Abstract
Alpha emitting radiation sources are typically hard to detect due to the short range of alpha particles in air. A remote detection of alpha radiation in air is possible by measuring the ionization-induced fluorescence of air molecules. The alpha-induced ultraviolet (UV) light is mainly emitted by molecular nitrogen and its fluorescence properties are well known. The benefit of this method is the long range of UV-photons in air. The main challenge of the optical method is to discriminate the weak fluorescence signal from the background lighting. The issue is addressed in the present paper by means of spectral filtering of the UV light. A portable demonstration device, utilizing spectral separation of fluorescence from the background lighting, is presented and the performance of the method is reported. Using specially selected room lighting, the device is able to detect a 1 kBq alpha emitter from the distance of 40 cm with one second integration time.

Introduction
Conventional alpha detectors require direct interaction with the particle which makes the localization of contamination a laborious task. Furthermore, alpha active nuclear materials pose a serious risk if they proliferate among rogue organizations. In this context, the research on novel alpha detection methods is well justified.

Previous studies have shown that remote detection of alpha radiation is possible by measuring the ionization-induced UV fluorescence of air molecules. It was shown that the UV fluorescence can be detected from a distance and even through a plexiglass of a clove box (Lamadie et al. 2005). Furthermore, the detection is possible even under a strong beta and gamma radiation background, because they do not induce as localized fluorescence as alpha radiation (Baschenko 2004). UV fluorescence is typically detected with photomultiplier tubes, but Lamadie et al. (2005) showed that it is also possible to use a CCD-camera and combine the fluorescence image with a normal photograph to gain position information. However, the camera detection requires very long integration times from several minutes to hours.

Fluorescence of air is mostly fluorescence of nitrogen, and molecular nitrogen has fluorescence peaks in the wavelength range between 300 nm to 430 nm. Table 1 shows the wavelength location of the most intense fluorescence peaks of nitrogen. The peaks are having a full-width of half-maximum of about 1 nm. The fluorescence properties of nitrogen have been intensively studied using electron excitation (Waldenmaier 2006), which might be the excitation mechanism also in the alpha radiation excited fluorescence. The secondary electrons are supposed to be responsible for the excitation of the fluorescence.

Table 1. Main fluorescence peak wavelengths of neutral (2P) and ionized (1N) nitrogen molecule. Peaks have full-width of half-maximum of about 1 nm. Two integers in parenthesis mark for vibration state in upper state and lower state, respectively.

Wavelength (nm) / transition
316 / 2P(1,0)
337 / 2P(0,0)
354 / 2P(1,2)
358 / 2P(0,1)
375 / 2P(1,3)
380 / 2P(0,2)
391 / 1N(0,0)

In this work, an optical detection method was developed with short integration time of about 1 second. The method is based on sensitive detection with photomultiplier tubes in photon counting mode, and spectral filtering of the fluorescence signal. The fluorescence peaks of nitrogen between 300 nm and 340 nm are used to record fluorescence signal, and the background reference is detected at 300 nm wavelength.

Material and methods

The optics for the demonstration device was designed with FRED Optical Engineering Software (Photon Engineering LLC). The software is based on optical ray tracing method to calculate the function and performance of the optics. A point like alpha emitter was modelled with the FRED software by assuming the alpha particles to travel 4.1 cm in air at maximum. During the alpha particle trajectory, it creates secondary low-energy electrons that are assumed to excite the fluorescence. Figure 1 (a) shows how the excitation sites are distributed around the point like alpha emitter. From these sites, the photons are emitted to random directions, as shown in fig. 1 (b). Thus, the point like alpha emitter forms a fluorescence emitting volume around itself. As the fluorescence source is not a point source, it causes some challenges to the optics and spectral wavelength separation.

The aim of the optical design is to collect as much of the emitted photons as possible. This yields to a large numerical aperture optics i.e. large collection angle for the optics. With the large collection angle and the volume emitter source, the spectral wavelength separation cannot be made by conventional spectrographs without losing the most of the photons. Thus, interference filters was selected for the demonstration device. The fluorescence is collected with a 40 nm bandpass filter (Semrock, Inc.) having the center wavelength at 320 nm. The effect of background lighting was detected by combining the fluorescence filter with a 15 nm bandpass filter having the center wavelength at 295 nm, which effectively limits the background detection to a narrow wavelength range of 299 nm – 303 nm.

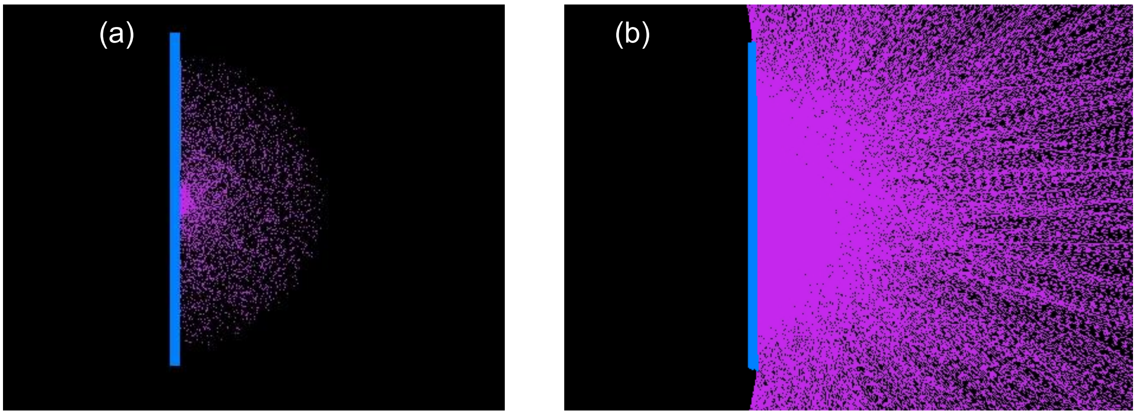

Fig. 1. Model of point like alpha emitter on surface acting as light source. (a) Alpha particles are inducing fluorescence photons in volume inside of the hemisphere having radius of 4.1 cm. (b) Fluorescence photons are emitted to random directions.

Figure 2 shows the optical design of the demonstration device without the interference filters. The design is optimized for the maximum collection efficiency for a detector having diameter of 15 mm. The total collection efficiency was calculated to be 0.12 % when the point like alpha emitter is located at 40 cm distance from the first lens having the diameter of 75 mm. The interference filters are placed in the both sides of the beam splitter in front of the detectors.

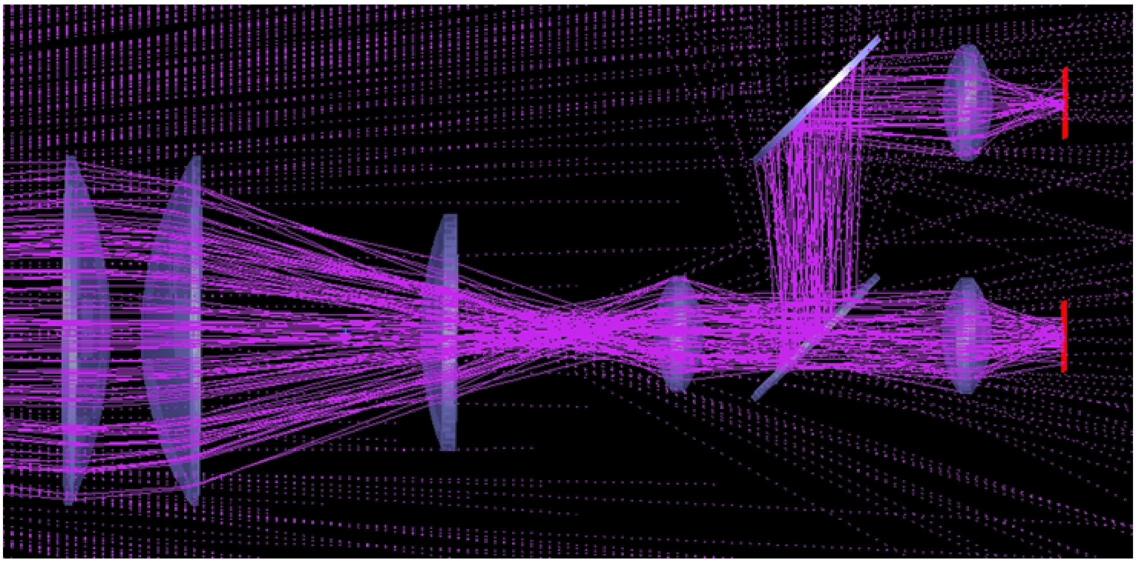

Fig. 2. Optical model of demonstration device. Vertical red lines at the right side are photomultiplier cathode surfaces. The lower channel detects the fluorescence signal at wavelength range of 300 nm – 340 nm, and the upper channel detects background lighting at 300 nm. The wavelength filters are not shown in the figure.

The optics is mounted in side of a tube, so that all the lenses are having the same optical axis. The tube is sealed in a way that no light will leak to the detector from the side. The only optical access to the detectors is through to the first lens. Channel multipliers MP 1982 (PerkinElmer Optoelectronics) were used as detectors. Figure 3 shows the demonstration device without the cover. The optics was packaged with detectors, electronics and a battery to a box having the total weight of 6 kg. The device can be used by free hands or on top of a tripod. The current detector readings are printed on a small display in the back of the device. The data can also be transferred out from the device in real time through a standard network connection.

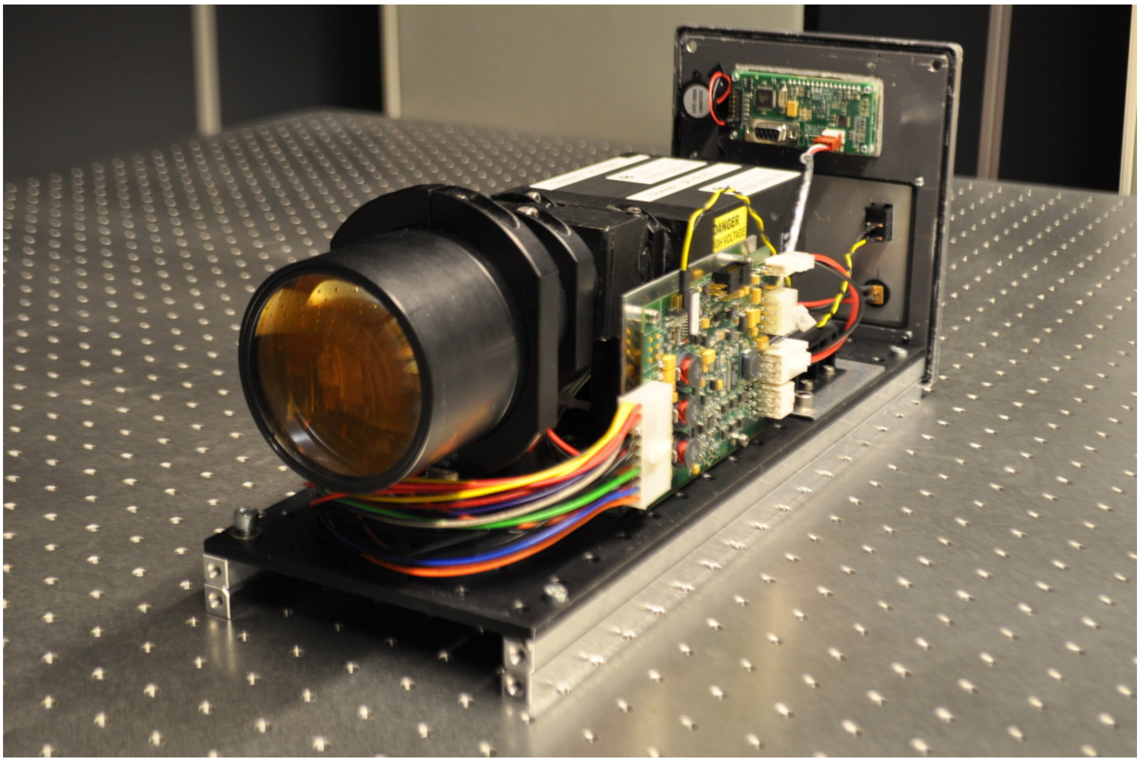

Fig. 3. Portable demonstration device for optical remote detection of alpha radiation. The cover of the device has been removed to show the optics (3" diameter), photon counting detectors, and electronics.

Results and discussion

The detection method was studied using a 10 kBq ^{241}Am source from an old smoke alarm device. The detectors counted about 3 cps dark counts in total darkness. In these conditions and without any spectral filters, the 10 kBq source yielded 150 cps signal to the detectors. The same experiment was repeated using N_2 purge as the same time. The measurement setup was covered with a box and the N_2 purge was replacing the air inside the box with nitrogen. As a result, the fluorescence signal increased to the value of 650 cps, which means more than 4 times enhancement in the signal. This is most likely due to the removal of oxygen that is effective quencher of the nitrogen fluorescence (Waldenmaier 2006). The removal of oxygen is not a relevant method in the most operational conditions, but it was valuable to notice that the fluorescence signal strength was enhanced with nitrogen purge as it can be predicted based on earlier studies with electron excitation (Waldenmaier 2006). The result of this little test is highlighted in the table 2.

Table 2. Fluorescence photon counts per second in normal atmospheric conditions and under nitrogen purge. The nitrogen purge was performed in a closed box to create a nitrogen atmosphere. Reduced quenching causes an increase in the fluorescence yield.

Fluorescence in air (cps)	Fluorescence under N_2 purge (cps)
150	650

The sensitivity of the demonstration device to the distance from the alpha emitter was studied. Figure 4 shows that the fluorescence signal is quite constant from 10 cm to 30 cm distance. The almost constant signal strength in this range is very good feature for operational work, as the operator does not need to tune the distance to the surface very accurately to get reliable readings. The fluorescence collection efficiency of the demonstration device drops rapidly as the distance gets longer than 30 cm, which is also predicted by the ray tracing model.

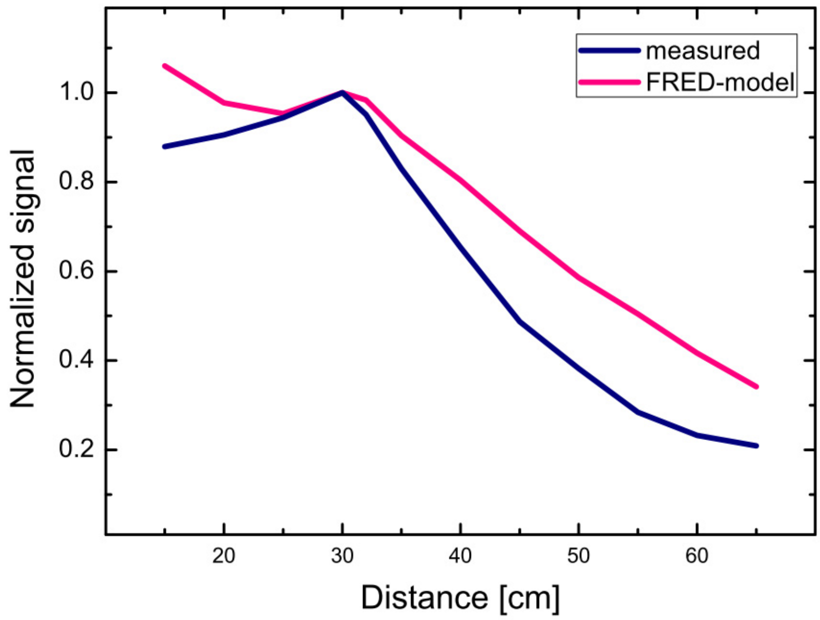

Fig. 4. Normalized fluorescence signal of demonstration device as function of distance from alpha emitter. The normalization is done at the distance of 30 cm from the alpha emitter to first lens surface of the device. The result of optical ray tracing model is shown as a reference.

The spatial sensitivity of the demonstrator device was studied by moving a point like alpha emitter transversally to the optical axis at the distance of 40 cm from the device. Figure 5 shows the measured curve as well as the one predicted by the ray tracing software. The agreement between the model and the measurement is very good, and it can be concluded that the ray tracing model is reasonably reliable. The spatial resolution of the detection is almost too good, as the 2 cm offset at the distance of 40 cm already halves the fluorescence signal. However, point like alpha emitters can be then localized very accurately.

The interference filters used in this work are having a transmittance of about 10^{-6} to 10^{-7} in the visible wavelengths. The visible light blocking efficiency of the demonstration device is enhanced by introducing three similar fluorescence filters in a row. The transmittance also drops at the bandpass wavelength, but as the transmittance of a single filter in bandpass is about 90 %, the effect is not pronounced. A small decrease in fluorescence signal is necessary to get rid of the visible background. Artificial lighting that does not produce UV light can then be used with such a filtering. The visible lighting is effectively filtered out, and the fluorescence is only marginally decreased.

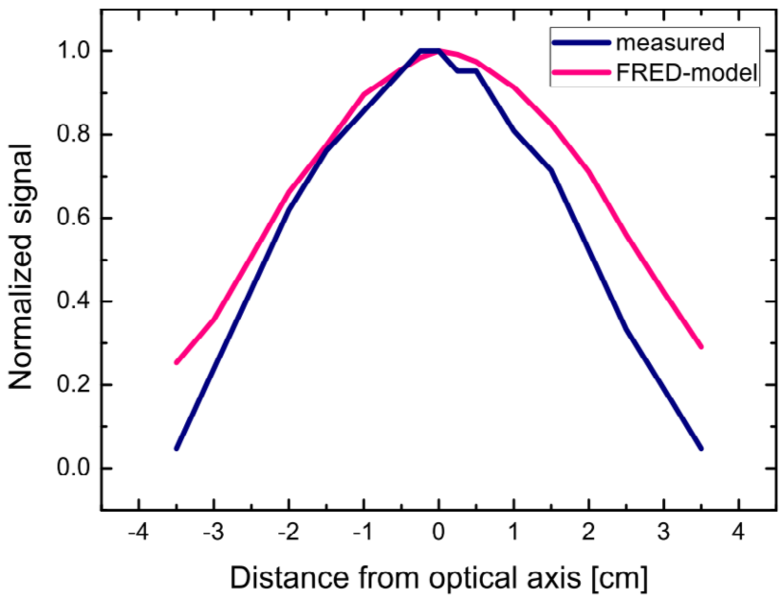

Fig. 5. Spatial distribution of normalized fluorescence signal of demonstration device as alpha emitter is moved away from the optical axis. The alpha emitter is assumed to be a point like source. The result of optical ray tracing model is shown as a reference.

Conclusions

A portable demonstration device with background compensation was constructed. The collected light consists of fluorescence signal and background light, which are divided with an optical beam splitter into two photomultiplier tubes. The both channels are filtered with interference filters to detect the fluorescence signal and the background light separately. The designed operating distance of the demonstration device was 40 cm from the point like alpha emitter. Using specially selected room lighting, the device was able to separate a 1 kBq alpha emitter from the background lighting with one second integration time. The new method looks promising for safety and security applications, where fast remote scanning of alpha radiation is required. However, the challenge of background lighting compensation needs always to be considered. The best practice is to work under artificial lighting conditions, where UV lighting can be avoided using LED-lighting or filtered lighting.

Identpro/SIA, an identification algorithm for statistically "poor" spectra – Application to mobile or pass-by systems for real time discrimination of sources of interest

Schulcz, Francis[1]; Gunnink, Ray[2]
[1] Mirion Technologies, FRANCE
[2] Consultant, USA

Abstract

Source or contamination searches with mobile systems is generally limited by sudden changes in natural background leading either to setting detection thresholds at the maximum value of background fluctuations or, if set at the average level, of accepting some false positive identifications. This can be overcome by monitoring spectrum changes in real time that is then used in a process that separates the isotopes of interest from the background components or from other innocent alarms like medical isotopes.

Identpro/SIA uses an identification method that has been developed for processing statistically "poor" spectra. While laboratory measurements typically yield spectra with counts in the 100000 range, Identpro/SIA is able to process spectra with a few hundred counts from the source of interest in the presence of thousands of counts of background. Identpro/SIA uses a combined ROI / deconvolution iterative method. This method does not use a peak search technique and therefore is well adapted for low counts spectra with a having large statistical fluctuations.

It supports the full isotope library for homeland security needs as defined by the ANSI, IAEA, and IEC standards. Furthermore it has been optimized for SNM identification including NORM or Medical masking scenarios with large unbalanced ratios, much beyond current standard requirements.

One typical application is the identification and real time rejection of innocent alarms when pedestrians pass by a spectrometric portal. Other applications are source or contamination searches and mapping with car-borne or air-borne spectrometric devices.

Results of extensive testing by spectra injections, by actual source testing and from field feedback are presented.

Introduction

Classically, radionuclide identification is performed using long acquisition time to avoid the influence of statistical fluctuations. Acquisition time is obviously also related to the detector technology and size, the radiation level, the expected precision, etc.

More recently, applications such as homeland security or large area scanning for lost sources or contamination have required detection sensitivities down to a fraction of the background in time periods of a few seconds. Gross counting detection methods cannot meet in practice such a challenge due to fast changing background rates especially in indoor or in urban areas. An additional issue is the discrimination of medical radio-nuclides that are the most commonly encountered sources in unrestricted areas. Such cases are even more important when considering “masking” scenarios, i.e. intentionally hiding an illegal source, with similar spectrum characteristics, in an otherwise legal source of a medical isotope

This can be overcome in a process that is able to analyze “instant” spectra in real time, identify the radionuclide, and so discriminate the isotopes of interest from the background components or from other innocent alarms like medical isotopes.

Identpro was originally developed by Ray Gunnink in the early 2000s, and then in collaborative efforts with Mirion Technologies, continued to improve it. The C language version is named Identpro/SIA and has grown more than three times in size over early versions.

Identpro/SIA method

The IDENTPRO/SIA identification algorithm is designed and optimized for identification with poor statistics, and for detectors with poor or medium resolution (NaI, LaBr3, CZT). The algorithm first determines intensities by region of interest (ROI). Currently more than 70 ROI’s are used ranging from 20 to 2614 keV. If a net intensity is found in the complex 260-460 keV and 565-830 keV regions, the peak intensities are refined by a fitting process. After all the ROI intensities are determined, the algorithm relates these intensities to the isotopes using interference coefficients that have been stored in spreadsheet file.

