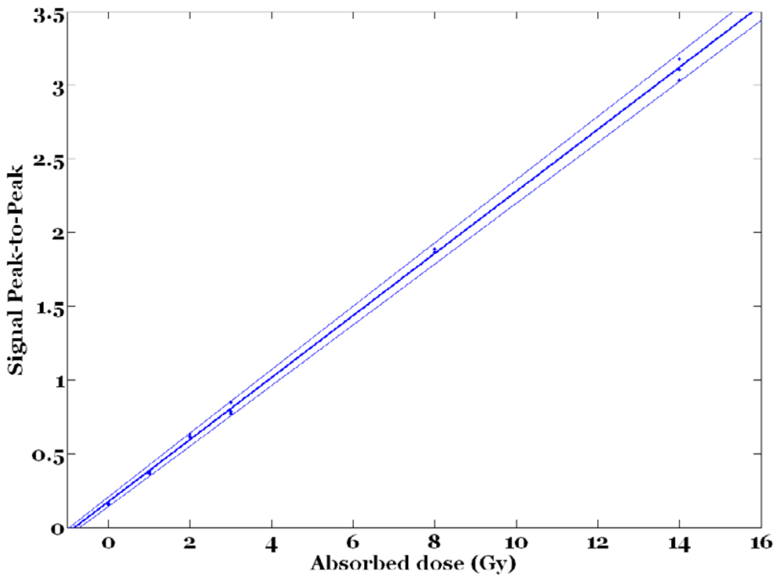

Figure 6. The dose response curve of sucrose. Signal peak-to-peak was measured in arbitrary units. The thinner lines indicate the limits of 2 standard deviations.

Conclusions

The EPR spectra of irradiated xylitol and sorbitol are analyzed regarding time evolution and microwave power. A chewing gum containing these sweeteners was analyzed regarding possibilities for retrospective dosimetry. An absorbed dose of 3.5 Gy given to a piece of chewing gum was possible to determine with an uncertainty of 5 %.

Categorisation of sources: Is it only legal instrument for authorities, or also a practical tool for qualified experts and exposed workers?

Koželj, Matjaž
Jozef Stefan Institute, Ljubljana, SLOVENIA

Abstract

The review of activity levels used in legislation is given and background discussed. We present basic presumptions, reference doses and scenarios used for calculation of *exemption level*, *clearance level*, *D-value*, A_1 *value*, A_2 *value* and level for *high-activity sources*. These levels are compared for some most common radionuclides.

Especially useful are A_1 *value* (for sealed sources), A_2 *value* (for unsealed sources) and *D-value* (for general sources). Practically in all incidents with sources below A_1 *value* or A_2 *value* it is highly improbable that the dose limits for professionals will be exceeded, if the persons involved are aware of source presence. If the persons are unaware of source presence, which could be the case when the source is uncontrolled, then the source with activity close to, or above *D-value* can be dangerous to all involved. The fact that the *D-value* is usually below or close to A_1 and A_2 *values* additionally supports the importance of source supervision and control.

It seems, as a rule, that in realistic circumstances and incidents with sources with activities below 1 GBq permanent injuries are not possible, and it is also very unlikely that dose limits for professionals would be reached. All sources with activities more than 1 TBq are very dangerous, with the potential to create permanent injuries, or even a person's death.

Introduction

During the licensing or registration process and also during the use of radioactive source all applicants, and later licensees or registrants, meet with some kind of the classification method when the source is categorised according to some predefined scheme. The purpose of this approach is to simplify legal decision process and to optimise requirements regarding required documentation and requests for safety measures and emergency preparedness.

Authorities use different categorisations for different purposes: the first and basic one is the decision whether some material should be considered radioactive source. For that purpose they use *exemption level*. And when some source should be released from regulatory control, the *clearance level* is used. For other categorisations *D-value* (for emergency preparedness requirements), A_1 and A_2 *values* (for transportation requirements) and *high-activity level* (for radiation safety and security requirements) are used.

For practically all radionuclides, all these levels are conveniently listed in relevant (but separate!) documents and available to all users. However, the real background of the values is not evident and clear to majority of people involved in authorisation process and use of sources. Therefore, we are going to review and describe scenarios that were used to develop and calculate the values that are used for categorisations and to compare them.

Since all values were calculated by experts and for realistic scenarios, they have also practical meaning and could be used as basis for quick and relevant estimates of potential exposure in different accidental situations.

Backgrounds of values used for categorisations, exemptions and clearance

The motivation for the introduction of categorisations, exemptions and clearance of sources originates in variety and quantity of practices where different radioactive sources with range of activities are used. The consequence is the quantity and complexity of requirements that should be implemented in legislation and supervision of sources. One of the basic principles of the system of radiation protection is optimisation, which also requires that the legal requirements and control should be commensurate with the potential magnitude and nature of the hazard. Similarly, the application of the requirements of legislation and practical radiation protection measures should be commensurate with the characteristics of the practice or source and with the magnitude and likelihood of the exposures (IAEA 1996).

Considering these requirements, the use of categorisations has positive influence on the following aspects of radiation safety:

- Regulatory measures: enables graded system for notification, registration, licensing and inspection, ensuring also optimisation of human and financial resources;
- Register of sources: provides ground for (optimised) decision which sources should be included and required level of details;
- Import/export controls: provides ground for (optimised) decision regarding the level of import/export controls and facilitates the communication between national authorities;
- Emergency preparedness and response: ensures that emergency preparedness and response to accidents are appropriate with the hazard posed by the source. It can also serve as a guide for prioritisation when control over multiple orphan sources must be regained;
- Security measures: enables graded basis for assisting in the choice of security measures;
- Communication with the public: provides basis for explaining relative hazards associated with events involving radioactive sources.

Use of exemption and clearance levels relies on similar foundations: besides establishing formal border between natural materials and radioactive materials (where exclusion does not apply), it also prevents unreasonable spending of resources and efforts on sources with insignificant radiation risk for workers or population.

Exemption levels

According to (IAEA 1996) and (EUC 1996), the basic criteria for the exemption of radioactive sources (and practices) are as follows:

a. The radiation risks to individuals caused by the exempted practice or source must be sufficiently low as to be of no regulatory concern;
b. The collective radiological impact of the exempted practice or source must be sufficiently low as not to warrant regulatory control under the prevailing circumstances; and
c. The exempted practices and sources must be inherently safe, with no appreciable likelihood of scenarios that could lead to a failure to meet the criteria in a. and b.

These criteria were elaborated in (IAEA 1988) and later in (EUC 1993) with conclusion, that source within practice may be exempted without further consideration if the following criteria are met in all feasible situations:

- The effective dose expected to be incurred by any member of the public due to the exempted practice or source is of the order of 10 μSv or less in a year, and
- Either the collective effective dose committed by one year of performance of the practice is no more than about 1 man·Sv or an assessment for the optimization of protection shows that exemption is the optimum option.

The value 10 μSv/year was chosen making an allowance for the possibility that more than one source can contribute to the exposure.

In the calculations for specific radionuclides effective dose value 10 μSv/year and equivalent dose 50 mSv/year to skin was used for normal working conditions and disposal, while for accidents, misuse and unexpected situations dose limit for members of public was used. Calculations were performed for 299 radionuclides, starting from six physical forms considered to cover existing range of use: gas/vapour, liquid/solution, dispersible solid (e.g. powder), non-dispersible solid, thin film/foil, and sealed source/capsule. All three exposure pathways were considered and total dose calculated summing across pathways. The most limiting value from all calculations was chosen for the exemption level. For activity concentrations, the source size of 1 m^3 was taken into account.

The rounded results of these calculations are summarised in tables with exemption levels (exempt activity concentrations and exempt activities of radionuclides) in (IAEA 1996) and (EUC 1996) and are used internationally.

Clearance levels

The EC Directive (EUC 1996) does not define clearance levels, except for provision that clearance levels shall follow the basic criteria used for exemption as stated in Annex I of the Directive and shall take into account any other technical guidance provided by the EU. The problem of clearance levels is more complex than the problem of exemption levels since it is not possible to satisfactory predict and describe all specific circumstances and destiny of radioactive material released from the control.

A specific approach is required e.g. for buildings, rubble and metals originating from dismantling nuclear installations. The European Commission has prepared and published special recommendations regarding these subjects (EUC 1988, EUC 1998, EUC 2000A and EUC 2000B). One of these documents, namely (EUC 1988), has been published at the end of the eighties, and was used as a basis for establishing basic criteria for exemptions, as we have already mentioned in the previous subchapter.

Ten years ago, EC introduced general clearance levels to cover any possible application (EUC 2000D, EUC 2001), without special restrictions on the origin and type of material to be cleared. These general clearance levels apply to any solid, dry material, also to natural radiation sources. Basic criteria for clearance are based on requirements of the EC Directive, as we have discussed previously in relation to exemption levels.

In scenarios used for calculation of general clearance levels, the following exposure pathways to a member of the public were considered: inhalation, ingestion, external gamma radiation and beta skin irradiation. In each case the most restrictive of the scenarios was adopted and the mass activity concentration resulting in dose 10 μSv/year was used to define the radionuclide specific clearance level. To clarify these calculations additionally, we will enlist some of used scenarios: inhalation of contaminated dust on the workplace during the whole year, inhalation of dust during a whole year by an infant, ingestion of material on the workplace (hand-to-mouth pathway, 20 g/year intake), a child playing on the soil with undiluted material (100 g/year intake), landfill worker who is working full time on the waste, person living in the house for which cleared building rubble has been used in construction, etc.

Ingestion via water pathways and vegetable consumption was also considered in clearance calculations. Rounded general clearance levels are listed in Table 1 in (EUC 2000D).

A_1 and A_2 values for transport

The risk associated with the transport of radioactive materials is specific and relates to manipulation and transfer of packages in conditions that are not controllable. Therefore, it is not possible to anticipate possible smaller or larger incidents, or even accidents. Even more, we can say that incidents and minor mishaps represent part of normal transport.

Type A packages are intended to provide economical transport for large numbers of small activity consignments, while at the same time achieving a high level of safety. They are tested for routine (incident free) transport conditions and normal transport conditions (with minor mishaps, like falling from vehicles, being dropped during manual handling, being exposed to the weather, being struck by a sharp object, or having other packages or cargo stacked on top). However, it is not possible to expect that the package will retain integrity in accident. In that case, we have to expect that integrity of built-in shielding or integrity of containment will be degraded. As a result, exposure of workers and/or public to the source is highly probable. The only possible solution for limiting the risk to workers or members of the public in that case is to limit the content (activity) of the package.

A_1 and A_2 *values* are used as limiting values for Type A package contents. These values were calculated with realistic scenarios for special form radioactive material (either an indispersible solid radioactive material or a sealed capsule containing radioactive material; integrity of both must be preserved under all applicable conditions, even an accident) and non-special form material. The Type A package contents limits are:

- A_1 – for special form material, and
- A2 – for non- special form material.

The contents limits are set so as to ensure that the radiological consequences of severe damage to a package are acceptable. Although the dose limits do not apply to potential exposures, it was decided (as described in (IAEA 2002)) that the dose limits for professionals for effective, committed and equivalent dose shall be used. The assumptions of potential exposure following the transport accident were as follows:

a. The effective or committed effective dose to a person exposed in the vicinity of a transport package should not exceed a reference dose of 50 mSv.
b. The dose or committed equivalent dose received by individual organs, including the skin, of a person involved in the accident should not exceed 0,5 Sv, or in the special case of the lens of the eye 0,15 Sv.
c. A person is unlikely to remain at 1 m from the damaged package for more than 30 min.

Scenarios used in calculations considered the following exposures and exposure pathways:

- external dose due to photons (0,5 h exposure at 1 m from the source),
- external dose due to beta emitters (0,5 h exposure at 1 m from the source),
- internal dose via inhalation (committed dose from 10-6 fraction of package content)
- skin contamination and ingestion doses (5 h exposure from beta contamination with 10-3 fraction of package content per m2 of skin)
- submersion dose due to gaseous isotopes (0,5 h exposure)

Results of calculations can be found in (IAEA 2002) together with derived A_1 and A_2 *values* for different radionuclides. These values are used internationally (IAEA 2005A) as a part of legislation for the transport of dangerous goods

D-values

The idea behind the introduction of *D-values* (D for "dangerous source") is to provide the tool for risk based ranking of different sealed and unsealed radioactive sources. Sources with high activity, if not managed safely and securely, can cause severe deterministic effects to individuals in a short period, whereas low activity sources are unlikely to cause exposures with harmful consequences. The *D-value* is that quantity of radioactive material, which, if uncontrolled, could result in the death of an exposed individual or a permanent injury that decreases that person's quality of life (IAEA 2006). In the calculation of *D-values*, the dose criteria listed in Table 1 were used (IAEA 2005B).

Table 1. Reference doses for D-values (from IAEA 2005B).

Tissue	Dose criteria
Bone marrow:	1 Gy in 2 days
Lung:	6 Gy in 2 days from low LET radiation 25 Gy in 1 year from high LET radiation
Thyroid	5 Gy in 2 days
Skin/tissue (contact)	25 Gy at depth of 2 cm for most parts of the body (e.g., from a source in a pocket), or 1 cm for the hand for a period of 10 hours
Bone marrow:	1 Gy in 100 hours for a source that is too big to be carried

In possible scenarios different realistic accident situations were considered and also dispersion situations that may be relevant to malevolent acts. It was found (IAEA 2006, IAEA 2003) that the following realistic scenarios for sealed source and dispersal of source are the most limiting:

a. An unshielded source being carried in the hand for one hour or in a pocket for 10 hours, or being in a room for days to weeks
b. Dispersal of a source, for example by a fire, explosion or human action, resulting in exposure due to inhalation, ingestion and/or skin contamination.

The results of calculations for each radionuclide were two values: D_1 for sealed source and D_2 for dispersal of source. Values are listed in Table 1 in (IAEA 2006) but for regulatory use, only one (lower!) value was designated as *D-value* for that particular radionuclide.

D-values for particular radionuclides serve for ranking the radioactive sources and practices in five risk categories, according to involved source activity (IAEA 2005B). In Table 2 risk categories of sources, corresponding A/D ratios and brief descriptions of associated risk are listed.

Table 2. Risk categories with corresponding A/D ratios and risk description for radioactive sources (from IAEA 2005B).

Category	Activity Ratio (A/D)	Risk Description
1	A/D ≥ 1000	Extremely dangerous to the person
2	1000 > A/D ≥ 10	Very dangerous to the person
3	10 > A/D ≥ 1	Dangerous to the person
4	1 > A/D ≥ 0.01	Unlikely to be dangerous to the person
5	0.01 > A/D ≥ Exempt. Lev./D	Most unlikely to be dangerous to the person

High-activity value

The legal term high-activity sealed source was introduced in the HASS Directive (EUC 2003) issued by European Commission as a result of a recommendation from the Working Group on Control of Sources, which was established by EURATOM Treaty Article 31 Group of experts. The aim was to improve the safety and security of sources, prevent orphan sources from arising and to harmonise requirements between EU countries without imposing unnecessary additional burden to holders of small sources.

The Directive introduced special requirements regarding authorisation, transfers, records, common requirements for holders, identification and marking, training and information, special arrangements for dealing with orphan sources, request for financial security and international cooperation and information exchange.

Technically, the high activity source is a sealed source that produces a dose exceeding 1 mSv/h at the distance of one meter. In the HASS Directive, the *high-activity values* for the most important radionuclides are listed, and for other (non-listed) the instruction to use 0.01 fraction of A_1 *value* from transport legislation (IAEA 2005A) is given.

Comparison of values

In Table 3 Exemption level, A_1, A_2, *D-value* and *high-activity level* are listed for some more common radionuclides. The data of Table 3 are also presented on Figure 1, but on the chart the order is changed to illustrate the relations between particular values.

Table 3. Different activity levels for some more common radionuclides.

Radionuclide	Exemption level (Bq)	A_1 (Bq)	A_2 (Bq)	D (Bq)	High-activity level (Bq)
Co-60	$1\times10^{+5}$	$4\times10^{+11}$	$4\times10^{+11}$	$3\times10^{+10}$	$4\times10^{+9}$

Ir-192	$1\times10^{+4}$	$1\times10^{+12}$	$6\times10^{+11}$	$8\times10^{+10}$	$1\times10^{+10}$
Ra-226	$1\times10^{+4}$	$2\times10^{+11}$	$3\times10^{+9}$	$4\times10^{+10}$	$2\times10^{+9}$
Am-241	$1\times10^{+4}$	$1\times10^{+13}$	$1\times10^{+9}$	$6\times10^{+10}$	$1\times10^{+11}$
Cf-252	$1\times10^{+4}$	$1\times10^{+11}$	$3\times10^{+9}$	$2\times10^{+10}$	$5\times10^{+8}$

As can be seen on Figure 1, the prevailing order is: *exemption level*, *high-activity level*, *D-value*, A_2 *value* and A_1 *value*. This is not completely true for pure beta sources (the highest is *D-value*, but very close to A_1 and A_2) and heavy radionuclides (where A_2 is low, due to their radiotoxicity,).

Except for heavy radionuclides, A_1 and A_2 *values* are quite close. We can also see that *D-value*, A_1 and A_2 values are close for all radionuclides, except for heavy radionuclides, again. For these, the *D-value* is approximately the geometrical mean of values A_1 and A_2.

For all listed radionuclides (except for Am-241) the *high-activity level* is lower than other levels. It seems that the value is really well chosen and could be used not only for sealed sources, but also more generally.

For majority of sources practically all levels are between 10^{10} Bq and 10^{12} Bq. For heavy radionuclides these values are between 10^{9} Bq and 10^{11} Bq. It seems that we can use, as a rule of thumb, that with any source below 10^{9} Bq we cannot expect permanent injury in realistic scenarios. We can also conclude that there is just a small probability that the dose limits for professionals would be achieved. On the other side, sources with an activity over 10^{12} Bq are always extremely dangerous for all radionuclides.

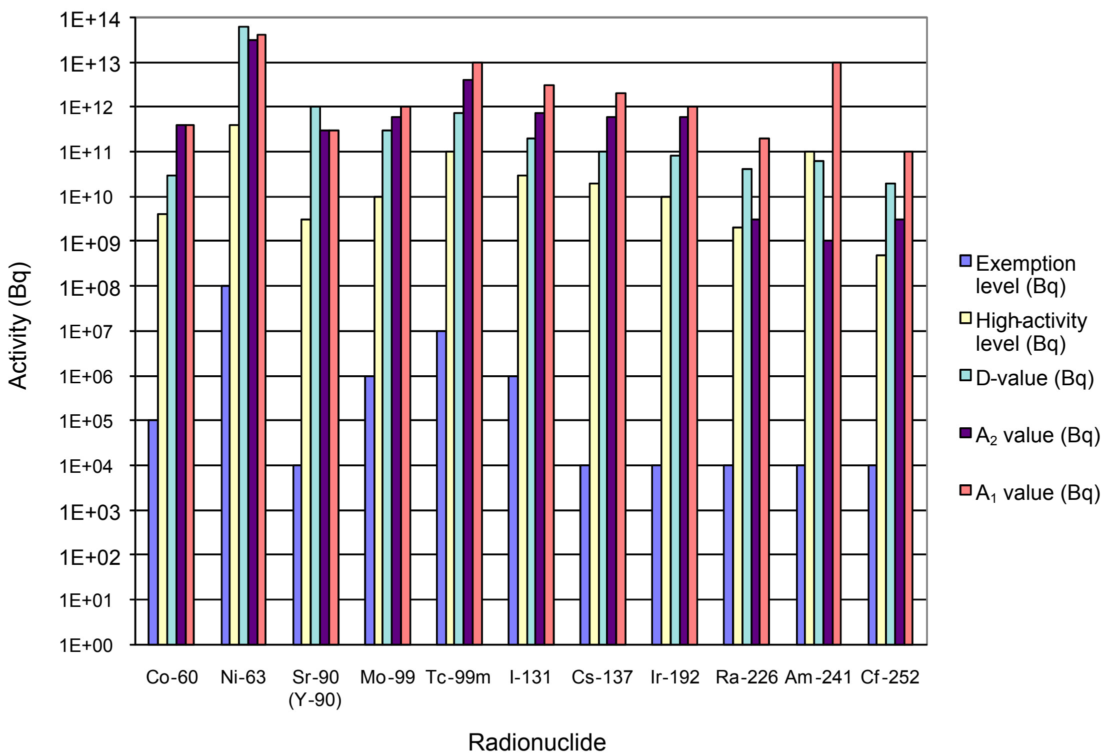

Figure 1. Activity values for some common radionuclides in prevailing order.

Conclusions

We have seen that different activity levels used in the legislation have also a practical meaning: the calculation was based on realistic foundations and scenarios. We can use them as an orientation regarding potential exposures and for rough assessment of dose in possible incidents or accidents.

It seems that especially useful are *A_1 value* (for sealed sources), *A_2 value* (for unsealed sources) and *D-value* (for general sources). We can say that when the persons involved in incident are aware of the source presence (like exposed workers or emergency personnel) and when the activities are below A_1 or A_2 value (as appropriate), it is highly improbable that dose limits for occupationally exposed workers will be exceeded. When the source is not under control and persons involved are unaware of it, and activities are close to or above *D-value*, then the source could be dangerous to involved persons.

The *high-activity value* could be used for simple and straightforward calculation of dose rate from the sealed source.

For the majority of examined radionuclides values are increasing in the following order: *high-activity level*, *D-value*, A_2 and A_1 *value*, while the e*xemption level* is at least four orders of magnitude below these values. The fact that *D-value* (when the source is considered dangerous) is usually below or close to A_1/A_2 *values* additionally supports the importance of supervision and control of sources.

Except the *exemption level*, the values of other levels for almost all common radionuclides are higher than 1 GBq. Therefore, it seems that in realistic circumstances and accidents it is very unlikely to expect permanent injury, or even achieving the dose limits for professionals for sources below 1 GBq. Sources with activity over 1 TBq are always very dangerous with the potential to create permanent injuries, or even a person's death.

Emergency response to accidents involving radioactive material: Italian fire fighter experience

Rosiello, Luca; Mazzaro, Michele; Pianese, Emanuele
Corpo Nazionale dei Vigili del Fuoco (C.N.VV.F.), ITALY

Abstract

Since 1987 Italy has not been producing electricity through nuclear fission; nevertheless, due to the presence of four Nuclear Power Plants undergoing decommissioning and to the increasing use of radioactive sources in medical, industrial and research applications, potential accidents involving radioactive materials can still occur (and actually took place). Italian Fire Brigades, which are a national Organization, represent one of the main government structures involved in this kind of events, as far as the initial phase in concerned. Actually, Italian Fire Brigades teams act as first responders for any kind of calamity.

Accidents involving radioactive substances may be accompanied by hazards of different nature, and in these cases the wide range of tasks Italian fire fighters are used to face and their high level of training greatly simplify the approach to intervention.

During the last five years some small accidents took place in Italy involving radioactive materials such as orphan sources; in all cases the action of the first responders has proved of fundamental importance. Italian Fire Brigades have special trained teams equipped with suitable devices and dresses for monitoring and protection, and they are able to manage emergencies involving radioactive materials.

The aim of this article is to show the Italian response system provided by the Italian fire brigades from the very beginning of the accident until the post-emergency phase: some examples will be shown concerning recent events. Moreover the fire fighter's way of training, as far as radiation protection is concerned, will be presented.

The authors will illustrate also the co-operation between different organizations and services involved when a relevant accident occurs.

Introduction

A valid response to the emergency starts with an efficient organization in which the formation and maintenance of operational capabilities are constantly pursued goals.

Below, the position of C.N.VV.F. about it is shown and it will be shown how, through that organization, it has been possible to deal effectively with three types of radiological emergencies completely different from each other.

Material and methods

The organization of C.N.VV.F. in radiological emergencies

Control of radiation hazard is one of the institutional duties of C.N.VV.F. that, as a national technical organization, gets involved from the very beginning of the emergency. The response provided by C.N.VV.F. is based on a pyramidal structure in which at the bottom each Italian province is able to ensure first intervention just with limited equipment and training.

The intermediate level is represented by 22 special NR (Nuclear and Radiological) intervention teams, that are able to make more detailed assessments and measurements.

At the top of the pyramid there is the personnel of a specific laboratory in Rome with the most advanced equipment and training in Italy (Fig. 1).

Fig 1. Dislocation of the teams in Italy.

Basic team

103 teams, one for each provincial fire brigade headquarter, are able to respond within an hour from emergency. They may assess mainly the dynamics of the accident, getting useful technical information and performing instrumental measurements limited to gamma exposure (effective dose and effective dose rate) and to the presence of surface and air contamination (counts per second relative to the environmental level). The

instrumentation and preparation do not allow to quantify the level of risk but only to asses and monitor an anomalous presence of radiation. Self protection is the fundamental skill for these teams, through safely dressing and sampling.