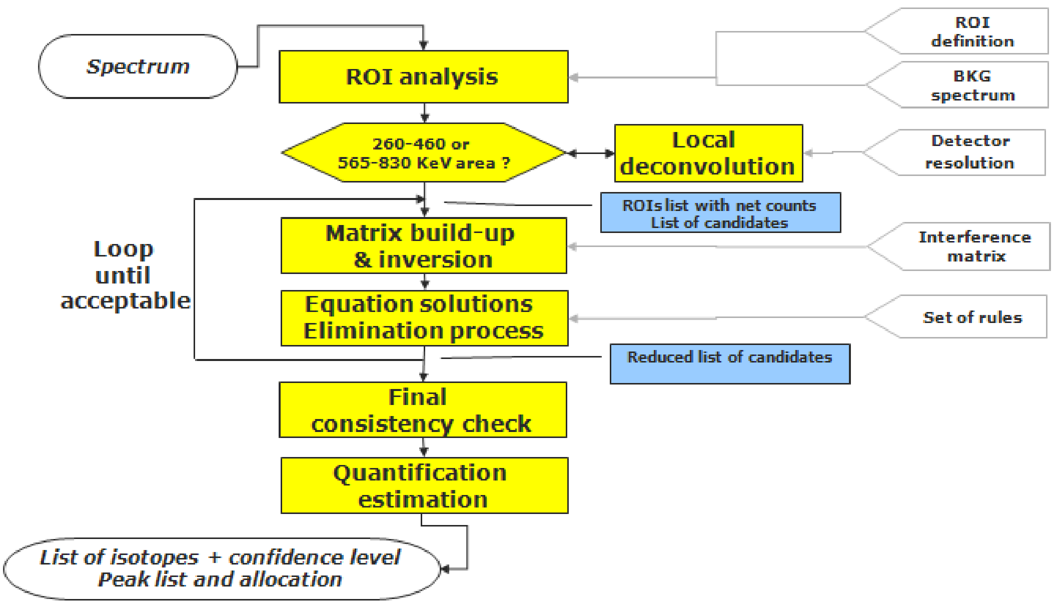

Fig 1. Flow chart of Identpro/SIA.

The next step is to solve the resulting set of linear equations by the method of least-squares, followed by rejecting isotopes yielding unacceptable results and starting a new loop with the reduced number of candidates. Finally the remaining isotopes are screened using additional criteria and decision logic tests

This method does not use a peak search technique and therefore is well adapted for low counts spectra with having large statistical fluctuations. While laboratory measurements typically yield spectra in the 100 000 counts range, Identpro/SIA is able to process spectra with a few 100 counts in the presence of 1000 counts of background

Testing the algorithm performances

Appropriate performance testing and evaluation of systems against approved standards in third party labs such as ORNL, PNNL, Austrian Research Center is mandatory, particularly for sources containing SNM. Despite the benefits we received from performance testing, one must recognize that the standard sources available in such laboratories cover only a limited number of scenarios. Furthermore the tests are go/nogo tests that do not evaluate the performance limits.

The most practical way to extensively test the identification algorithm is to use the so called injection method. Using a library of well defined spectra, i.e. with good statistics and with known intensities, one can weight, add and downscale to create sets of spectra corresponding to draws of various scenarios. It is critical that the process keep the proper statistical variation of counts within the channels, such as the Poisson law for low counts. The response of the algorithm to a set of downscaled spectra is then analyzed. The RASE program lead by the IAEA is an example of such a method.

We have used a color code to score the results of 100 draws:

Dark green: acceptable decision >95% of the cases
Light green: acceptable decision or acceptable decision +unknown >80% of the cases, wrong decision < 20% (remaining cases may be no decision)
Yellow: acceptable decision or acceptable decision +unknown >50%, wrong decision < 20% (remaining cases may be no decision)
White: acceptable decision or acceptable decision +unknown <50%, wrong decision < 20% (remaining cases may be no decision)
Orange: same as light green but added wrong isotope
Red: wrong decision substituting to right decision >20%

Table 1. Sample of the injection study output, scored with the color coded scale.

We acquired hundreds of actual spectra from type testing, evaluation programs, and field feedback which allow us to downscale preferably real spectra. Real spectra have the benefit of showing unexpected cases such as unexpected secondary isotopes that are included in some sources. As an example, we observed Tl-200 and Tl-202 at low levels in medical Tl-201, high enough to be confused with masked Pu if not properly taken into account.

Single isotopes versus level and integration time

Identification of single isotopes can be challenging when one tries to go beyond the classical condition as set by current standards. For Pedestrian Portals used in dynamic mode, the reference conditions are 50 nSv/h and a passage duration of 2 to 3s.

We studied how the ID decision relates to the dose rates contribution and how it relates to the integration time.

As expected, high energy radio-nuclides such as Co60, K-40, U-238 and radio-nuclides having many peaks spread over the spectrum such as Ra-226 and daughters and Th-232 and daughters, are the most demanding cases. Isotopes with simple structure such as Cs-137, Co-57, Am-241 are easier to distinguish from background. One can note that Pu and enriched U are quite easily identified whereas DU is more difficult.

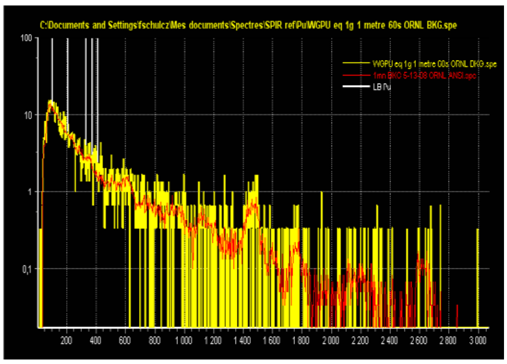

Fig 2b. Same with 3s duration. Although Pu is unnoticeable by eye, Pu warning flag is activated by Identpro/SIA.

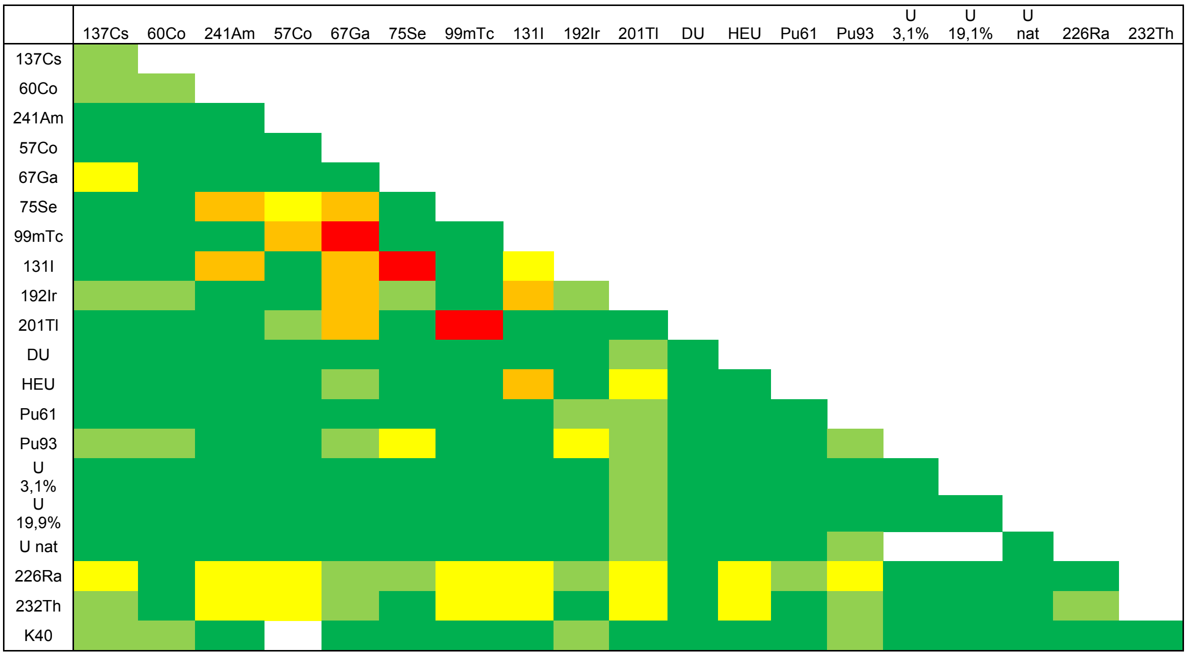
Mixed isotopes results

We also evaluated the algorithm's response to isotopes mixed in 1 to 1 ratios. Table 3 shows that most of the cases are properly identified. The "Red" colored cases correspond to some mixed medical radio-nuclides which are unlikely due to the short half-life of medical radio-nuclides. The algorithm tends to make a safe decision when a second isotope added to a medical one is suspect because it may be an attempt to mask a threatening radio-nuclide.

Table 4. Identification results 3*3 NaI(Tl), 60s, 50nSv/h of each radio-nuclide plus background.



Masking scenarios

The most well known masking case is Tc-99m and HEU due to the proximity of the 186keV peak of U-235 and the 141 keV Tc-99m peak. With high levels of Tc-99m, even using sophisticated pile up rejection, a pulse pile-up tends to mask HEU in very unbalanced scenario (fig 4).

A very difficult combination is certainly I-131 and Pu (fig 3) especially when the intensities are largely unbalanced.

Other cases are less known, but also very difficult. E.g. Tl-201 has a secondary peak at 167 keV that can mask the 186 keV peak of U-235. Ga-67 has a 93keV peak and a 185 keV matching the X ray region and the 186 keV peak of U-235.

Even Cs-137 can mask HEU due to the backscattering peak and can also mask Pu, especially when it is shielded because the addition of a weak source of Pu only changes slightly the Compton edge distribution of Cs-137 spectrum.

We demonstrated the ability of the spectrometric pedestrian portal SPIR-Ident to identify masked SNMs in in-vivo medicals using short 2s spectra for all 16 scenarios involving mixtures of the most popular medicals (Tc-99m, I-131, Tl-201, Ga-67) and SNMs (DU, HEU, RGPu, WGPu) in ratios of 1:10. We also tested the scenarios using

1:20 ratios. These analyses still gave good results with the exception of I-131 and Pu and Ga-67 and HEU (Table 5).

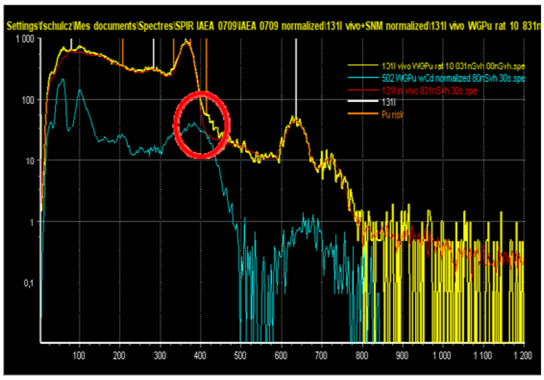


Fig 3. Addition of WGPu to in-vivo ^{131}I, ratio 1:10. Only a very slight bump can be seen on the right side of the 364 keV ^{131}I peak.

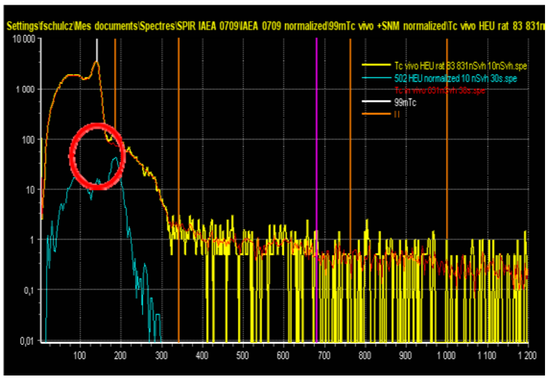

Fig 4. Addition of HEU to in-vivo ^{99m}Tc, ratio 1:10. Very low 186 keV peak hidden in ^{99m}Tc pile-up.

Experimental data: spectrometric pedestrian portal for airport

At airports or seaports, where large crowds must be checked, alarms due to medicals radio-nuclides cause a laborious and time consuming secondary inspection procedure that is annoying to front line officers as well as to innocent passengers.

Results of practical testing and of injection studies (see above) now allow us to set a dose rate threshold for medical isotopes uunder which a spectrometric portal will detect masking scenarios with acceptable performance, avoiding the need of secondary screening, and over which a secondary screening is still necessary.

Therefore, the crucial question is if such a threshold will significantly reduce the need for secondary screening. In order to gain practical experience in this question, a SPIR IDENT portal has been installed at the Vienna International Airport in early April 2009 and has been in continuous operation there since

Fig 5. SPIR-Ident layout at Vienna's airport non Schengen exit.

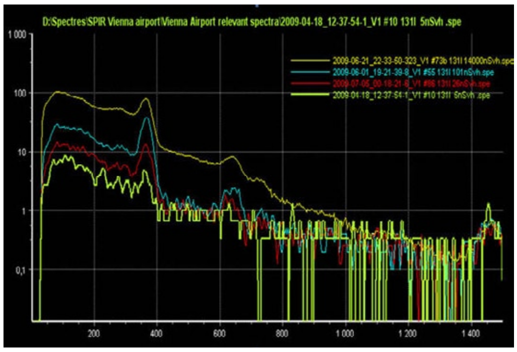

Fig 6. ^{131}I spectra 14µSv/h, 101nSv/h, 26nSv/h and 5 nSv/h maximum dose rate, captured at Vienna's airport exit.

Table 6. Results of 160 days operation with 170 medical alarms for about 1 million passengers.

all events for 160 days	all levels detected	all levels identified	max>15 nSv/h detected	max>15 nSv/h identified	max>25 nSv/h detected	max>25 nSv/h identified
201Tl	92	54	53	50	45	45
99mTc	35	30	15	15	12	12
131I	25	22	18	18	16	16
226Ra	7	3	4	2	0	0
125I?	5	0	0	0	0	0
111In	1	1	1	1	1	1
67Ga	1	1	1	1	1	1
unknown	1	1	0	0	0	0
possible Th	1	0	1	0	0	0
123I	1	1	0	0	0	0
Total	170	114	93	87	75	75
% identified		67%		94%		100%

Summarized results are the following:

- 170 cases during 160 days, one per 7000 passengers
- Tl-201 55% of the cases, Tc-99m 20% and I-131 15%
- Other isotopes are very rare but several cases of Radium
- Very low statistical alarm rate (2 per month)
- Many weak alarms 55% of the cases <25nSvh max,
- Few large alarms: 5% > 1µSv/h max

Identification capability of the SPIR-Ident spectrometric pedestrian portal has been demonstrated: 94% of the cases with peak level >15nSv/h maximum and 100% of the cases with peak level >25 nSv/h max are identified in real time when passing by. No incorrect identifications were observed and no false positives were reported despite cases with saturation

Experimental data: car-borne real time identification

Another application is source or contamination search and mapping with car-borne or airborne spectrometric devices. In the SPIR-Ident mobile implementation, a 2s spectrum is analyzed every 0.5s. Level information is continuously memorized along with the position given by a GPS. Levels are color coded on a map that can originate from Google Earth or from a preloaded map. When a detection occurs the spectra and the ID decisions are saved and a summary of the event is displayed as shown in Fig 7 and Fig 8.

Fig 7. Passing-by a legally transported source on the motorway.

Fig 8. Pedestrian and car driver with Tc-99m in the vicinity of a hospital.

The technology in SPir-Ident Mobile allows us to distinguish sudden background changes due to different road construction materials from actual alarms. Fig 7 shows a detection of a legally transported source at the moment the monitoring car passes by. The alarm duration was only 1 second but Cs-137 was identified within this duration. The monitoring car waited for the truck to get closer again to confirm the alarm which gave a second detection of about 20s. Fig 8 shows the detection and identification of persons injected with Tc-99m in the vicinity of hospital.

Poor statistical definition of actual spectra acquired during a car-borne survey can be seen in fig 9 and fig 10.

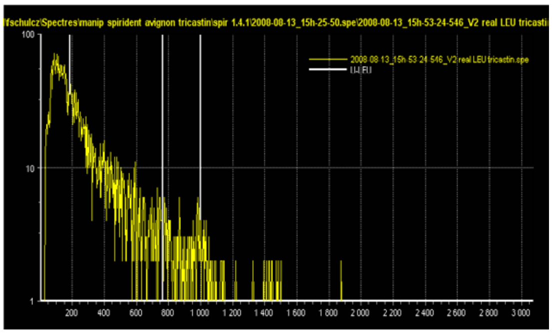

Fig 9. Uranium identification at background level when passing by an enrichment facility.

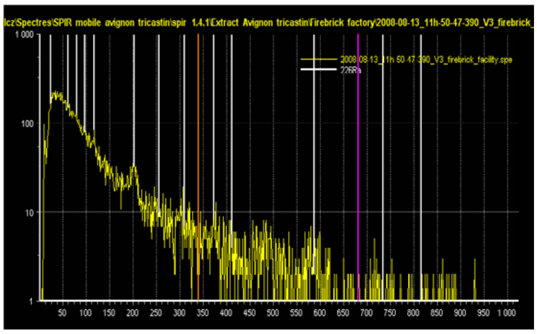

Fig 10. Ra-226 identification when passing-by a firebrick factory.

Conclusion

We gave an overview of Identpro/SIA as a valuable solution for identification of statistically “poor” spectra such as spectra processed by spectrometric portals in dynamic operation, spectra acquired in real time during mobile survey by handhelds, back-packs and larger mobile detection systems. So called “injection” studies have been widely used to improve ID algorithm and characterize the response to numerous scenarios, including demanding masking scenarios.

Developments in radiological-nuclear support to security through the Canadian CBRNE Research and Technology Initiative (CRTI)

Quayle, Debora; Ungar, Kurt; Hoffman, Ian; Korpach, Ed
Health Canada Radiation Protection Bureau, CANADA

Abstract

The Chemical, Biological, Radiological-Nuclear, and Explosives (CBRNE) Research and Technology Initiative (CRTI) was created to fund projects in science and technology that will strengthen Canada's preparedness for, prevention of, and response to potential CBRNE threats to public safety and security (1). Canada's federal radiological community – collectively known within CRTI as the Radiological Nuclear Cluster – has benefitted enormously from the collaboration upon which CRTI insists in order to qualify for funding.

During the past few years, the RN Cluster has taken steps towards becoming more operational, through field exercises, providing reachback support for responders and, on occasion, forward-deploying scientists and technicians for major events. This foundation, coupled with creative application of technologies developed by partners, enabled Canada's radiological community to rapidly and efficiently develop a smart, scalable solution for radiation security at the Vancouver 2010 Olympic Games.

Introduction

The Chemical, Biological, Radiological-Nuclear, and Explosives (CBRNE) Research and Technology Initiative (CRTI) was created under the leadership of Defence Research and Development Canada (DRDC) in 2002. Its mandate is to fund projects in science and technology that will strengthen Canada's preparedness for, prevention of, and response to potential CBRNE threats to public safety and security. Twenty-one federal government departments and agencies have signed an agreement to work together, through CRTI and related programs at the DRDC Centre for Security Science, to help further the meaningful application of science to address problems and challenges in the CBRNE domain.

One of the greatest strengths of the CRTI program is its insistence on collaboration. To qualify for funding, project proponents must partner with scientists and end-users from outside their own organizations, including other government departments (federal, provincial or municipal), first-responder and first-receiver groups, academia, industry, and the international community. In addition, scientists and response personnel are invited to participate in science "clusters" – one for each

C,B,RN, and E discipline, and an additional one for forensics – to share knowledge, target gaps in prevention or response capabilities, and generally identify synergies and common interests to further smart and complementary use of resources.

Recently, the clusters have taken steps towards operationalizing their science in a very real way – not only by putting new technologies into the hands of traditional response personnel, but by more actively providing reachback support for responders and, on occasion, forward-deploying scientists and technicians for major events. This paper will briefly describe the evolution of field teams within CRTI's Radiological-Nuclear Cluster, and highlight how they were deployed for radiological surveillance and support to security for the Vancouver 2010 Olympic Games.

For reasons of operational security, a number of details have been withheld from this discussion.

Preparation

Almost 20 years before CRTI was created, Prime Minister Pierre Trudeau ordered the Department of Health and Welfare (now Health Canada) to design a framework that would allow federal RN expertise to be harnessed and directed towards RN emergency response, in a hurry, if required. The current version of this framework is the *Federal Nuclear Emergency Plan* (FNEP, (2), with an updated Appendix 5 (3) that describes primary and secondary responsibilities for all federal departments with a role to play in the response *following* a radiological or nuclear emergency. Most of the departments tasked under FNEP are now also members of the RN Cluster.

When the Vancouver 2010 Olympic Games appeared on the Canadian security horizon, it became clear that a new framework was needed for departments with a role to play before a full-blown RN emergency is realized – specifically, for pre-event surveillance and support to federal security personnel[1]. Documents such as the IAEA draft planning guidance for nuclear security at major events (4), as well as communication with radiation and nuclear security organizations from countries who had hosted similar events (including Finland, Greece, and the United States) formed the planning basis, and a concept of operations was developed jointly with the Royal Canadian Mounted Police National CBRNE Response Team [2](RCMP; responsible for CBRNE security within the Olympic domain) and federal radiation scientists. Planning was made significantly easier due to good relationships between all parties, developed through CRTI-funded projects and exercises, and by leveraging a mix of mature, relevant capabilities pre-existing within the Cluster.

Team-building through exercises, 2003–2010:

One of the very first projects ever funded through CRTI involved a series of four, increasingly challenging field exercises using actual radioactive materials. The first was held in 2003; teams of scientists and technicians from four departments were sent out into a field to locate, identify, quantify and retrieve a variety of sealed sources. They had little difficulty dealing with the sources, but the experience was eye-opening in

[1] Border security and support to municipal responders were handled separately and will not be discussed in this paper.

[2] The core of the National CBRNE Response Team is composed of RCMP, military assets and biological experts from the Public Health Agency of Canada; experts from additional domains were added for the Olympics.

terms of recognizing the logistical requirements for a field deployment, not to mention the need for all-hazards expertise and police officers when dealing with unknown agents and possible terrorists.

Science Teams

Over the years, steps were taken to address the short-comings and learn the lessons identified in the first and subsequent exercises. Roles were defined, equipment upgraded, and operating procedures drafted and tested. In 2007, a few months prior to the fourth and final exercise in the original series, a concept of operations document was written for the newly-named Federal Radiological Assessment Team (FRAT). FRAT was originally conceived as an *ad hoc,* multi-agency, multi-disciplinary group of RN experts who can be deployed to the site of an incident when specialized equipment and/or expertise are required for consequence management. FRAT is not a standing organization; rather, departments and agencies provide resources to FRAT on an as-required basis depending on the nature of the incident and other operational commitments. Contributing organizations include: Atomic Energy of Canada Limited, National Defence (Defence Research and Development Ottawa and Defence Nuclear Safety Division), Health Canada and Natural Resources Canada. Personnel from these organizations train together periodically, participate in the planning and execution of exercises and, lately, join forces to provide scientific support for major events. Any one of these can supply the Team Lead for a given operation and, typically, for exended deployments, personnel from different home organizations will rotate through the lead position.

Security Teams

The exercises, as well as additional training and simulation opportunities and joint CRTI projects, provided opportunities to interact with the responder community and, specifically, the National CBRNE Response Team (National Team). It would be fair to say that the scientific community was ready to embrace the policing community well before the police were ready for the scientists. However, as the exercise series progressed, participation changed from scientists alone, to scientists and police working separately on concurrent scenarios, to finally scientists and police working together. This mutual exposure was crucial to enabling the two groups to begin to understand each other and, subsequently, to find ways to make science truly work in a security context. By March 2008, FRAT had begun to expand its field capabilities from strictly post-incident response to include pre-incident surveillance and support to interdiction and intervention.

Deployment for V2010

In December 2008, the Government of Canada approved a request from the National CBNE Response Team for chemical and radiological scientific support prior to and during the Vancouver 2010 Olympic Games. Biological scientific support had been integrated with the National Team for years; the addition of chemical and radiological capabilities provided an unparalleled degree of technical reachback. The collective C,B, and RN deployed assets, along with a mobile forensic capability, became known as "Science Town." This paper focuses on the radiological assets; however, it should be understood that these are just one aspect of a broader initiative to complement security with operational science.

Specific support tasks fell into the following categories:

– Scientific reachback and advice
– Sample analysis
– Surveillance

Scientific Reachback and Advice

Throughout the deployment, the RN Science Advisor was the main liaison between the RCMP and the rest of the radiological science team. All information gathered by the scientists flowed through the Science Advisor to the RCMP; and all direction and information from the RCMP flowed through the Science Advisor to the rest of the radiological team.

The Science Advisor was required to have a strong background in radiation physics and health physics, good communication skills, experience working with RCMP, and a good knowledge of the expertise and skill sets that could be called upon from within the RN Cluster, if required. Four RN Science Advisors from three different organizations rotated through the six-week Olympic operation; each also served as the lead for the multi-departmental FRAT while deployed.

Sample Analysis

Samples and swipes were counted and characterized on-site by analysts using a variety of detectors in a vehicle-based platform, or "mobile laboratory." Mobile labs have been used by some cluster members for decades. In 2005, building on lessons learned from partners' earlier iterations, CRTI funded four identical mobile nuclear laboratories, strategically locating them with host organizations across Canada. The labs are very simple – they are effectively mobile bench-space with power and sufficient climate control to allow operation in the extremes of Canadian weather – making them extremely portable. In order to maintain operational readiness, they are routinely used by their hosts for decommissioning, field trials, and training and exercises. In the year prior to the Olympics, CRTI was able to fund a fifth mobile nuclear lab, piloting a new design which maintains mobility while adding workspace, networked computing, and some new features for improved detection and sample handling (especially for nuclear forensics). Future deployments will also include a trailer with mounted satellite and workspace for command and control.

During the Games, samples were collected by police and brought back to the scientists; under no circumstances were scientists to enter areas where there were unknown or significant non-radiological hazards. Samples would arrive at the forensic trailer first for basic triage, sample logging, and collection of traditional (non-CBRN) evidence. Scientific Advisors from all three disciplines and forensic experts would then discuss the situation and potential hazards in order to determine the safest and most expedient way to proceed with identification and characterization of CBRN agents. In addition to minimizing risk to scientists (by not forward deploying them) and limiting disruption to a potential crime scene, this approach also allows for centralization of equipment thereby minimizing the overall footprint of the deployed reachback.

Surveillance

RN surveillance for security purposes was something relatively new to both the scientists and the police in Canada; consequently, it took some time for the idea to gain acceptance from all stakeholders. In addition, the other elements of security planning with which RN surveillance had to mesh were extremely elastic; as a result, the strategy had to be flexible and adaptable, allowing for last-minute changes and adjustments even after installation. Because both buy-in and planning guidance were somewhat slow in coming, the team had less than a year to implement the strategy.

In addition to the short timeline, constraints were as follows:

- Discretion was paramount. The Olympics are considered a sporting event, not a security event; consequently, surveillance had to be discreet and minimally intrusive.
- Olympic venues were spread over a geographic area of more than 1000 km^2.
- Money and personnel were both very limited resources.
- A large amount of detection equipment was required for a very short time.

The solution centered on rapid detection and identification with reliable, well-characterized instruments and systems. It combined mobile and portable networked systems of spectroscopic detectors, which allowed a very few people to monitor very large areas, with less costly and sophisticated human-portable detectors, worn by police officers and other security personnel at strategic locations to add depth and redundancy. Finally, costs and procurements were justified by ensuring that almost all of the equipment was re-usable for future major events, and much would be re-deployed out to regional offices or used to replace aging inventory in environmental monitoring networks.

Discussion

The approach allowed the RN Cluster to play to its strengths, as well as to extract as much use from our limited resources as possible. Fortunately, the problem of monitoring a large area with few people is a common one in Canada and so it was possible to leverage existing capabilities – specifically those used for environmental monitoring, survey and mapping -- and re-apply them to security in a number of cases. By re-deploying or building on systems that were already extremely well understood and deploying the “normal” users to operate them, performance risk was kept to an absolute minimum, as was the need for specialized training.

In addition, using mobile and portable equipment ensured that detectors could be re-distributed throughout the Olympic domain if the threat assessment changed. Looking to the future, it is also now relatively easy to re-deploy this equipment for major events in other parts of the country.

Where possible, data was automatically captured and routed to a central location, where it could be accessed and analyzed locally or remotely. This allowed analysis duties to be shared between personnel deployed to Vancouver and those at home in Ontario, thereby ensuring that sufficient personnel were available to do the work while keeping the deployed footprint small, and minimizing wear-and-tear on personnel in the field. Again, this reduces performance risk and also helps ensure the well-being of the people in the field, increasing the likelihood that they'll be willing to participate again in future events.

It can be argued that relying on data transmission for a surveillance system is risky in that, if communications are lost, so is the ability to monitor. For the Games, redundant systems were in place, albeit less sophisticated ones, so that monitoring would continue uninterrupted even if a whole network was disabled. In addition, and on a strictly practical note, the risk was considered and accepted in light of the significantly greater situational awareness and significantly reduced personnel costs afforded by a distributed network of unmanned detectors and centralized data analysis.

Technology was a big part of what FRAT brought to the Vancouver Olympic Games. However, what the police wanted – more than detectors and data – was information from a reliable source. This what they always want, whether for a major event or a crisis in the middle of the night. For years, the only essential components for effective scientific support have been a telephone and a 24/7 phone number. The detectors and the data help during a large public event, but it is the context that an experienced RN subject matter expert can add to a detection (or suspected detection) that makes the information truly valuable. Fortunately, this context can be applied – with less precision, perhaps – even in situations where the data is collected by instruments and operators less familiar to the expert. Now that the Olympics are over, the challenge for FRAT will be to sustain the momentum built up over the past couple of years and find ways to ensure that the expertise remains accessible to those who need it.

Conclusions

The support and incentive provided by CRTI to develop capabilities in RN counter-terrorism encourages the Canadian federal radiological community to find ways to apply science and technology to security problems. This includes developing technologies and networks that can be adapted and exploited for multiple uses, both emergency and peace-time. Further, exercises, deployments, and collaborative work with Canadian police and security organizations provide opportunities to test and demonstrate the applicability of newly developed technologies for security purposes, and to reinforce the applicability of specialized expertise in helping responders deal with CBRN agents. Overall, CRTI has helped foster a climate in which scientists and responders are comfortable and well-positioned to combine their assets to defeat CBRN threats, as was evidenced by the successful deployment for the Vancouver 2010 Olympic Games.

Abstract

From December 7 to 19, 2009 Denmark hosted the United Nations Climate Change Conference, COP15. For an event of such magnitude, security was a major concern. Danish Police in cooperation with UN decided to establish a dedicated CBRN (Chemical, Biological, Radiological, and Nuclear) security and emergency management project. The National Institute of Radiation Protection (NIRP) was expert advisor on the radiological security measures. These included access control and radiological surveillance at the conference site (Bella Center) and a mobile team that could perform screening tasks and emergency assistance in the Copenhagen area. Daily screenings of key locations in Copenhagen were made with carborne gamma spectrometry in cooperation with Danish Emergency Management Agency (DEMA).

The radiological security check at Bella Center was constructed to be discreet and with a minimal distraction of the traffic of delegates. The conference access control area was airport style with all together 25 lines with metal detector and x-ray machines for luggage scan. It was expected that approximately 15,000 delegates, journalists and NGO members would pass the security control over the course of the meeting.

For personal screening walk-by plastic scintillation detectors were installed. Detection of any gamma radiation above 60 keV would trigger an alarm. Police and UN-security personal were instructed to stop the traffic in the access control area in case of an alarm and to contact the radiation expert. NIRP radiation experts remotely monitored the detectors from a nearby office and could arrive at the access control area within a minute after an alarm. Their equipment included a mobile HR Ge-detector that could produce a high resolution gamma spectrum in minutes. Three incidents were recorded with persons who had received radiopharmaceuticals.

Introduction

Danish police had the main responsibility for security during the United Nations Climate Change Conference, COP15. The conference was held in Copenhagen from

December 7 to 19, 2009 and was the largest UN conference ever held outside the UN building in New York. UN had several specific requests to security including CBRN security and emergency preparedness measures. NIRP was therefore asked to plan and implement the radiological security action in accordance with the UN requirements.

NIRP is part of The Danish National Board of Health and is the Danish authority on radiation protection. This includes a 24-hour emergency service with one radiation expert on duty that can respond to any unintended incidences with radioactive materials. The radiation expert can also offer qualified assistance to police and other authorities in case of malicious acts involving radioactive or nuclear material.

However, the magnitude of the COP15 conference, required a corresponding reinforcement of the radiation security and emergency management. Internal education and training of in-house radiation protection officers started 8 month before COP15 and altogether 15 radiation protection officers took part in the event. This number does not include administrative personnel and lab technicians who were on-call duty during the cause of the event.

DEMA participated in the security actions with two vehicles equipped with carborne gamma spectrometry and with four HAZMAT (HAZardous MATerials) teams each trained to conduct sampling and measurements in case of a CBRN incident.

Material and methods

Altogether 3 different radiological security actions were arranged a) daily radiological screening of key localities, b) a mobile radiation expert team, c) access control at Bella Center, the conference venue.

Daily Radiological Screening

The purpose of the daily screenings on the streets of Copenhagen and in the vicinity of the conference centre was to observe any diversion from the normal radiological picture. The screening effort was concentrated around high security hotels and other places where VIP delegates were or could be present.

Several months in advance of the conference NIRP had contacted all licensed users of radioactive sources and companies transporting radioactive sources to ensure that NIRP was notified prior to the use of sources and transportation during the conference period. A ban on transport of high activity sources was issued. The screenings were performed by DEMA's carborne gamma spectrometry vehicles equipped with an Exploranium 4L NaI(Tl) detector (256 in^3, 16"x 4"x 4"). Measurements were made as 2-seconds real time. For neutron detection a NUCSafe Guardian PRST neutron detector was used.

Radiation Expert Team

The mobile radiation expert team was on 24 hour on-call duty and could be requested by the Police. It could respond to any situation involving radioactive substances or suspicion of use of radioactive substances in the Copenhagen area within an hour. The team was equipped with hand-held radiation instruments including FieldSpec Na(I) gamma spectrometers for nuclide identification. They would be able to advice Police and HAZMAT teams in setting up controlled areas and could handle and secure minor radioactive sources.

Radiological Surveillance and Access Control

The radiological access control at Bella Center was probably the greatest challenge since this had to be coordinated with several other security measures and involved close cooperation between Police, UN security personnel and a private security company. The radiological security measures had to be coordinated with x-ray luggage scans and metal detection of all conference delegates and their luggage. Access to the conference centre was open 24 hour a day and altogether 25 lines with luggage scanners and metal detectors were open during conference peak hours between 7 and 10 am. Up to 5,000 individuals were passing through the access control area within this time interval. Police and UN–security required that radiological security check was discreet and that any false alarms and incidents could be solved quickly and with minimal distraction of the traffic in the access control area. The main concern was false alarms from delegates who had been examined or treated with radiopharmaceuticals, as previously observed in international events where radiological security measures was performed (IAEA, 2009).

The problem was solved by installing three walk-by detectors placed between the first security check and the entrance to the accreditation area (Fig. 1 A). The walk-by detectors were Canberra Portia highly sensitive 40 x 60 x 5 cm^3 plastic detectors that were set to record any gamma radiation above 60 keV. The alarm level was set to trigger an acoustic and visual alarm if a source corresponding to 370 kBq Cs-137 passed the detector within 1 m. A more sensitive setting was possible, but impractical, since the alarm would be triggered by a radioactive source too far from the detector, and hence it would be more difficult to identify the source in a large crowd. Police and UN-security personal were instructed to stop the traffic in the access control area in case of an alarm and contact the radiation expert. NIRP radiation experts remotely monitored the detectors from a nearby office and could arrive at the access control area within a minute after an alarm. During peak hours a NIRP expert was present at the access control area together with other security personnel. NIRP experts were equipped with Thermo RadEye B20-ER GM detectors for dose rate measurement and Thermo GX 2'' Na(I) detectors for high sensitive gamma detection (Fig 1 B). All radiation experts wore Thermo EPD personal dosimeters. In case of an alarm from a walk-by detector, with many people present, NIRP experts could find the radioactive source with hand-held detectors.

The radioactive person or object was hereafter escorted to a visitation room for nuclide identification and activity. For radionuclide identification a Canberra Falcon 5000 portable cryo-cooled HR Ge-detector was used (Fig 1 B and C). The Falcon uses Falcon 5000 software as well as Genie2000 detector software. The software nuclide library was updated with all likely radionuclides used in industry and medicine.

Lu-177	Gamma Beta	208 490	11	6.71 days		Therapy

Table 1 lists the most commonly used radionuclides in radiopharmaceuticals in Denmark. The Falcon 5000 software is designed to suggest radionuclides from the library as soon as a significant peak is found in the spectrum. The most recent background spectrum is automatically subtracted, when a radioactive source is measured. The radiation expert on duty measured a background spectrum each day. The background spectra contained K-40, U, Th and their typical decay series isotopes.

The radiological security measures in Bella Center also included background radiation measurements at specific localities in the centre and dose rate and surface contamination measurements at plenum halls and other key localities (Fig. 1 D). For surface contamination measurements we used Thermo RadEye AB100 detectors.

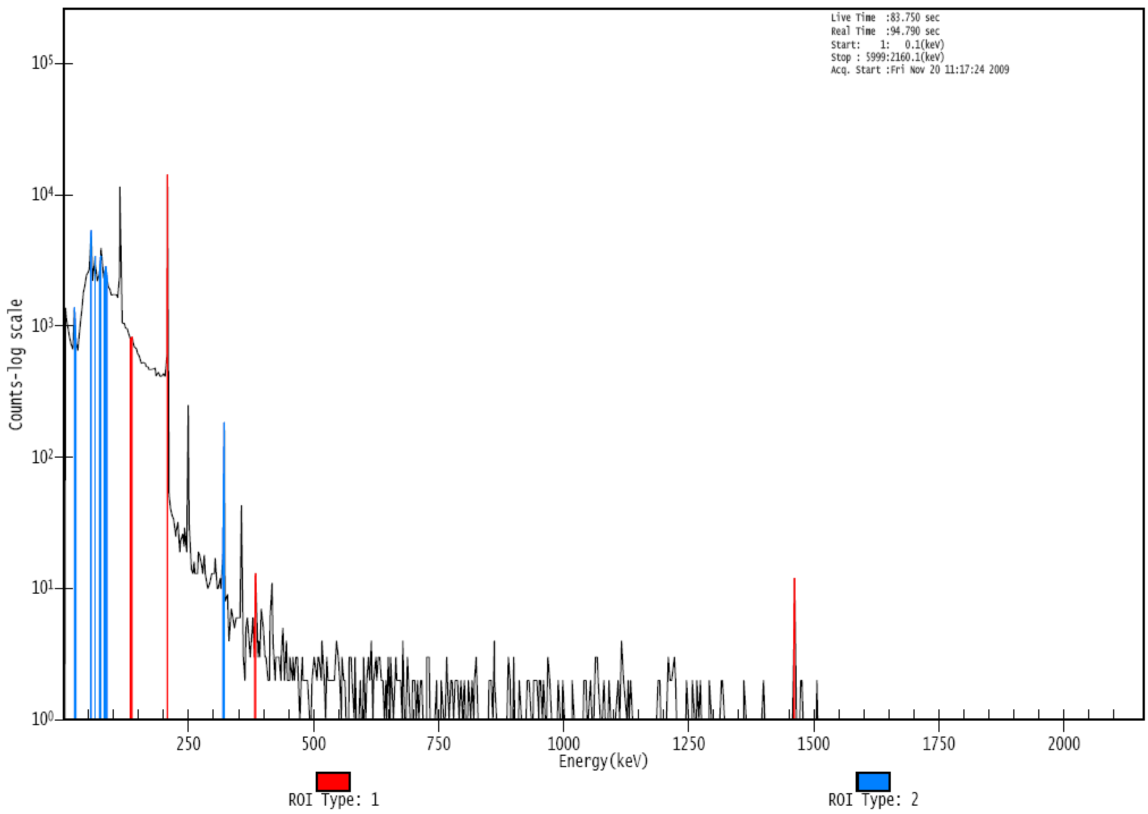

Fig. 2. High Resolution gammaspectrum taken 1 m from a patient who has been treated with radiophamaceutical containing Lu-177. A measuring time of little more that a minute is sufficient for precise radionuclide identification.

Radiological Incidents

During the entire operation 3 incidents were recorded, all at the access control area in Bella Center. All incidents were so called “innocent alarms” related to delegates or employers who had received radiopharmaceuticals. The radionuclides detected in the three cases were I-131, Tl-201 and Lu-177. In all cases, the delegate triggering the alarm of the walk-by detector was approached by a radiation expert with a handheld instrument, and the delegate was hereafter measured in the visitation room with the HR Ge-detector. Tl-201, a radionuclide used for heart diagnostics, was not on our original list of potential radiopharmaceutical, since it is not used in Denmark (Table 1). Identification was, however, fast from the Falcon 5000 nuclide library and since the delegate was aware that he had been examined, the measurement took only a few minutes.

All radioactive delegates were equipped with a certificate of the measurement with radionuclide and corresponding dose rate. They were kindly asked to report to the radiological expert on duty prior to every transit of the access control area in order to be guided past the walk-by detectors.

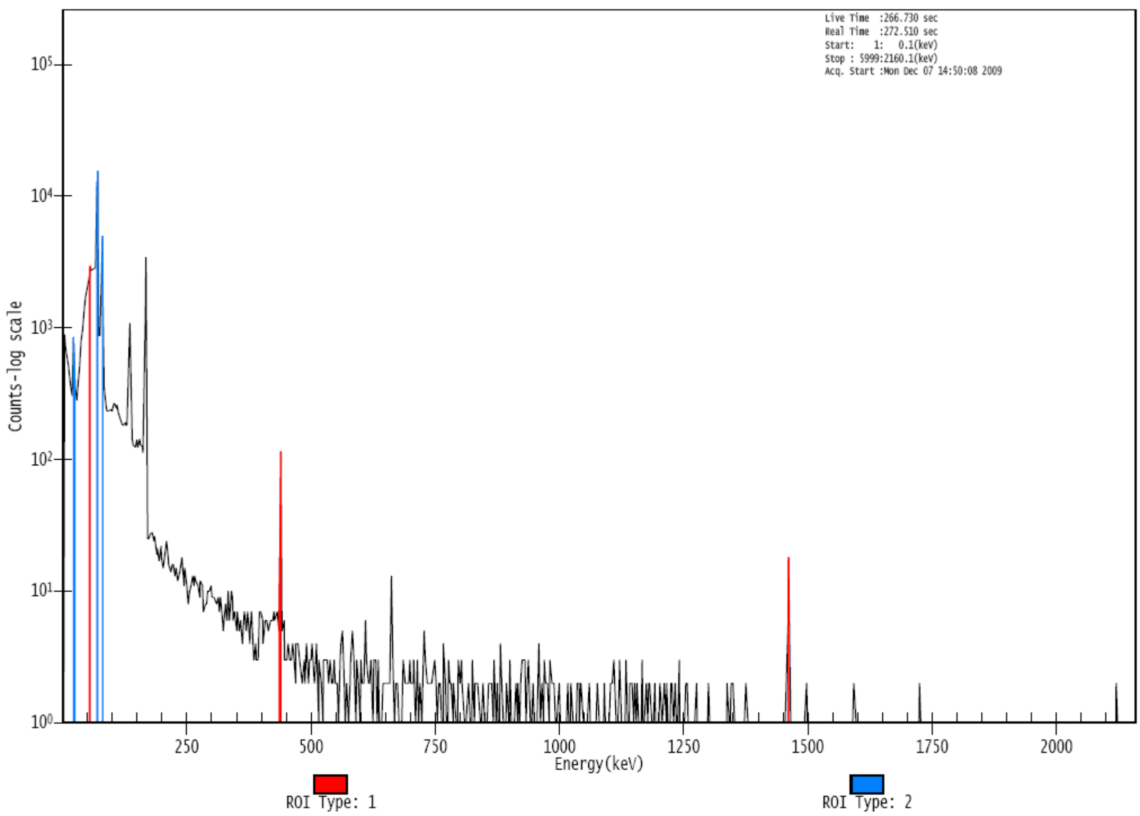

Fig. 3. High Resolution gamma spectrum taken 1 m from a patient who has been treated with Tl-201. The characteristic gamma energies from Tl-201 are at 69 and 167 keV, respectively. Note also the gamma energy from Tl-202 at 440 keV.