Special NR team

22 teams are distributed throughout national territory, roughly one in each region. They are able to respond within 3-4 hours when alerted. The members of these teams are instructed in a theoretical-practical course three weeks long and then they are called annually for the retraining. In addition to the basic teams, the special teams use instruments to perform qualitative analysis on gamma-emitting radioisotopes and neutron dose measurements; moreover they sample environmental matrices, manage the containment and confinement of contaminated objects, and provide to the staff monitoring and decontamination.

Central NR Laboratory

A central laboratory is located in Rome and it is the apical response of C.N.VV.F. when a radiological emergency occurs. Personnel in the laboratory carries out dosimetric control activities of staff, qualitative and quantitative measurements of alpha, beta and gamma spectrometry, dose evaluation to personnel and operational planning to perform in accordance with Italian and international rules, together with other organizations relevant in post-emergency phase. The laboratory personnel manage the training of all the teams, the verification and calibration of instruments used by the teams and coordinate the staff in case of national or interprovincial emergencies.

Results

Although in Italy there are no more working nuclear power plants, increasing industrial, medical or research activity, use of radioisotopes is a source of significant risk.

The accidental scenarios that can be faced with the organizational structure of C.N.VV.F. include localized or diffuse emergencies in terms of released contamination, with restoration of normal conditions in the short or long term and emergencies requiring the employment of several special teams.

As an example three different situations that occurred in Italy over the past two years will be considered. These emergencies tested the system response confirming the effectiveness of the organization.

Discussion

The first case is the accidental melting of a source of ^{137}Cs in a brass refinery in Brescia.

The second concerns the presence of radioactive sources in the waste during the maxi emergency in Campania mainly in Naples.

The third arose by pellets with high concentration of ^{137}Cs coming from Eastern Europe that have been used for domestic stoves.

Accidental melting of a radioactive source

Too often sealed radioactive sources are hidden in metal scraps going to melting plants. If these sources are not detected they can be melted in the ovens and spread in the metallic ingots or dust.

In November 2008 a ^{137}Cs source was melted in a metal refinery working brass; ingots and bags of dust that were accidentally produced and sent to Germany for the recovery of residues of brass.

The alarm was triggered after several days, when the German authorities blocked some of these bags at the boundary because they were exceeding the threshold of radioactivity. They immediately informed the Italian authorities about it.

Fig 2. Brescia. Brass dust sampling for measurement of gamma spectrometry.

In that occasion all 3 levels of the fire brigades organization were involved. Actually after the first intervention performed by the basic team, the central Laboratory took over: its experts planned a thorough activity that went on for two months with a strong contribution of the special NR teams.

In summary, under the coordination of the central area three main activities were carried out:

- Boundaries and zoning of industrial area and access control
- Monitoring of remediation of contaminated plant components
- Measurements on samples of dust and ingots in order to authorize the release of the store and the resumption of the activity (Fig. 2)

This emergency was confined, since it involved just the area of the refinery and material contained within bags. Nevertheless, the duration of operations made it necessary to involve three special NR teams working alternated.

Emergency Campania radioactive waste

In June 2008 the region was the scene of a maxi emergency for the presence of large amount of waste in the streets and the lack of suitable locations to store it.

It was decided to ship the waste towards burning plants in Germany until a storage place was identified. As the previously shown emergency, German authorities detected some radioactive substances in the refuse. Then, a strict radiological monitoring of leaving waste was requested. This monitoring activity was managed by C.N.VV.F.

Fig 3. Naples. Measurements of dose rate on the field

In this case, with the central laboratory management, activity took about five months and involved many special NR teams coming from all over Italy as well as local basic teams that were working mainly to make measurements (Fig. 3).

Several radioactive sources were found and isolated, almost entirely of hospital origin.

Radioactive pellets emergency

In June 2009, widespread in north-central Italy, unusual concentration of ^{137}Cs were found in ashes coming from the combustion of certain types of pellets. The specific activity values were so high that, according to Italian law, ashes could have been included into restrictions for detention.

In order to contain the emergency some type of pellets supplies not yet sold were seized and a monitoring activity was scheduled. A collection of ashes in the houses of people who had requested help calling the emergency phone number was possible.

Although it was already clear that the concentrations did not show a serious radiation hazard, alarm and concern of citizens were such as to require a real response from the authorities.

In particular, using the widespread presence of local Fire Departments, tens of thousands of visits were conducted from the basic teams. When measurement's results were showing to pass a threshold of five times the value of the environmental background in total measures alpha , beta and gamma, samples of ashes were taken and related unburned pellets to evaluate later by gamma spectrometry.

The samples were brought at the nearest special NR teams building to carry out gamma spectrometry in order to estimate a presence of ^{137}Cs at least twice the environmental background.

Fig 4. Rome. Radioactive pellets samples.

Following this screening, positive samples of ashes and related unburned pellets were sent to the central NR laboratory for quantitative analysis (Fig. 4).

Sometimes, concentrations of ^{137}Cs up to 80 *kBq/kg* were found in the ashes while concentrations of about 300 *Bq/kg* were found in the unburned pellets.

Conclusions

Currently in Italy, as far as radiological emergencies is concerned, C.N.VV.F. is the organization most directly involved, certainly in the initial phase, due to widespread presence, but also in later stages. The C.N.VV.F. can provide technical experts who are able to plan operations in the medium and long term on the basis of assessments and measurements that could be conducted in complete autonomy from trained personnel for this purpose.

The current organization, together with relationships with technical personnel from other relevant authorities in radiation protection allows to maintain a sufficient team's level of training and to increase the professionalism of radio protection area.

Analyses of causes and consequences of internal contamination incidents at NRG

Draaisma, Folkert[1]; Minkema, Jeroen[2]

[1] Nuclear Research and consultancy Group, Quality, Safety and Environment, NETHERLANDS

[2] Nuclear Research and consultancy Group, NETHERLANDS

Abstract

In the last years several unforeseen events happened leading to internally contaminated workers and members of the public. Beside committed effective dose estimations incident investigations were performed into the direct and underlying causes. Using the Tripod method Basic Risk Factors were identified and used for prioritizing actions to prevent occurrence of these incidents in the future. Besides poor design characteristics, human failures could be traced back to organisational shortcomings as procedures, education and training and communication. An important finding was the personal perception of an internal contamination leading to concern and anxiety by those exposed. Justifying investment in terms of means and human capital according to the ALARA principle in relation to the gain in terms of dose reduction this fear perception is not taking into account. This suggest that a kind a “psychological” weighting factor must be introduced correcting for the enhanced ‘dose’ perception of internal contamination and in this way justifying extra effort preventing internal contamination.

Investigating microphone noise in mobile gamma-spectrometric HPGe measurements using accelometers

Kock, Peder

Medical Radiation Physics, Lund University, SWEDEN

Abstract

Microphonic noise caused by vibrations can be a problem in mobile gamma-spectrometric measurements using HPGe detectors. When driving on uneven roads moderate speeds might give raise to a considerable amount of vibrational stress. The resulting distorted spectra can be difficult to interpret, and potentially important spectral information may be lost. However, accelerometers can be used to detect and quantify the vibrations. These measurements can then be used to reduce the vibrational stress on the detector system.

To demonstrate the impact of noise from detector microphonics, vibrational data was gathered along with spectral measurements from an experiment with a car-borne mobile platform. The acquired accelerometer data could then be connected to the spectrum where distortions were observed. Speed and position on the road was also recorded and stored in the same record. This technique makes it possible to evaluate and compare different detector mounting configurations.

As this article shows, a sane mounting configuration will reduce the microphonic noise. This could be crucial for example in an orphan source emergency situation, where measurements must be gathered with speed and accuracy. Using accelerometers can be one way of achieving a reliable car-borne HPGe system by reducing the interference from microphonic noise.

Introduction

Vibrations causing small movements of the components in a Germanium detector's mounting can alter the capacitance between the field effect transistor (FET) gate and the detector bias supply. This may change the noise characteristics of the detector and in turn give raise to an electrical signal. Even a small change (10^{-7} pF) in the capacitance can cause an electrical signal equivalent of a few keV (Gilmore 2008). This mechanically generated noise is referred to as microphonic noise. Its main sources during normal operation conditions are environmental acoustic noise, vibrations of the surrounding equipment and events connected to liquid nitrogen such as turbulence and bubbling in the dewar affecting the cryostat (Morales et. al 1992).

Although this should be a common problem in mobile gamma spectrometry using HPGe detectors, where, by necessity, some vibrations occur, most of the literature found on the topic of microphonic noise deals with low background experiments (Baudis et al. 1998; Morales et al. 1992) or electrically cooled semiconductor systems (Upp et al. 2005). Ways of discriminating microphonic pulses include digital signal processing (Keyser et al. 2008) and statistical rejection techniques (Morales et al. 1992).

Possible explanations for the lack of applied studies are;

- NaI(Tl) detector systems are more frequently used in mobile gamma spectrometry
- The microphonic noise mainly affects low energy region (<100 keV)
- The ambient background is not controlled, hence disturbances might be overlooked

This article shows the importance of a vibration dampening mounting configuration when using a HPGe detector in mobile measurements and how accelerometers can be used to optimize the same configuration. Digital signal processing and statistical rejection techniques are out of the scope of this work since they do not deal with the source of the problem, but rather its consequences.

Material and methods

Spectrometry system

In the experiments a ruggedized, coaxial, P-type High-Purity Germanium (HPGe) detector[1], model no. GEM 100-S, with 123 % relative efficiency from Ortec[2] was mounted in a GMC van at a height of approximately 1 m above ground. The detectors cylinder axis was horizontally orientated with the end-cap facing the rear of the van. A digital, portable, Multi-Channel Analyser (MCA, Ortec Digidart), with the conversion gain set to 2048 channels was used. The MCA communicated with a laptop-PC over the USB (Universal Serial Bus) interface, sending a new pulse height distribution when requested. Measurements in the region below 40 keV using a P-type HPGe detector is normally pointless due to the thick dead-layer. But these noise pulses could potentially have effect on critical things higher up in the spectra, leading to peak-broadening.

A linear 3-axis accelerometer from ST Microelectronics (LIS3LV02DL) was mounted on the detectors aluminium cap to measure vibrations. The sensors can measure accelerations up to ± 6 g in three orthogonal directions, with a specified resolution of about 4 mg at 610 Hz. Acceleration directions are henceforth referred to as X, Y and Z, where -X is an acceleration in the driving direction, +Y to the van's right when driving and +Z down towards the ground.

To scrutinize the influence of the detector mounting configuration, two different sets of dampeners were used. Fist the ‘bare-bone’ configuration, where the detector was mounted directly on the floor of the car. Second the ‘dampener’ configuration, where the detector was mounted in a plastic tube, isolated with approximately 10 cm of polyester foam.

1 s/n p41629A

2 Ortec, 801 S. Illinois Ave., Oak Ridge, TN, USA.

Experiment

By observing spectra while driving on an uneven road, conclusions about different mounting configurations and their effect on the microphonic noise level can be drawn. In this work, a straight stretch about 400 m long was driven repeatedly while sampling spectral and vibrational data. To estimate the radiation background, 22 stationary 60 s background spectra was first measured at ~ 20 m intervals along the road. The straight stretch was then driven at three different velocities; 10, 20 and 30 km h^{-1} to gradually increase the mechanical stress on the detector. Each speed was driven four times, giving a total of 12 measurement sets. Spectrometer, accelerometer and GPS data were collected at 1 Hz using in-house software written in C#. This procedure was repeated for both mounting configurations.

Statistical analysis

To separate the microphonic noise from the ambient radiation background a region of interest **R** was chosen, ranging from the cut-off energy at 10 keV to 100 keV. The distribution of the number of gross counts per second n_b within **R** will be approximately normal with mean m_0 and standard deviation $\sigma = \sqrt{m_0}$, if measured repeatedly. Thus an observation *x,* which is significantly greater than m_0, would be an indication that microphonic noise was detected in a spectrum.

Using the null hypothesis, H_0, "no microphonic noise detected" and the research hypothesis, H_1, "microphonic noise detected" the test statistic

$$u = \frac{\bar{x} - m_0}{D} \tag{1}$$

where $D = \frac{\sigma}{\sqrt{n}}$ was calculated for each set $x_1, x_2, \dots, x_n$ of measured spectra. Under H_0, u will be observations from N(0,1). The null hypothesis can thus be rejected on the 1-α level if $u \geq \lambda_\alpha$. The single sided critical regions for u are presented in Table 1.

Table 1. Significance levels for the test statistic *u*.

Significance	*	**	***
α	0.05	0.01	0.001
u	1.64	2.33	3.09

The sample size of the test group, n, was chosen to be 3 spectra to avoid the worst fluctuations and the level of significance, α, was set to 0.001. The limit for rejection of H_0, then becomes

$$u_l = \sqrt{3}\,\frac{\bar{x} - m_0}{\sigma} \geq 3.09 \tag{2}$$

Results and Discussion

Figs. 1-2 show the results from the hypothesis tests using the 'bare-bone' and 'dampener' configurations. The results summarized in Table 2 show that the number of rejected samples increases with increasing driving speed, which was expected. At the slowest speed (10 km h^{-1}), the statistical tests showed no evidence of microphonic noise being detected. By increasing the driving speed to 20 km h^{-1} about 19 % of the measurements showed a significant number of microphonic noise pulses in the low energy region, **R**, when using the 'bare-bone' configuration. The number of rejected samples increased to 79 % when driving at the fastest speed (30 km h^{-1}) using the same configuration. By mounting the detector in the 'dampener' configuration, these numbers sank drastically. The rejection fraction, also shown in Table 2, was 2 and 19 % for 20 and 30 km h^{-1} respectively. To summarize, the total rejection fraction, i.e. the total fraction of measurements showing an significant increase of the count rate in **R** due to microphonic noise were 20 and 4 % for the 'bare-bone' and 'dampener' configurations respectively.

Table 2. Summary of hypothesis tests.

Test group	Samples	Rejection of H_0	Rejection of H_0 (%)
bare-bone u_{10}	391	1	0.2
bare-bone u_{20}	213	40	18.8
bare-bone u_{30}	138	109	79.0
dampener u_{10}	392	0	0.0
dampener u_{20}	219	4	1.8
dampener u_{30}	146	28	19.2
bare-bone total	742	150	20.2
dampener total	757	32	4.2

Two samples with extreme test statistic values from each mounting configuration, thus containing significant levels of microphonic noise were analysed in detail. The samples, labelled A, B, C and D are marked in Figs. 1-2. Acceleration data for these four samples are presented in Figs. 3-4 and spectra in Figs. 6-7.

The accelerometer data in Figs. 3-4 reveals both vibrations and more shock-like events. The detector is subject to forces mainly in the Z (up, down) and Y (left, right) directions, while the data show more moderate vibrations along the detector's cylinder axis (X). An offset of about 1 g is present in the Z-direction due to gravity. The frequency of the vibrations seems to be generally higher in the samples A and B (bare-bone) than in C and D (dampener) while the amplitudes show a reversed relationship. This clearly demonstrates the complexity of the microphonic noise problem. By introducing a dampening material much of the microphonic noise disappears. As shown in Table 2, but some measurements with large (several g's), shock-like, accelerations still appear because of the uneven road and high velocities.

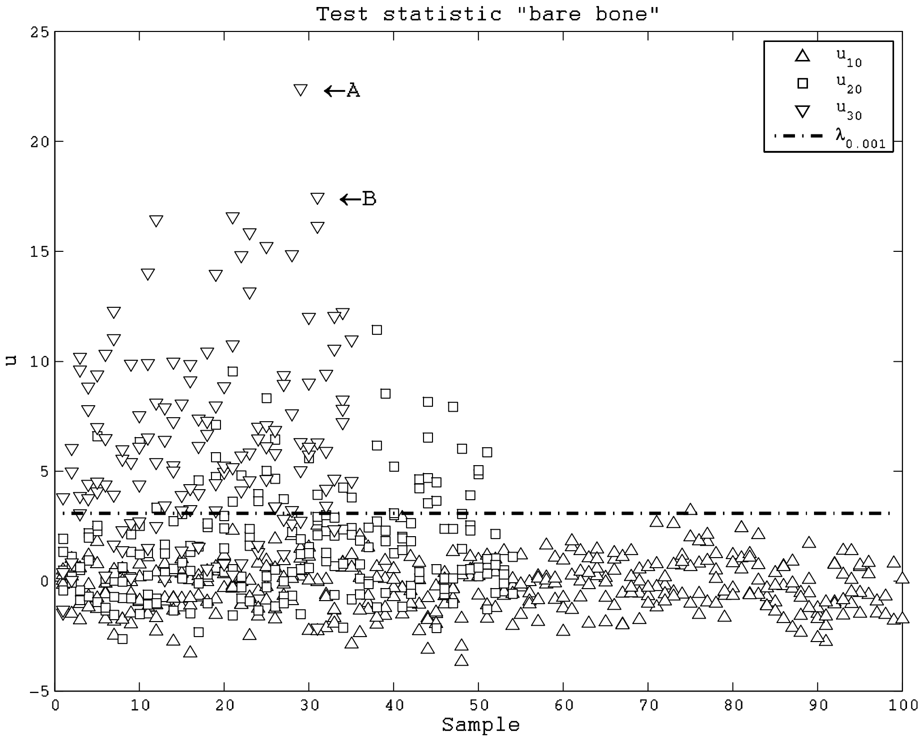

Fig. 1. Test statistic *u* for the 'bare-bone' configuration. The limit for rejection of H_0, λ_α, is marked with a dash-dotted line.

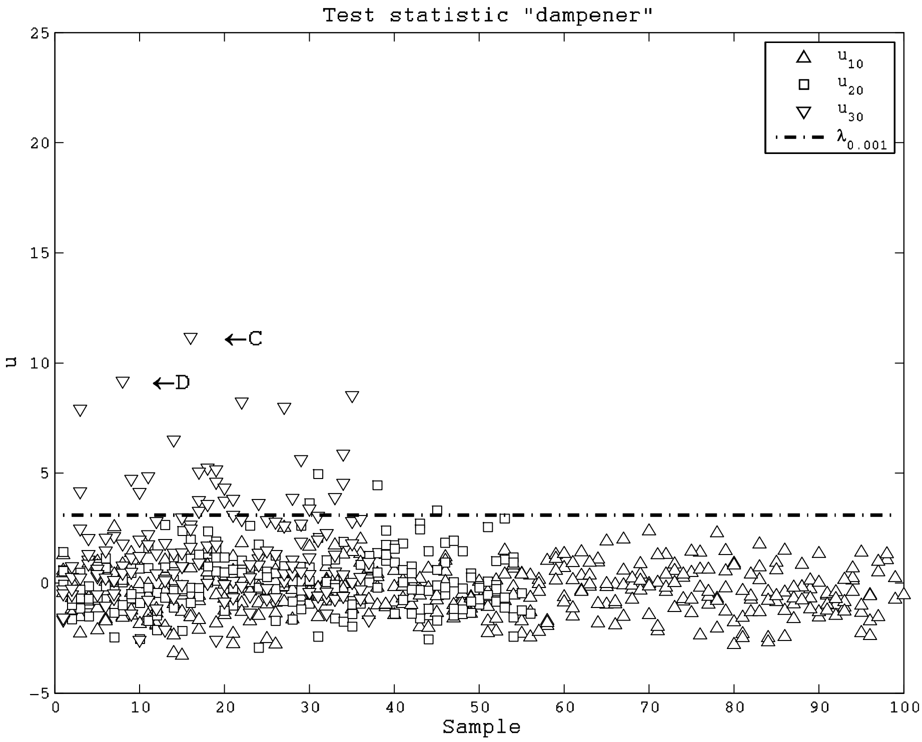

Fig. 2. Test statistic *u* for the 'dampener' configuration. The limit for rejection of H_0, λ_α, is marked with a dash-dotted line.

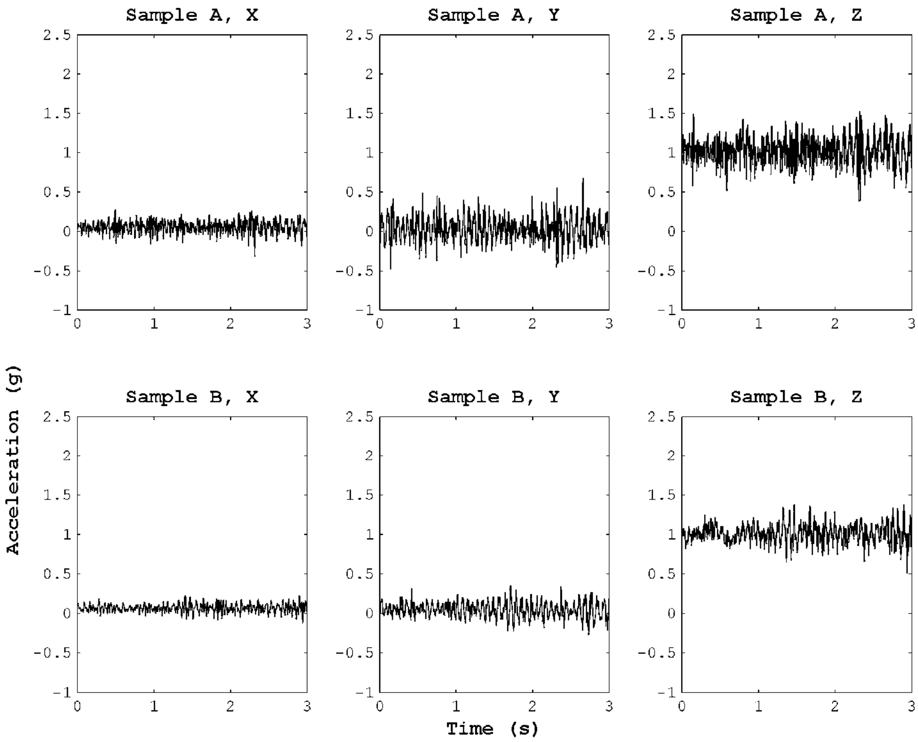

Fig. 3. Accelerometer data for 'bare-bone', samples A and B. No shock-like events are present, rather a steady ripple, especially in the Y and Z-directions.

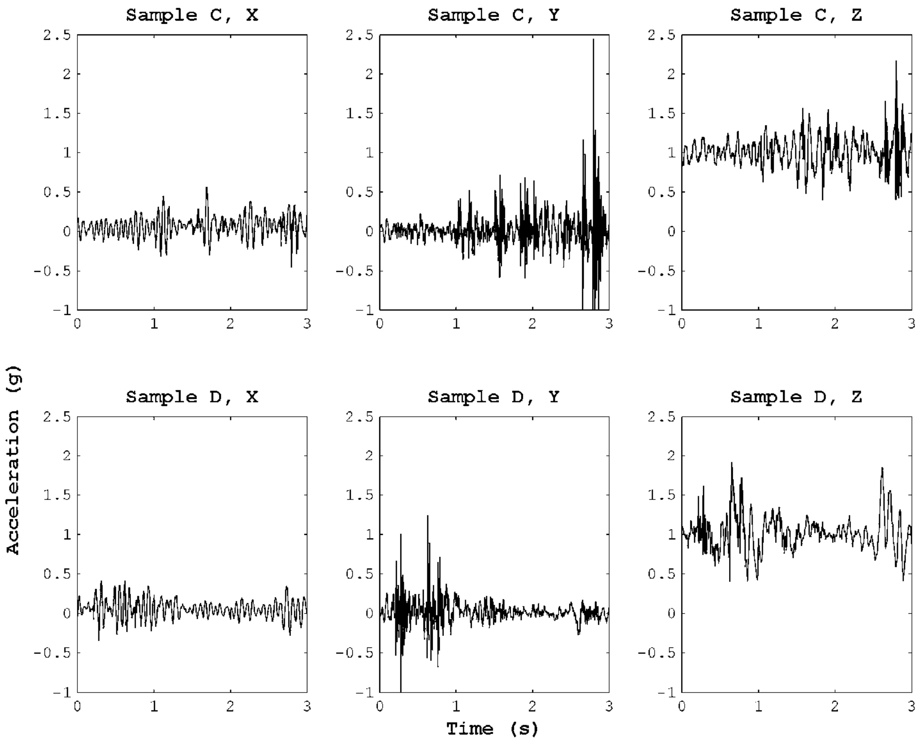

Fig. 4. Accelerometer data for 'dampener', samples C and D. Some shock-like events can be observed in the Y and Z-directions.

That a frequency shift occurs when introducing the dampener is confirmed in Fig. 5, where the single-sided Fast Fourier Transform (FFT) of all Z-direction acceleration measurements at 30 km h^{-1} is presented. All measurements for each of the two configurations were summed to show the different vibration characteristics. While frequencies in the range 10-50 Hz dominated in the 'bare-bone' measurements, the 'dampener' shows a peak below 25 Hz. When introducing the 'dampener' the total mass of the vibrating body also increases. This could be one factor that leads to a shift of vibration frequencies. The most obvious reason is of course the introduction of a soft dampening material - the polyester foam between the van's floor and the detector.

Spectral data for the four samples A-D are presented in Figs. 6-7. The microphonic noise mainly adds pulses in the low energy region below 20-30 keV. As much as 80 extra pulses per second due to microphonic noise were recorded (sample A). The 'bare-bone' samples A and B show more microphonic pulses than the 'dampener' (C and D), which also can be seen in the test-statistic, *u*, when comparing Figs. 1 and 2.

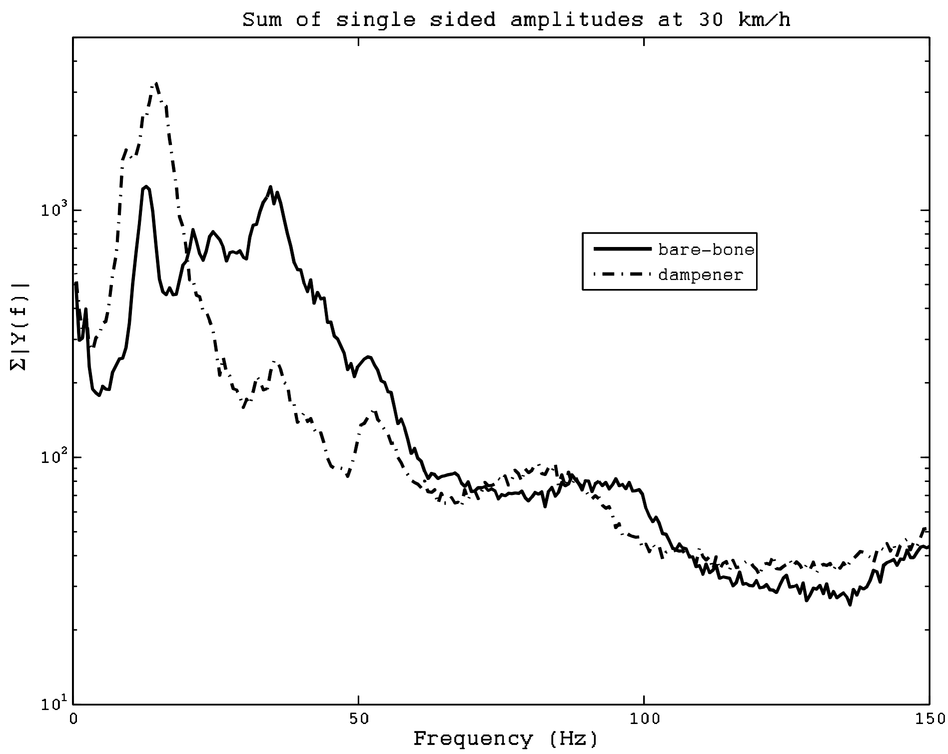

Fig. 5. Summed Single sided Fast Fourier Transform plot for all Z-direction acceleration measurements recorded at 30 km/h. A frequency shift occur when changing from the 'bare-bone' to the 'dampener' configuration.

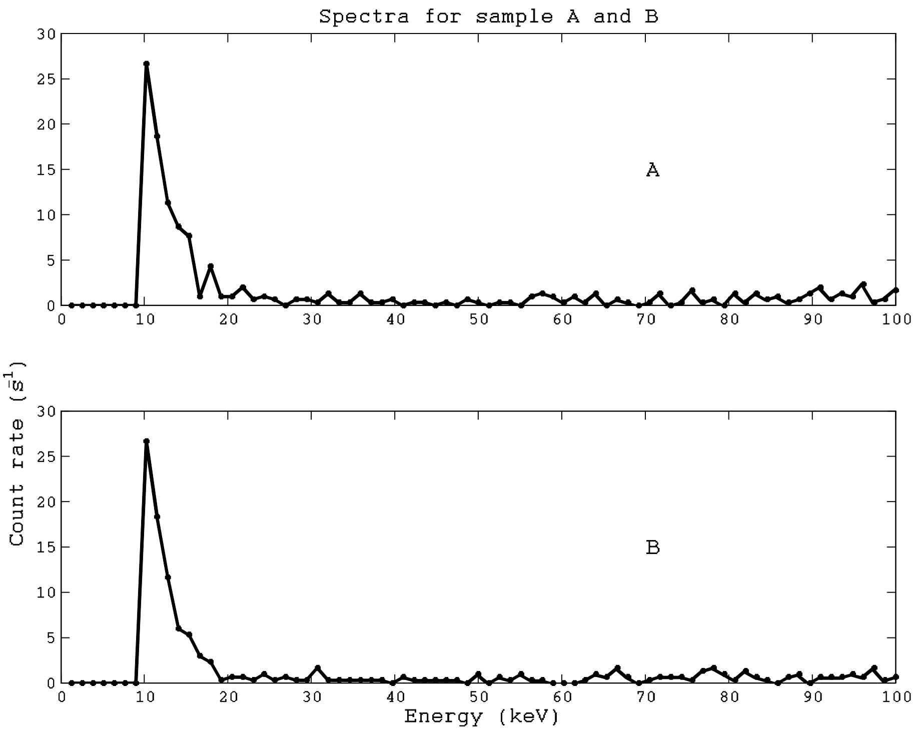

Fig. 6. Spectra for 'bare-bone' samples A and B. The main contribution in the low enery region (below 30 keV) is from microphonic noise.

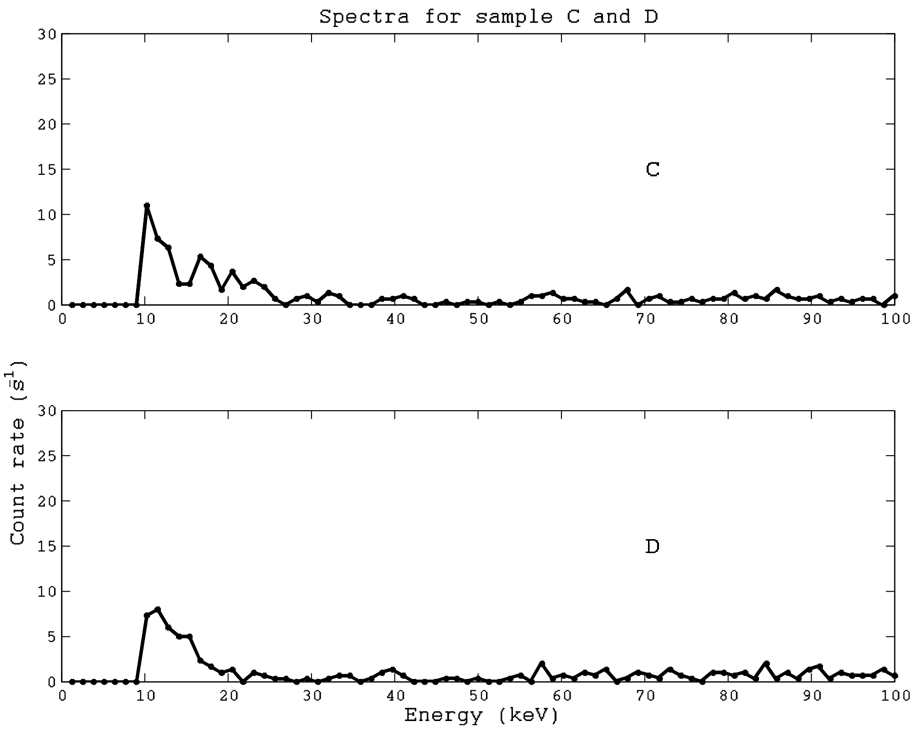

Fig. 7. Spectra for 'dampener' samples C and D. The main contribution in the low enery region (below 30 keV) is from microphonic noise.

Conclusions

As shown in this work microphonic noise occur when driving on uneven roads in moderate speeds. The microphonic noise increases as the speed of the vehicle, and hence the vibrations, increase. However, a few simple measures can reduce the microphonic noise considerably when using a car-borne HPGe detector system. A polyester foam dampener led to a reduction of the microphonic samples from 20 to 4 % of the total number of samples. Using a 3-axes accelerometer this work shows that the reduction was mainly due to a frequency shift in the vibrational forces acting upon the detector.

The results presented in this paper are hard to generalize, since they depend on a specific detector model, possibly even on an individual detector. However, it should be possible to conduct a more general experiment in a controlled laboratory environment using induced vibrations.

Assessment of potential consequences of hypothetical radiological incidents in the seas of North-West Region of Russian Federation

Pavlovski, Oleg; Krylov, Alexey
Nuclear Safety Institute of Russian Academy of Sciences, RUSSIAN FEDERATION

Abstract

In Northwest region of Russia there are the sites of storage and decommissioning of retired nuclear submarines, their nuclear reactors, spent nuclear fuel and radioactive waste. Many of those sites are not isolated and protected. There are also the atomic shipbuilding plants, naval objects. In the seas there is the traffic of atomic-powered vessels (submarines, ice-breakers). There is a hazard of release of radioactivity from those sites. This was the reason of implementing of the International Project “Improvement of the Murmansk region system of radiation monitoring and emergency response” (Project), managed by the European Bank for Reconstruction and Development. The Nuclear Safety Institute (NSI) of Russian Academy of Sciences was the main executor of the Project. Hypothetical scenarios and consequences of accidental radioactive contamination of coastal waters of North-Western region of Russia are discussed in this work. The scenarios assume the location of the hypothetical accidents to be in the White Sea and in the one of the Bays of the Barents Sea. The modeling of possible consequences of radiological incidents was implemented for water bodies that strongly differ in size (from 5 to 300 kilometers), tides, currents, and characteristic times of water exchange with Arctic Ocean. The modeling of migration of the radioactive substances was carried out with the use of computer model developed by the specialists of the NSI. This model is based on the well-known three-dimensional Princeton Ocean Model. The results of modeling of considered scenarios of accidents have shown that these hypothetical incidents do not constitute danger to the areas of industrial fishing in the Arctic Ocean as so as to the sea-shore coasts outside the water bodies were the hypothetical accident have taken place.

Management of the radiological situation regarding the wreck of the cruiser Murmansk

Eikelmann, Inger Margrethe H.; Selnæs, Øyvind Gjølme
Norwegian Radiation Protection Authority, NORWAY

Abstract

In December 1993, the decommissioned cruiser Murmansk was torn from its towing towards India for dismantlement and ran aground just outside the fishing village Sørvær on the coast of Finnmark in Northern Norway. The Norwegian Radiation Protection Authority (NRPA) received information about the wrecked vessel from the Norwegian Defence Command Headquarters. The coast guard carried out measurements and collected sea water samples. The initial concern was the possibility that there might be nuclear materials onboard the vessel, either in form of nuclear weaponry or spent nuclear fuel. NRPA made initial assessments and concluded that it was very unlikely that the vessel would contain radioactive substances that could pollute the surrounding area In June 2007 NRPA was notified by a private recycling firm that items taken from the wreck of the cruiser Murmansk showed sign of gamma radiation. The source was sent to a low level radioactive waste depository. Friday 1 August 2008 major Norwegian newspapers have lead stories on public concerns regarding radioactive substances at the ship. NRPA realized the need for a more thorough follow-up and decided to visit the wreck for new investigations. The investigations on the wreak was gamma dose rate measurements and collected samples of sea water and biota inside and outside the wreck. All samples was analysed and compared to expected values based on the Norwegian marine monitoring programme. The analysis did not show any radioactive contamination from the wreck. Also further measurements of concentrated sea water samples, alpha spectrometry of biota and sediments samples have not shown any trace of radioactivity. Handling of media was a main challenge through this event and it proved to be the most publicised news bulletin concerning NRPA in 2008. NRPA received very good public, political acceptance for handling the case and lead to a good cooperation between responsible authorities.

Overview of the observations on airborne and deposited radioactivity in Finland after the Chernobyl accident

Abstract

The Chernobyl nuclear accident happened in the former Soviet Union on 26 April 1986. The air parcel trajectories originating from Chernobyl at the time of the accident show that the radioactive plume moved first northwestwards Over Lithuania the plume separated to two main paths. At lower altitudes (750-1000 m) the plume continued towards Sweden and Norway. At higher altitudes (1500-2500 m) the plume turned towards north. The plume arrived in South-Western Finland 27 April at 12 UTC for a release height of 2000 m. Then the plume went across the country north-eastwards and back to Soviet Union.

An aerosol beta activity monitor reacted to the Chernobyl-derived airborne radioactivity at Nurmijärvi, 40 km north-west of Helsinki, on the afternoon of 27 April. Unfortunately the alarm issued by the instruments did not cause any action due to a civil cervants' strike. The first alarm leading to a nation-wide alert occurred at Kajaani, north-eastern Finland, on the evening of 27 April 1986. A monitoring station of the Ministry of the Interior measured an increased exposure rate value of 0.1 mR/h (≈ 1 μSv/h) in connection with a rain shower. 29 April a rain area moved from the west coast of Finland in an easterly direction. The rain scavenged the activity to the ground causing notable increases in the external dose rate at several monitoring stations.

The monthly mean total beta activity concentration in April 1986 was the highest ever recorded, 1 Bq/m^3. The total beta activity concentration decreased five orders of magnitude at Nurmijärvi from 27-28 April to 31 May. In northern Finland the concentration level was clearly lower. In striking contrast to the 1960's nuclear weapons test fallout, the Chernobyl fallout was very unevenly distributed in Finland. The existence of "hot particles", highly radioactive agglomerates, in the Chernobyl plume was a specific feature during the early stages of emissions.

Introduction

The Chernobyl nuclear accident happened in the former Soviet Union, 130 km north of the city of Kiev, 26 April 1986. The reactor model, RBMK-1000, at Chernobyl was a graphite-moderated design using light water for cooling. The electrical output of the reactor model is 1000 MW. The accident destroyed one of the four reactors of the plant and released a huge amount of radionuclides into the atmosphere (International Atomic Energy Agency 1986).

The fourth unit of the power plant was scheduled for a regular maintenance shutdown 25 April 1986. In this connection a test programme was planned to be conducted. During the test a power surge in the reactor caused two subsequent explosions destroying the reactor and its surroundings. The graphite moderator caught fire and was burning for at least a week, thus prolonging the emissions of radioactivity into the atmosphere (International Atomic Energy Agency 1986). According to the Soviet estimates, all the radioactive noble gases of the core inventory were released during the accident as well as 10-20 % of the volatile nuclides and 2-6 % of plutonium isotopes and other refractory nuclides, e.g. ^{95}Zr and ^{144}Ce. A summary of the meteorological and radioactivity observations made in Finland is given in the following based on the paper of Paatero et al. (2010a).

Meteorological and hydrological situation

The energy released during the accident caused the radioactive plume to break through a ca. 400 metres thick inversion layer to the free troposphere. The air flow in the area around Chernobyl above the inversion layer was towards Poland and Lithuania, anti-cyclonally around the high pressure area in Russia (Fig. 1). Over Lithuania the plume separated to two main paths. At lower altitudes (750-1000 m) the plume continued towards Sweden and Norway. At higher altitudes (1500-2500 m) the plume turned towards north. The plume arrived in South-Western Finland 27 April at 12 UTC for a release height of 2000 m. Then the plume went across the country north-eastwards and back to Soviet Union. A frontal zone north of this route hindered the plume to reach northern Finland. The air stream brought, taking into consideration the season, exceptionally warm weather to southern Finland (Paatero et al. 2010a).

During 27 April, when the passage of the plume associated with the initial explosion occurred, there was no or very light rain in southern Finland. Slightly larger amount of precipitation occurred along the previously mentioned frontal zone from south-western Finland north-eastwards (Fig. 2a). During 28 April the weather was also quite dry in southern Finland except some local showers but during the next three days there was heavy precipitation along a zone from the coast of the Bothnian Bay south-eastwards towards the Kotka region (Fig. 2b). One third of the country was still covered by snow and even in southern Finland the agricultural activities hadn't started yet (Fig. 3)). Also the cattle was kept still indoors. This reduced the effects of the accident on various agricultural products during the early phase of the accident.

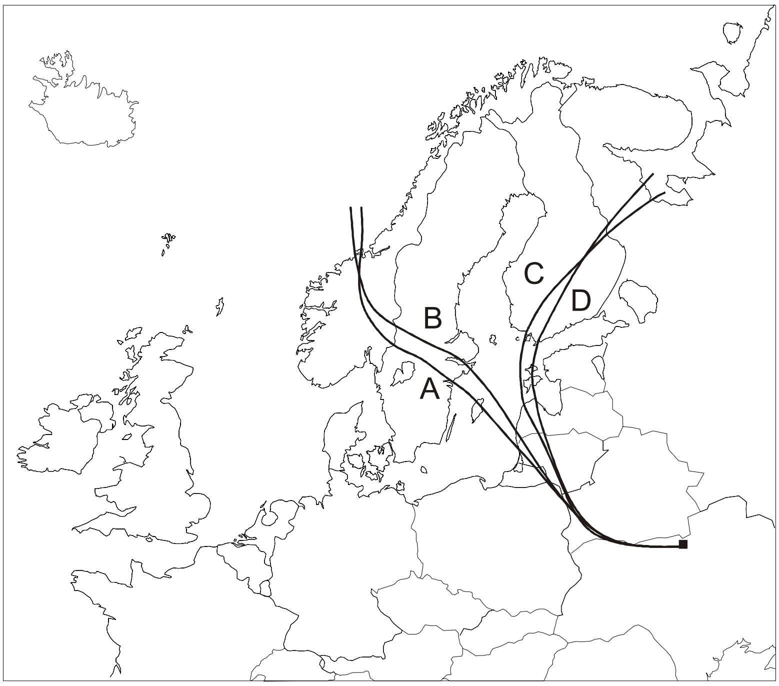

Fig. 1. Air mass trajectories from Chernobyl on 25 April 1986 at 21 UTC calculated with the TRADOS computer code (Redrawn from Valkama et al. 1995). Effective release heights: A = 750 m, B = 1000 m, C = 1500 m, and D = 2500 m.

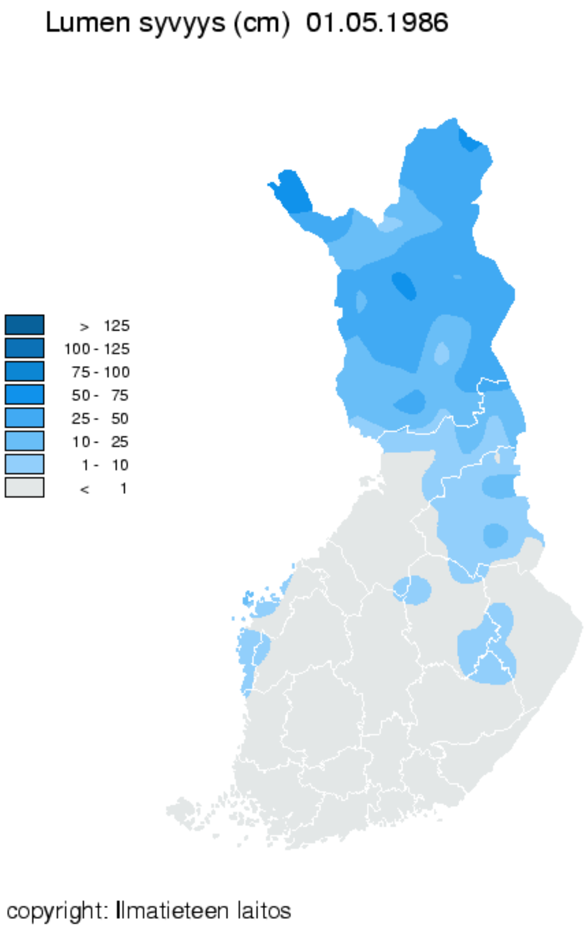

Fig. 3. Depth of snow cover (cm) in Finland 1 May 1986 (Data: Finnish Meteorological Institute).

Airborne radioactivity

An aerosol beta activity monitor (Paatero et al. 1994a) of the Finnish Meteorological Institute (FMI) reacted to the artificial radioactivity at Nurmijärvi but not in Helsinki on the afternoon of 27 April despite the only 40 km distance between the monitoring stations ((Fig. 4). This was probably due to the convection over inland Nurmijärvi while the lower troposphere was stratified in Helsinki due to the cold sea surface. Unfortunately the alarm at the Nurmijärvi monitoring station did not cause any action due to the civil cervants' strike. Most of the FMI's aerosol beta activity monitors in southern and central Finland detected artificial radioactivity on 28 April, especially in the afternoon owing to the increased vertical mixing of the troposphere.

The FMI has collected daily aerosol samples with a high-volume filter sampler at Nurmijärvi since 1962. The filter samples have been measured for total beta activity. The measurements are carried out five days after the end of sampling when the short-lived daughter nuclides of radon-222 have decayed to lead-210 (^{210}Pb) and the radon-220 progeny have decayed to stable lead (Mattsson et al. 1996). The measured activity consists of ^{210}Pb and possible artificial beta-emitting fission products. The monthly mean total beta activity concentration in April 1986 was the highest ever recorded, 1 Bq/m^3 (Paatero et al. 1994b). However, the time-integrated activity concentration was significantly higher in the early 1960s due to the Soviet and U.S. atmospheric nuclear tests. The total beta activity concentration decreased five orders of magnitude at Nurmijärvi from 27-28 April to 31 May (Fig. 5). Simultaneous data from Sodankylä showed that the daily activity concentrations were 1-4 orders of magnitude lower in northern Finland compared with Nurmijärvi during the first two weeks after the plume arrival.

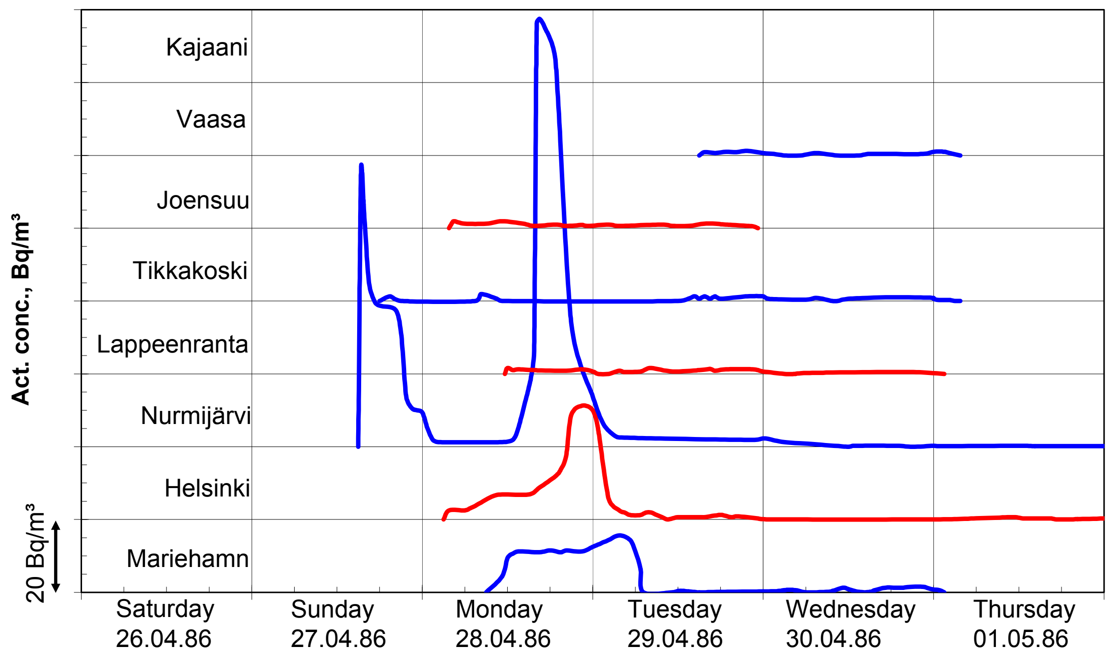

Fig. 4. Artificial aerosol beta activity in ground-level air (Bq/m^3) in Finland 26 April – 1 May 1986 (Redrawn from Mattsson and Hatakka 1986).

Between 28 April and 16 May 1986 the concentration of ^{137}Cs in ground-level air at Nurmijärvi decreased four orders of magnitude, starting from 10^4 mBq/m^3 (Finnish Centre for Radiation and Nuclear Safety 1986a). On 28 April the ground-level air at Nurmijärvi contained 32 µBq/m^3 of ^{239,240}Pu and 506 µBq/m^3 of ^{242}Cm (Jaakkola et al. 1986). For comparison, the annual mean ^{239,240}Pu concentration in the air in Helsinki varied between 7 and 26 µBq/m^3 in 1962-1964 due to the atmospheric nuclear tests (Jaakkola et al. 1979). Carbon-14 and tritium could be observed in the air in Helsinki only during the first three days after the arrival of the Chernobyl plume (Salonen 1987).