Gamma Spectra Recorded

Fig. 2 shows a typical gamma spectrum for a person who has received Lu-177. All gamma lines in the spectrum originate from Lu-177 (Table 1) or background U, Th and K isotopes. The background was, as previously mentioned, subtracted before the nuclide library match is performed.

The gamma spectrum for Tl-201 is shown in Fig. 3. It is well known that Tl-201 often contains traces of Tl-202, which can be seen in the spectrum at the characteristic gamma energy at 440 keV. In fact, Tl-202 is probably responsible for most of the dose rate from this particular patient since its half life is 12 days compared to 73 hours for Tl-201. The patient had received his examination a week before attending the conference and the dose rate was 0.2 μSv/h at 0.5 m from his torso at the time the gamma spectrum was obtained.

Conclusions and Lessons Learned

Events involving radioactive material intended for malicious purposes were not detected. This in itself is an important result.

We learned the following from the radiological security arrangements during COP15:

- The key element, and challenge, in the planning was the cooperation with other authorities concerned with security, which had not previously worked with radiation protection authorities.
- Training of radiation experts together with testing and preparation of equipment was of great value. It is important to test and practice any equipment prior to use during the operation.
- It is vital that instruments are purchased and tested in adequate time before an event, and that all radiation experts are familiar with the equipment used.
- It is important to recognise problems with innocent alarms and establish procedures for dealing with these. All innocent alarms recorded during COP15 came from radioisotopes for medical diagnosis or treatment. These cases were quickly recognised since a highly advances HR Ge-detector was used directly at the first “line of defence”.
- It is likewise important to reduce the possibility for innocent alarms by reducing transport of radioactive sources during the event and to require notification of use of sources in the public room.
- Considerations should be given to possible radionuclides in radio-pharmaceuticals. A nuclide library as complete as possible should be established and radiation experts should be trained accordingly.

Testing of a portal monitor to detect illicit trafficking of anthropogenic radioactivity in operational field use

Ramseger, Alexander[1]; Kalinowski, Martin[1]; Schwartz, Christian[2]; Rosenstock, Wolfgang[3]; Hands, James[1]; Büker, Michael[1]

[3] Fraunhofer Institute for Technological Trend Analysis Euskirchen, GERMANY

Abstract

Measurements were conducted at a cargo container checkpoint of the German Customs Office at the Hamburg Harbour. At this checkpoint a radiation portal monitor (RTM 910 of MIRION Technologies) has previously been installed. The RTM 910 is capable of neutron and gamma detection with a low energy-resolution. To detect the gamma radiation plastic scintillators are used. In this field experiment 30 to 40 cargo containers were controlled per hour. In this time approximately three alarms per hour were given. To examine what kind of radionuclides caused these alarms, it was necessary to analyse spectra of the radiation when such an alarm occurred. For the identification of the radioactive substances two other gamma detectors were used in addition to the RTM 910. One detector was a high purity germanium detector with an energy resolution of better than 2 keV. The other detector is based on sodium iodide and has an energy resolution of about 10 keV. Both were used to take spectra exactly at the time an alarm was given by the RTM 910 and to identify the alarm causing radionuclides by analysing the spectra with two different programmes. All the detected radionuclides are naturally occurring.

In addition measurements with the germanium detector were conducted in order to estimate radionuclides which cause the background.

Introduction

To detect illicit trafficking of radioactive material, radiation portal monitors are used at border crossings. The currently most widely used detector material is plastic scintillator. These plastic scintillators are sufficient for gross counting but they have disadvantages in nuclide identification due to their low energy resolution. Therefore their performance is compare to detectors with much higher resolution like e.g. sodium iodide (NaI) or high purity germanium (HPGe). This comparison helps to estimate how an appropriate use of such detections systems is possible under operational field conditions. Therefore spectra, recorded with such high resolution detectors, have been analysed regarding possible radionuclides. Furthermore measurements have been conducted to get an overview about naturally occurring radioactive materials (NORM) like e.g. potassium or the products of the uranium and thorium natural decay series which lead to an appreciable radiation background.

Material and methods

To get a first overview on the situation of cargo-control, measurements were conducted at the cargo container checkpoint of the German Customs Office at the Hamburg Harbour.

At this checkpoint a radiation portal monitor has been installed. This monitor, RTM 910 which was developed by MIRION Technologies, is capable for neutron- and gamma-detection with a low energy-resolution. To detect gamma radiation and to produce signals proportional to the intensity of the radiation, plastic scintillators are used. The signals are then collected by a central monitoring system (CeMoSys).

Thereafter the signals are analysed and compared to the radiation background. If the adjustable alarm limit is exceeded an alarm is given. The measured radiation is divided into six ranges of energy. This allows to discriminate between certain types of radionuclides (e.g. NORM or SNM: Special Nuclear Material).

The RTM 910 has two detectors (each detector 50 x 80 x 5 cm plastic scintillator) on both sides of an incoming street to the checkpoint. The distance between the two detector parts is six metres and the cargo containers are transported through this portal monitor with an average velocity of 30 km/h.

In the field experiment 30 to 40 cargo containers were controlled per hour. In this time approximately three alarms were given by the CeMoSys. To examine what kind of radionuclides caused these alarms, it was necessary to analyse spectra of the radiation when an alarm occurred.

For the identification of the radioactive substances two other detectors were used in addition to the RTM 910. These detectors were high-resolution spectrometric gamma detection systems.

One detector is called ReGeM and was produced by Canberra. This is a high purity germanium detector (coaxial germanium cristal, length: 59 mm, diameter: 60.5 mm) with an energy resolution of 0.3% at 662 keV. The other detector (Spir Ident, produced by Mirion Technologies) based on sodium iodide (40 x 10 x 5 cm) and has an energy resolution of 8% at 662 keV.

The idea was to take spectra exactly at the time an alarm was given by the RTM 910 and to discover the alarm causing radionuclides by analysing the spectra. To record the spectra simultaneously to RTM alarms it was helpful that the Spir Ident could be triggered on radiation above background level.

It was not possible to trigger the ReGeM on radiation increase in order to inspect the relevant containers. Therefore short time spectra (3- 4 seconds) had to be taken manually.

All measurements were conducted during a period of ten days. In this period approximately 320 cargo containers were inspected per day. During one hour, three to four alarms were given by the RTM 910, but due to problems with the central monitoring system only a small amount was recorded.

The second purpose was to determine the naturally occurring radionuclides which causes the radiation background. For that purpose 24 spectra had been taken with the ReGeM detector over 20 minutes each. The ReGeM detector was most suitable for this due to its high energy resolution.

Results

The results of the measurements with the Spir Ident are quite satisfying. It was possible to discover radionuclides in the spectra that were simultaneously recorded to RTM alarms. The identified radionuclides were potassium and products of the thorium and uranium decay chains. All these radionuclides are classified as NORM. The spectra were analysed with two different programmes; SMI (a product of Mirion Technologies) and Genie-2000 (a product of Canberra).

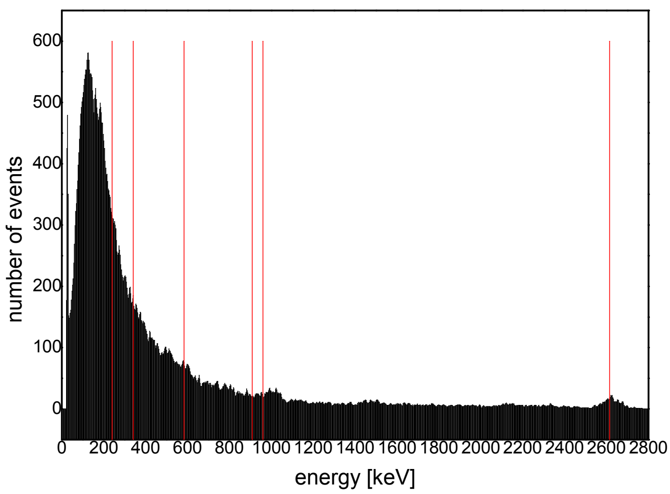

Fig. 1. Spectrum obtained with the Spir Ident due to an increase of background radiation and simultaneously recorded to an alarm given by the RTM 910. The positions of peaks related to the characteristic energetic lines of Th-228 are marked with red lines. Only at 2614 keV a peak was found, but it was sufficient to identify the presence of Th-228 with a probability of 60% by the key line of its daughter product Tl-208.

As written above all alarms can be explained with naturally occurring radioactive materials. The identification probability was 20 – 30 % in case of uranium (four times detected), 40 – 90 % in case of thorium (three times detected) and 40 – 70 % in case of potassium (ten times detected). The results of the SMI software were confirmed with the Genie 2000 Software.

The short time spectra recorded with the ReGeM detector were not usable since the measured rate of radiation was too small in order to get statistically significant information on possible radionuclides, even if several channels were aggregated.

The estimation of background causing radionuclides was analogous to the spectrum analysis before. Based on 24 spectra recorded with the ReGeM detector (each measurement time 20 minutes), the presence of several radionuclides has been determined. These radionuclides occur also naturally and were again nuclides like potassium or the products of primordial radionuclide decay chains, e.g. Bi-214 or Pb-14. Table 1 shows occurring naturally radionuclides as they were found in the recorded spectra.

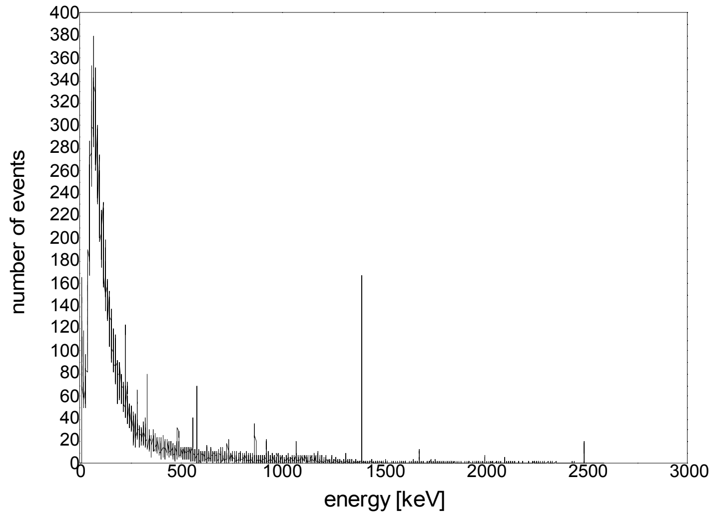

Fig. 2. Spectrum obtained with the Regem detector. The duration of measurement was 20 minutes.

Table 1. Radionuclides, discovered in background spectrum shown in figure 2 recorded with the ReGeM detector. As an example the count rate obtained from the spectrum shown in Fig. 2 is given for each emission line.

Radionuclide	Emission line [keV]	Count rate
K 40	1461	1030
Pb 214	295.224	88
Pb 214	351.932	291
Bi 214	609.312	253
Bi 214	768.356	49
Bi 214	1120.287	59
Bi 214	1238.110	35
Bi 214	1377.669	40
Bi 214	1764.494	71
Bi 214	2204.21	18
Pb 212	238.632	273
Tl 208	510.77	124
Tl 208	583.191	184
Tl 208	2614.533	155
Av 228	911.204	128
Ac 228	968.971	77

Discussion

All identified nuclides (10 x potassium, 4 x uranium, 3 x thorium), which are supposed to be the reasons for the alarms given by the RTM 910, occurred naturally. They are often contained in building materials but even they can be found in litter or K-40 fertilizer. Since such materials are often transported through the Hamburg Harbour their occurrence is not anomalous.

Conclusions

The Spir Ident detector is suitable for container inspections; every RTM910 alarm was also simultaneously accompanied by a detection of a higher radiation background by the Spir Ident and instantaneous nuclide identification with SMI.

The ReGeM detector was not suitable for container control because of the low count rate that did not allow for any detection. The detection efficiency of a germanium detector is too low for short time measurements. However the ReGeM detector was suitable to estimate natural radionuclides that occur in the measurement area permanently. Therefore 24 spectra had been analysed. It was possibly to identify the typically occurring radionuclides that are part of natural decay chains of uranium or thorium. These spectra can further be used for consistency checks of e.g. radiation background estimations.

The measurements at the Hamburg Harbour were conducted in cooperation with MRION Technologies (RADOS) GmbH in Hamburg, the Fraunhofer Institute for Technological Trend Analysis in Euskirchen (INT) and the technical service of the German Customs Office in Hamburg.

Detection of radiation sources and assessment of measurement signals for nuclear security

Karhunen, Tero; Smolander, Petri; Toivonen, Harri
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract
Nuclear security is an important item at major public events and political meetings. The organizers and the law enforcement have to guarantee that no radioactive material is hidden at the venues. Portal monitoring is effective in controlling flow of people and goods. Alone, however, it is not sufficient for radiological security. Mobile measurements have to be carried out during pre-event search and during the event itself. Radionuclide detection capability is needed inside and outside the venues, and also at the major traffic nodal points. Mobile measurements are technically demanding.

The Radiation and Nuclear Safety Authority (STUK) started a project, known as VASIKKA, for in-field measurements. With EU-support another project, SNITCH, was launched for data management. Together they are intended to detect criminal use of radionuclides at the major public events and political meetings. End-users of the system are law enforcement agencies.

VASIKKA and SNITCH secure critical venues through integrated radionuclide detection capability, based on mobile monitoring, efficient data communication (in-field sensors) and data management, including automated data exchange from database to database via Internet. SNITCH transfers the alarms and the key analysis results immediately to experts or to duty officer. This gives timely response, based on assessment of the key findings, for the law enforcement against unauthorized or criminal acts related to nuclear or other radioactive materials.

Radiation measurement system VASIKKA
A backpack size measurement system called VASIKKA has been designed to be used by the field teams. The system consists of a gamma-ray spectrometer, a neutron count rate detector and a rugged data collection and management computer. $LaBr_3$ scintillation detector is used in the gamma spectrometer. The spectrometer has good energy resolution (< 3 % @ 662 keV) and performs well in different environments.

The measurement system uses a short acquisition time to enable mobile measurements with good spatial resolution even with relatively high speeds. A robust summation algorithm is the basis of the peak detection. VASIKKA has three modes of operation, fast, medium and slow:

- SRCH (4 s)
- MON1 (40 s)
- MON2 (400 s)

The user does not have to select any measuring mode; the monitoring modes run in the background, and provide alarms when the triggering level has been exceeded. The alarm is based on the concept of peak significance (Table 1).

Table 1. Confidence on nuclide identification in VASIKKA software. The initial categorization is based on peak information. In addition, nuclide-specific discard rules are implemented to avoid false identification. For definition of the peak significance *S*, see text.

Confidence level	Number of peaks	Rule	Comment
1	1	$1 \leq S \leq 1.5$	Small peak (H_0)
2	1	$1.5 < S \leq 2$	Small but clear peak (H_0)
3	1	$S > 2$	Unequivocal peak (H_0) - no other information on nuclide ID. Typically ^{137}Cs @ 661 keV
4	2	$1 \leq S_{1,2} \leq 1.5$	Two small peaks (H_0)
5	2	$1.5 < S_1 \leq 2$ $1 \leq S_2 \leq 2$	Two small peaks, at least one of them clear (H_0)
6	2	$S_1 > 2$ $S_2 \geq 1$	Two peaks, at least one of them unequivocal (H_0)
7	≥ 3	$S_1 > 2$ $S_2 > 2$ $S_3 \geq 1$	Three or more peaks, two of them unequivocal (H_0)
8	2	$S_1 > 2$ $S_2 > 2$ $0.7 < A_1/A_2 < 1.3$	The ratio of the measured peak areas is within 30 % as predicted by the decay data and the efficiency curve. No low energy line is considered.
9	≥ 3	$S_1 > 2$ $S_2 > 2$ $S_3 > 2$ $0.7 < A_i/A_j < 1.3$	The ratios of the measured peak areas of three most significant peaks are within 30 % as predicted by the decay data and the efficiency curve. No low energy line is considered.
10		Human review	

The peak significance (S) is defined as the normalized ratio of the peak area and its standard deviation. S is calculated in such away that it receives a value of 1 at the false positive risk level of 1:10^6 ; this means that the normalization factor is the abscissa $k_\alpha = 4.75$ of the Gaussian distribution.

All measurement and analysis results are stored in the local LINSSI database running in the data management computer.

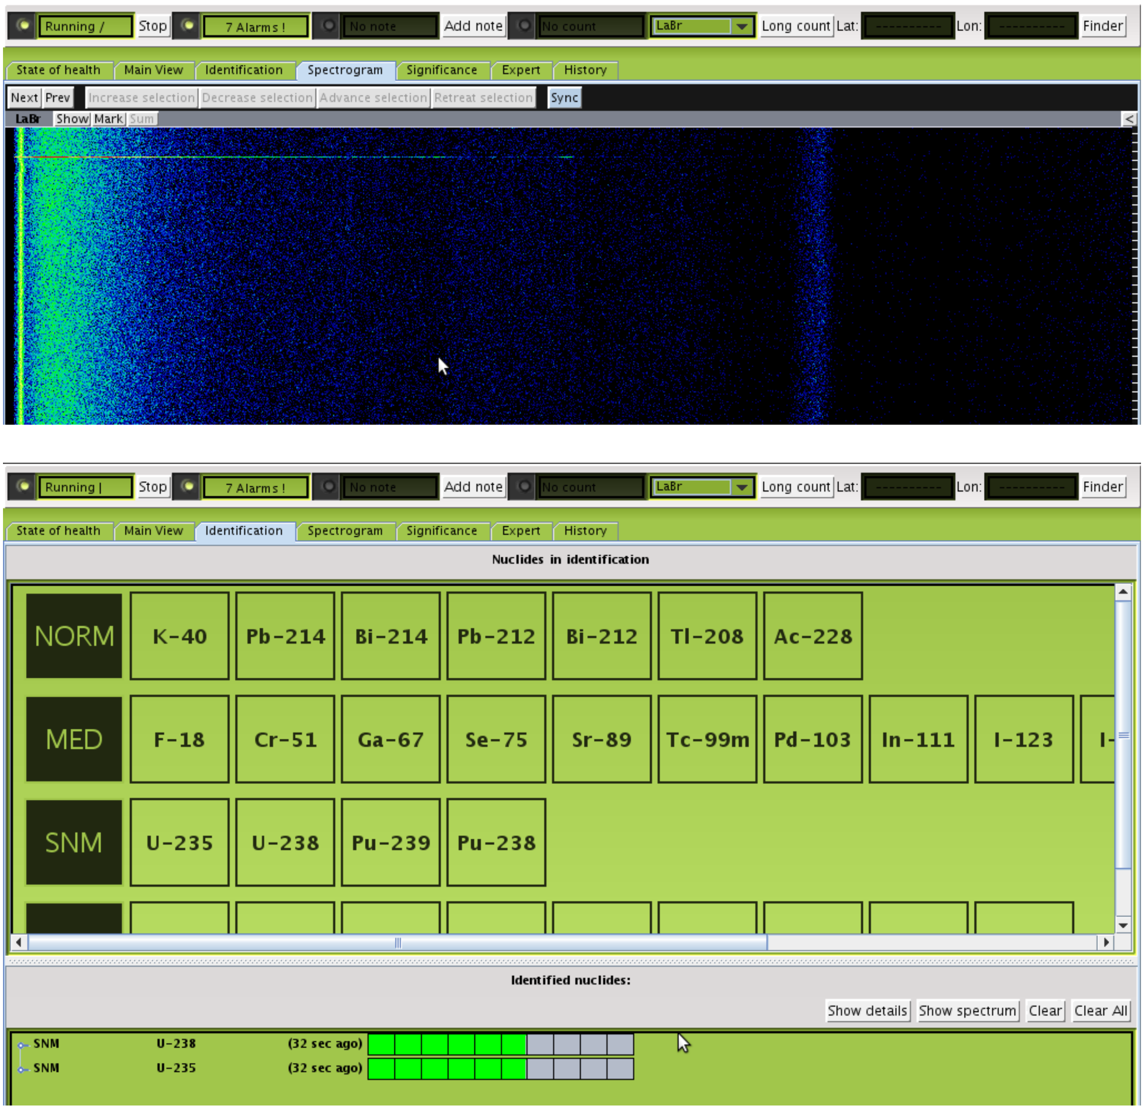

Figure 1. Screenshots from the VASIKKA user interface.

VASIKKA implements an automated connection to the SNITCH remote data management and analysis system. Several automated data transfer modes can be used to send the data to the reachback facility (e.g. all measurements, measurements with signals above the preset alarm limits, manual long measurements only) depending on the band width of the data transfer link. If the on-line data transfer is not possible, the measurements can be saved to a memory stick and sent manually to the reachback facility.

SNITCH – a data management system

An important element of integrated radionuclide detection capability is mobile monitoring. SNITCH provides efficient data communication and management, including automated data exchange from database to database via Internet. SNITCH transfers the alarms and the key analysis results immediately to Command and Control for alarm handling. This gives timely response capability for law enforcement against unauthorized or criminal acts related to nuclear or other radioactive materials. SNITCH also provides means for reachback functionality to expert organizations. Measurement results can be sent manually or automatically to an expert organization for detailed analysis and the analysis results can be sent back to the field team.

Main usage model of the SNITCH system can be described as "multiple users – single expert" model. The expert in the model can be a person or the automated analysis pipeline inside the SNITCH system. The automated pipeline can be regarded as an expert because the SNITCH system server may implement more powerful analysis tools than the simple mobile devices can.

SNITCH provides a user-friendly way to exchange measurement data and analysis results. Depending on the level of integration of the measurement device to the SNITCH system, the data exchange can even be fully automatic and no user actions are needed. However, data can be sent to the SNITCH system manually and the results can be retrieved manually also.

SNITCH is built around the LINSSI database version 2.2 and thus the native data exchange method is the exchange of LINSSI markup language files (lml-files). In addition to lml-files, four commonly used open file formats are supported: ANSI 42.42 (n42-files), IEC 61455 (iec-files), CTBTO IMS 2.0 pulse height data (phd-files) and IAEA ASCII file format recommendation for gamma spectrometers (spe-files). However, only lml-files contain analysis results.

Inside the SNITCH system the processing of the data are broken down into small sub processes that each work in "first in first out" (FIFO) fashion. This means that they will process the tasks they receive in the order that they received the tasks.

Data exchange interfaces in the SNITCH system

Currently two data exchange (upload) interfaces have been implemented: email message interface and web browser interface. Email messages are versatile enough to support SNITCH data exchange. All supported file formats are basic ASCII text files; therefore, they can be sent as message body text, but file attachments are also supported. Multiple files can be sent in single message as file attachments, where as only one file can be sent in the message body. Also the additional information files can be sent as email attachments, if other data file formats than lml-files are sent. The subject field of the email message is used for the processing instructions. Currently only the database and analysis methods are selected based on the keywords in the subject field. Sending of email messages can also be automated with scripting languages and mail sending software that has a command line interface.

Web browser interface is mainly used for manual data insertion. Web browser file upload is a well known and simple way to upload data. Web browser is also a great way to collect additional information needed when uploading files other than lml-files. Additional data can also be checked and validated before the uploaded data files are inserted to the data processing. The additional data are also saved to the server into the user profile, so that user does not have to input the same data several times. Web browser interface has intrinsic encryption feature through the https protocol. This eliminates the possibility to capture the data in transit. The web browser interface is a safe way to send classified data.

Web services interface is used for the fully automated machine to machine data transfer. Several services can be provided. For example, different service will be provided for each of the supported file formats, because they all have different additional data needs and they must be inserted into different preprocessing FIFOs. Web services is implemented with the SOAP protocol that can be transmitted over the https protocol. Thus, the inherent encryption features of the https can again be used to prevent in transit data capture and simple username and password can be used for the user authentication.

Data processing in the SNITCH system

Data processing in the SNITCH system has been broken down into small sub processes. Each of the sub processes process the data in FIFO manner. However, this does not ensure that the data flowing through the multiple FIFOs is processed in FIFO manner as a whole. Data entering the data processing first might not come out first if some branching/splitting occurs. Also all sub process steps process data simultaneously, so several incoming measurement data messages are processed simultaneously, if needed.

Data processing has the following generic sub processes

1. file format conversion to lml
2. upload lml-file to database
3. notify upload
4. run automated analysis
5. send email messages

Some of the sub processes are used several times in the processing of the incoming data. Generic flow of data is show in Figure 2. The experts can do manual analysis to the incoming measurement data or they can review the results produced by the automated analysis sub processes and add their own comments to the final results.

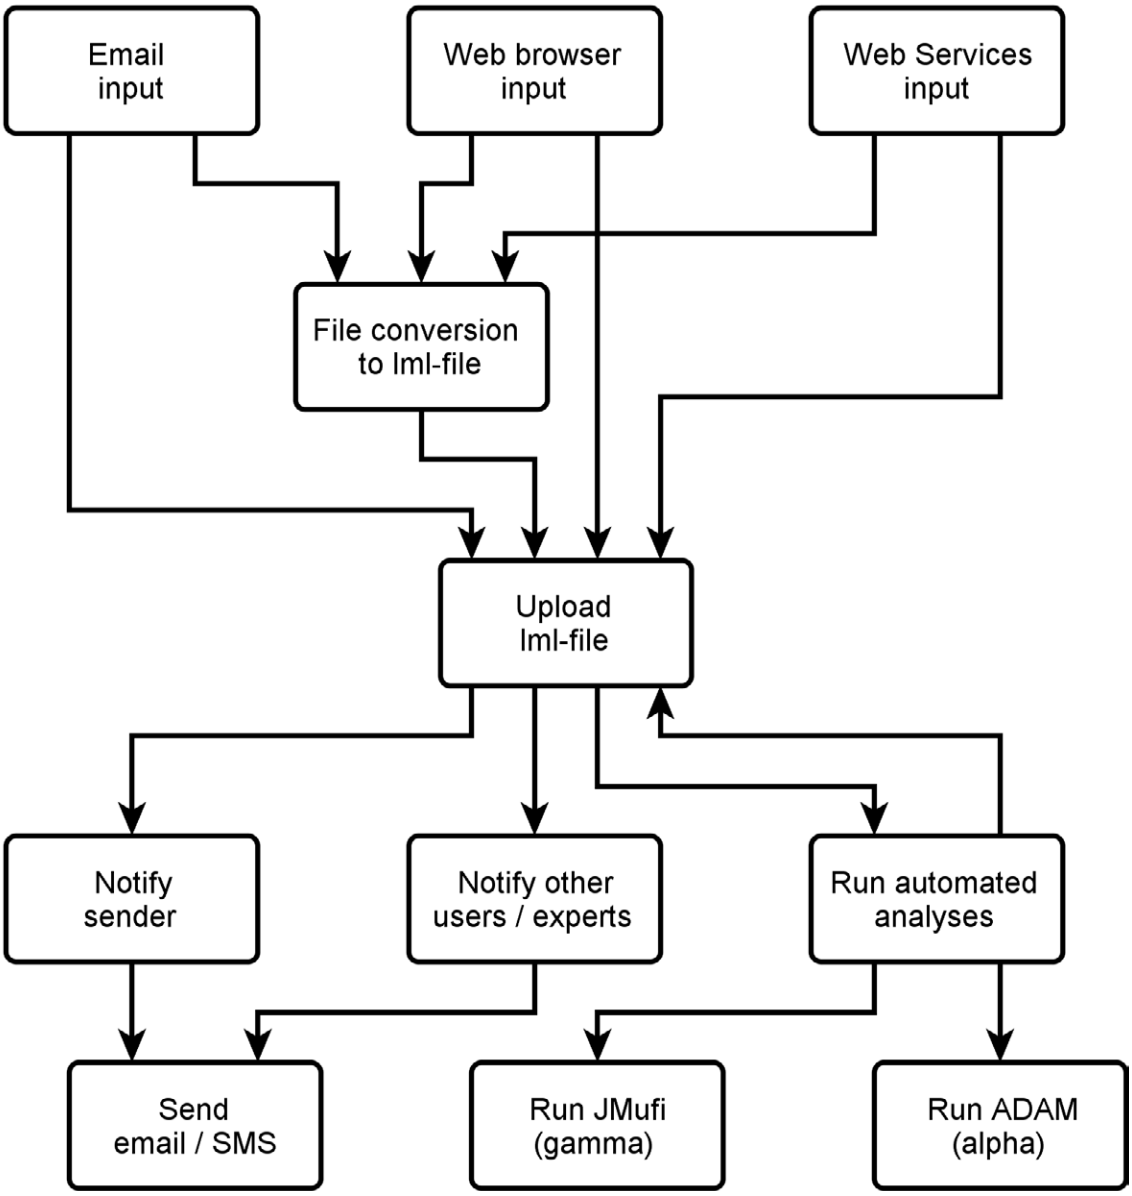

Figure 2. Generic flow of data in the SNITCH system. SNITCH can launch different analyses processes; two of them are shown, JMufi for gamma spectrometry and ADAM for alpha spectrometry.

SNITCH training package

A crucial factor in the successful deployment of the SNITCH reach back capability is the ability of the field team to make the relevant radiation measurements and to retrieve the expert analysis results and recommendations from the SNITCH system. The law enforcement officers in the field team need some additional training to operate the radiation measurement system and the SNITCH data management system. To address this issue, a training package has been composed. The training package will give the law enforcement officers the basic knowledge needed to make the radiation measurements safely and properly, so that the radiation expert in the remote location can trust the validity of the measurement data received through the SNITCH system. The training package comprises the following subjects:

1. SNITCH data management system;
2. Basic training on radiation, radioactive material and radiation protection;
3. Radiation measurement and surveillance;
4. Operational awareness in RN-situations;
5. Security screening of places, people and goods; and
6. seven different scenarios involving radioactive material.

The first three items are designed to give the basic knowledge on the SNITCH system, radiation safety and radiation measurement techniques. Operational awareness in RN-situations module will teach how to collect and process information other than radiation measurement information to support the evaluation of the situation. The Security screening module provides useful radiation measurement tactics that give reliable results when places, peoples and goods need to be screened with limited resources and timetable. In this case the reliability means that radioactive materials are found or absence of them can be proved with adequate certainty. Scenarios in the sixth module include criminal usage of RN-material with varying threat levels and amounts of material actually used.

VASIKKA - SNITCH interplay

Data flow between the field team using VASIKKA measurement system and the reachback expert facility using the SNITCH data management system is shown in Figure 3. The process is

1. Field team makes a spectrometric measurement of the suspect material or area.
2. Measurement is automatically analysed by VASIKKA software. In a simple case the measurement is analyzed correctly and the field team can jump directly to step 7.
3. However, in a complex case the measurement cannot be fully analyzed in the field and the measurement data (with the results of the automated analysis) are sent automatically to the remote expert facility.
4. Automated data handling will store the data to the LINSSI database in the SNITCH server, makes the predefined automated analyses and alerts the expert either via email or SMS. Alert to the expert can be an optional step if more powerful automated analysis tools are needed.
5. Expert on duty can look into the results of the automated analyses and make additional analyses manually. Expert on duty can insert his remarks and recommendations to the final analysis results.
6. Final analysis results with the remarks and recommendations of the expert on duty are transferred automatically back to the VASIKKA system used by the field team.
7. Field team takes appropriate actions based on the received final analysis results and/or the recommendations of the expert on duty.

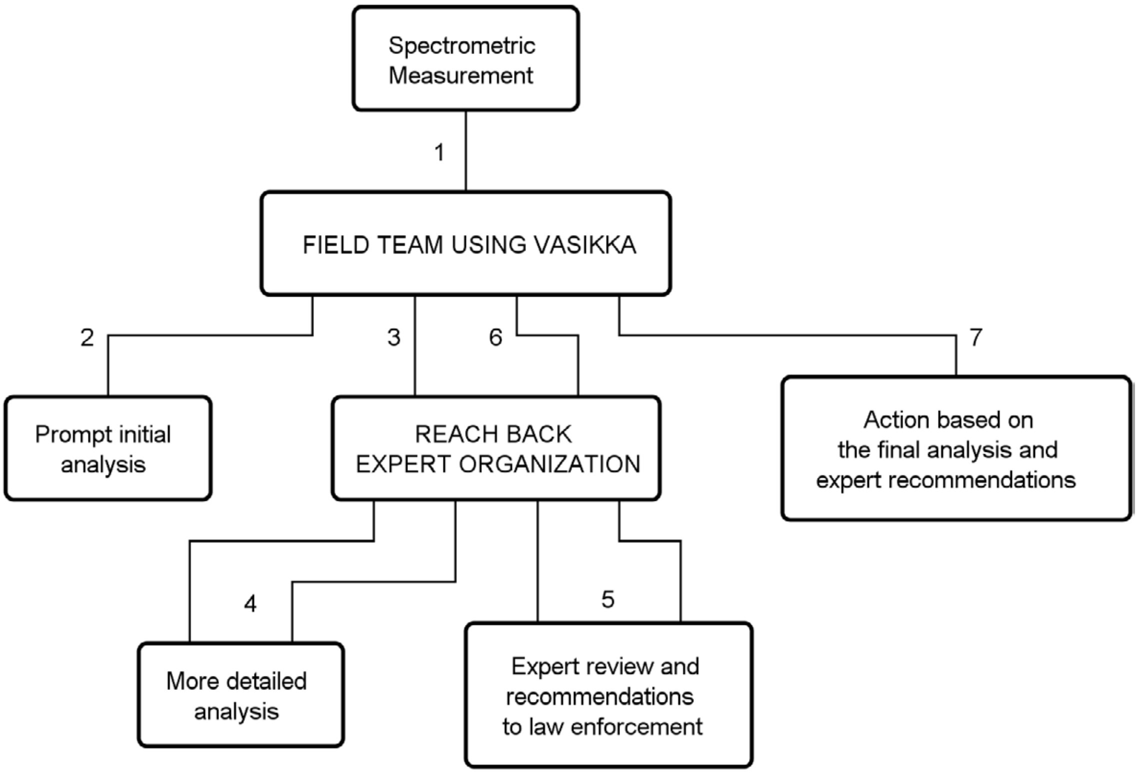

Figure 3. Integrated measurement and remote analysis concept.

Manual use of the SNTICH system is also possible. In step 3 the data can be sent via email or web page and the feedback (steps 6 and 7) can also be received via email or a web page.

Conclusions

The automated VASIKKA – SNITCH mobile measurement and remote data management system is a valuable tool in a radiation incident management. It increases the reliability of the correct interpretation of the measurement made in the field. The system has already been tested in real operational conditions by a Finnish counter terrorist unit, and the performance has been satisfactory.

Acknowlegements

SNITCH system has been developed with financial support from the European Commission - Directorate-General Justice, Freedom and Security under the Prevention of and Fight Against Crime Programme 2007.

Indoor positioning for nuclear security

Ilander, Tarja[1]; **Toivonen, Harri**[1]; **Meriheinä, Ulf**[2]; **Garlacz, Jolanta**[3]
[1] Radiation and Nuclear Safety Authority, FINLAND
[2] VTI Technologies, FINLAND
[3] Laurea University of Applied Sciences, FINLAND

Abstract
Mobile measurements are needed to search for nuclear material out of regulatory control at major public events and political meetings. The mobile measurement teams may have to screen hotels, living quarters and other venues before the event and during the event. Measurement and positioning information are crucial for planning the mission and for reporting the findings.

Traditionally the global satellite navigation system is used for positioning outdoors. Positioning indoors is difficult. Various indoor positioning technologies are available on the market. However, they often need a specific infrastructure installed in the building which limits their use.

Radiation and Nuclear Safety Authority (STUK) has performed indoor positioning tests with Ekahau's wireless network based system. The experiences with the field tests were encouraging. Also a novel indoor positioning system has been developed by VTI Technologies. In this system navigation is based on the measurement of the length and direction of every step of a person. It uses a chest-worn speed and distance measurement module, originally developed for the sports market, together with an instrument-grade gyroscope and a magnetometer.

Introduction
Searching for nuclear material is of utmost importance in security arrangements at major public events or political meetings. The mobile measurement teams go through hotels and event venues and search for radioactive material. STUK has developed a portable device, VASIKKA, for mobile measurements. The measurement system is based on spectrometers that write measurements and analysis results to the LINSSI database (a database for gamma-ray spectrometry). Simultaneously the navigation system writes the positioning data to the same database. The measurements and position data are linked together with time stamps. The idea of separating the radiological measurement system from the navigation system makes it possible to use various kinds of positioning systems for indoor and outdoor applications.

The spectra and measurement analysis results together with the team locations are transmitted to the command and control centre for further analysis. The results of the measurements are shown on screen, including the movement of the teams on the online digital map. In case radioactive material is found, an alarm is generated and, the mapping system indicates the place on the map. The command and control centre uses the information and gives instructions to the field teams.

Indoor positioning

Traditionally a global satellite navigation system (e.g. GPS) is used for positioning. It works well outdoors, but positioning inside a building is challenging. Navigation is difficult or impossible in areas where satellite reception is limited. Indoors navigation could be carried out manually by pointing out the current position on the digital layout of the building. In this case there is always a risk for a human error. The possibility of loosing track increases when the person doing the measurement is not familiar with the building to be searched.

There are various indoor positioning techniques available. They are usually meant for tracking goods in a warehouse or tracking people at a hospital. They need a specific infrastructure installed in the building or a time-consuming model of the building before they can be used. For authority work, the navigation system should be easy to set up and easy to use in buildings where there are no pre-installed techniques available.

Ekahau's Real-Time Location System

Ekahau is a Finnish company specialized in indoor positioning systems. One of their products, the Real-Time Location System (RTLS), has been tested together with VASIKKA in mobile measurement field tests. The Ekahau RTLS is a Wi-Fi-based positioning solution. It uses existing wireless local area network infrastructure. The Ekahau RTLS consists of the Ekahau Positioning Engine (EPE) server software, the Ekahau Location Survey (ELS) and battery powered Wi-Fi tags. Ekahau RTLS uses existing Wi-Fi standard access points as the reference devices for tag location.

Before Ekahau Wi-FI positioning is operational in a new environment, a positioning model of the building has to be made. It requires a layout of the building in digital format. The site survey is made by walking through pre-defined tracks and by registering the available wireless network access points. When the model is completed it is uploaded to the EPE server.

The Ekahau RTLS was used in field test in the STUK head office and in the Itäkeskus shopping centre. In the tests VASIKKA was used for radiological measurements and a separate Java program, IPARM (Indoor Positioning Aware Radiation Measurement), as a navigation system (Garlacz 2009). IPARM retrieves position data from the Ekahau server and writes it to the LINSSI database. The average accuracy of the Ekahau RTLS is one to three metres.

The initial test results on the Ekahau system were promising (Syrjälä 2009). The first field test was carried out in the STUK head office (Fig. 1). A Cs-137 calibration source was used in the test. The measurement team walked along the corridors and passed the table where the source was placed. The system clearly detected the source and created an alarm. The alarm is shown as a pink spot on the map. The test proved that the accuracy of the positioning is good enough to find even low-active radiation sources.

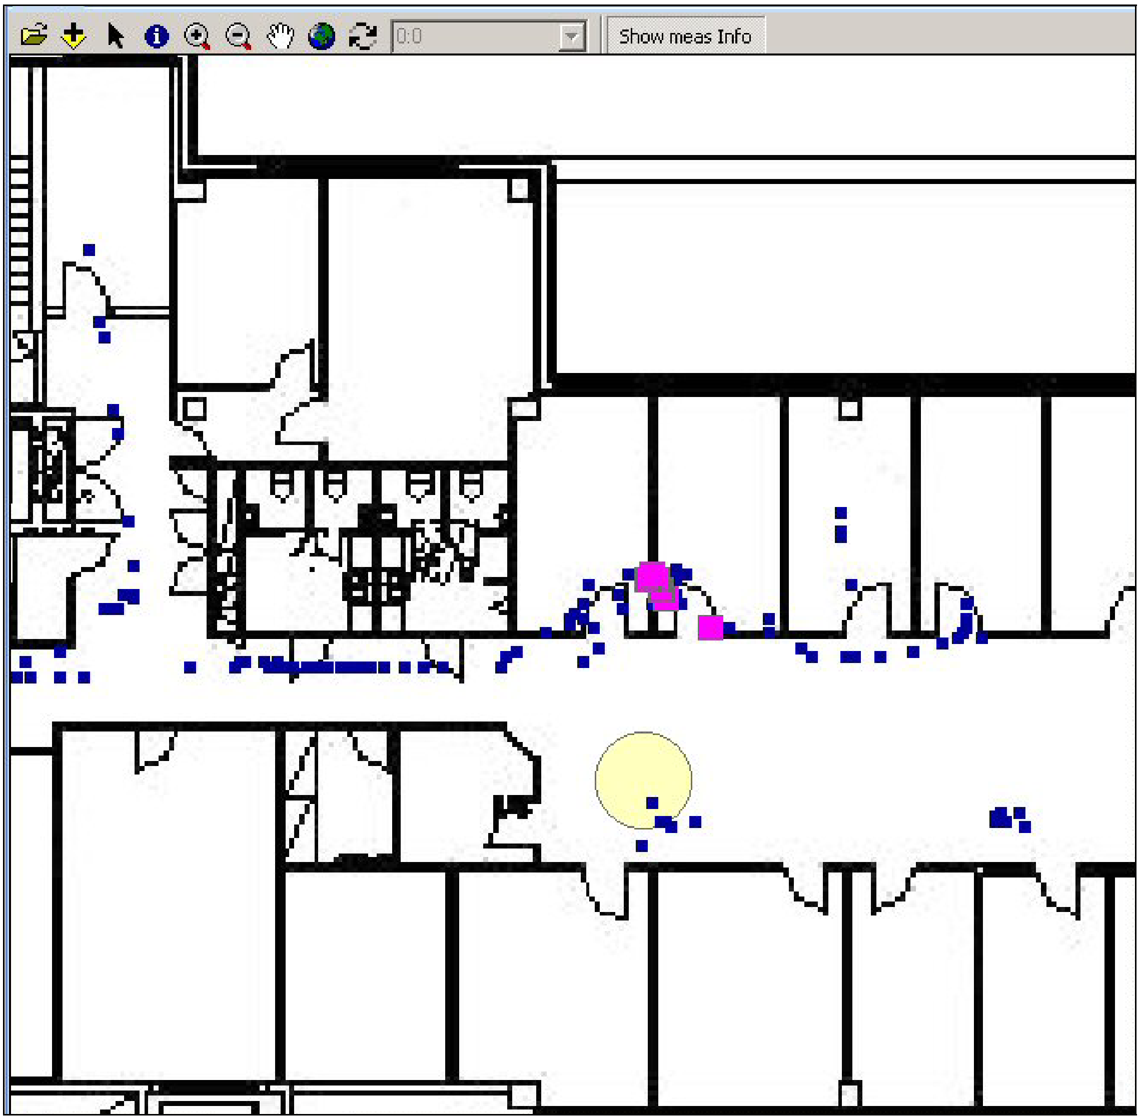

Fig. 1. Ekahau RTSL used together with VASIKKA in field test. In the test Cs-137 calibration source was placed on a table in the corridor (yellow circle).

The Ekahau positioning system has also been tested in the Itäkeskus shopping centre (Garlacz 2009). The first test was carried out in June 2009 and the second test period was in February 2010. The positioning system worked well, but the complex environment made the building of the model more problematic. The constructions in the shopping centre caused errors in the connections between the Wi-Fi tags and the positioning server. It was also noticed that the wireless network access points of the shops were not in the fixed places they were supposed to be. Some of the access points had been moved to a different place and, therefore, the model had to be rebuilt.