Highly radioactive agglomerates, so-called hot particles, were observed in Finland among other countries. These particles were either fragments of the nuclear fuel or particles formed by condensation of radionuclides and inactive structural materials of the reactor (Devell et al. 1986, Raunemaa et al. 1987, Lancsarics et al. 1988). The aerodynamic diameter of the Chernobyl-originated hot particles varied from one to several hundred micrometres; gravitational settling thus had to be taken into account when assessing their transport behaviour in the atmosphere (Pöllänen et al. 1997). Dozens of hot particles having an activity of over 50 Bq were detected from daily aerosol samples collected at Nurmijärvi, southern Finland between 27 and 30 April

(Fig. 6). The air volume of these samples was about 3500 m3. The number of particles with the activity ranging from 0.05 to 50 Bq in these filters varied between several hundreds and over ten thousand during these first days. Starting from 1 May only a few occasional hot particles were found (Mattsson and Hatakka 1986).

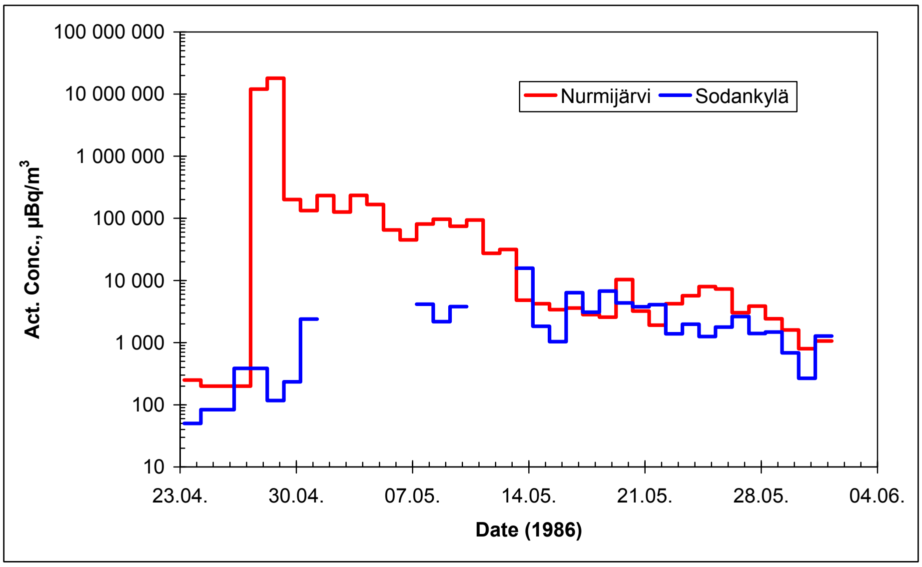

Fig. 5. Total beta activity concentration in ground-level air (µBq/m^3) at Nurmijärvi and Sodankylä 23 April – 31 May 1986 (Paatero et al. 1994b).

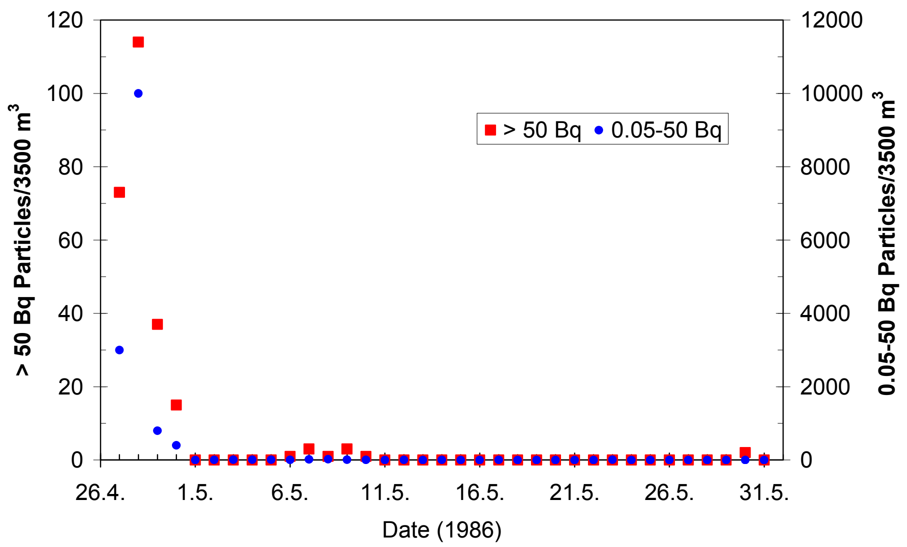

Fig. 6. Hot particles (> 50 Bq and 0.05-50 Bq) in the ground-level air at Nurmijärvi 27 April – 31 May 1986 (Mattsson and Hatakka 1986).

Deposited radioactivity

In striking contrast to the 1960's nuclear weapons test fallout, the Chernobyl fallout was very unevenly distributed in Sweden and Finland (Paatero et al. 2010b). In Finland the regional deposition pattern of different nuclides has been studied by in-situ gamma spectrometry and by collecting lichen, peat, soil and precipitation samples followed by laboratory analysis. Two main deposition patterns have been found. Refractory nuclides, such as ^{95}Zr and transuranium nuclides, were mainly deposited on a relatively narrow band from southwestern Finland towards north-east (Fig. 7. This pattern is associated with the passage of the air mass, that was over the Chernobyl region during the explosion of the reactor, and that contained debris of the reactor fuel (Paatero et al 2010a). The second pattern is associated with the volatile radionuclides, e.g. ^{134}Cs and ^{137}Cs. The deposition pattern of these nuclides is dominated by a heavy fallout area from western Finland towards south-east. The emissions of the volatile nuclides were more affected by the fire of the reactor ruins. The deposition pattern of these nuclides resembles the precipitation map of 28 April – 1 May in Figure 2b showing the importance of wet deposition mechanisms for removing these nuclides from the atmosphere.

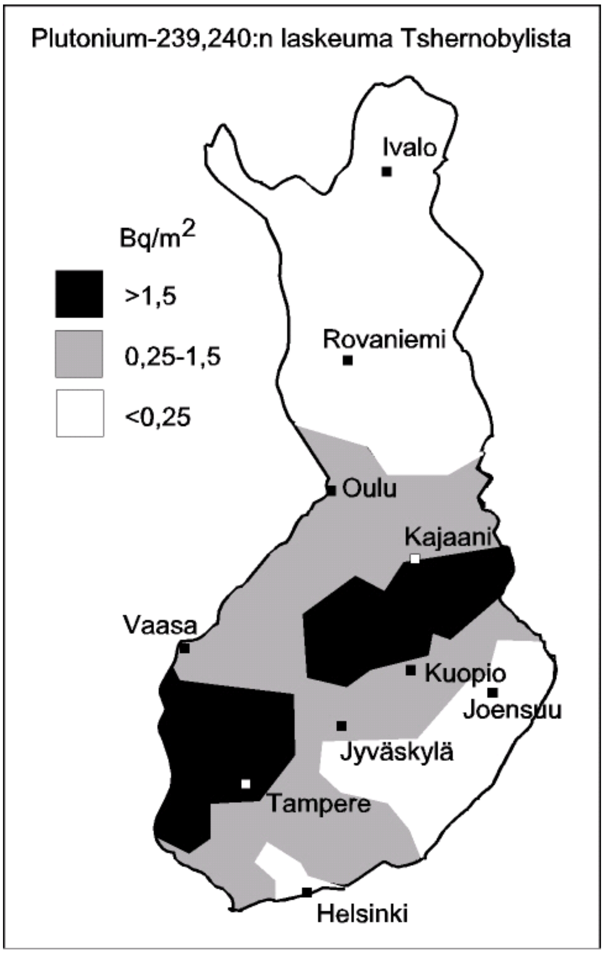

Fig. 7. Deposition of $^{239,240}Pu$ (Bq/m^2) in Finland after the Chernobyl accident (Paatero et al., 2006).

External radiation

The external dose rate was not significantly affected by the radioactivity in the ground-level air. The first alarm leading to a nation-wide alert occurred at Kajaani, north-eastern Finland, on the evening of 27 April 1986. A monitoring station of the Ministry of the Interior measured an increased exposure rate value of 0.1 mR/h (≈ 1 μSv/h) in connection with a rain shower scavenging the radionuclides to the ground (Finnish Centre for Radiation and Nuclear Safety 1986b). However, at the time the ground-level air there, as well as in most of Finland, was still practically clean from artificial activity excluding the above mentioned Nurmijärvi (Mattsson and Hatakka 1986).

Two days later, 29 April, a rain area moved from the west coast of Finland in an easterly direction. The rain scavenged the activity to the ground causing notable increases in the external dose rate at several monitoring stations. The recording of the external radiation in Uusikaupunki, on the west coast of Finland, is depicted in Fig. 8. The local rescue chief reported 2 May 1986 that the rain started just after the noon, at 12:30, of 29 April 1986 (Paatero et al. 2010a). Within three hours there was a 20-fold increase in the external dose rate. After its maximum, 3.7 μSv/h at 20:00 of 29 April 1986, the dose rate started to decrease with a half-time of 4.8 days. This suggests that much of the external radiation was due to ^{131}I (half-life 8.0 days) and ^{132}Te/^{132}I. The half-lives of ^{132}Te and ^{132}I are 3.2 days and 2.3 hours, respectively.

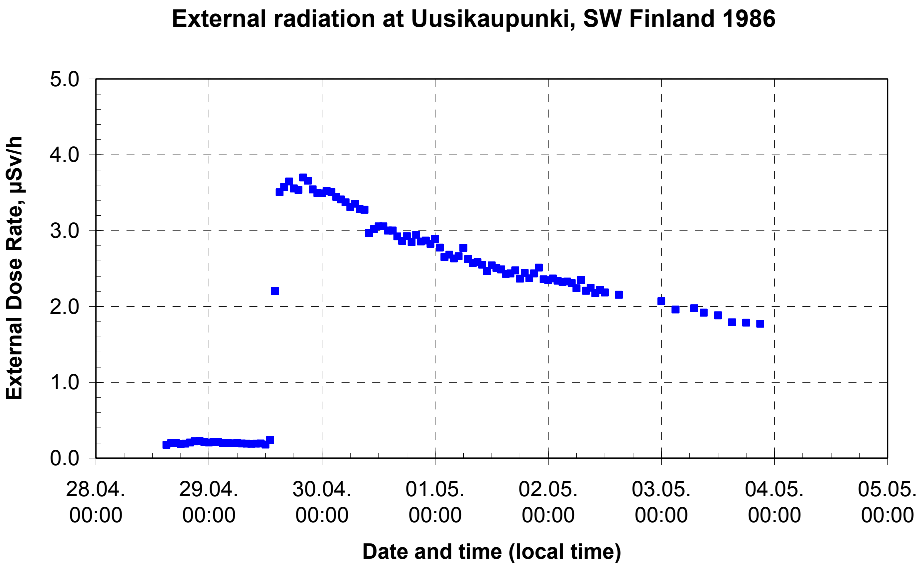

Fig. 8. External dose rate (μSv/h) in Uusikaupunki 28 April – 4 May 1986 (Data: Ministry of the Interior, Rescue Department).

Conclusions

The Chernobyl accident once again showed how a released radioactive or otherwise hazardous plume can, under certain meteorological conditions, rapidly move over long distances. A similar case was observed in December 1966 when radioactivity from a leaking underground nuclear test in Semipalatinsk, Kazakhstan, then USSR, was transported to Finland in three days (Kauranen et al. 1967).

In Finland medical consequences of the accident were mild and mostly psychological. No increase in birth defects or thyroid cancer occurrence has been observed in Finland (Harjulehto-Mervaala et al. 1992, Auvinen et al. 2001, Ikäheimonen 2006).

The Chernobyl accident revealed serious shortages in information dissemination between different agencies in Finland and abroad and to the mass media and the general public. After the accident a lot of resources in Finland were invested to improve the situation. These actions include both technical and organizational improvements. The authorities participating in the national radiation surveillance programme were able to obtain a variety of new radiation measurement equipment during the months and years following the accident. An important lesson was also that the proper functioning of the operational weather service, including weather observations, numerical weather prediction models and dispersion models utilising the previous two, has to be secured in all circumstances. Finnish authorities and university researchers managed, thanks to the experience gained since the late 1950's and the very rapid organisation of a coordinated research programme and funding by the Academy of Finland, to produce a huge amount of data in a very short time period after the accident covering a large variety of radiation protection aspects. Much of the information was gathered by research teams other than the actual radiation protection authorities. A possibility for such an ad hoc cooperation is important in a small country like Finland with limited human, economical and technological resources.

Hot particles from atmospheric nuclear explosions

Lamminmäki, Suvi[1]; Ikonen, Jussi[1]; Siitari-Kauppi, Marja[1]; Lehto, Jukka[1]; Paatero, Jussi[2]; Lipponen, Maija[3]; Zilliacus, Riitta[3]
[1] University of Helsinki, Laboratory of Radiochemistry, FINLAND

[3] VTT Technical Research Centre of Finland, FINLAND

Abstract

Hot particles were often observed with autoradiography in the 1960s and 1970s as a result of the atmospheric nuclear tests. These particles were formed by condensing material, both radioactive and inactive, from the exploding nuclear device, underlying soil etc. The Finnish Meteorological Institute (FMI) has monitored atmospheric radioactivity since the early 1960's at several monitoring stations in Finland by collecting aerosol particles onto paper or glass-fibre filters. After the measurement of total beta activity the collected filter samples have been archived. Since the mid 1960s some of the filters were also examined with autoradiography. Hot particles were frequently observed after atmospheric nuclear tests in Lop Nor, People's Republic of China. In this work the archived filters were analysed by digital autoradiography for screening the radioactive particles from them. Further analyses were done by scanning electron microscopy and energy dispersive X-ray spectrometer to study morphology, size and surface elemental composition of the localized radioactive particles. Based on electron microscopy results gamma and alpha measurements were performed. After this the samples were analysed by fission track technique to find out if fissile material is present in the particles. ICP-MS analyses were performed to determine plutonium and uranium content of the particles. Pu-239/Pu-240 ratios were determined with a sector mass spectrometer and U-235/U-238 ratios with a quadrupole mass spectrometer. The objective was to utilise modern instrumentation in the detection and analyses of hot particles in order to get new information on their physical and chemical characteristics. Contrary to particles found in e.g. lake or sea sediments or ice cores, the particles can be connected to individual nuclear tests. According to the preliminary results, uranium and plutonium were found in particles with a diameter of about 10 microns.

Biological dose reconstruction techniques operated by BfS

Romm, Horst; Oestreicher, Ursula; Kulka, Ulrike
Federal Office for Radiation Protection (BfS), Dept. Radiation Protection and Health, GERMANY

Abstract

Biological dosimetry is an internationally established, independent method, employed in the area of radiation protection. Mainly utilised in addition to physical dosimetry, biodosimetry provides a chance for individual dose reconstruction and is often performed after an unclear or suspected radiation exposure in man. The field of application involves detailed individual dose assessments as well as fast, rough estimations in case of a large-scale radiological event. In this context, special cytogenetic markers such as chromosome aberrations and micronuclei analysed in blood lymphocytes turned out to be highly reliable and solid biological endpoints and are therefore widely used for biodosimetry purpose. The Federal Office for Radiation Protection (BfS) operates a laboratory which represents the national reference laboratory for biodosimetry in Germany. The focus lays on the dicentric analysis with dose effect curves for various radiation qualities, on FISH-analysis of stable translocations and on the analysis of micronuclei. The method of choice depends on the particular circumstances. Over the years, individual dose estimations in one or only a few persons have been a routine task. However, a new challenge has emerged in recent years in the form of a possible large-scale radiological event with the potential to involve a large number of exposed persons. In order to be prepared to act in an efficient manner in such an event, the BfS biodosimetry laboratory has improved its own capacity, in particular by increasing the throughput of analysed cells, e.g. by automation or by optimisation of the calculation mode in dependence of the required information. Nonetheless, the power of a single laboratory is only limited. To meet the requirements in case of a mass casualty, the BfS has established close working arrangements with several biodosimetry laboratories in Europe as well as on international level and is actively involved in national and global networking.

^{85}Kr in industrial krypton gas: origin, identification and dosimetry

Fischer, Helmut W.[1]; Bielefeld, Tom[1,2]; Hettwig, Bernd[1]

[1] University of Bremen, Institute of Environmental Physics, Bremen, GERMANY

[2] Belfer Center for Science and International Affairs, Harvard Kennedy School, Cambridge,MA, U.S.A.

Abstract

Industrial krypton gas is produced by fractionated distillation of liquefied air, in which it has a natural abundance of about 1 ppm_V. The radioisotope ^{85}Kr is present in the atmosphere at a concentration of about 1.5 Bq/m^3, due to continuous emissions from nuclear installations. Pure krypton gas thus will contain 0.35 MBq/kg of ^{85}Kr, and gas cylinders will contain many MBq of the isotope, making it detectable by radiation monitors. A case of an explosion of such a cylinder inside a facory building with subsequent detection of increased radiation levels by the fire brigade, followed by evacuation of the building and decontamination of persons, is reported in the U.S. press.

We report on a case of transcontinental transport of krypton gas, triggering of a radiation alarm and subsequent in situ measurement by different radiometric techniques. Quantitative in-situ gamma spectroscopy identified the isotope ^{85}Kr and revealed activity levels consistent with its atmospheric concentration and with measured and calculated dose rate values.

Possible other cases of such „TEARM“ (technonogically enhanced artificial radioactive material) and possible techniques for detection and discrimination from attempts of nuclear smuggling are discussed.

Introduction

The radioisotope ^{85}Kr is a main fission product and contributes significantly to the releases of nuclear power installations. The main emissions occur during fuel reprocessing and are estimated as about 10^4 TBq/GW·yr (UNSCEAR 2000). In 2008, the main emitter worldwide was the fuel reprocessing plant at La Hague, France, having released about $1.55 \cdot 10^{17}$ Bq of this isotope (BMU 2009). The atmospheric distribution is homogeneous and currently the equilibrium between atmospheric releases and radioactive decay results in a concentration of ^{85}Kr in air of about 1.5 Bq/m^3, relatively constant with location and time.

The radiological properties of ^{85}Kr, apart from the well-known half-life of 10.756 yr and $ß^-$ decay mode, include a low-abundance (0.43%) gamma emission of 514 keV.

Stable krypton is an inert gas, which is present in the Earth's atmosphere at a concentration of about 1.1 ppm$_V$ (CRC 1984, Aoki 2005). It is used industrially in the production of halogen sealed beam headlights and high-efficiency dual-pane and triple pane windows. Pure krypton is obtained by fractionated distillation of liquefied air. Given the abovementioned concentration of ^{85}Kr in the atmosphere, a ^{85}Kr concentration in pure krypton of about 350 kBq/kg can be predicted.

The documentation for industrial krypton gas mentions the „slightly radioactive“ property (Air Liquide 2005a), in one case a value of 300 Bq/g is given for the activity concentration (Air Liquide 2005b).

Press records reveal an event involving the explosion of a krypton gas cylinder in a factory building located in Jacksonville, FL, USA, on January 31 2006 (New York Times 2006, First Coast News 2006). During rescue operations, a radiation alarm was triggered, and in consequence, about 40 persons were decontaminated. Apparently, the radioactive propertiy of pressurized krypton was neither known to the company using it nor to the first responders, nor was the uselessness of decontamination measures known when dealing with an inert gas.

Material and methods

Record of events

A cargo of industrial krypton in 159 steel cylinders, each containing about 30 kg of pressurized gas, was shipped from Russia to the U.S.A. by truck and ship. On its way it had activated a radiation alarm during a border crossing in East Europe, but was allowed to continue its itinerary. No records of the measurement had been taken, and none of the persons involved was aware of the inherent radioactive properties of the cargo. The authors' institution was asked by the shipping company to identify the source of the radiation and to determine the possible dose to workers during a planned manual repacking of the cylinders.

In situ measurements

The cargo was investigated using standard handheld instruments (beta/gamma contamination monitor and dose rate meter) in a first field trip, and by application of in-situ high-resolution gamma spectroscopy, using a hpGe detector of 10% relative efficiency, performed one day later. A photograph of the cargo with the dose rate meter in measurement position is shown in Fig. 1. A sketch of the measurement geometry for gamma spectrometry (with the detector in the same place) is displayed in Fig. 2.

Dose and dose rate calculations

External and internal doses and dose rates were calculated by different methods, in order to take into account radiation protection issues of the current situation and of the reported gas cylinder explosion.

Results

Handheld instruments

The measurements using handheld instruments revealed values about 50% above background (dose rate and count rate of the contamination monitor), at various positions on top of the cargo. Background subtraction resulted in a net mean dose rate of 0.058 µSv/h at the cargo surface. Shielding of natural background radiation from the ground by the cargo was assumed to increase this value.

Fig. 1. Cargo of steel cylinders containing pressurized krypton gas, with the dose rate meter in measurement position.

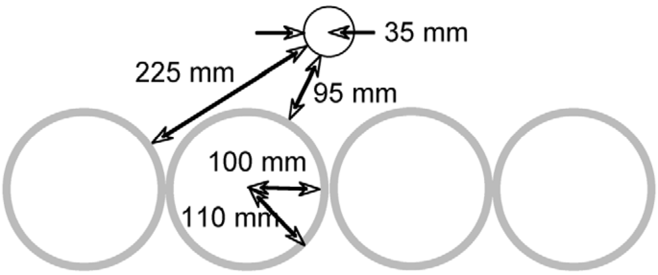

Fig. 2. Schematic representation of the geometry applied in the gamma spectrometry measurements.

Calculation of dose rate from activity concentration

After the first set of handheld meter measurements, an attempt was made to estimate the expected dose rate under the hypothesis of ^{85}Kr being responsible for the increased values. This was done using a handbook developed for photon shielding calculations (Foderaro 1976). The handbook did not provide the complicated geometry present in the measurement (similar to the gamma spectroscopy geometry shown in Fig. 2). Instead, a simplified planar geometry of 20 cm of pressurized krypton gas below 1 cm of steel was used. Including build-up effects, a dose rate of 0.074 µSv/h was obtained. The measured dose rate increase above the cargo was 0.058 µSv/h, plus an unquantified contribution from shielding of natural background. In view of this uncertainty, the result could be considered satisfactory.

In a second calculation, the Monte Carlo code EGS-Ray (Kleinschmidt 2001), which is based on the code EGS4 (Nelson 1985), was used with the same goal. Here, the geometry could be modelled more precisely, resembling the structure shown in Fig. 2. The obtained result was 0.77 µSv/h, in good agreement with the estimate based on tables.

Calculation of internal and external dose after a krypton gas release

Internal and submersion doses for the case of a release of krypton gas were obtained by applying tabulated dose conversion factors. The applied scenario was the complete release of the content of one gas cylinder (about 30 kg) and its homogeneous distribution within an air volume of 10,000 m^3, like it could be expected in a factory building, leading to an activity concentration of about 1000 Bq/m^3. The exposure time was taken as 10 minutes, and no ventilation was assumed (both values together were intended to be conservative for most situations). Dose conversion factors were obtained from ICRP Publication 72 (ICRP 1996) and German state regulations (BfS 2001). The former include doses from inhalation together with beta and gamma submersion, whilst the latter, also based on the ICRP model, allow for discrimination between the different dose contributions. Results are shown in Table 1 and reveal the dominant contribution of beta submersion. In general, doses are low, but the isotope concentration might trigger radiation alarms.

Table 1. Organ and effective doses resulting from a 10-minute exposure to the content of one krypton gas cylinder released accidentally into the air volume of a 10,000 m^3 building.

Exposure path	Conversion factor (Sv d/Bq m^3)	Data source	Dose type	Dose value (µSv)
Inhalation, beta and gamma submersion	2.2 10^{-11}	ICRP 1996	Effective	1.5 10^{-4}
Gamma submersion	1.4 10^{-13}	BfS 2001	Skin	9.6 10^{-7}
Gamma submersion	7.8 10^{-14}	BfS 2001	Effective	5.4 10^{-7}
Beta submersion	1.1 10^{-9}	BfS 2001	Skin	7.8 10^{-3}

In situ gamma spectrometry

Spectra recorded on the cargo surface (in the geometry shown in Fig. 2) and at 1 m lateral distance both revealed a prominent peak at 514 keV, proving the involvement of ^{85}Kr. The spectra also revealed the 511 keV e^+/e^- annihilation peak and several signals from natural isotopes (indicated in Fig. 3).

After performing a numerical efficiency calibration for the detector in measurement geometry by means of a commercial program (LabSOCS, Canberra Inc.), the obtained activity concentration in the cargo was 0.37 MBq/kg, in very good agreement with the expected value of 0.35 MBq/kg. Furthermore, the comparison of the spectra on top of the cargo and at the side of it revealed a decrease of the peaks resulting from natural background by about 40% or more. This finding supports the assumption of a decreased natural background dose rate above the cargo.