With the wireless network technique, building the model and defining the wireless network access points can be time-consuming. If the wireless network environment is alternating, the model may have to be rebuilt every time the model is used for navigation to ensure best positioning accuracy. Therefore, it is suitable for stable environments where there is a fixed wireless network.

Step navigation by VTI Technologies

A novel indoor positioning system has been developed by VTI Technologies. In this system the navigation is based on the measurement of the length and direction of a person's every step. The step length is measured using a MEMS (Micro Electro Mechanical System) accelerometer and a novel and robust algorithm converting acceleration to horizontal speed. The direction of each step is measured with a MEMS angular rate sensor. The initial direction could be taken, for example, from some well-defined event or using radio navigation (e.g. GPS). If an electronic map of the premises is available, active map matching and filtering can be used to get initial position and direction or improve overall accuracy.

Results from the step navigation prototype test below indicate an accuracy of a couple of meters during a 5-minute walk with a total of 2520º turns.

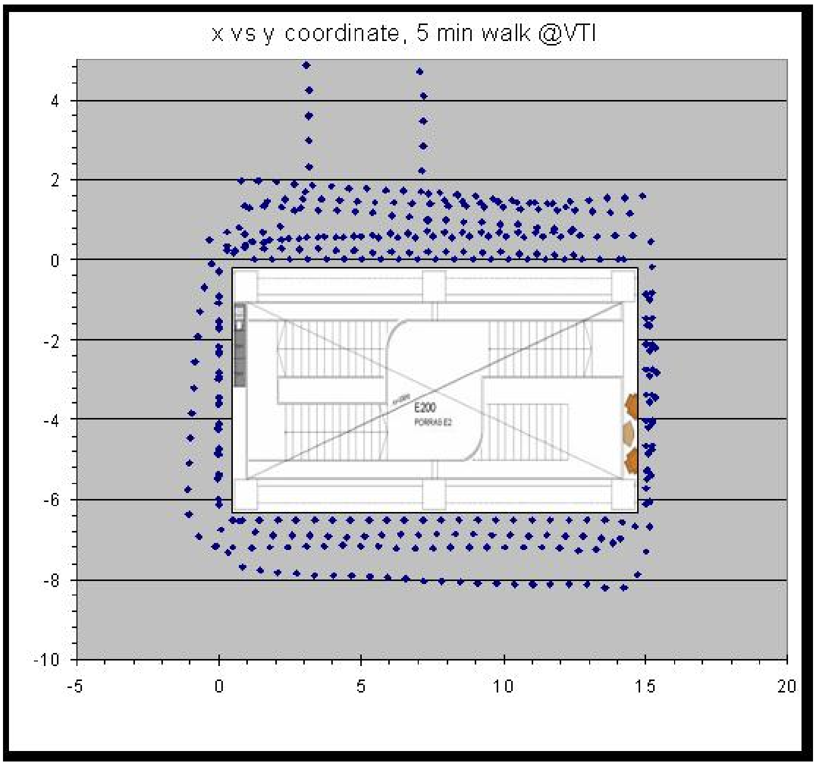

Fig. 2. Results from a short step navigation session at VTI premises using the combination of an accelerometer and an instrument grade gyro.

There is ongoing work to improve the accuracy and robustness of the step navigation system as well as to widen its usability to other motion, like e.g. crawling.

Conclusions

Although there are some indoor positioning systems available they are not technically ready for in-field use by mobile measurement and search teams.

In the wireless network based system, building the model is time-consuming and the model has to be updated every time there are changes in the wireless network. It is not suitable for ad hoc navigation. It can be used in stable environments such as hotels or conference facilities with fixed wireless network.

The step navigation system is easy to build up but it is still under development. The idea seems good but it has not yet been tested in a real time environment.

The radiological measurement should work the same way indoors and outdoors whereas only the navigation system may vary. The online mapping system should be able to detect whether the position is indoors or outdoors. It is envisaged that in the future the user does not have to know when the system is using satellite or indoor navigation system for positioning but the software behind the system performs all the necessary actions.

Control of nuclear materials and related radiation safety

Janzekovic, Helena
Slovenian Nuclear Safety Administration, SLOVENIA

Abstract

Nuclear materials are special fissionable materials and source materials, namely uranium, plutonium, thorium, etc. The definition of nuclear material is very often related to implementation of nuclear safeguards. Handling nuclear materials is strongly regulated by national legislations, e.g. laws regulating nuclear safety or physical protection, as well as by international agreements e.g. EURATOM Treaty from 1957, Non – Proliferation Treaty from 1970, Convention on the Physical Protection of Nuclear Material from 1979. The material can be found at different premises, namely laboratories, storages, workshops etc. When handling such material not only radiation risk should be taken into account but also other risks. A comprehensive analysis of all risks should be done and it is vital that harmonised safety measures are applied. The regulations of nuclear material are changing from the first regulations in the middle of the last century, when such material was called "a product" in the Manhattan project. Especially after the Second World War the nuclear material became a subject of very intensive investigations and as a consequence the development of regulations followed. A special attention to nuclear materials was intensified after 11 September 2001 regarding serious threats. The article gives an overview of the development of regulations related to nuclear materials taking in parallel the development of radiation safety standards. It focuses on specifics of different national and international definitions of nuclear materials as well as on a use of other terms related to nuclear materials, e.g. special nuclear materials, source material, byproduct material. An overview of relation between present standards regarding nuclear safeguards and radiation safety requirements (ICRP 103, EU BSS, IAEA BSS) is given, taking into account a control of the material from its cradle to grave, e.g. finally to its disposal as radioactive waste.

Direct Alpha Analysis for Forensic Samples (DAAFS): Techniques, applications, and results

Hoffman, Ian[1]; Ungar, Kurt[1]; Bean, Marc[1]; Pöllänen, Roy[2]; Ihantola, Sakari[2]; Toivonen, Harri[2]; Karhunen, Tero[2]; Pelikan, Andreas[3]

Abstract

The goals of the DAAFS project are to develop new methods of sample acquisition and analysis for in-situ measurement of alpha radiation. In-situ alpha tests of DAAFS have been performed using either a well-characterised swipe technique with a fluoropore membrane filter, or a vacuum sampling system and optional surface impactor. The unique components of the DAAFS system include: 1) a variety of specialized sampling techniques, 2) a Monte Carlo spectral acquisition simulation software called Advanced Alphaspectrometric SImulation (AASI) that simulates the alpha spectra by using the specific geometry and sample collection parameters, 3) an Advanced Deconvolution of Alpha Multiplets (ADAM) software package for fitting actual sample spectra, and 4) an advanced MySQL database management/telemetry subsystem called LINux System for Spectral Information (LINSSI) with alarming and notification via email and SMS.

In addition to the nuclear safeguards and security design goals, other potential uses for DAAFS are: thoron progeny identification and possibly quantification of alpha emitters in drinking water, urine analysis, decommissioning and contamination measurements in nuclear reactors and laboratories.

Introduction

Currently, analysis of alpha emitters in field samples in either a nuclear security or safeguards context requires time consuming full radioisotope chemical separation to obtain a high level of specificity. Additionally, the ability to perform high-throughput alpha analysis capability became apparent during the Litvinenko ^{210}Po (a pure alpha emitter) incident in the UK. The DAAFS system was designed to function in a mobile laboratory as a platform for rapid direct measurement of samples. The system will be fully tested through field and lab exercises by the end of the project in 2011.

Conventional alpha spectroscopy is not well suited to nuclear security applications when a timely response is desired. Traditional techniques employed in alpha spectroscopy often require radioisotope chemical separation methods – a time consuming process when rapid response time is essential. The requirement for full laboratory support to perform conventional techniques is neither amenable nor practical in field deployment, on-site analysis, or other common situations where malevolent use of alpha radiation has occurred. In the event of a Radioactive Dispersion Device (RDD) incident, rapid alpha assessment would be an ideal capability to have to detect radioactive materials that are easier to identify and quantify using alpha detection such as ^{241}Am.

The direct spectral measurement methodology of DAAFS is very different from conventional alpha spectroscopy techniques in a number of key areas. The primary difference between the DAAFS approach and conventional techniques are the acquisition and handling of samples. Samples for analysis are collected in a highly controlled and repeatable fashion to minimise sample variations. Minimising sample variability provides consistent input to the ADAM spectral deconvolution (Toivonen et al. 2009) and AASI (Siiskonen and Pöllänen 2005) simulation software. Samples are not subjected to any radiochemical treatments, making the DAAFS process a non-destructive analysis technique, resulting in relatively rapid (on the order of minutes to hours) assessment. The non-destructive nature of DAAFS is ideal as evidence is intact for criminal prosecution. Additionally, the ability to perform other radio analyses on the same sample can be very valuable as it minimises the number of samples required along with the necessary sampling equipment. Both of these are important features for incident response. Training first responders in common sample collection techniques minimises the training and knowledge level required of non-expert personnel.

The equipment for performing direct measurement of samples was designed to be field-portable. The measurement equipment used for DAAFS is shown in Figure 1. The system is compact and is easily portable in a mobile laboratory. The materials used to perform sampling vary depending on application. Figure 1 shows the largest piece of sampling equipment for DAAFS - the Lilliput vacuum sampler. All the other sampling equipment is more portable, requiring only a single person to operate and perform all procedures.

Figure 1. DAAFS spectral acquisition equipment (left) and sampling of clothing from pre-Olympic Exercise with Lilliput vacuum and nozzle (right).

DAAFS was designed for rapid assessment, and as such, it emphasizes qualitative observations over quantitative. Risks to the public and responders are known as efficiently as possible, when a positive result occurs, the quantitative results can be requested via conventional radiochemistry techniques performed by a laboratory. The

Litvinenko incident, where a pure alpha emitter, ^{210}Po, was used as a poison is a prime example where application of DAAFS technology would have been more useful than conventional techniques to identify the hazard, rapidly define and assess the crime scene, and indicate areas needing decontamination.

During field use, a single non-expert can perform the sampling and spectra acquisition with a brief training session, with minor advice coming from off-site if necessary. Once the spectrum is acquired, the DAAFS system is designed so that all sample and measurement associated data can be sent via e-mail to offsite experts for analysis. This “reachback” capability is made possible through the use of an open source database using the LINSSI database design (Aarnio et al. 2008), and computer hardware capable of wireless WLAN access.

Material and methods

DAAFS sample collection types can be broadly described as being a member of one of the following categories: swipe, air filter, and liquids. Each category has a specific methodology for sample collection to obtain optimal results in a direct alpha measurement system.

Acquiring a high quality swipe sample requires a media with the key feature of not allowing sample material to penetrate the matrix. Rather than using conventional glass fibre airfilters, a fluoropore membrane filter is used (Pöllänen and Siiskonen. Fluoropore membranes are an ideal choice as the media resists sample penetration and the resulting alpha particle energy absorption. This means superior peak resolution and allows an accurate match to the energy calibration. Swipe samples are most successful when used to sample hard surfaces.

Air filter samples are acquired using the same type of media as the swipe above, but using a vacuum either with a nozzle or without. For field use, a portable battery powered vacuum sampler called Lilliput (Senya Ltd.) is used. The vacuum provides an intake flow rate up to 12 m^3/h, and uses standard round air filters. The filters are mounted and laminated for insertion into the nozzle apparatus or direct attachment to Lilliput for aerosol sampling. A sample is collected for approximately 15 min when used in airborne collection mode. The optional nozzle is used to collect samples from textiles and other soft surfaces. Samples collected using Lilliput are acquired in triplicate for analysis using other desired techniques.

Once the sample is acquired it is measured in a standard commercial alpha spectrometer. The analyst has two novel tools at their disposal. The first tool is a spectral simulation package called AASI. The program simulates the results of the spectral acquisition process, when relevant physical parameters associated with the sample and measurement is provided. AASI allows an expert to examine the impact of parameters associated with sampling (for example particle size distribution), measurement (detection geometry), and calculation of detector efficiency and coincidence factors. More importantly, it allows an expert to determine and examine the validity of their assumptions about the sample collection and measurement process. The second and most important component is the advanced spectral fitting package, ADAM. The program performs the fitting using a Gaussian peak model with two-component exponential low-energy tail, and is capable of performing calibrations and accepts coincidence correction factors. ADAM is capable of operating in either batch or non-interactive mode, and includes a comprehensive alpha emission library based on ENSDF data.

Results

The DAAFS systems has undergone preliminary testing on many different samples and participated in one field exercise. In preparation for the 2010 Olympics in Vancouver, Canada, the DAAFS system was deployed for a simulated Olympic terrorism scenario. During the exercise, a suspect was apprehended, who had an unknown substance that was thought to be radioactive in origin on his clothes. The DAAFS system was activated to acquire a sample and perform an analysis. Lilliput acquired a sample off the suspect's clothes, which was then counted at a sample-detector distance (SDD) of 13 mm. After only 10 minutes the analyst was able to conclude that a radioactive substance was present, and that the identity of the substance was ^{241}Am. Simulations performed in AASI using 100000 decays of Am seem to reasonably approximate the observed spectra (Fig. 2).

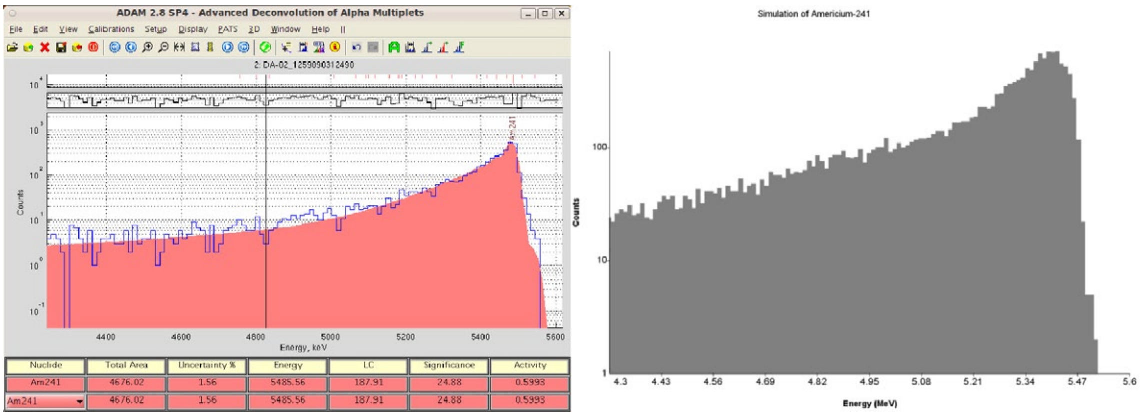

Figure 2. ADAM (left) analysis and AASI (right) simulation of Lilliput vacuum-sampled clothing from pre-Olympic Exercise showing ^{241}Am being identified.

Preliminary examinations of liquid samples were performed using an IAEA drinking water intercomparison sample that appears to have been spiked with ^{230}Th (blue). In the resulting spectra, acquired after 24 hours of direct measurement at a SDD of 13 mm, the possible presence of a ^{232}Th impurity (red) can be seen in Figure 3. The presence of the impurity is not conclusive, but is reasonable hypothesis if the thorium was separated from spent nuclear fuel.

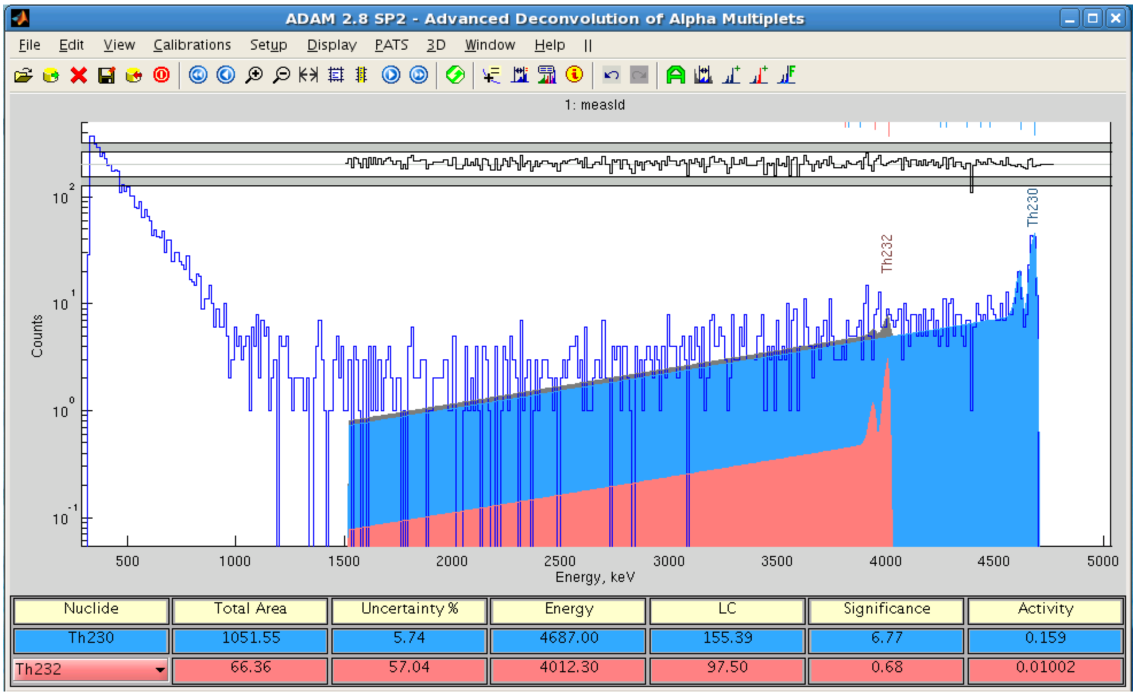

Figure 3. Analysis of an evaporated IAEA drinking water sample on planchet showing main peak Th-230 and presence of possible impurity Th-232.

The final example is an aerosol sample from a basement with high radon levels. The Lilliput vacuum sampler was used in an aerosol collection model of operation, or without using the sampling nozzle. The progeny of radon (^{212}Po – purple, ^{214}Po – yellow, ^{212}Bi – blue, ^{218}Po – red) are shown immediately after sampling with a spectral acquisition time of roughly 2 hours.

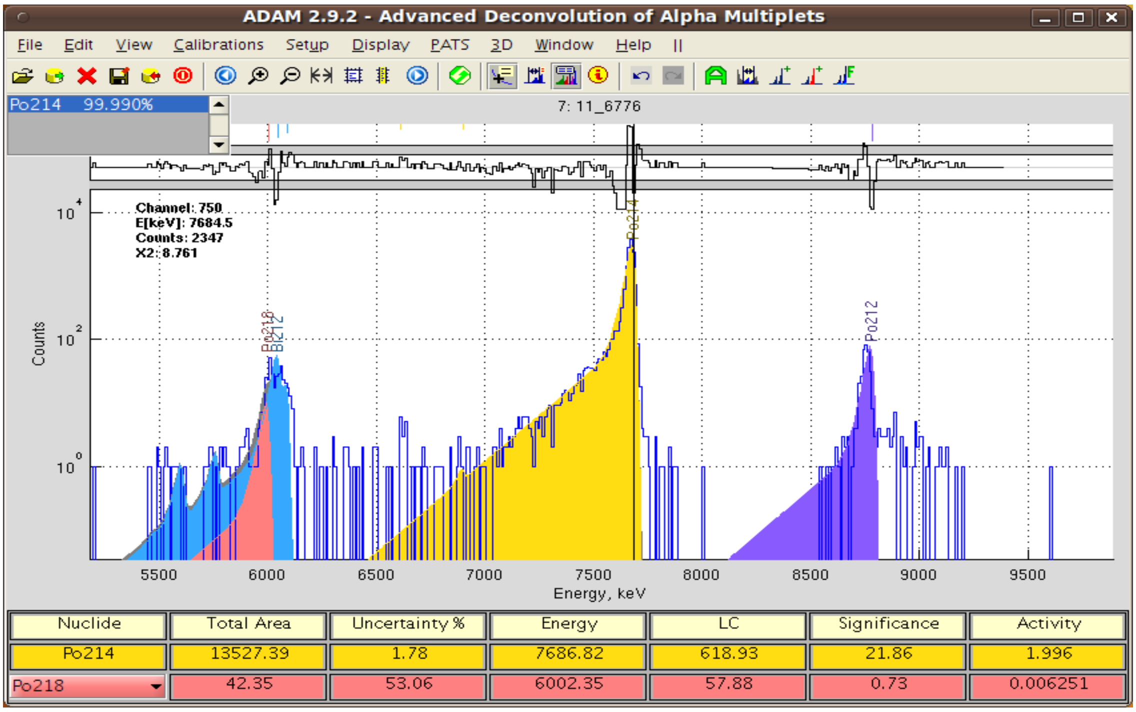

Figure 4. Analysis of aerosol sampler from a basement showing radon progeny after 2 hours acquisition.

Discussion and conclusion

DAAFS has been used on a wide variety of samples and radioisotopes to identify alpha-particle emitting isotopes. DAAFS has demonstrated success for nuclear security applications requiring qualitative assessment under specific conditions where a “thin” sample can be produced. Successful field trials illustrated the portability and off-site real-time expert support available to users of the DAAFS system. Further testing on different radioactive materials and the use of new sampling techniques such as ion specific sampling materials (3M Empore^{TM}) will be tested during the final year of the project (2010-2011). Planned trials for the DAAFS system include: depleted uranium, fresh and spent nuclear fuel, further liquid trials, and decommissioning feasibility studies.

Abstract
The results of several field tests in which the short life-time radioactive matter (RaS) was released by explosion in the free or indoor environment are presented. The primary goal of these tests was to verify the detection methods applicable for the obtaining of relevant data set – time and space distribution of the dose rate, surface and volume activities which can be used for modelling analyses of short radioactive substances dispersion by explosion.

Introduction
Potential disuse chemical, biological or radioactive substances for committing a terrorist attack have brought new dimensions into possible scenarios of terrorist attacks. Specific place belongs to so – called "dirty bomb"[1-6], i.e. radioactive substances (RaS) dispersed using a conventional explosive or any other mechanism/system.