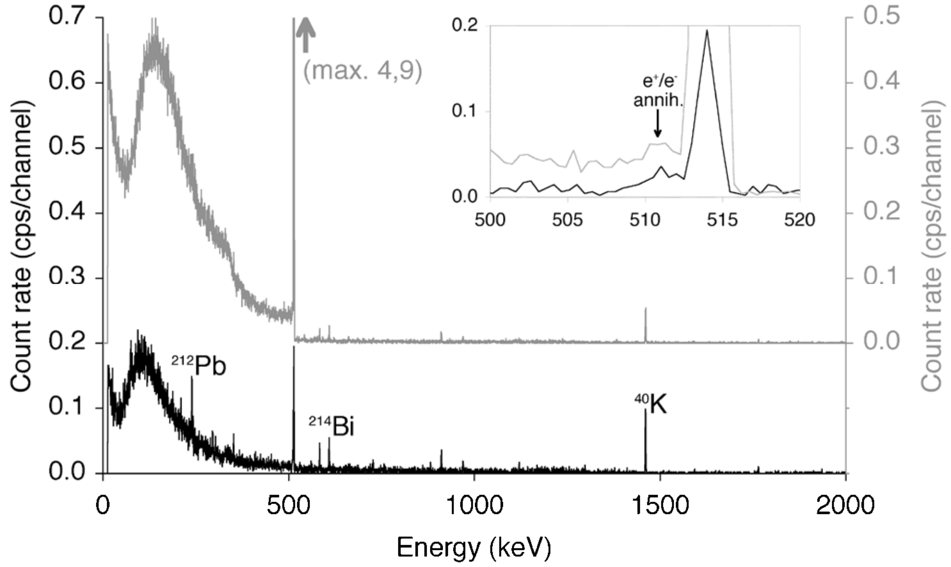

Fig. 3. In situ gamma spectra recorded on top (grey, right y scale) and at 1 m lateral distance (black, left y scale) of the gas cylinders. Spectra have been normalized for count rate. The insert displays the ^{85}Kr peak region, revealing also the 511 keV annihilation peak.

Discussion

By which methods could the isotope be identified unequivocally?

Knowing the concentration and the radioactive properties of ^{85}Kr in pressurized krypton gas, the measured dose rate is already a plausible indication for its presence. The increase of the reading of the (beta/gamma sensitive) contamination monitor by the same factor indicates the absence of external contamination by beta emitters. However, the expected dose rate is not readily available, e.g. in data sheets, and requires considerable knowledge and effort to be calculated. Judged from the present case, gamma spectroscopy appears to be the most straightforward way towards an unambiguous result. As in this case the characteristic gamma energy of 514 keV is extremely close to the 511 keV annihilation line, high resolution is required, requiring a semiconductor detector.

Which occupational doses could be expected?

Due to the low gamma emission probability in ^{85}Kr decay, despite the high activity involved (about 1.5 GBq in total), expected and measured external dose rates are very low.

Could an attempt of nuclear smuggling be excluded?

The overall consistency of the results revealed ^{85}Kr as the main radiation source. An additional source of radiation, which might have been hidden within the cargo, would have been detected in the gamma spectra in case of a gamma source of considerable activity. Pure alpha or low energy gamma emitters would not have been detected, but they would not have been found either by any other radiometric procedures.

Can similar cases be expected in the future?

The authors expect similar findings to appear with increasing frequency, due to the increase of the numbers of radiation monitors at borders, ports, scrap yards and waste repositories. The author's laboratory experience includes findings of ^{60}Co in stainless steel, depleted uranium in scrap metal and ^{131}I in hospital waste. The common property of these objects is their artificial origin and their concentration in specific materials due to human technical action. The authors therefore propose the usage of the term "TEARM" (for technologically enhanced artificial radioactive materials) in analogy to "TENORM" (for technologically enhanced naturally occurring radioactive materials). Labeling of such materials might help to identify them as (often weak) radiation sources and to discriminate them from potentially more hazardous material.

Conclusions

The measurements, calculations and considerations show that

– ^{85}Kr in industrial krypton gas is a weak source of radiation, often unknown to persons involved in its usage or transport;
– it might be advantageous to label materials like krypton gas as "slightly radioactive", indicating expected dose rate levels;
– high resolution in situ gamma spectroscopy appears to be the method of choice in the unambiguous identification of unknown radioactive materials.

Airborne and satellite data acquisition of the contaminated landscape for the countermeasures in agriculture

Hulka, Jiri; Cespirova, Irena
National Institute for Radiation Protection, CZECH REPUBLIC

Abstract

In case of the fallout from large accident of a nuclear power reactor or other large-scale release of radioactivity into the environment, a large area to the extent of 10 000 – 100 000 km^2 could be contaminated. To find out as quickly as possible the extent, magnitude and radionuclide vector of the contamination is important task for agricultural countermeasures and foodstuff restrictions in early/middle phase of accident. In this paper are analyzed the modern data gathering methods of landscape contamination. They are based on combination of satellite technology and airborne gamma dose rate and/or gamma spectroscopy. The issue of optimal height of flight, plane velocity, "hot spot" detection and strategy of mapping process are discussed. This work was supported by the grant of the State Office for Nuclear Safety Czech Republic No. 1/2008 "The new methods for evaluation of landscape contamination after large accident of NPP".

Long-term development of incorporation dose at Korma County (Belarus) after the Chernobyl accident

Dederichs, Herbert; Heuel-Fabianek, Burkhard; Hill, Peter; Lennartz, Reinhard; Pillath, Jürgen
Forschungszentrum Jülich GmbH, 52425 Jülich, GERMANY

Abstract

Radiological long-term measurements were performed between 1998 and 2007 in Korma County, Belarus. The internal radiation exposure of the inhabitants in the village of Volincy was assessed by mobile in-vivo monitoring and has experienced a significant decrease from a high level. This was the result of the decreasing environmental contamination (top soil and crops) and specific advice offered to the population.

Presently the internal dose is only slightly enhanced over background values and of no special relevance to health. It is expected to decrease to less than 0.2 mSv/a in 2011 and to below 0.1 mSv/a in 2020.

Introduction

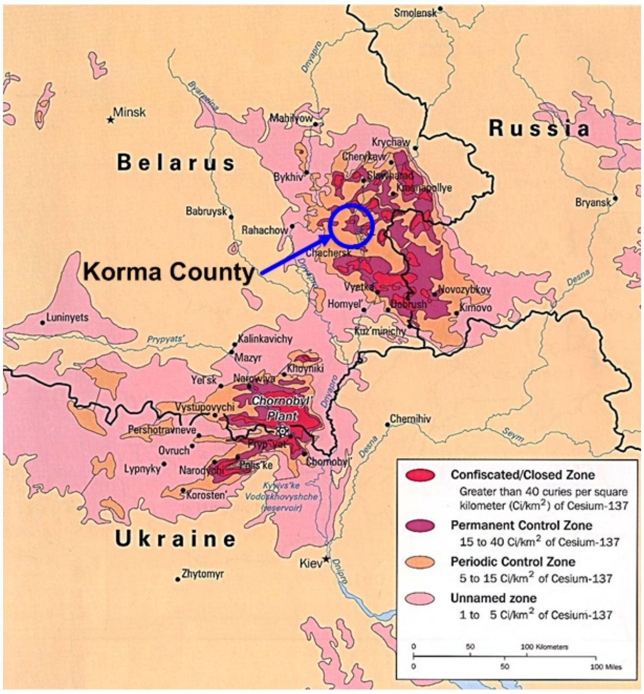

Fig. 1. Confiscated/closed and control zones after the Chernobyl accident; location of Korma County indicated (CIA 1996).

Due to the Chernobyl accident (Hill 2003) in 1986 large parts of Belarus (fig.1) suffered from radioactive fall-out. The German Chernobyl project (Hille et al. 1996] assessed the situation of the population during the years 1991-1993. Approx. 317.000 mobile in-vivo measurements had been performed in more than 240 settlements of Belarus, Russia and the Ukraine. Environmental measurements and some direct measurements of external dose added to the assessment of population dose.

In follow-up studies the long-term development of population dose has been investigated in highly contaminated regions. One project concentrated on the situation in Korma County (Dederichs et al.

2009). The measurements included among others mobile in-vivo monitoring of the population. We report on measurements performed between 1999 and 2007.

Korma County is situated approx. 70 km north of the city of Gomel/Belarus and about 200 km from the Chernobyl NNP (fig. 1). There are areas of comparatively low contamination, but also confiscated zones. The municipality of Volincy is quite remote, since it can be reached only by a road (fig.2) passing through the confiscated zone of Strumen. The municipality of Volincy is situated in the forest belt of Korma County. Though there is some agriculture it can be considered to have a more forestal character. On this account elevated body burdens had to be expected.

Fig. 2. Mobile in-vivo monitoring laboratory on the road to Volincy (Dederichs et al. 2009).

Material and methods

Mobile in-vivo monitoring

Van type mobile in-vivo monitoring laboratories were used to assess body burdens. The most recent version was based on a Mercedes Sprinter van. Fast enough to be moved from Germany to Belarus in a reasonable time and small enough for the small roads typically encountered at the remote areas it still is able to carry the weight of a heavily shielded incorporation monitor. The latter one is a self-designed whole body counter based on two large NaJ-detectors (40cm x 10cm x 10 cm). Data acquisition and analysis is PC-based. The calibration is weight dependent. A brick phantom (Kovtun et al. 2000) had been used to determine peak efficiencies.

Dose calculation

The calculation of dose is based on dose factors directly related to body burdens since a more or less chronical incorporation can be assumed. They were derived from age-dependent dose factors given in ICRP67 (ICRP 1994). For youths and children dose factors were extrapolated for each year of birth.

Results

At the municipality of Volincy mobile in-vivo measurements from autumn 1998 to autumn 2006 and at the municipality of Starograd from spring 2004 to spring 2005 are included in the present evaluation. Measurements were performed for a total of 499 individuals at Volincy and 274 individuals at Starograd. Measurements were sometimes done twice a year (spring, autumn), sometimes once a year (spring or autumn) and there were no measurements in 2003. Though many persons participated regularly in the measurements this has not been the case for everybody. A complete list of more than 2600 measurements including the results for each individual is given in the final report of the project (Dederichs et al. 2009).

In-vivo measurements at the municipality of Volincy

The municipality of Volincy consists of the three settlements Volincy, Kljapin and Klapinskaya-Buda. The conditions of living are slightly different in the three settlements. Measured body burdens (spring values) have been plotted in dependence of the year of birth of the person concerned for each of the settlements individually (Volincy fig.3, Klajpin fig.4, Kljapinskaya-Buda fig. 5).

Generally the highest body burden has been observed at Volincy itself. The bulk of body burdens strayed within a range of values which was more or less the same in each year.

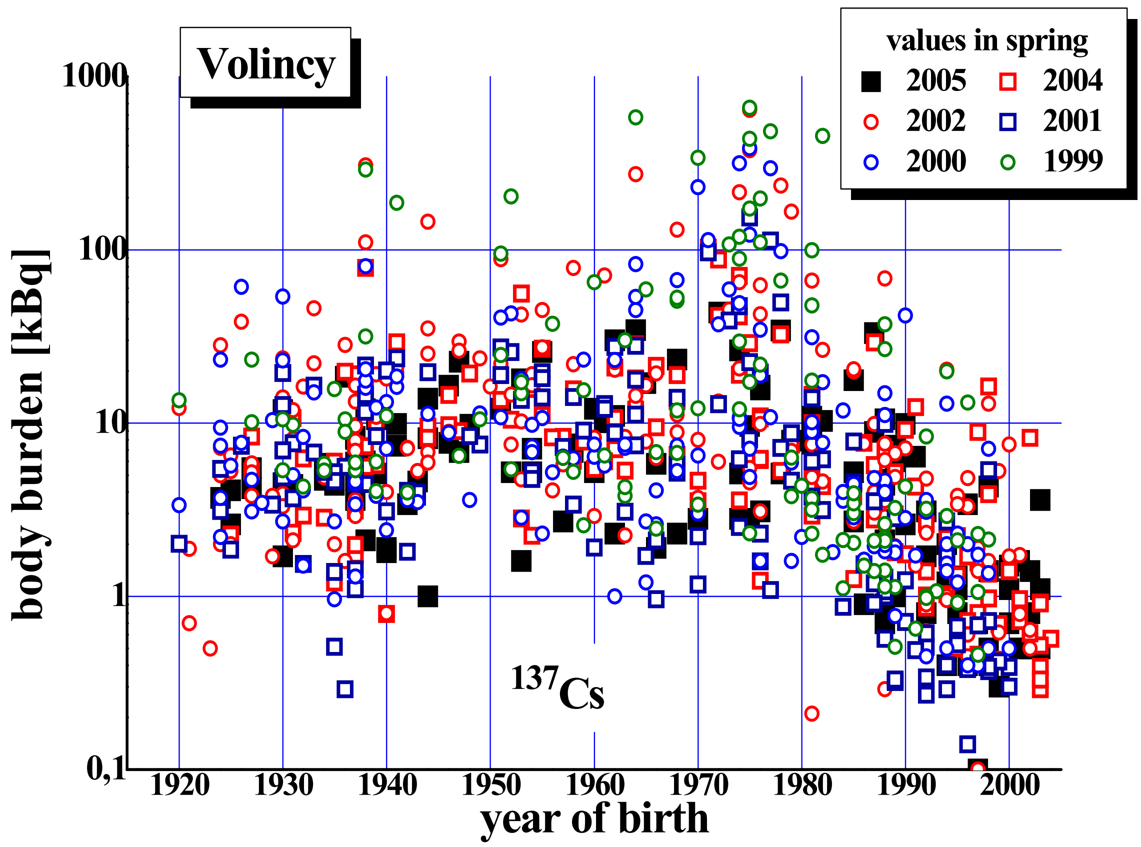

Fig. 3. Body burden (Cs-137) of the population at the locality Volincy (Dederichs et al. 2009).

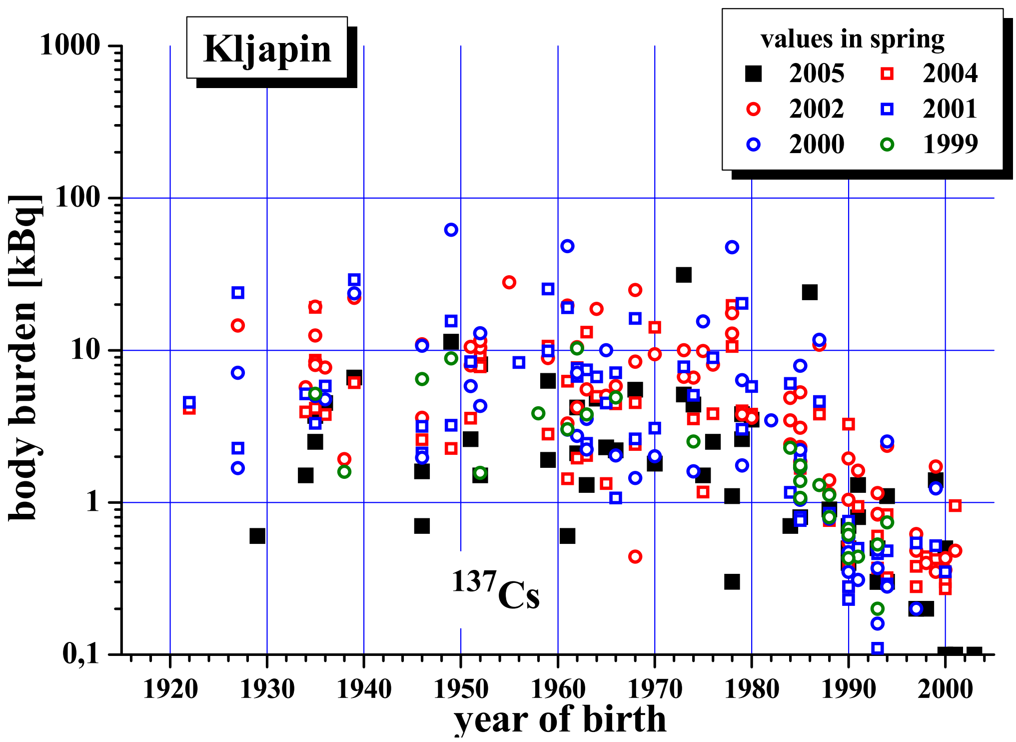

Fig. 4. Body burden (Cs-137) of the population at the locality Kljapin (Dederichs et al. 2009).

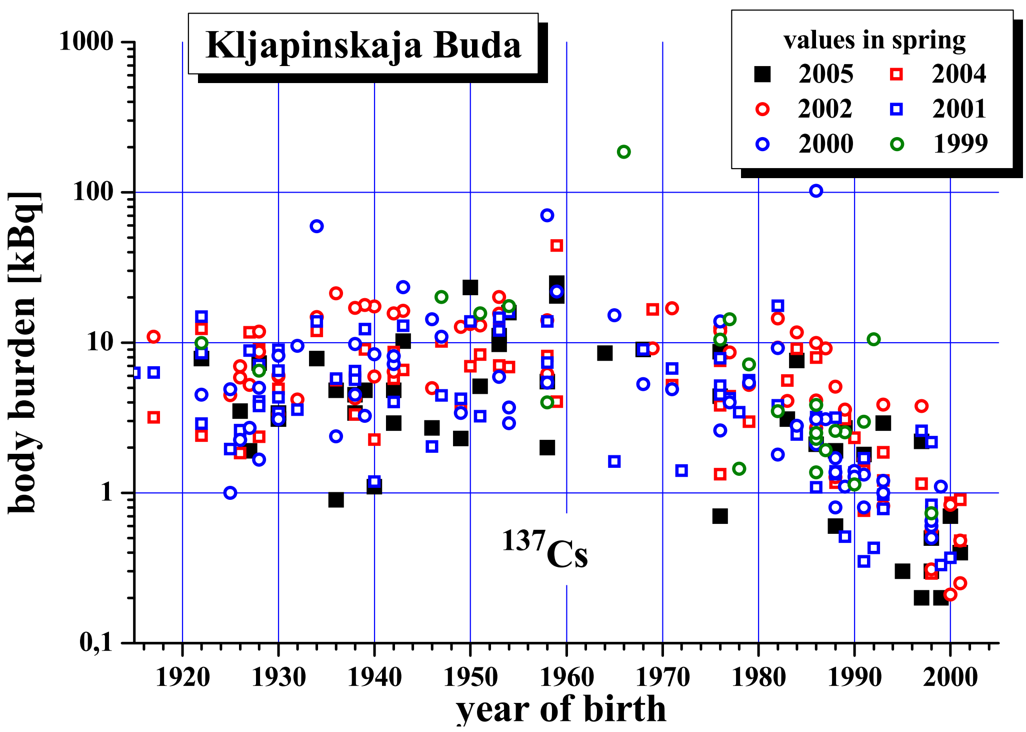

Fig. 5. Body burden (Cs-137) of the population at the locality Kljapinskaya-Buda (Dederichs et al. 2009).

Body burdens at Volincy were in the beginning generally 4 times higher than in the other two settlements and even in 2005 still two times higher. High values of several hundred Kilo Becquerel Cs-137 were occasionally observed and got less over the years. Such values were more common with people born between about 1970 and 1980 than with others. This effect of age was neither seen at Kljapin nor at Klapinskaya-Buda, the latter however not having much inhabitants born in those years. The population of Kljapin is characterized by a large fraction of employees of the local school.

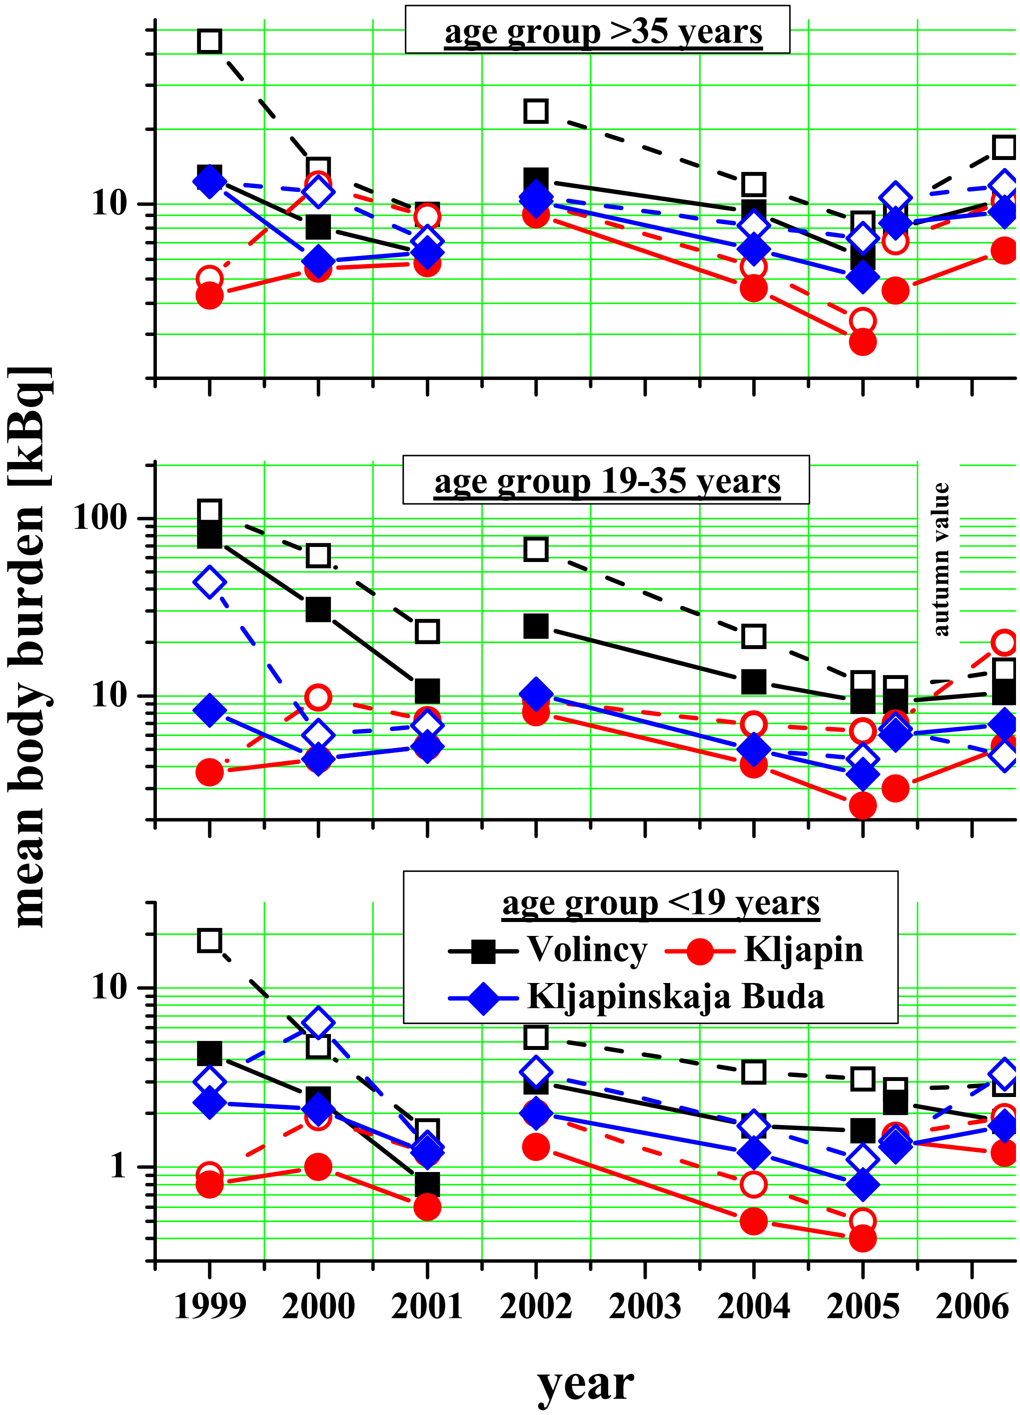

Fig. 6. Time-development of mean body burdens (Cs-137) at the municipality Volincy for different age groups and localities (Dederichs et al. 2009).

The arithmetic means of the body burdens have been evaluated for the municipality Volincy and each of its localities Volincy, Kljapin and Klapinskaya-Buda. Their development with time is shown in Fig. 6 for three different age groups:

- Adults > 35 a
- Young adults (19 a – 35 a)
- Children and other young people (<19 a).

Open symbols represent mean body burdens obtained by including all measurement results. Closed symbols represent mean body burdens calculated by excluding all outliers deviating from the mean more than three times the standard deviation obtained from the variance of the distribution of results.

In 1999 body burdens were quite high, especially in the locality Volincy. Over the time body burdens generally dropped significantly: 66% at Volincy itself and about 50 % in the other two localities. This can be compared to a decrease of Cs-activity in the environment of about 30%. It should be noted that people had been individually advised on possible means of dose reduction by the measuring team.