Model analyses focused on evaluating possible consequences of a terrorist attack using a RaS are performed in a number of countries [2-6]. The National Radiation Protection Institute (SURO) in Prague in the frame of the State Office for Nuclear Safety (SUJB) grant[1] realized set of tests in which a radioactive substance (RaS) was dispersed by explosion. The main goals of these tests were:

- to verify in real conditions set methods appropriate for evaluation dispersed radioactive substance - assessment distribution dose rate, surface and volume activities, aerosols mass concentration, etc.,
- to obtain relevant set of data usable for testing and development of the mathematical codes/models fit for testing and evaluation of a propagation these substances on a short distance,
- to verify possibility realize tests and in more complex geometry (indoor environment, terrain obstacles, etc.).

The presentation is focused on the description, comparison and evaluation of the two tests carried-out in free areas (tests No. 1 and 2) and two tests in free area with

[1] Project SUJB No. 8/2008 "Methods and measures to reduce the occurrence and liquidation of consequence of terrorist abused of radioactive matters is handled by the SURO in Prague with by an extensive team of contract-bound research workers and institutions.

artificial obstacles (tests No 1P and 2P). Two tests in the small house and in the bus are shortly mentioned.

Tests characteristics

For the tests a combined controlled explosion system (industrial explosive) with the RaS dispersion in the selected space angle was chosen. As radioactive substances Tc-99m activities ≤ 1 GBq was used. Radionuclide was diluted in water coloured with potash and put (Fig. 1) in a spheric glass bottle (volume of 6 ml).

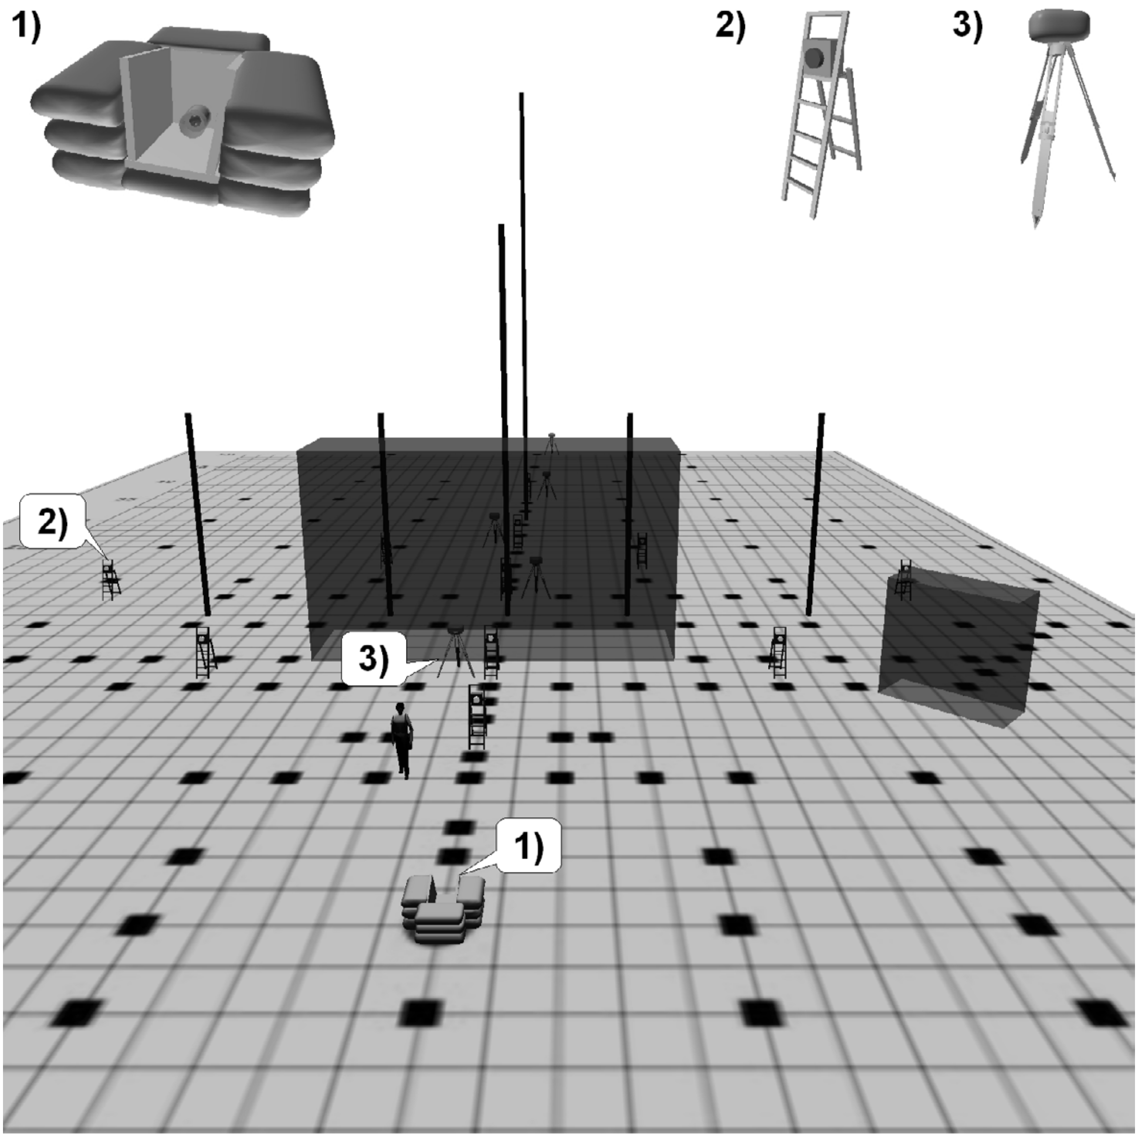

Figure 1. Location of filters, detectors and obstacles on the polygon – test 2P (table 1); the configuration of an explosive – a glass sphere with RaS is demonstrated in figure on left side above (1); No. 2 labels a localisation of aerosols collectors, and 3- DustTraks in the figure.

The survey performed and in this paper presented tests is given in the Table 1.

Tests were carried out on testing polygon of the National Institute for Nuclear, Chemical and Biological Safety (SUJCHBO) Příbram – Kamenná, based on the permit given by the SUJB and an appropriate Mining office board.

Material and methods

Optical and infrared (ThermaCAM P65 infrared imaging system) technology was used to record the time development of the scanned scene before and after a controlled explosion.

Measurement of selected meteorological values was carried out using a mobile automatic weather station with the following being measured – wind speed and direction, air pressure, temperature and humidity.

The measurement of dose rates was carried out by portable devices (GR135 miniSpec, Exploranium and NB 3201, Tesla).

Table 1. Characteristics of the tests.

Test No.	Date	Explosion time	Activity (MBq)/date, time (h)	
1	15.05.2008	11:30	1058	15.05.08, 10:10
1P	21.10.2008	12.34	900	21.10.08, 11:00
2	05.05.2009	12:22	1222	05.05.09, 12:22
2P	14.07.2009	12:42	1088	14.07.09, 11:00

The surface activities were detected using paper collection filters located densely both directly on the polygon area of app. 50x40 m^2 and in selected places on vertically placed columns (height $z \leq 12$ m). To evaluate the time distribution of the RaS dispersion, some of the filters were changed after the explosion in selected times. Up to 550 filters were located and measured in one test to evaluate the surface activities (Fig. 1). Filters activities were measured by HpGe semiconductor gamma spectrometry at 9 spectrometric chains in special shielding.

Radionuclide's volume activities (activity concentrations) in air were determined in several selected (up to 10) sites using aerosols sampling devices (SENYA - JL-150, HUNTER, DWARF 100) including a cascade impactors to determine the aerosol's size distribution.

By means of the DustTrak - DT model 8520 (TSI) laser nephelometers, a distribution of a mass concentration of an atmospheric aerosol in time with a very short (1 s) integration time was monitored - the particle masses within the size range (0.24-10) µm were effectively determined.

The more details of the tests experimental arrangements are described in [7, 8].

Results, discussion

The meteorological conditions characteristics for tests carried-out in free area with and without obstacles are summarized in Table 2.

Table 2. Summary of meteorological conditions in tests performed in free area with and without obstacles.

Test No.	1	1P	2	2P
Date	15.5.2008	21.10. 2008	5.5.2009	14.7. 2009
Explosion time	11:30	12:44	12:22	12:42
Temperature [°C]	22.2 - 22.3	14,8 - 15,05	9.7 - 10.4	23.6 - 27.9
Relative air humidity [%]	41 - 47	68 - 71	42 - 56	51-71
Condensation point [°C]	8.4 - 10.6	9,3 - 9,8	0 - 1.5	15.8 - 18.6

Air pressure [hPa]	1009.1 - 1009.2	1012.9 - 1013.2	1021.2 - 1022.9	1012.5-1013.4

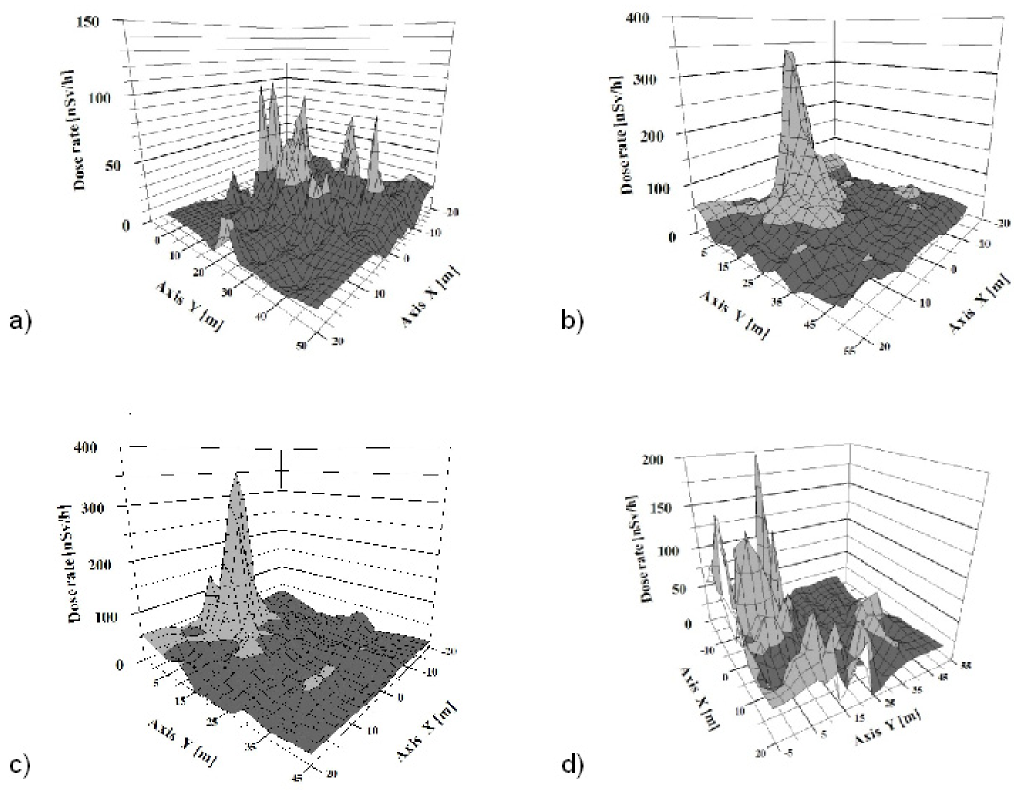

Figure 2a – 2d: Dose rate distribution [nGy/h] - direction of RaS spread – from left to right - axis y; axis x – perpendicularly to the spread axis y; a - test 1, b - test 2, c – test 1P, d – test 2P. [9].

Note:
The black area in Figs. 2a-2d represents territory where the dose rates are lower than 20 nGv/h (after subtraction of the background value in given locality), i.e. an area of the high uncertainties.

Results of the *dose rates* measurements for these 4 tests are presented on Fig. 2a – 3d. The nature of the dose rate distributions in individual tests strongly depended on meteorological conditions, e.g. stable conditions in the 1st test, high temperature and very low wind velocity without gusty evoked lower values of dose rates with less decrease in y – axis direction in the comparison to test 2.

A comparison of the ***surface activities*** distribution on the ground for 4 analysed tests is demonstrated in Fig. 3a – 3d.

Small amount of the RaS dispersed - tenths as far as percentages only was deposited on the test polygon (app. 50 x 40 m^2) in the performed tests - in the 1st test 0.8%, in the 2nd test 2.8% and in the 1P and 2P tests 0.25% and 0.18 % respectively. Differences were given different weather conditions (wind speed and direction, gusts wind, air humidity, temperature - inversion – see tab. 2) influencing the deposition at otherwise practically the same arrangements of the tests. Nevertheless, generally low values of the surface activities correspond of findings (see below), that prevalent amount of the RaS released is transferred outside polygon in the first minutes after explosion.

During 1P and 2P tests practically immediately after explosion, a wind direction gently shift from direction of the RaS propagation (y-axis). Due to this shifts maximum values of surface activities for the given distance on the y axis shifted on the right (on x-axis) in the test 1P (Figs. 3c) and to left in the test 2P (Figs. 3d,).

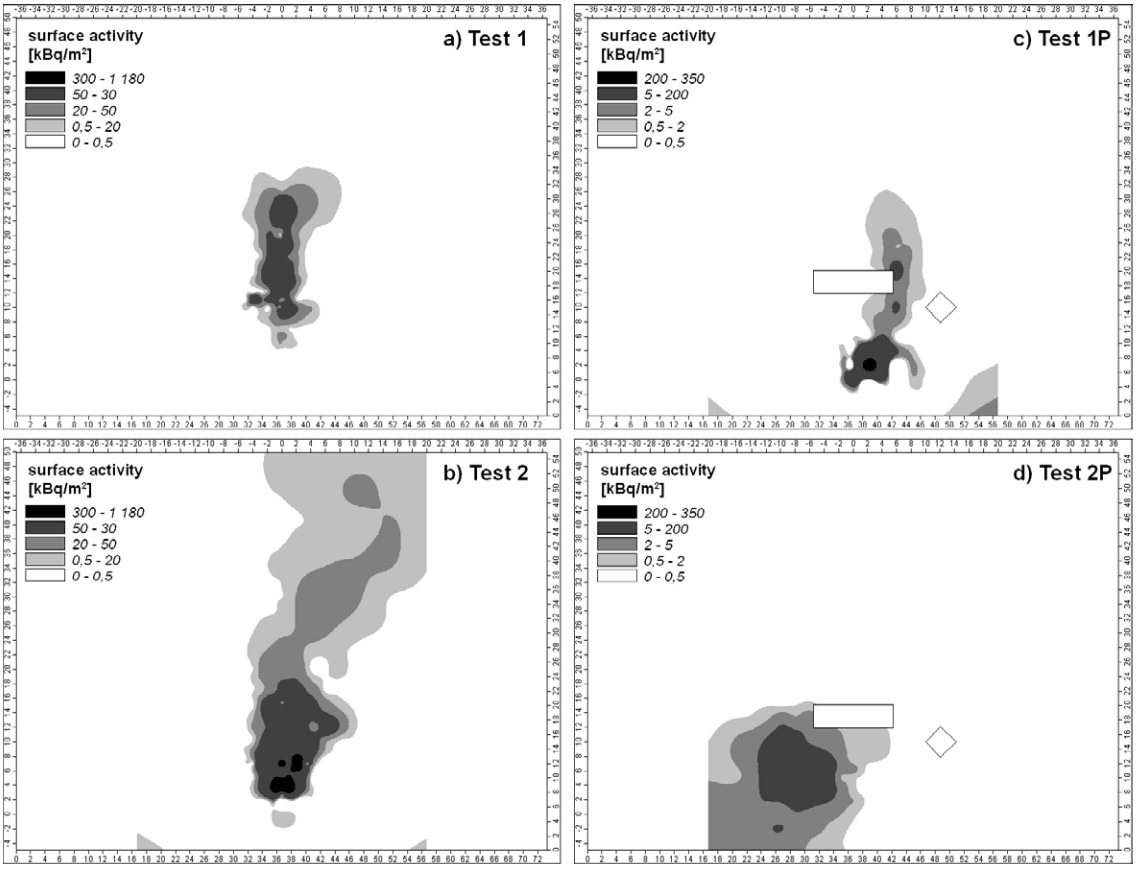

Figure 3a – 3d. Interpolation (Multilevel B-Spline) [15] distributions of surface activities [Bq/m^2] on polygon area - direction of RaS spread (axis y) – bottom-up.

Up to a distance of y < 20 m, the *horizontal surface activity* along the x axis ≤ ±5 m decreased by more than two orders of magnitudes, which indicates that the angle delimited for the RaS dispersion is relatively narrow. At distances of y ≥ 20 m, the value of the maximum surface activity for given y was shifted depending on instantaneous meteorological conditions in direction of the x-axis by more than ± 5 m. More detailed information on surface activities distribution during these tests is given in [8].

Fig. 4a shows time distributions of the surface activity average rate ($Bq/m^2/min$) for the exposure time of a given horizontally situated filter (test 2). Along the axis of the RaS propagation the surface activity in further sampling procedures was lower by two orders of magnitude compared to the first sampling. At higher distances perpendicularly to the propagation axis (x = ± 8 m), the decrease in the activity with time was much slower, but activities in the first sampling were lower by orders of magnitude.

This finding is also demonstrated by measurements of volume activities fig. 4b, as well by measurements of the aerosols mass concentration by laser nephelometers DustTraks [8,10].

The RaS dispersion in *vertical direction* was more uniform than along x – axis (again due to directionality of the RaS release). No marked and reproducible maxima in z – axis direction were manifested; in several cases, at a maximal height (z < 12 m), the activities were comparable with or higher than subsurface activities measured on the ground. Time distribution of vertical measured surface activities was similar as for horizontal measured activities.

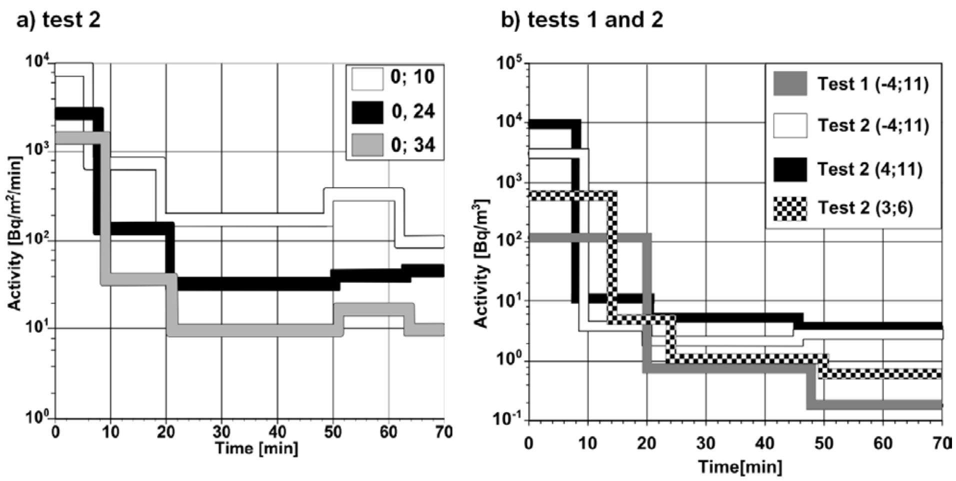

Figure 4. Time distribution of the surface activities rate - 6a (test 2) and the volume activities – 6b - (tests 1,2).

Notice: numbers in the Figs represent position [x,y] m of the collecting filters or position of the aerosol collectors.

Table 3 presents the total activities (the sum of the **volume activities** of all particle sizes), distribution (in %) of ***volume activities*** in dependence of aerosol aerodynamic diameter (AD) for test 1, 2 and 2P. High values of volume activities measured in first minutes after explosion are an explanation of the low total surface activities on collecting filters covered area – the bulk of released RaS leaves the monitored polygon in the first minutes after the explosion, even if meteorological conditions are very stable. The distributions were slightly bimodal with the boundary around 0.4 µm and so the activity median aerodynamic diameters (AMAD) and their geometric standard deviations (GSD) were estimated without taking into account the activities connected with the finest particles (AD < 0.39 µm). AMADs and GSDs are presented in the table 3 too. In the test No 1 collecting substrates from certain stages were combined and counted together and the AMADs and GSDs were not possible to estimate. The cascade impactor in the test 2P in the distances (0, 18) m and (0, 25) m were placed behind the obstacle.

The aerosol by size corresponds to the industrial aerosol (a large proportion of particles with AD > 1.3 µm) with a relatively high GSD value.

Table 3: Distribution of the volume activities in dependence of the aerosol aerodynamic diameter (AD) - tests 1,2, 2P.

Test No	1			2			2P

Notices
The cascade impactor in the test 2P in the distance (0,18) m was placed behind the obstacle.

Tests in enclosed places

Two pilot tests in enclosed places were also carried out in 2008:
- Jul 22, 2008 – test in a single-storey building - “Small house“;
- Sep 30, 2008 – test in a bus - “Bus“.

The **Small house** test was carried out in a single-storey building with two rooms (industrial explosive, RaS - Tc-99m 302 MBq activity in glass sphere of 6 ml -similarly as in the free-area tests). Omnidirectional RaS dispersion took place in this case.

An identical method as in free-air tests used for the detection of surface activity. Filters were located (app. 300 filters were located and measured) in both rooms on floors, walls and ceiling, in a staggered arrangement in a distance of app. 1 m from each other (with an exactly defined position). Apart from filters and devices for aerosol taking, 6 phantoms simulating presence of persons in the building were located in the “Small house” – see Fig. 5a.