A first period of funding ended in spring 2001. Villagers did not expect an early continuation of the field missions and the campaign in spring 2002 somehow seemed to catch them by surprise. The discipline in following dose avoidance procedures had begun to decrease and not surprisingly the mean body burden increased significantly. However at continuation of regular field missions in 2004 mean body burdens had dropped down back to reasonable values.

To account for seasonal effects some measuring campaigns have been performed in autumns. In spring 2006 no assessment could be done since the municipality Volincy was not accessible by the mobile in-vivo monitoring laboratory due to high waters at the river Sotch. The mean body burdens for autumn 2005 and autumn 2006 are comparable. Only the age group of adults older than 35 years shows a slight enhancement, which is attributed to the consumption of mushrooms and the especially large number of mushrooms available in 2006.

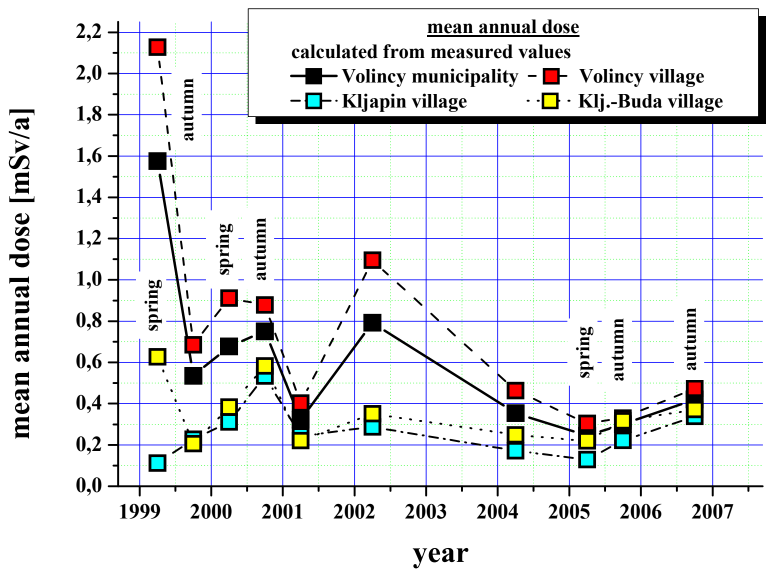

Fig. 7. The mean annual dose due to internal contamination (Cs-137) observed for different localities in Volincy municipality (Dederichs et al. 2009)

Internal doses have been calculated from measured body burdens individually. It has been assumed that for conversion to annual dose a seasonal factor of one can be applied. The mean annual dose is shown in fig. 7 for Volincy municipality as a whole as well as for the three localities separately. No distinction has been made between the different age-groups. Outliers have been included in the calculation of the mean. Though age-dependant dose factors have been applied time-development of the mean annual doses show the same tendencies already observed for the underlying body burdens: sharp drop from high to moderate values, increase in 2002, back to reasonable values in 2004 and stabilization of doses received in subsequent years. Especially in spring 1999 some rather high individual doses have been observed , in one case even exceeding the annual limit for professional radiation workers and in some other cases getting quite close to it.

In-vivo measurements at the municipality of Starograd

At Starograd and its different localities measurements were performed in spring 2004 and spring 2005. The people measured were mainly pupils, as can be seen from fig. 8 which is once more a plot of body burden against year of birth. Body burdens at Starograd are much lower than in the municipality of Volincy. The contamination of ground is comparatively low and the municipality's basic character is more agricultural. There is no necessity to plot the results obtained for the different localities of Starograd separately. The results correspond to internal doses of less than 0.1 mSv/a, with the exception of one single child, which only slightly exceeds this value.

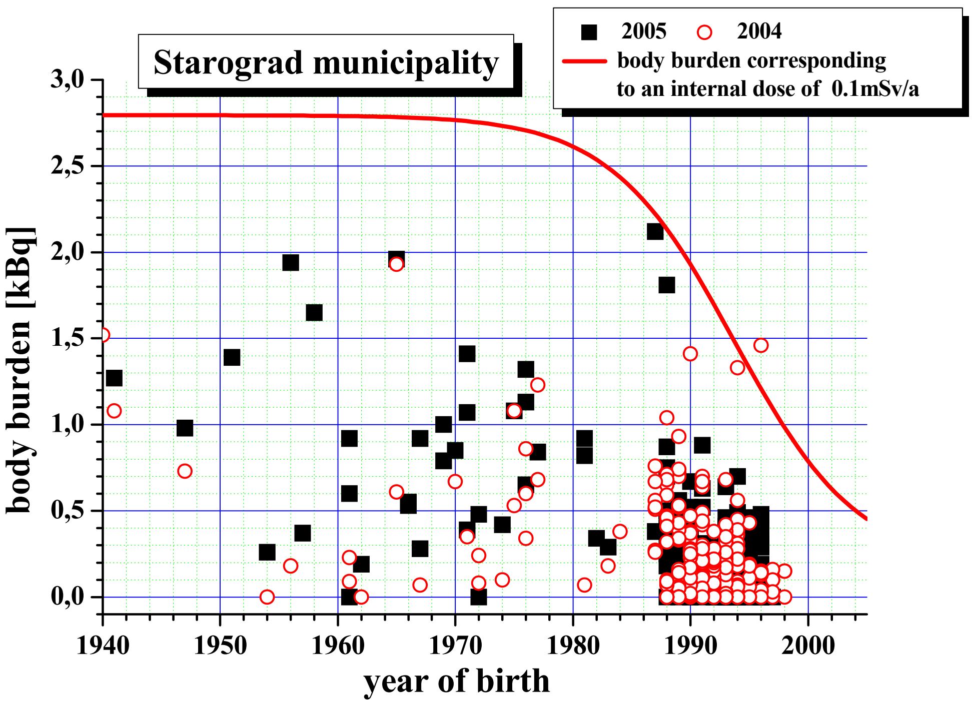

Fig. 8. Body burden (Cs-137) of the population at the municipality Starograd (Dederichs et al. 2009).

Discussion

In 1999 body burdens were quite high. Over the time body burdens dropped significantly. Besides the knowledge of the personal burden individual advice provided by the measuring team led to a changed attitude towards the consumption of contaminated food. Body burdens stabilized at more reasonable values. A slight increase in autumn 2006 is believed to be connected with the measuring campaign correlating with the end of the mushroom season and especially large harvest of mushrooms.

Comparison of different population groups at Volincy

The body burden of children and teens is quite low. Mean values of internal dose where below 0.2 mSv/a both at Kljapin and Klapinskaya-Buda after autumn 2000, at Volincy below 0.3 mSv/a. Children and teens usually receive meals at school where ‘clean’ foodstuff is used. It is obvious that additional meals taken at home do not create any considerable internal burden.

In the age group of 19-35 years old the situation is completely different. Whereas in the other two settlements the mean internal dose is comparable to other adults, at Volincy up to the 4-5 fold has been observed in some years. After thorough individual counselling mean values finally in 2005 and 2006 got more close to those of the older adults. It seems that members of this age group were especially careless in consuming forest products and contaminated meat.

Generally men seem to have about two times higher body burdens than women. About the cause can only be speculated (different composition of food, different fat/muscle ratio….).

Comparison of agricultural and forestal districts

The municipality Volincy is situated in a forestal area with elevated ground contamination, whereas the municipality Starograd is situated within an agricultural area which belongs to a part of Korma County where deposition of Cs-137 had been comparatively low.

Mean values of body burdens at Volincy and Starograd are shown in table 1 for the years 2004 and 2005. For the total population the incorporation in Volincy is about 20 times higher than in Starograd. This is more than the difference in deposition would count for.

It is known (Dederichs et al. 2009) that agricultural products and garden products contain considerable less activity than forest products. Forest products contribute essentially to body burdens observed.

The huge difference in body burdens is in agreement with an habit of consuming local food with no or only marginal exchange of products between different settlements of the county.

Table 1. Comparison of mean values of body burdens at the municipalities of Volincy and Starograd.

Population Group	Volincy 2004	Starograd 2004	Volincy 2005	Starograd 2005
Total	8.1 ± 7.0 kBq	0.38 ± 0.28 kBq	5,7 ± 4.9 kBq	0,28 ± 0.23 kBq
Adults	12,2 kBq (19-35 a) 8,5 kBq (>35 a)	0,84 kBq (> 18 a)	7,1 kBq (19-35 a) 6,4 kBq (>35 a)	0,52 kBq (> 18a)
Children and youths	2,4 ± 4,1 kBq	0,27 ± 0,18 kBq	1,6 ± 2,1 kBq	0,23 ± 0,19 kBq

Contribution of internal dose to population dose

The internal dose is only part of the population dose. Within the project also the contribution of the external dose has been evaluated. It could be shown that in the municipality of Volincy the major part of population dose is due to the external dose. Over time it seems to drop more slowly than the intermal dose (Fig. 9).

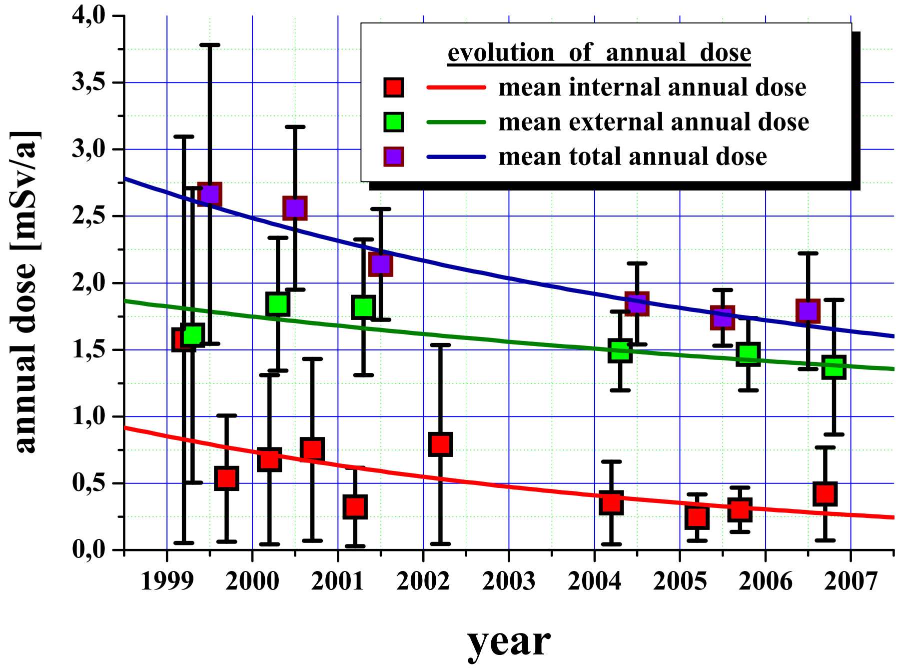

Fig. 9. Evaluation of annual dose at Volincy from 1999-2007 (Dederichs et al. 2009).

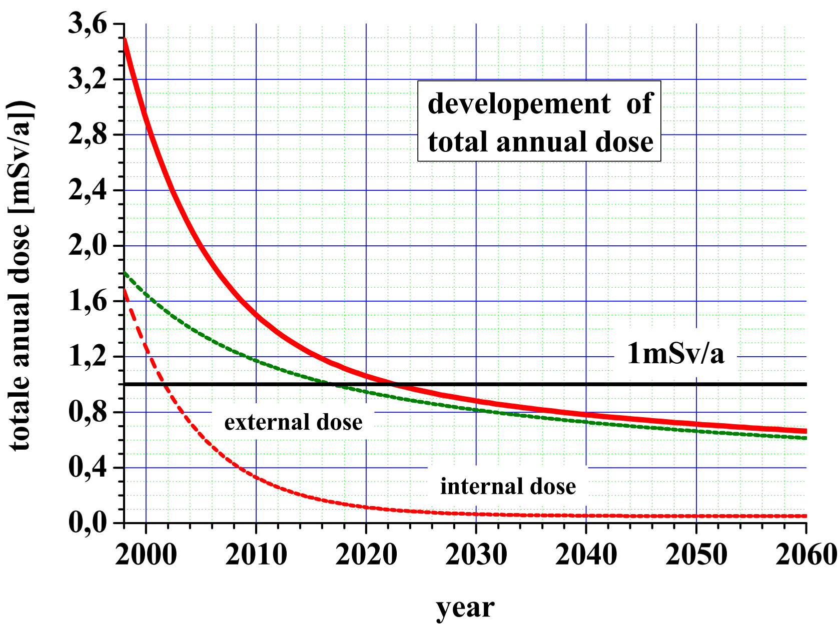

Fig. 10. The projected long-term development of population dose at Volincy (Dederichs 2009).

A model of the transfer of Cs-137 in the environment (Dederichs et al. 2004) has been applied to investigate the long-term development of population dose. The results are shown in fig.7. The mean annual internal dose (Cs-137) is likely to drop below 0.3 mSv in 2010. This value is comparable to the dose typically received from the natural body content of K-40.

In the years to come internal dose will gradually become negligible in relation to external dose, which already now governs population dose. It should be noted that the underlying estimation of external dose is rather conservative. Hence in the real world the population dose might drop below 1 mSv/a already before the year 2022 as forecasted by the model.

Conclusions

Generally the mean incorporation dose is about to drop below 0.3 mSv/a , a value comparable to the dose obtained by the body content of K-40. This was the result of the decreasing environmental contamination (top soil and crops) and specific advice offered to the population.

Presently the internal dose is only slightly enhanced over background values and of no special relevance to health. It is expected to decrease to less than 0.2 mSv/a in 2011 and to below 0.1 mSv/a in 2020.

Acknowledgements

The funding by the German Federal Office for Radiation Protection and the Walter-Gastreich-Trust are greatfully acknowledged. We are indebted to J. Höbig, W. Marquardt, H. Mertens and H. Preiß, who took part in the measurements.

A real-time interaction environmental survey management system for nuclear and radiological emergencies

Fang, Hsin-Fa; Chang, Bor-Jing
Institute of Nuclear Energy Research, TAIWAN

Abstract

In emergency events, environment could be polluted very severely and need a variety of environmental surveys. The environmental survey workers may be exposed to radiation and radioactive pollution. There is a need to confirm these survey workers are safe when they are working for emergency response.

This study attempts to establish a management system with real-time interaction for environmental monitoring, which could analyze monitored environmental quality immediately, and manage the plans and areas of monitoring action online. The plans and areas of monitoring action could be adjusted interactively according to the managers' decision and monitoring results of environmental radioactivity. If the analyzed monitored results of the environmental quality exceeds a threshold standard, it can be an index of warning. Another purpose of this study is to provide a management system which could provide a safe area of monitoring actions with real-time interaction for environmental monitoring teams. The management has a data processing apparatus which could analyze the monitored data of the monitoring apparatus and send warning signal when it found that the monitored data exceeds threshold value. Then the monitoring teams and personnel could execute the work in safety.

Introduction

After nuclear power plant accidents at Three Mile Island and Chernobyl, Taiwan has intensified the efforts on the works of radiological emergency response and preparedness as other countries. Institute of Nuclear Energy Research (INER) belongs to Atomic Energy Council, Taiwan. One of INER's important mission is to continuously develop the tool for nuclear and radiological emergency response and research the effective strategy and police. However, the 911 event in 2001 in USA made us realize that the environmental survey for radiological emergency should be more active than conventional methods because of the increasing uncertainty on locations, environments, source terms, and occasions of radiological emergency events.

INER launched a project for establishing a mobile environmental survey system for Taiwan in 2003. At that time, Internet and geographic information system (GIS) have become the essential technologies of radiological emergency response that should be good at monitoring and data management for communicating and decision making [Jaromir Kolejka et al. 2002; NEA 2000]. We also noticed that GPRS (General Packet Radio Service), one of early stage wireless data internet services provided by GSM (Global System for Mobile communications) network, was in service in Taiwan and thought it can help submitting data real-time for environmental survey. Finally, we established a mobile survey system for the survey task of radiological and nuclear emergency in 2004. The mobile survey system was tested by encircling Taiwan Island mission. There was no monitoring data lost in the mission that shows very good network stability. After the successful mission, the system has been used in the radiological bomb emergency and nuclear emergency exercises in recent years.

There are more and more attentions paid on the safety and health of first responder. U.S. Department of Homeland Security (DHS) issued ”Planning Guidance for Protection and Recovery Following Radiological Dispersal Device (RDD) and Improvised Nuclear Device (IND) Incidents HS Planning Guidance provided a summary of radiation emergency worker guidelines (DHS 2008). Following that, “Planning Guidance for Response to Nuclear Detonation” was developed by U.S. Homeland Security Council (DSC 2009). This guidance emphasizes that Incident Commanders should make every effort to employ the “as low as reasonably achievable” (ALARA) principle when responding to an incident. Protocols for maintaining ALARA doses should include the following health physics and industrial hygiene practices.

The assessment error of evaluating contamination distribution for emergency response is usually very high comparing to real monitoring data. The error could lead first responder to a dangerous situation and exposure an unnecessary radiation dose. This study attempts to establish a management system with real-time interaction for environmental monitoring, which could analyze monitored environmental quality immediately, and manage the plans and areas of monitoring action online. The plans and areas of monitoring action could be adjusted interactively according to the managers’ decision and monitoring results of environmental radioactivity. If the analyzed monitored results of the environmental quality exceeds a threshold standard, it can be an index of warning. Another purpose of this study is to provide a management system which could provide a safe area of monitoring actions with real-time interaction for environmental monitoring teams. The management has a data processing apparatus which could analyze the monitored data of the monitoring apparatus and send warning signal when it found that the monitored data exceeds threshold data. Then the monitoring teams and personnel could execute the work in safety. We hope this study could give first responder more safety and health.

Material and methods

The primary working framework of the mobile survey system is shown in fig 1. The system consists of the mobile unit and the monitoring center. The mobile unit and the management center are connected by the wireless data service network (GPRS, 3G, HSDPA, et al.). The mobile unit was operated by a PDA initially, but it has been extended to could be operated by smart phone or notebook now. The monitoring center is operated by a server with GIS and SQL database. The coverage of wireless data network service is very good in Taiwan. The monitoring data collected from remote place could be displayed on the screen of the monitoring center in 10 seconds normally in the encircling Taiwan Island mission.

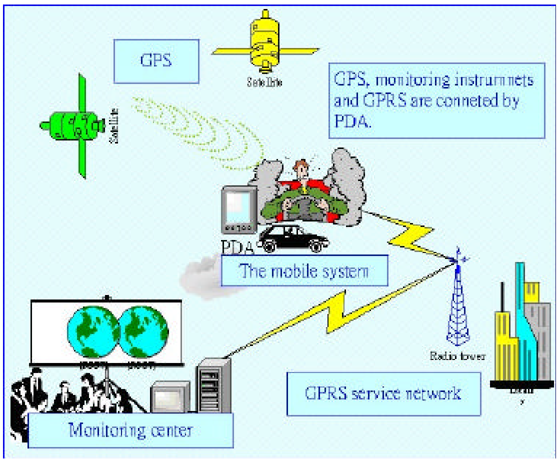

Fig. 1. The primary working framework of the mobile survey system.

The mobile unit could receive the survey mission map in a GIS electronic map format. Then the environmental survey workers execute environmental survey according to the map. The map also could include the GIS information of survey mission and dangerous areas and their expected survey data values. The warning signal of the mobile unit will be initiated when it gets into any dangerous area or the survey data value exceeds the preset limit of the specific areas. The preset limit of the specific areas can depend on the assessment results or regulation. The monitoring center can update the survey mission map according the new survey results and send the new mission map to the mobile unit through wireless data network immediately. The procedures could be explained by Fig. 2. The system could check the position data and the monitoring data automatically. It also could calculate the error between the monitoring data and the prior assessment if it found the monitoring data did not comply with the tolerance limit of the prior assessment. When the monitoring data exceed the preset limits, the monitoring center will send the warning message to the mobile unit and display is on its screen. The update of the mission map is determined by the survey manager.

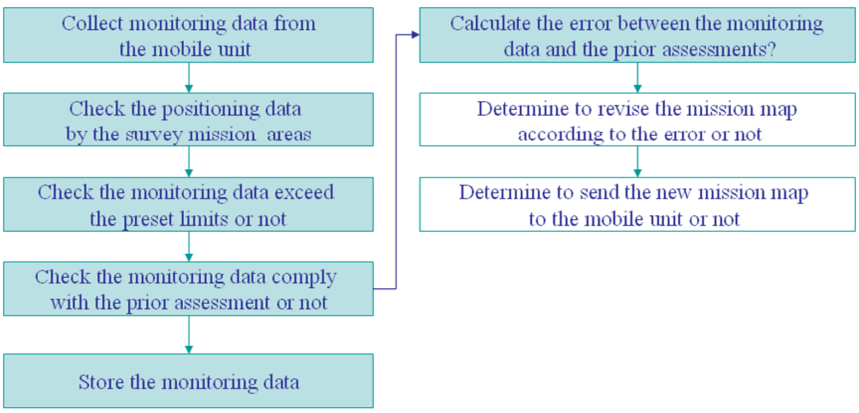

Fig. 2. The procedures for updating the mission map.

The mission map needs to be revised by the survey manager's professional judgements before sending to the mobile unit. The revision mainly depends on the error. The system provides a function to get the correction factor from the error to adjust the preset value of the survey mission map. The manager could determine the final value of the correction then the system will change its survey mission map automatically. The survey manager could examine and investigate the survey the survey mission map before pushing the bottom to send the new survey map to the mobile unit. Figure 3 is the screen of the mobile unit showing the survey mission map and its position.

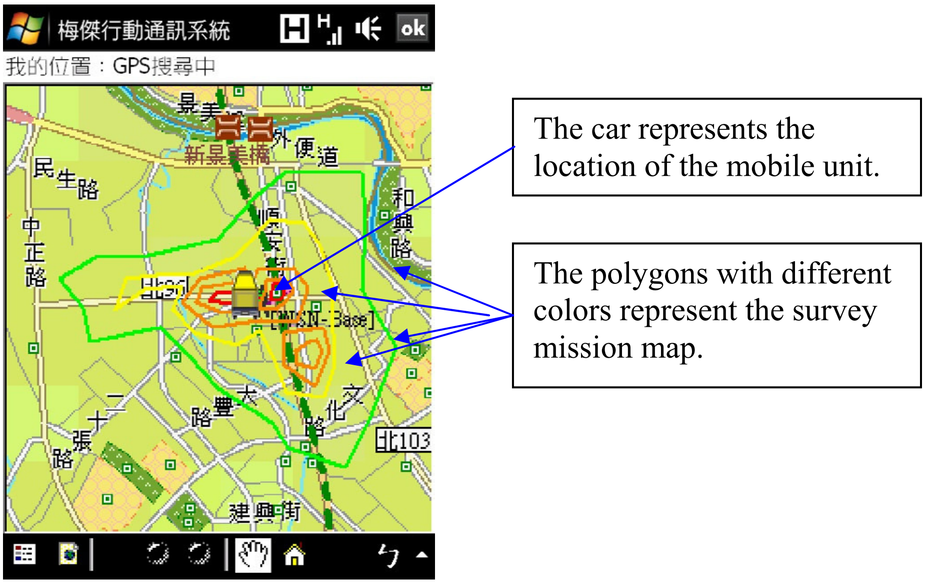

Fig. 3. The mobile unit and the survey mission map.

Discussion

The development of information and communication technologies has provided opportunity and stress. INER has established a mobile survey system that can really support environmental surveys, especially for nuclear/radiological emergency response. The benefits include:

- ✧ Visulization of showing the survey results;
- ✧ Imporving the ability of integrating survey data and relative information;
- ✧ Higher quality and quantity for collectind survey data;
- ✧ Inquiring survey data and making reports sooner;
- ✧ Interactions between the field survey workers and the survey manager;
- ✧ Better ability to reanalyze the data (fig. 4).

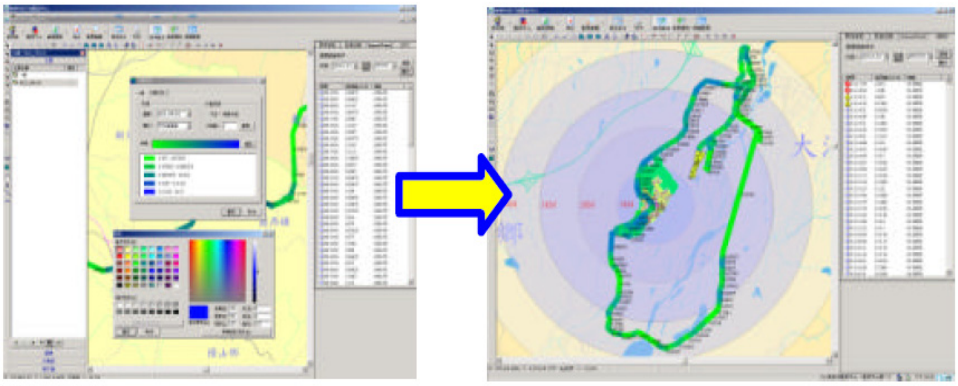

Fig. 4. Reanalyzing and visualizing survey results by classification with colours.

The protection of survey worker for emergency response has become a very important issue recently. However the environmental situation could change very quickly. A real-time interaction environmental survey system could be a very effective and helpful tool to the issue. That is a major purpose of developing our mobile survey system. The mobile units can get the survey mission map from the monitoring center before the survey workers go to the field of the nuclear/radiological events. The survey workers execute the mission according to the survey mission map. When the mobile unit arrive in the target area, the survey data will be sent back to monitoring center continuously. The mobile unit also could judge the position of the survey relative to the specific area of the survey mission map and send the relative message to the survey worker, including dangerous warning message. So the survey worker could be protected according to the initial assessment result. After collecting survey data, the survey manager could real-time revise the survey mission map through wireless network. Then the survey workers could be protected according to the real situation.

Conclusions

There are many ways that modern technologies could benefit environmental survey. INER has established successfully a mobile survey system by integrating modern electronic map, positioning and wireless data network that can really support environmental surveys, especially for nuclear/radiological emergency response. The protection of survey worker for emergency response has become a very important issue recently. A real-time interaction environmental survey system could be a very effective and helpful tool to the issue. The mobile survey system developed by INER could be a very effective and helpful tool to the issue.

Detection of and response to nuclear security events

Colgan, Peter John
International Atomic Energy Agency, AUSTRIA

Abstract
The paradigm of nuclear security continues to evolve. Whilst a body of work and a collective with relevant expertise is forming, the relationship and interconnectedness with the fields of nuclear safety and nuclear verification (safeguards) still needs day-to-day management to ensure States have in place an effective judicial, legislative, regulatory and policy framework which, when supported by coordinated implementation procedures, will assist in the prevention of malicious acts upon nuclear and/or associated facilities, as well as reducing the threats posed from the malicious use of lost, missing or stolen nuclear or other radioactive material to harm persons, property, society or the environment.

This is particularly the case in the detection of and response to malicious acts involving nuclear and other radioactive material out of regulatory control. Here the States' traditional response arrangements need to be enhanced and coordinated to ensure that threats posed by criminal or unauthorised acts involving such material, and any dispersal event occurring as a consequence of a successful malicious act, are adequately dealt with in terms of both the need to detect the presence of the nuclear or other radioactive material in the lead-up to a nuclear security event, as well as the proper collection and control of evidence to ensure successful prosecution of the offenders consistent with the relevant international legal instruments to which States may subscribe. This paper outlines these additional considerations.

Introduction
The IAEA maintains an Illicit Trafficking Database (ITDB) which contains confirmed reports of criminal or unauthorised acts involving nuclear or other radioactive material. The ITDB currently contains 1884 confirmed reports from the 110 States that participate.

While the circumstances of each ITDB case vary significantly, some credible reports indicate that criminal organizations have shown interest in nuclear material and facilities. The threats include criminals or terrorists acquiring and using nuclear material to build a rudimentary nuclear explosive device (in the worst case, an existing nuclear explosive device); using a radioactive source as an exposure device or achieving the dispersal of radioactivity by the construction of a radiological dispersal device; or through an act of sabotage at a nuclear facility or other installations or place where radioactive substances are used, stored or transported.

Since the consequences of the use of an improvised nuclear explosive device would be catastrophic, such events cannot be neglected although their probability may be much lower compared to the potential of an RDD or an act of sabotage. Intentional dispersal of radioactivity would, no doubt, have very significant psychological, health and economic consequences.

In responding to the threat the international community has developed a large range of international legal instruments, both binding and non-binding, which taken in their entirety outline the field of nuclear security best practice for States to consider in their ongoing efforts to combat nuclear terrorism. Although many of the international legal instruments were originally drafted to principally address non-proliferation or safety concerns they do, when combined with the newer counter-terrorism instruments originating principally after Sept 2001, contribute to the global framework that defines nuclear security. The primary instruments and documents include:

- Convention on the Physical Protection of Nuclear Material [CPPNM] and its Amendment of 2005 [1],
- International Convention for the Suppression of Acts of Nuclear Terrorism[2],
- United Nations Security Council Resolution 1540 [3]
- Code of Conduct on the Safety and Security of Radioactive Sources [4]

In the broad sense, these instruments deal with nuclear security issues, and in particular they are all related to malicious acts at the sub-national level (i.e. by non-state actors), involving nuclear or other radioactive materials. Combined these instruments require States to, inter alia:

- Criminalize, i.e. make punishable under national law certain offences, such as malicious acts and threats
- Make every effort to establish measures for preventing or protecting nuclear material and facilities and other radioactive material against such acts, and
- Take appropriate actions should such malicious acts occur. In this regard, preparations should include the recovery of material, its return and assistance and cooperation among States and the IAEA.

While recognising the sovereign right of States over matters of security, the IAEA has responded to requests to provide guidance that States can use to meet their committments and obligations with respect to these international legal instruments. The draft versions of this 'top-teir' guidance include:

- Nuclear Security Fundamentals [5]
- Nuclear Security Recommendations on Nuclear Material and Nuclear Facilities (INFCIRC/225/Rev.5) [6];
- Nuclear Security Recommendations on Radioactive Material and Associated Facilities [7]; and
- Nuclear Security Recommendations on Nuclear and Other Radioactive Materials out of Regulatory Control [8].

While the nuclear security series covers the entire spectrum of recommendations to a State in developing and sustaining a nuclear security regime, of particular interest in the inter-relationship between nuclear safety, nuclear verification and nuclear security is the detection and assessment of alarms and alerts and for a graded response to any criminal or intentional unauthorized acts involving nuclear or other radioactive material out of regulatory control. These ‘detection and response’ elements of a nuclear security regime cover the confirmation of a credible threat, assessment and interdiction of an attempted act and response to a nuclear security event and are contained principally in the latter of these documents.

Background

The draft Nuclear Security Recommendations on Nuclear and Other Radioactive Materials out of Regulatory Control document (the draft document) was prepared by the IAEA Secretariat in consultation with experts drawn from Member States, and has been the subject of a Technical Meeting in March 2010. The comments from the Technical Meeting were incorporated, as appropriate, into the draft document which is currently out for 120 day Member State review.

The summary of the more important contents of the draft document are given below, but may be subject to change prior to publication once Member State comments are received. In essence the draft document recommends that for the State to have an effective nuclear security regime for nuclear and other radioactive material out of regulatory control, they need to ensure the existence of two main elements, namely:

- A comprehensive and complete set of legislative provisions through adoption of criminal and administrative laws for providing relevant administrative and enforcement powers to the various competent authorities within the State, so that they can undertake their activities in an effective manner; and
- Provision of sufficient and sustained resources to the various competent authorities to enable them to carry out their assigned functions, including:
    - Measures to prevent a criminal or an intentional unauthorized act involving nuclear and other radioactive material out of regulatory control;
    - Detection, through an instrument alarm and/or an information alert, of the presence or indications of a criminal act or an unauthorized act with nuclear security implications involving nuclear or other radioactive material that is out of regulatory control and, in particular to:
        - develop a detection strategy;
        - establish detection systems; and
        - perform the initial assessment of the instrument alarms and information alerts promptly and assess the possibility of a nuclear security event.
    - Response to the nuclear security event, in particular to:
        - notify the competent authorities
        - assess the validity and potential consequence of the nuclear security event;
        - locate, identify, categorize and characterize nuclear or other radioactive material;

- secure such material and apply other response measures appropriate to the nuclear security event, such as neutralization of the device;
- recover, detain and/or seize and place such material under regulatory control;
- collect, preserve, store, transport and analyse evidence including the application of nuclear forensics measures related to a criminal act or an unauthorized act with nuclear security implications that involves such material; and
- apprehend and subsequently prosecute or extradite alleged offenders.

Legislative, Regulatory, Policy and Administrative Controls

The draft document recommends that, as part of an overall regime, the State should establish and maintain effective legislative and regulatory controls to govern nuclear security, including those that define any conduct which they consider to be a criminal act or an intentional unauthorized act involving nuclear and other radioactive material, and establish such offences as criminal offences under domestic law.

For effective and sustainable detection and response measures, it is important to rely on multidisciplinary infrastructures implemented by several independent competent authorities in the State, and to ensure proper cooperation, coordination, information exchange and integration of clearly defined activities and responsibilities within some form of coordinating body or mechanism

The following list of organisations could have some role in, or may be a competent authority for aspects of the nuclear security regime within a State. Consequently they should, if appropriate, be considered for involvement in this coordinating body or mechanism:

- Judicial bodies;
- Legislative authorities;
- Policy authorities;
- Intelligence services;
- Military forces;
- National threat assessment bodies;
- Law enforcement bodies;
- Border Forces;
- Customs authorities;
- Police;
- Regulatory bodies;
- Medical and/or health authorities;
- National nuclear energy agencies;
- Civil Defence; and
- Emergency Services.

The draft document recommends that the coordinating body or mechanism should inter alia:

- ensure the development of a comprehensive national detection strategy based on a multilayered defence in depth approach within available resources;
- ensure development of a national response plan for any nuclear security event in a graded approach commensurate with the threat and based on available resources;
- oversee the development and implementation of the national detection and response systems;
- re-evaluate and identify possible nuclear security gaps and resource needs and initiate proper corrective actions on a regular basis;
- ensure the establishment of contact points within the competent authorities as part of an overall coordination within the State,
- encourage the timely sharing of operational information among competent authorities within the State;
- ensure the establishment and maintenance of a reliable and comprehensive set of records for each nuclear security event, and encourage the exchange of information among competent authorities concerning any such event, using a common reporting and notification format; and
- ensure appropriate coordination and cooperation with relevant authorities in other States and international organizations.

The functions of the competent authorities as outlined in the draft document should include, inter alia:

- contributing to the development of the national detection strategy and response plan;
- developing, operating and maintaining the national detection systems, assessment procedures and the national response plan and providing the resources necessary for implementing and testing the associated activities;
- providing adequate training and information to all personnel involved in carrying out nuclear security detection and response measures;
- sustaining the detection and response capabilities and ensuring operational preparedness through sound management practices, addressing instrument maintenance, personnel training, exercises and process improvements; and
- cooperating with the coordinating body, other competent authorities and bilateral and multilateral counterparts as applicable, in part to ensure the effectiveness of their detection and response procedures and responsibilities.

The competent authorities would cooperate in the exchange of relevant information on the nuclear and other radioactive material that is authorised or 'under regulatory control', with a view to strengthening the capabilities of all concerned with nuclear security. Where appropriate, they should also cooperate with their counterparts in other States.

The draft document recommends that regulatory authorities should take appropriate actions when nuclear or other radioactive material is reported to be out of regulatory control, i.e., lost, missing or stolen. In particular, they should inform promptly the other competent authorities in the event of a suspected criminal or an intentional unauthorized act.

In addition the draft document recommends assigning priorities and designing the detection and response systems based on a national threat assessment, using a risk based approach in combination with an assessment of the:

- vulnerability to a criminal act, or an unauthorized act with nuclear security implications, both within and outside their borders;
- relative attractiveness of identified targets to a nuclear security threat;
- possible consequences of a criminal act or an unauthorized act with nuclear security implications, that involves the use of nuclear or other radioactive material; and
- possible evolution of the threat or vulnerabilities

Detection Measures

Detection of nuclear and other radioactive material that is out of regulatory control can be achieved via an instrument alarm or an information alert. The draft document recommends that the State should design and implement nuclear security systems based on such indicators, and ensure that the detection measures are supported by effective response measures

In order to prevent illegal transfer of nuclear or other radioactive material and detect the falsification of relevant documents, it is recommended that competent authorities have the power to adopt measures for authenticating documentation and package labelling for authorized shipments and for verifying the declared content of the authorized shipment of nuclear or other radioactive material by appropriate means

Using the national threat assessment, the draft document recommends that competent authorities should establish nuclear security systems for detection by instruments of nuclear and other radioactive material that are out of regulatory control. The detection systems should be based on a multilayered defence in depth approach and on the premise that such material could originate from both within or outside the State, and provide the necessary detection capability and capacity.

To assist in this regard, the draft document recommends that by while taking into account the prioritization of available resources, the competent authorities should develop an appropriate detection instrument deployment plan, considering the following:

- transportation routes inside the State's territory, at locations where likelihood of detection is maximized or in proximity to locations where nuclear or other radioactive material is produced, used, stored, consolidated or disposed;
- the existence of any strategic location;
- operational and detection performance specifications of the detection instruments, in accordance with national and international standards and technical guidelines;
- capabilities, constraints and limitations on detection instruments at both officially designated and non-designated air, land and water border crossings points;

- mobile and relocateable detection systems to provide flexibility and adjustments to evolving threat;
- detection requirements in support of law enforcement operations associated with information alerts; and
- detection of radiation at an event of national significance, such as a major public event or at a strategic location that is considered to be vulnerable to a malicious act using nuclear or other radioactive material.

Further the draft document recommends that the competent authorities should ensure that the following elements are included in the instrument deployment plan:

- initial installation, calibration, and acceptance testing of equipment; the setting up of a maintenance procedure, and the adequate training and qualification of users and technical support staff;
- systems and procedures for conducting a radiation survey or a radiation search for nuclear and other radioactive material out of regulatory control;
- defining threshold levels of an instrument alarm;
- establishing systems and procedures for performing initial alarm assessment and other secondary inspection actions such as localization, identification, categorization and characterization of nuclear and other radioactive material, including obtaining technical support from experts to assist in the assessment of an alarm that cannot be resolved on site; and
- provision and sustainment of supporting infrastructure to ensure effective detection, including personnel training, equipment maintenance, safe and secure disposition of discovered material and documented response procedures.

While the use of instruments is a major method of detecting potential malicious acts involving nuclear and other radioactive material, another major component of detection measures is the detection by the use of information. Here the draft document recommends that the State should continuously gather, store and analyse operational information with the goal of identifying any threat, suspicious activity or abnormality involving nuclear or other radioactive material that may indicate the intention to commit a malicious act within the State. The draft document also recommends cooperation with other States to provide and obtain information for better understanding of any threat, and the development of a policy on the dissemination of information to the news media with the aim of informing the public of lost, missing or stolen nuclear or other radioactive material so as to educate them in the risks associated with the material and to elicit information from the public about such material, taking care not to cause undue public concern.

As part of the information led detection measures the draft document recommends that procedures and protocols are implemented requiring health professionals, medical institutions and health authorities to immediately report the occurrence of any suspicious radiation injuries or illnesses to the relevant competent authorities, in accordance with domestic public health reporting policies. Such collection and analysis of information from medical surveillance as part of detection measures should, as appropriate, be reported and investigated by relevant competent authorities to determine the cause and consequence of the injury or illness.

It is further recommended that the competent authority with regulatory responsibility should require authorized persons to report immediately any non-compliance which they suspect could have nuclear security implications. Such a report would enable the competent authority to assess the event with the aim of preventing a consequent malicious act. Further the draft document recommends that any competent authority that receives a report that such material has been reported as lost, missing or stolen, promptly inform other relevant competent authorities.

Finally the draft document recommends that any instrument alarm or information alert should lead to the conduct of an initial assessment. The relevant competent authorities should implement procedures and protocols with the view to interdict and interrupt the potential criminal act or unauthorized act with nuclear security implications.

Response Measures

To ensure an adequate response to the detection of nuclear of other radioactive material out of regulatory control and that could be used for a criminal or intentional unauthorised act, the draft document recommends that, using legislative instruments as necessary, the State develop a comprehensive national response system for responding to such acts.

In particular the draft document recommends that the State should ensure that the responsibilities for implementing the various response measures are assigned to the relevant competent authorities, together with sufficient resources to effectively undertake these tasks.

The implementation of the response system of the State should be documented in a national response plan outlining the various response measures, and should be implemented coherently by the various competent authorities, ideally coordinated by the coordinating body. It is important that in responding to nuclear security events, the responsible competent authorities should complement and support the safety emergency response activities to mitigate and minimize the radiological consequences to human health and the environment at the international, federal, state and local levels. The coordination of competent authorities is vital for an effective response at the scene.

An important aspect of this response, as outlined in the draft document, is the recommendation that the State should adopt a graded approach to respond to the various possible nuclear security events and differing degrees of consequences. In order to determine the appropriate response and follow-on actions, the State should strive to develop its own national capability to quickly grade nuclear security events, based on health and safety concerns and on circumstantial factors and the involved nuclear or other radioactive material.

If the initial assessment described in the detection measures above are not conclusive, the draft document recommends that the relevant competent authorities ensure the establishment of procedures and protocols for final resolution of an instrument alarm which may result in the determination that a nuclear security event has occurred. The determination of a nuclear security event should lead to the activation of the national response plan by the relevant competent authority using the graded approach discussed above. For the assessment of information alerts, the competent authorities should obtain the necessary assistance from the assigned experts and the support organizations, in accordance with the established procedures and protocols.

The location of any nuclear security event should be managed as a potential crime scene. The draft document recommends that the competent authorities should ensure coordination among those involved in recovering control over the nuclear or other radioactive material, those concerned with safety and treating victims and those concerned with gathering evidence for possible subsequent investigation and prosecution.

It is important for the State to apply nuclear forensic techniques on any seized nuclear or other radioactive material in its designated laboratories for the purpose of identifying the source, history and the route of transfer, taking into account the preservation of evidence. Furthermore, traditional forensics should also be applied in designated laboratories for contaminated evidence, as necessary.

The draft document recommends that persons involved in the response should be suitably qualified and trained and should, as appropriate, be aware of the basic concepts of radiological crime scene management, evidence collection and radiation protection.

In order to manage the nuclear security event, the draft document recommends the establishment of a comprehensive national response plan (the Plan) in combination with, inter alia, the national radiological emergency plan. The Plan should serve as:

- A basis for establishing compatible operational tools needed for prompt and effective response; and
- A guide for the competent authorities who should ensure that all necessary preparedness and response tasks are given the appropriate resources and support.

The draft document recommends that the Plan:

- describes the process for various competent authorities to fulfil their obligations and responsibilities in response to nuclear security events, including steps to:
    - notify and activate all relevant competent authorities;
    - notify the relevant international organizations and potentially affected States;
    - coordinate various organizations and command and control units of a nuclear security event, including coordination of federal, state and local response organizations;
    - locate, identify and categorize nuclear and other radioactive material;
    - detain and/or seize, recover and control material or render harmless any threat or associated device;
    - collect, secure and analyse evidence;
    - isolate, classify, package and document, any nuclear or other radioactive material, for transport, carriage, storage or disposal and placement under proper regulatory control; and
    - initiate relevant investigations.
- contains an appropriate command structure with integrated command, control and communication systems to effectively respond to a nuclear security event, preferably with a single person or competent authority assigned to direct the response at the scene;

- has provisions for coordination among the competent authorities, including exchange of relevant information concerning their respective roles, responsibilities and procedures;
- describes the roles, responsibilities and procedures for the competent authorities for medical services, handling of hazardous material, radiation protection and safety and other technical support organizations and for nuclear and conventional forensic laboratories;
- arranges for informing the news media and public, as appropriate, in a coordinated, understandable and consistent manner;
- contains provisions for the transport of any seized or recovered nuclear or other radioactive material in accordance with the national transport safety and security regulations and requirements;
- identifies the standard operating procedures at the local level for nuclear security events. In addition, all local level response plans should be integrated into the Plan;
- takes into account, and coordinates with, the existing national radiological emergency plan and radiological emergency response procedures;
- incorporates the possibility of multiple and simultaneous nuclear security events. In addition, the Plan should incorporate the possibility of disruption of response infrastructure that would delay an effective response capability; and
- incorporates the mechanisms for requesting assistance, both domestically and internationally, when necessary, such as assistance for the recovery of nuclear and other radioactive material, rendering harmless the device and nuclear forensics.

The draft document further recommends that, upon detection of nuclear or other radioactive material out of regulatory control at a border crossing point, the State should work with the State of origin and other relevant States to return the material to regulatory control. The State should adopt a graded approach for such response that depends on the circumstances of the case and the nature of the material.

Nuclear forensics techniques to determine the source and route of transfer and to investigate loss of regulatory control are an important part of nuclear security. The draft document suggests that investigations may entail cooperation between or amongst States to identify the origin, history and the route of transfer of the nuclear or other radioactive material. Cooperation on nuclear forensics should be subject to the State’s domestic laws, regulations and policies and the draft document recommends that for States without sufficient nuclear forensics expertise and capabilities they enter into arrangements with other States or relevant regional or international institutions for the purpose of nuclear forensics analysis and interpretation.

Perhaps the biggest deterrent to the use of nuclear and other radioactive material for criminal and other intentional unauthorised acts involving nuclear and other radioactive material is the existence of comprehensive nuclear forensics libraries. The draft document recommends that a State should consider establishing nuclear forensics libraries for their inventory of nuclear and other radioactive material. These libraries should include databases of all material produced, used and stored in the State and, if applicable, supported by sample and literature archives. The State should be capable of responding to queries of other States regarding recovered nuclear or other radioactive material that may have been produced, used or stored on the State's territory.

Conclusions

Nuclear security is a distinct and growing body of knowledge relating to the use of nuclear and other radioactive material for criminal or intentional unauthorised acts. Aspects of safeguards and safety are fundamental to a successful nuclear security regime in a State, particularly related to the accountancy of nuclear material, and the register of radioactive sources. For nuclear and other radioactive material out of regulatory control, the Secretariat and Member States of the IAEA have drafted a guidance document to assist them in establishing an effective nuclear security regime.

This draft document is currently with Member States for 120 day review and copies of the draft document are available on the Agencies website at: http://www-ns.iaea.org/security/nuclear.security.series.htm, and comments are welcome from all Member States. It is anticipated that once comments are received and reviewed, another Technical Meeting will be held at the IAEA to ratify the final version of the document, before initiating the publication process.

Abstract

It is described how ongoing work will extend European standard decision support systems currently integrated in the nuclear power plant preparedness in many countries, to enable estimation of the radiological consequences of atmospheric dispersion of contaminants following a terror attack in a city. Factors relating to the contaminant release processes, dispersion, deposition and post deposition migration are discussed, and non-radiological issues are highlighted in relation to decision making.

Introduction

Over recent years the world has become increasingly aware that malevolent acts involving atmospheric dispersion of radioactive matter may occur and could severely affect large urban populations, both by leading to high radiation doses from dispersed radionuclides and by causing social disruption and fear. A comprehensive and reliable decision support system that can be operated in real-time is essential to ensure that the repercussions are addressed optimally and consistently from the very beginning and seen in the context of the actual health hazards. The dispersion could be carried out in different ways, involving, e.g., 'dirty bomb' devices, simple aerosol generators placed on a rooftop, or emission from an aeroplane. Depending on both the dispersion process and the initial contaminant matrix, aerosols with very different size spectra and physicochemical characteristics can be produced. The importance of aerosolisation processes, atmospheric dispersion in complex urban terrain, and post-deposition contaminant solubility, fragmentation and migration are all discussed in relation to the dose modelling needed to form reliable consequence prognoses. The paper reports on how these issues are being dealt with in an extension of existing European standard decision support systems to cover the consequences of terror attacks. Also non-radiological perspectives of radiological terror attacks are discussed.

Methods and results

A very wide range of radionuclides could at least in theory be envisaged for use in a radiological dispersion terror attack. In reality, however, the list of radionuclides that would be of primary concern would be likely to have only of the order of ten entries. The limiting factors include availability of existing sources with sufficient strength, problems in handling strong sources, initial physicochemical form of sources, types of radiation emitted, energies and photon/particle yield, and physical half-life of the contaminant(s). There seems to be almost consensus that this list would include ^{60}Co, ^{137}Cs, ^{90}Sr, ^{192}Ir, ^{226}Ra, ^{238}Pu, ^{241}Am, and ^{252}Cf (Andersson et al., 2009), but of course authorities and planners should also keep an open eye for the unexpected, as one of the main targets of all terrorism acts is to provoke a feeling of unpredictability, unpreparedness and uncertainty, which can in itself contain a considerable potential for anxiety, distrust and social disruption. In this section, factorial dependencies of radiological consequences, as well as non-radiological implications, of malicious atmospheric radiological dispersion are discussed.

Aerosolisation, dispersion and deposition

There has been a tendency to focus on the risk that terrorists might detonate a so-called ‘dirty bomb’ radioactivity dispersion device. It is considered likely that a ‘dirty bomb’ attack would have maximum societal impact if detonated in a highly populated area (Andersson et al., 2009; Sohier & Hardeman, 2006). Unless the explosion leads to evaporation of the contaminants, followed by formation of small condensation particles, most of the contaminant particles generated by this type of explosions would be large (some of it will be spread ballistically rather than being aerosolised), but it is likely that there would also be a significant release of particles in the size range of only a few microns (Andersson et al., 2008). These latter particles could disperse with the wind over a rather large city area. The initial physicochemical form (e.g., metal, powdered, solution, ceramic) of the applied source can in general greatly influence the aerosolisation process and thus the dispersibility in the environment. Radionuclide compounds that might plausibly be applied range from the virtually insoluble to readily soluble, e.g., depending on their previous application (Andersson et al., 2009). The extent to which phase transition will occur in the explosion process, thus potentially leading to formation of smaller and highly dispersible aerosols, also depends on how successfully the bomb is dimensioned. However, experimentation has shown that phase transition does not occur in connection with contaminants on ceramic form (Harper et al., 2007). Aerosolisation spectra based on data from experimentation are being incorporated in an ongoing extension of the European standard decision support systems (DSS) to predict the consequences of ‘dirty bombs’. It should be stressed that the aerosol spectra that would arise after a ‘dirty bomb’ explosion would in many cases be completely different from those expected at some distance from a large nuclear power plant accident, and parameters applied so far in European DSS (ARGOS, RODOS) can thus not be applied for ‘dirty bomb’ scenario calculations.

One parameter that greatly influences the size of the area over which the contaminants are spread in a ‘dirty bomb’ scenario is the plume rise. This also determines the significance of plume interaction with environmental structures (e.g., buildings, trees). The initial rise of the contaminated material after the blast will occur due to buoyancy and initial momentum. As the cloud rises, its movement will cause turbulent mixing with non-buoyant ambient air. Deceleration through decreasing buoyancy will reduce the boundary turbulence to that of the ambient air, by which point the 'initial' plume will have been formed. In the new feature of the European standard DSS dealing with 'dirty bombs', the parameterisation of plume rise relates to several independent blast studies (e.g., data from a US blast test series conducted in 1963 to investigate the effect of accidental conventional explosions spreading radioactive material from a nuclear device). The plume rise strongly depends on the amount and type of explosive applied.

For modelling the subsequent airborne dispersion of the contaminants over the environment, it is important to apply methods that adequately account for the mechanisms governing the flow and deposition in relation to the given dispersion altitude and scale. Here a considerable degree of simplification is traditionally applied in decision support models, which are designed to describe the long-range transport of contaminants from high-altitude releases following large nuclear power plant accidents. Since the plume here generally passes well over the various environmental obstacles, the influences on the plume propagation in inhabited areas can be reasonably simulated through the use of different overall roughness and deposition rate parameters compared with, e.g., rural areas (Päsler-Sauer, 2007; Mikkelsen et al., 1984; Mikkelsen et al., 1997). However, investigations made over recent years have shown such simplifications to be problematic, when the contaminant dispersion partially takes place at street level, as would be the case following a 'dirty bomb' explosion. This is particularly true for scenarios involving shifting wind directions (Astrup et al., 2005). Here, higher resolution models are required to address the issues of plume interaction with and flow along obstacles in the inhabited environment. Therefore, a new atmospheric dispersion module for inhabited areas, URD (Urban Release and Dispersion), based on Gaussian puffs and a calculation grid with highly resolved buildings, has been developed at Risø-DTU. This new implement is in some of its basic features inspired by the UDM code developed by the UK Defence Science and Technology Laboratory (Hall et al., 2002), and incorporates plume interaction with environmental obstacles in three different ways. The obstacles form barriers limiting the magnitude of horizontal eddies in the atmosphere, which in turn reduces the large-scale horizontal dispersion. At the same time, the interaction will increase the small-scale turbulence over a city, which will lead to greater small-scale dispersion. Finally, obstacles like downstream building walls constitute barriers that will to some extent delay the further dispersion of parts of the contaminants (Fackrell, 1984).

Obviously, deposition of aerosols on the different surfaces in an urban complex also depends strongly on particle size. Small liquid or vapour condensation particles can be formed, which will have a low deposition velocity to surfaces in the environment. Fragmentation particles will have a considerably higher deposition velocity, leading to a more concentrated contamination pattern over a somewhat smaller area. For instance, the dry deposition velocity to a lawn is typically higher by a factor of about 30 for 20 μm particles than for 2 μm particles (see, e.g., McMahon & Denison, 1979), and due to the different processes (Brownian diffusion, impaction, interception, gravitational settling, etc.) governing the dry deposition of particles with different sizes on environmental surfaces of different materials and orientation, also the distribution of the contamination on the various surfaces in the inhabited environment will be highly dependent on particle size. This issue is also addressed in ongoing DSS extension, through the inclusion of a series of data libraries describing the deposition of aerosols in intervals of the relevant size ranges for five different deposition 'modes': dry deposition, deposition in light rain, deposition in heavy rain, deposition in snow, and dry deposition to a snow-covered environment.

As mentioned above, also other types of malicious atmospheric dispersion of radioactive aerosols may occur, and aerosol formation processes may be simple. Small particles could for instance be formed over longer time by a nebulisation arrangement, perhaps on a rooftop in a city. Figure 1 shows a particle size spectrum measured with a Berner low pressure impactor in the vicinity of an aerosolisation arrangement, where an injected air stream generated particles by nebulisation of an indium acetyl-acetonate powder dispersed in alcohol. A simple medical inhalator nebuliser was used for this arrangement. These particles have a very low deposition velocity, and could thus travel far in the wind. It is foreseen that also estimation of the consequences of this type of scenarios will be enabled in the extended European DSS systems.

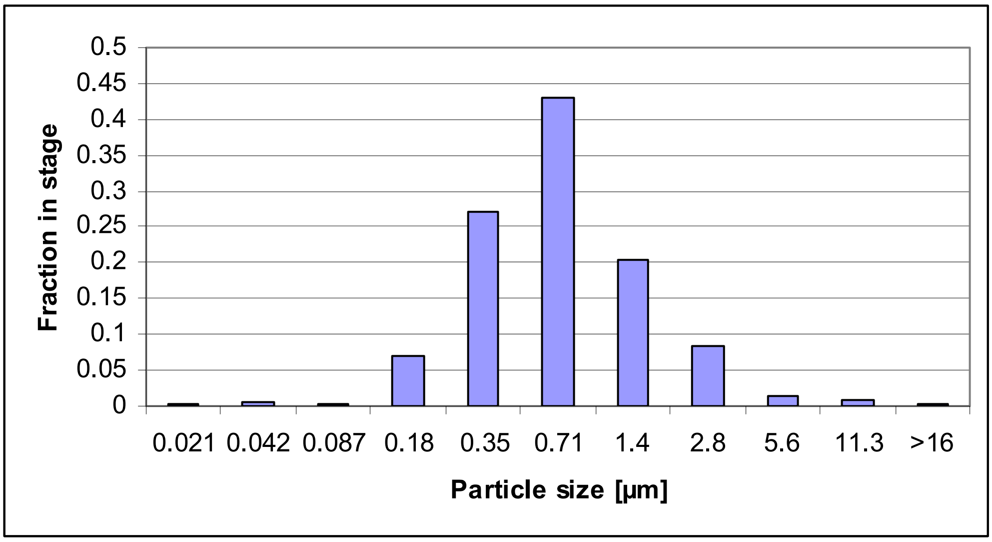

Fig. 1. An example of a size spectrum of aerosols generated by simple means through nebulisation.

Post deposition contaminant behaviour

With respect to post-deposition mobility, it is essential to distinguish between the different physicochemical forms of the deposited contaminants. For instance, aerosolisation of metals in a 'dirty bomb' has been reported to require phase transition, and the solubility and environmental behaviour of small particles created by condensation of evaporated contaminants would be expected to be very different from that of the larger particles generated by physical fragmentation of a virtually insoluble material. It is important to take into account that large particles are considerably easier to remove from surfaces in an inhabited environment, both by natural and forced processes, than are small particles and contaminants in solution. This can be illustrated by results obtained by hosing water at the same pressure on similar sandstone walls that had been contaminated by the Chernobyl accident, in Pripyat only about 3 km from the power plant, and in Vladimirovka, some 65 km away. In Pripyat, where much of the contamination was in the form of large and insoluble particles, the treatment removed some two-thirds of the caesium, but as far away as Vladimirovka, where the contaminants were primarily in the form of small, soluble condensation particles, only about one-fifth of the caesium could at the same time be removed (Roed & Andersson, 1996).

Kashparov et al. (2004) demonstrated that the dissolution in soil of deposited contaminant particles with high chemical stability could, depending on soil pH, be a process lasting over several years. This will delay the migration in soil of the contaminants initially present in a low solubility matrix. The current data in the European DSS describing the migration of contaminants in the urban complex is practically exclusively based on measurements of readily soluble ^{137}Cs from the Chernobyl accident (see Figure 2). The mechanisms that govern the fixation on most urban surfaces of radiocaesium on cationic form are highly element specific, and the values can therefore not be applied for scenarios where a different contaminant is of major importance.

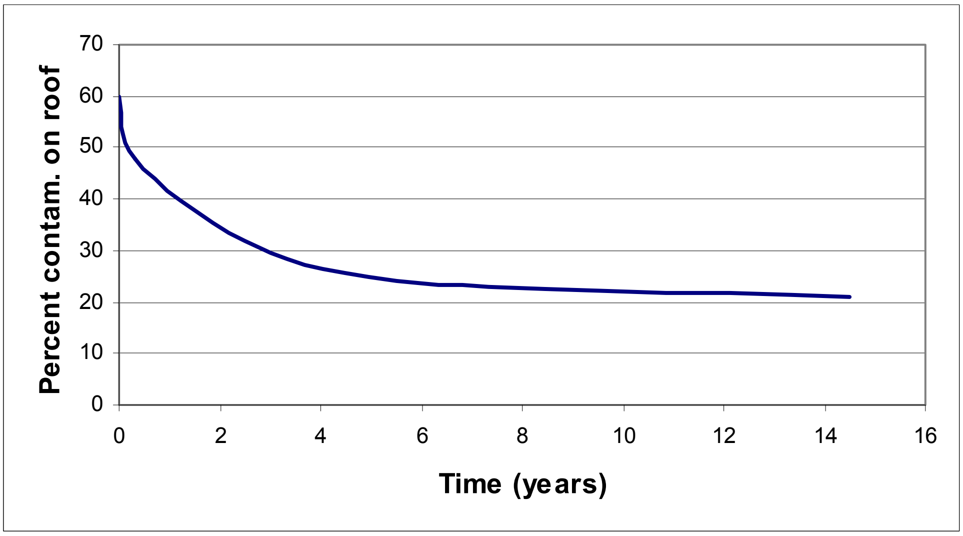

Fig. 2. Natural loss of Chernobyl radiocaesium on a clay roof through weathering over about 15 years (measurements made in Gävle city, Sweden; Andersson, 2009). The efficient long-term retention of a large part of the contamination is due to selective fixation of caesium cations in intact micaceous structures in the clay tiles.

It should also be noted that recent observations on contaminant particles from the Thule accident show evidence that natural spontaneous fragmentation of such low solubility particles can occur in, e.g., human body liquids. This means that large particles, which have high deposition velocities on human skin and in the human respiratory tract may be transformed into smaller particles that would have a longer natural clearance half-life. Thereby, the radiological consequences of the contamination would become more severe. This phenomenon requires further investigation.

Non-radiological concerns

Optimised decision making for intervention is an extremely complex process, which should take into consideration the full range of benefits and costs inflicted on the population as a whole as well as on population sub-groups. Not only radiological perspectives, but also a number of politically driven factors that can not be quantified on a generic scale will need to enter the decision matrix in the event of any contaminating incident. Such issues are often highly site and case specific, and can generally only to some extent be addressed in advance of a contaminating incident. Examples of factors that need to be included in a holistic justification/optimisation of intervention in the event of contamination of inhabited areas, but require quantification on the basis of political decisions, include the value of each unit of averted dose, the value of equity across the population, the value of public reassurance and psychological well-being, the value of maintaining societal functions, the value of lost income, the value of lost or damaged personal property, the societal value of preserving objects, and the value of avoiding environmental risks (Andersson, 2009). Involvement of citizens and stakeholders in the decision process for long-term restoration strategies is an important instrument in reaching generally acceptable and robust decisions that would not be prone to public resistance.

A number of tools have been created, which could be used to facilitate this process and help in balancing different types of factors against each other (Hämäläinen & Mustajoki, 2010; Belton & Stewart, 2002; Jackson et al., 1999; Zeevaert et al., 2001). The use of such systems in a participatory forum can, with the right facilitation and advisory support, form the basis for a case-specific ranking, which may seem reasonable and transparent to all involved, thus providing a useful platform for reaching agreement on the seemingly 'best' solution.. The weakness in the practical use of this approach lies in the valuing of weighting factors, and the summation over often many attributes to reach an estimate of the overall value of each countermeasure option may to some extent remove the focus from issues that demand undivided attention.

Specifically in relation to the psychological well-being of the affected population, it should be noted that both terror and accident victims may experience post traumatic stress disorder (PTSD) or acute stress disorder (ASD, occurring within a month of the impact). However, terror scenarios contain a number of psychological features that are different from those observed in connection with accidents. For instance trauma in connection with acts of terror can disrupt deeply held cultural assumptions about social values, and stressors of human design tend to produce specific senses of betrayal, blame and abandonment (O'Connor, 2009). A group that are at particular risk of developing lasting behavioural and emotional readjustment problems is the rescue workers, who very directly confront and witness the horrors of a terror impact. Therefore, contingency strategies should be developed carefully for this, and also other, population groups. Trauma triggers may include experience of life threatening danger or physical harm, bodily injuries, extreme violence and destruction, loss of communication, intense personal emotional demands, extreme fatigue, anticipation stress, and exposure to contamination (O'Connor, 2009). Specifically in connection with terror scenarios, 'information stress' can occur as people do not have a clue as to what is suddenly going on, and what the dangers might be, both in the very near future ('will more attacks follow soon?') and in terms of long-term consequences. Good communication strategies developed well in advance of an attack (including raising public awareness, since a well prepared public is less prone to panic) are essential in reducing the non-radiological impact. This is particularly important in connection with terror scenarios, due to their sudden and violent occurrence, which is not countered in other types of scenarios and leaves little or no time for any preparation (Danieli et al., 2005). Further discussions of non-radiological factors of concern can be found in Oughton & Forsberg (2009) and Andersson et al. (2009).

Conclusions

The above text illustrates how European decision support systems currently in operation for nuclear power plant preparedness will be extended to enable estimation of the radiological consequences of terror attacks involving atmospheric dispersion of radioactive matter. In relation to contaminant aerosolisation, dispersion and deposition, new source terms are being defined, together with release and deposition parameters that reflect the actual characteristics and dynamics of the contaminants originating from, e.g., ‘dirty bomb’ explosions. Also, a more refined urban aerosol dispersion model has been developed that takes into account the special features of dispersion at low altitude in a complex, inhabited terrain. It is demonstrated that also post-deposition migration parameters currently applied in the European decision support systems are inapplicable in describing the fate of contaminants from a radiological terror attack, and therefore new data libraries are being created for this purpose also. Finally, the implications of non-radiological factors for optimisation of intervention were discussed, and some factors relating to the psychological well-being of terror victims were highlighted.

Nuclear inspections on container traffic in the port of Antwerp

Fias, Pascal[1]; Meylaers, Tom[1]; Himpe, Pieter[1]; Peeters, Tanja[2]
[1] AV Controlatom, Authorised inspection body (Class I), BELGIUM
[2] Customs and excise, Megaports Initiative, BELGIUM

Abstract
Since 2007 Belgian Customs has been inspecting containerized shipments on the presence of nuclear smuggling with radiation portal monitors. Although no incidents of nuclear smuggling were found, several cases were found where non-natural radioactive materials were present in consumer goods.

Introduction
After the 9/11 events in the US an international programme against nuclear smuggling was started as part of the effort to tackle terrorism. The goal is to deter, detect and interdict the smuggling of special nuclear materials. One of the key aspects of this program is to equip border crossings with nuclear detection equipment.

In 2004 the Belgian government signed a memorandum of understanding with the US Department of Energy on the installation of detection equipment in the port of Antwerp. In February 2007 the inspections started in the port of Antwerp. In 2009 the seaport of Zeebrugge was also equipped. On a daily basis about 20 000 containers pass through the portal monitors in the Belgian ports causing about 150-200 alarms per day. Almost all alarms are due to the presence of NORM (naturally occurring radioactive materials).

One of the most important features of these inspections is to release containers with NORM or licensed radioactive materials in the shortest time possible. In order to minimise the effect of the inspections on the container flow, the inspections are performed in a standard three-phased approach.

The decision process is based on the Belgian regulations on radiation protection, international standards for nuclear inspections at borders, and experience from a research project with radiation portals in the port of Antwerp. [1-4] This decision process is part of a standard procedure, agreed on by Belgian Customs and the Belgian Federal Agency on Nuclear Control (FANC).

As a consequence Belgian Customs do not only look for the presence of nuclear smuggling in containers. In the decision process radiation protection concerns also play an important role, such as the safe transportation of radioactive substances (ADR class 7) and the incidental presence of radioactive material.

Material and methods

The Belgian Customs use a standard three-phased approach for nuclear inspections. In figure 1 this decision process is described in a general manner. For a more detailed standard of procedures please contact the authors.

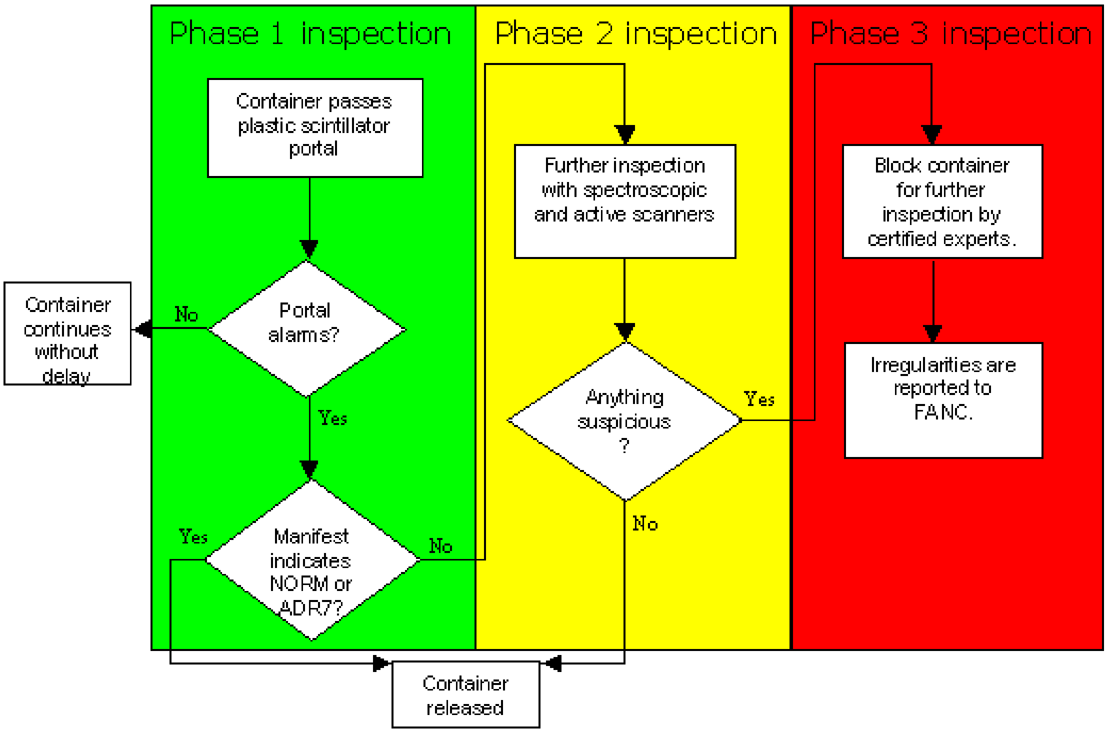

Fig. 1. Summary of the standard of procedures for nuclear inspections by Belgian Customs.

In each phase following procedures and equipment are used:

1. A primary inspection consists of a passage of the container through a radiation portal monitor equipped with both He-3 neutron detectors and plastic scintillator gamma detectors. If the portal detects an increase in radiation compared to the natural background, an alarm is raised. Containers that cause alarm are blocked and await a decision by a Custom Officer in charge. Decisions in this phase are based on the declared content of the container, which is compared to a database of known NORM materials. About 99% of the blocked containers are released in this phase because a known NORM substance is present inside. Note that licensed ADR 7 shipments are released without being blocked.
2. If the information regarding the content is not sufficient to release the container, a secondary inspection will be performed. This inspection consists of measurements of the gamma radiation present with spectroscopic equipment: (1) handheld Ge-detectors, (2) advanced spectroscopic portal monitors (ASP), or (3) car top systems. In most cases this is combined with an active scan of the container with X-ray scanners (3-6 MeV) in order to inspect the physical content of the

container. The X-ray scan image can identify smuggling scenarios such as lead shielding inside the container. In figure 2 the standard setup for secondary screening is depicted. If necessary these measurements can be performed with mobile spectroscopic systems, and a mobile active scanning unit.

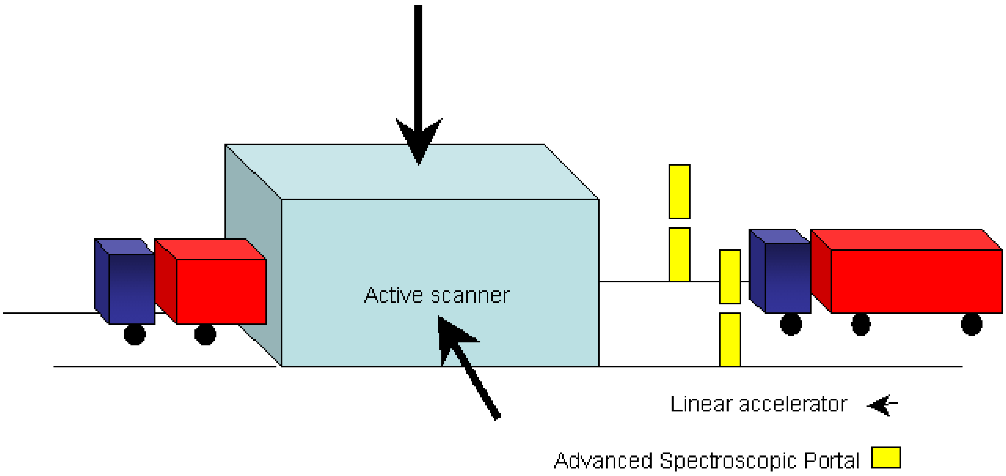

Fig. 2. Standard secondary setup in the port of Antwerp.

3. A tertiary inspection is performed in all cases were Customs cannot release the container based on the primary or the secondary inspection. In these cases a certified radiation expert or FANC itself takes over the inspection.

Results and discussion

The primary inspections with the portal monitors have a reasonably constant alarm rate, being about 1,4%. In the period 2007-2008 the installations were expanding in the port of Antwerp, resulting in growing numbers of occupancies. At present 43 portal monitors are installed in the port. In 2009 we experienced an effect of the global economic crisis resulting in a 7% decrease in occupancies.

Year	Number of Occupancies on primary portals	Number of alarms on primary portals	Alarm rate (%)
2007	1 447 386	20 501	1.42%
2008	2 868 650	40 991	1.43%
2009	2 659 259	36 785	1.38%

In most cases the primary inspection reveals the presence of NORM materials that are not subject to radiation protection regulations. The use of a NORM database has facilitated the recognition of NORM. At this point about 150 different classes of products, ores and consumer goods are present in this database.

The NORM database is used as a reference to release containers based on manifest information and alarm information. For each type of NORM an inspection limit is described. Above this limit Custom Officers will perform a secondary inspection and/or will demand more detailed information. Typically this information will consist of (1) the chemical composition of the product itself and (2) contact information of the manufacturer. The inspection limit is based on (1) statistical information taken from previous alarms on a certain type of NORM, (2) radiation protection regulations, and (3) expert judgement.

The number of secondary inspections has decreased over the years. Secondary inspections are performed on containers that cause suspicious alarms or alarms where the source of the radiation is not found after the primary inspection. At this point about one in 10 000 occupancies will result in a secondary inspection. The most important reason for this is the increased experience of Custom Officers.

Tertiary inspections revealed no cases of smuggling, but quite a large number of incidents involving contaminated materials and orphan sources. Typically one of the following scenarios arises:

1. Co-60 contamination of steel products due to the melting of a Co-60 source in a steel furnace.
2. In industrial by-products (example: concentrated metal ores) a contamination can be present, typically with Cs-137. This is due to an accidental processing of a radioactive source.
3. Cs-137 contamination of biological materials (including food) due to airborne Cs-137 after incidents (e.g. Chernobyl) or nuclear weapon tests.
4. TENORM (technically enhanced NORM) above exemption levels: e.g. radium paint on instruments, scaling on scrap…
5. Orphan sources in scrap.

Conclusions

Experience suggests that nuclear smuggling is not common. In the three years since the start of the inspections, no cases are reported in Belgium. On the other hand the installation of the equipment has proven to be a strong tool in protecting the public against the incidental occurrence of non-natural radioactive materials in consumer goods.