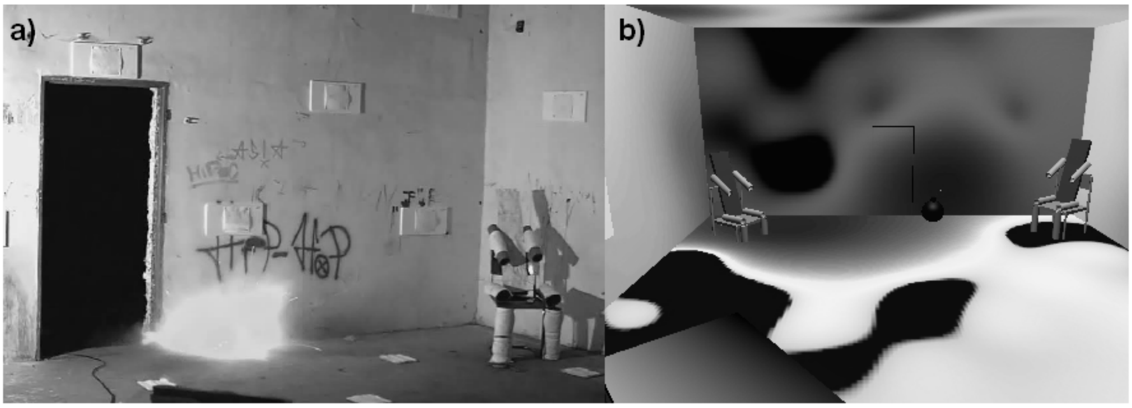

Figure 5. a) An explosion in which Ras was dispersed in “Small house” (location of collecting filters and phantoms can also be seen in the Figure); b) surface activity distributions after RaS dispersion in "Small house“ test.

The volume activities were measured by 4 sampling devices, two of which located in each room. The interpolated surface activity distribution in large room is demonstrated in Fig. 5. Table 4 presents the distribution of the volume activity in dependence of the aerosol aerodynamic diameter (AD).

Table 4. Distribution of the volume activity in dependence of the aerosol aerodynamic diameter (AD) - tests “Small house”.

AD interval [μm]	Volume activity [Bq/m3]	Volume activity [%]
> 8.85	664	50
1.13 - 8.85	391	30
0.34 - 1.13	114	9
< 0.34	149	11
Total	1318	100

Another test in enclosed places was carried out in the “Karosa” type **bus**. An identical explosive as in the “Small house“ test was used - collecting filters were located in an aisle between seats in the first and second row from the driver. 150 MBq of ^{99m}Tc solution was dispersed. The detection technique was the same – nearly 400 filters were placed on the floor, seats, walls and ceiling of the bus and 8 phantoms were put on seats. The cascade impactor was also used to measure the distribution of atmospheric aerosols. The impactor was placed on the final, back seat in the bus's direct axis with the entry towards the place of RaS dispersion. The dose rate and surface activity distribution is demonstrate in fig. 6.

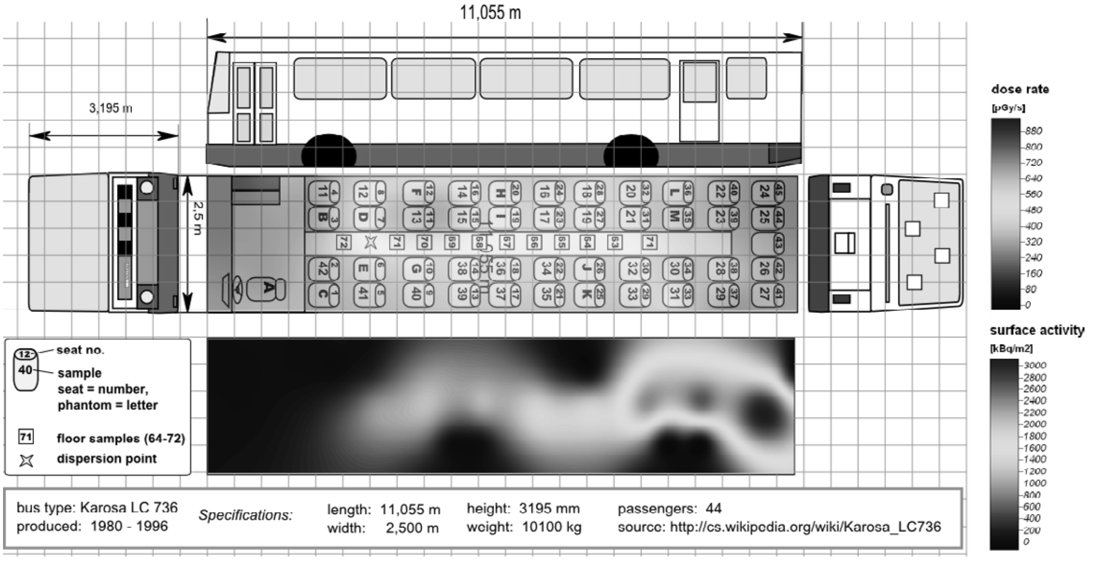

Figure 6a,b. Dose rates (a) and surface activity (b) distributions after RaS dispersion in "Bus“ test (location of collecting filters can also be seen in the Figure).

Regarding small distance between place of RaS dispersion and an entrance of the impactor in tests „small house" and „bus", majority of released RaS was captured on the great particles transferred by blast wave in the short time after explosion.

Conclusions

Presented comparison results demonstrates that the obtained set of data – dose rates, surface and volume activities, mass concentrations - is applicable for evaluation of the RaS propagation on short distances. It is easy to understand that absolute values of particular quantities will always be strongly dependent on the actual meteorological situation at the time of the RaS release under otherwise identical conditions.

The measurements of the surface and volume activities demonstrated the prevalent amounts of the released RaS are transferred across monitored area within very short time. For the vertical distributions (up to 12 m above the ground level) of surface activities the similar results were obtained. These findings confirmed as well measurements using DustTraks [8, 10], which showed, that a spread of aerosols driven by the explosion pressure wave up to a distance of 50 m during less than 1 sec, after that the distribution of surface and volume activities corresponds the propagation by the convection, depends on instantaneous meteorological conditions.

Preliminary evaluation made using different codes [11- 13] demonstrates that the obtained data/results may be used for purposes of model calculations and upgrade and development of existing models (programme IAEA EMRAS II [14].

Genomic-based biodosimetry monitoring analysis method

Benotmane, M. A.; Tabury, K.; Monsieurs, P.; Quintens, R.; Janssen, A.; Michaux, A.; Baatout, S.
Laboratory of Radiobiology, Molecular and Cellular Biology Expert Group, Institute for Environment, Health and Safety, Belgian Nuclear Research Centre, SCK•CEN, Mol, BELGIUM

Abstract
Large-scale radiologic emergency due to terrorism or large-scale accidents could result in potential radiation exposure of hundreds to thousands of people. The present guidelines for biological evaluation after such an event are still scarce. Therefore, there is a need for biomarkers of retrospective biodosimetry after radiation exposure and assessment human health risk. The frequency of chromosome translocations in individuals exposed to low to medium doses of whole-body irradiation served up till now these goals. Measurement of chromosome translocations in peripheral blood lymphocytes is presently the golden standard to quantify the effects of ionizing radiation and has been used for workers exposed to low or chronic doses. The major problem associated with the assessment of chromosomal aberrations is that it requires a considerable amount of time and labor for aberration scoring and that the sensitivity is rather low.

In this study, we used whole genome microarray expression profiling to identify genes with the potential to predict radiation dose across an exposure range relevant for dose discrimination and medical decision making in a radiologic emergency. Human peripheral blood from 10 healthy donors was irradiated ex vivo using mainly 0.1 Gy X-rays as low dose and 1 Gy as a high dose to be compared to non irradiated control cells, and global gene expression was measured at 8h after exposure identified previously as optimal time for gene expression. Data analysis revealed a clear cut in terms of the pathways modulated with the two doses. At the high dose (1 Gy) we observed mainly the induction of p53 responsive genes (MDM2, DDB2, XPC, EDA2R, SESN1, CCNG1) and pathways associated with cell death processes. In contrast, at the lower dose (0.1 Gy), we observed modulation of another set of pathways mainly associated with mitochondrial oxidative stress and chromatin remodelling.

In conclusion, our analysis method allowed us to discriminate between low and high dose exposures based on the modulated pathways, in contrast to other studies attempting to identify sets of marker genes expressed in a dose-dependent way, which might be biased by inter-individual variation.

Abstract
Numerous issues in radiation protection require appropriate activity measurements. Although today many methods are established to assess radiation exposure to man by physical models and mathematical simulations, there is also a strong requirement in technologically adequate, fair accurate, traceable and reliable activity measurements techniques and radionuclide analytics.

To ensure effectively traceable measurement methods for all medically and technologically used radionuclides up to end-user applications, a network of primary and secondary national metrological activity standards are provided by national metrology institutes under the coordinative umbrella of the Bureau International des Poids et Mesures (BIPM) in Paris. The international progress of activity metrology and measurement is scientifically supported by the International Committee for Radionuclide Metrology (ICRM).

In this paper, an overview of state-of-the-art activity measurement methods for all categories of radiation protection is presented. Special focus is given on current developments in emerging medical application, radioecology, NORM and radon measurements, and uncertainty assessment. Recent improvements and practical implementation on the metrological quantification of radionuclide activity – from fundamental metrology to end-user applications – are covered. The scientific support of ICRM in the field of radionuclide metrology is illustrated. Eventually, international, European and national standards and scientific and technological co-operations and networks in radionuclide metrology and analytics are discussed with regard to upcoming necessities determined by recent ICRP recommendations and IAEA & EU Basic Safety Standard development.

Introduction

To step into radionuclide metrology and activity measurement, one has to consider a common understandable and mostly agreed definition of the quantity activity. A widely agreed common scientific definition can be found in IEC 60050:2003:

> Activity A: quotient, for an amount N of radionuclide in a particular energy state at a given time, of $\langle \mathrm{d}N \rangle$ by dt, where $\langle \mathrm{d}N \rangle$ is the expectation value of the number of spontaneous nuclear transitions from this energy state in the time interval of duration dt.

$$A = -\frac{\langle \mathrm{d}N \rangle}{\mathrm{d}t} = \lambda \cdot N \qquad (1)$$

where λ is the decay constant of the radionuclide.

This definition is amended by the simpler and more operational definition in ISO 921:1997, entry No 23:

> Activity A: number of spontaneous nuclear disintegrations occurring in a given quantity of material during a suitably small interval of time divided by that interval of time.

In any case the unit of the quantity activity is defined in the International System of Units SI (BIPM, 2006) to s^{-1} with the specific name *becquerel* (Bq).

In many applications of radiation protection measurements derived activity quantities like activity concentration or surface contamination with their specific units are established eg. $Bq{\cdot}kg^{-1}$, $Bq{\cdot}m^{-3}$, and $Bq{\cdot}m^{-2}$.

Metrological activity measurement methods

For metrological purpose adequate standardisation measurement methods for representing the unit *becquerel* for specific radionuclides are given in the *Generic grouping of nuclides* (CCRI(II), 2008). The state-of-the-art radiation detectors, measurement geometries, radiation types and counting modes, currently used for metrological radionuclide activity standardisation, are shown in Tab. 1 and Tab. 2. The international key comparisons for primary standard activity measurement is supported by the *International Reference System* SIR of the *Bureau International des Poids et Mesures* BIPM in Paris (SIR, 2010).

The currently achievable measurement uncertainties in activity primary standardisation methods depend on the applied method and the radionuclide of interest. The expanded relative uncertainties (coverage factor $k = 2$ according to JCGM, 2008) of state-of-the-art activity primary standardisation methods range from 0,4 % to 5,0 %.

The international coordination of primary standard activity measurement capabilities supports the calibration services for activity measurement instruments of national metrological institutes and designated laboratories. Radiation protection is only one of various applications of activity measurement (eg. nuclear medicine diagnostics, brachytherapie).

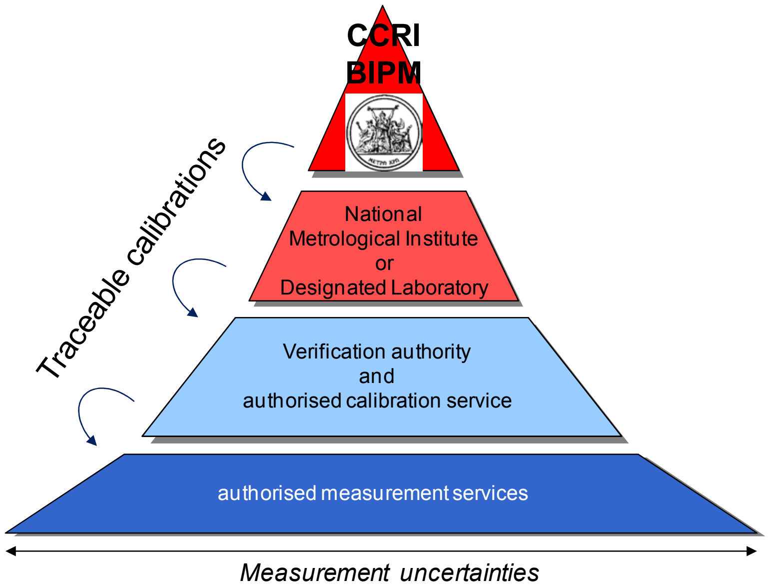

Figure 1. Traceability of measurements from CCRI - Consultative Committee for Ionising Radiation at BIPM - Bureau International des Poids et Mesures to authorised measurement services.

Comprehensive overviews on currently used methods for metrological radionuclide activity standardisation are given in Simpson & Judge (2007) and Pommé (2007).

Table 1. Radiation detectors and measurement geometries used in metrological activity standardisation measurement methods (source: Ratel, 2010).

Geometries	Radiation detectors
4π	Proportional counter
Defined solid angle	Pressurized proportional counter
2π	Liquid scintillation counting
Undefined solid angle	NaI(Tl)
	Ge(HP)
	Ge(Li)
	Si(Li)
	CsI(Tl)
	Ionization chamber
	Grid ionization chamber
	Bolometer
	Calorimeter
	PIPS detector

Table 2. Radiation types and counting modes used in metrological activity standardisation measurement methods (source: Ratel, 2010).

Radiation type	Counting mode
Positron	Efficiency tracing
Beta particle	Internal gas counting
Auger electron	CIEMAT/NIST
Conversion electron	Sum counting
Mixed electrons	Coincidence
Bremsstrahlung	Anti-coincidence
Gamma rays	Coincidence counting with efficiency tracing
X - rays	Anti-coincidence counting with efficiency tracing
Photons (x + γ)	Triple-to-double coincidence ratio counting
Photons + electrons	Selective sampling
Alpha - particle	High efficiency
Mixture of various radiations	Digital coincidence counting

The applicable primary standardisation measurement method depends on the decay scheme of the radionuclide of interest. In many cases high-geometry methods with solid angles of the sensitive detection volume around the radioactive source of almost 4π are chosen. For large-area sources 2π surface emission methods are used. Specific measurement methods used in high-geometry activity standardisation are 4π and 2π proportional counting including internal gas counting for gaseous samples, 4π gamma-ray counting, 4π beta + 4π gamma sum counting, 4π windowless sandwich spectrometer (CsI(Tl)) and liquid scintillation counting. Primary standardisation by LSC uses CIEMAT-NIST or triple-to double coincidence rate method. Some high-geometry methods are also high-efficiency methods. In this case, low and medium activity sources are suitable for satisfactory measurement uncertainties.

For alpha emitters defined solid angle methods taking into account the geometry factor Ω/4π are applicable. This method requires delicate sample preparation to avoid undefined self-absorption inside the source. The background rate for alpha detectors (PIPS) are comparable low around $1 \cdot 10^{-3}$ s^{-1}.

Coincidence counting is another applied method for activity primary standardisation. In this branch sum peak coincidence method, 4π beta-gamma coincidence and photon-photon coincidence counting has been implemented.

Examples for state-of-the art primary standardisation methods commonly used for metrological radionuclide activity determination are given in table 3. In this table the currently achievable expanded relative measurement uncertainties (coverage factor k = 2) are shown. These values are the metrological top level figures for traceable calibration of activity measurement instruments and methods.

Table 3. Examples of top-level primary standardisation methods for radionuclide metrology.

Geometry	Detector 1	Radiation 1	Detector 2	Radiation 2	Mode	Uncertainty range (k=2)
4π	liquid scintillation counter	beta particle or alpha particle or Auger electron or gamma ray or X-ray	---	---	CIEMAT/ NIST or triple-to-double coincidence ratio counting	0,4 to 3,5
4π	pressurised proportional counter	(beta particle or alpha particle) and gamma ray	---	---	high efficiency	1,0 to 4,0
4π	NaJ(Tl)	gamma ray	---	---	high efficiency	0,4 to 4,0
definded solid angle	PIPS detector	alpha particle	---	---	---	1,0 to 4,0
4π	proportional counter or pressurised proportional counter or liquid scintillation counter	beta particle or alpha particle	NaJ(Tl) or Ge(HP)	gamma ray	coincidence or anticoinciden ce	0,4 to 2,0

Activity measurement methods in operational radiation protection

Because radiation protection is mainly a health safety issue, activity measurements has to be carried out on a high quality level. This requirement leads to traceable calibration of activity measurement instruments. This means that any activity measurement done for radiation protection purposes have to been carried out by measurement instruments which are traceably calibrated at primary or secondary standards. In practice this technical claim is ensured by institutional authorisation or accreditation or verification of the used measurement instrument. The achievable measurement uncertainties of operational activity measurement methods are higher than metrological standardisation measurement methods due to uncertainty propagation in the calibration chain.

Different radiation protection branches (Tab. 4) require specific measurement methods.

Table 4. Radiation protection branches using activity measurement methods.

Radiation protection branches
Radiation protection of workers - operational RP
Individual monitoring – internal dosimetry
Environmental monitoring
NORM — Naturally occurring radioactive materials
Radon
Nuclear and radiological emergencies and incidents
Nuclear security and malevolent use of radioactive sources
Illicit trafficking
Radioactive waste management
Decommissioning of nuclear facilities
Education, training and research

In the following sections some general aspects of main relevant activity measurement method used in operational radiation protection are discussed.

Low-level gamma-ray spectrometry for environmental monitoring

Gamma-ray spectrometry for monitoring environmental material like water, air, soil, and food, is one of the most common radiometric method applied in radiation protection. Large volume high-purity germanium semiconductor detectors in special low-level shielding facilities support activity concentration measurement in different samples in the activity range from some mBq to some MBq, or expressed as activity concentration in the range from 10^{-5} to 10^{5} Bq·kg^{-1}.

Generally the Ge(HP) spectrometers are calibrated with standard reference activity sources and/or via Monte Carlo simulation methods. Depending on the efficiency of the detector / volume and geometry of the germanium crystal, sample volume and geometry, measuring time, and the decay scheme of the radionuclide of interest, achievable relative measurement uncertainties (k = 2) for this method are typically in the range of 4 % to 20 %. In most applications the achieved uncertainty fits the purpose because the measurement is done for environmental contamination assessment and not for individual monitoring.

One main problem of this method and restriction in measurement accuracy is the representative collection of samples. If enough measurement capacity is available, typically 15 to 30 samples of the monitored material are necessary to ensure similar uncertainty contributions as for the measurement itself.

Radon gas and radon progeny activity measurement

Dose exposition due to inhalation of radon progenies is of interest in radiation protection both at NORM workplaces and at home. Due to the simpler measurement of radon gas in many cases only radon gas activity measurements are legally regulated and carried out. To assess the lung and effective dose a mean equilibrium factor of typically 0,4 between radon gas and radon progenies indoor is applied. State-of-the-art conventional radon gas and radon progeny detection systems are working in the activity range from some Bq·m^{-3} to some 10^5 Bq·m^{-3}. Calibration of radon gas activity measurement instruments and radon detectors are done in radon chambers traceable to secondary or primary radon gas activity standards.

Again for these methods the representative collection of monitored air respectively the sampling position has large influence on the total uncertainty and individual dose determination. Whereas typical expanded relative uncertainties for measured Rn-222 activity concentrations in indoor air are in the range from 7 % to 20 %, the deviation between different sampling positions in the same room could be up to 30 % (eg. due to relative distance of the instrument / detector from fresh air and radon inflow ventilation flows inside the room). This fact leads to the necessity of careful detector / instrument positioning in the observed room.

Surface contamination activity measurement

This activity measurement method is widely used in all application branches of radionuclides eg. nuclear medicine, research laboratories or at NORM industrial workplaces. Purpose of this method is the safeguarding of radioactive contamination of workplaces to avoid unwanted exposition of staff members. Instruments for this purpose are hand-held and hand-foot-clothing monitors equipped with large-area proportional counters or plastic scintillation detectors.

Depending on the measured radionuclide, the covered activity-per-surface-area range goes from some 10^{-2} Bq·cm^{-2} to some 10^4 Bq·cm^{-2}. Required expanded relative uncertainty vales (k = 2) are in the range from 15 % to 40 % depending on the specific application and the radionuclide of interest. In many countries these types of instruments are calibrated with large-area surface standard activity sources. In Austria the traceability of these instruments are assured via legal verification (‘*Eichung*’) each second year.

Liquid scintillation counting in radiation protection

For many radionuclides – especially such with very low beta particle energy emission like H-3 or C-14 and all type of alpha particle emitting radionuclides – liquid scintillation counting technology is a simply accomplishable and up-to-date activity measurement method. For example in activity concentrations of alpha emitters in water samples could be carried out with this method with satisfactory accuracy, linearity and reproducibility in the range from 10^{-5} Bq·kg^{-1} to 10^5 Bq·kg^{-1}. For some radionuclides like uranium isotopes, radiochemical sample preparation is required before counting.

For simple activity measurement tasks like measuring the Rn-222 activity concentration in water, minimum expanded relative measurement uncertainties (k = 2) of 5 % could be achieved in very careful laboratory circumstances. In many cases the typical achievable range of the expanded relative uncertainty including sample preparation is from 10 % to 40%. Also these figures are useful for most applications in radiation protection like environmental and operational monitoring.

In Tab. 5 the currently most commonly used activity measurement detection systems and instruments are listed together with the available international IEC and ISO and European CENELEC (EN) standards. The Technical Committees for radiation protection measurements instruments and methods are at IEC[1]: SC 45B ‘Radiation Protection Instrumentation’, at ISO[2]: TC 85/SC2 ‘Nuclear Energy / radiation protection’ and at CENELEC[3]: TC 45B ‘Radiation protection instrumentation’. In all these standards the application conditions and technical requirements of the specific instrument types are included. At CEN[4] no specific technical committee on ionising radiation protection measurement is established so far.

Table 5. Activity detection instruments for radiation protection applications.

Detector type	Traceability reference source	International & European standards
Portable *α, β, α/β* counter	Area source	EN 60325, (prEN 62363)
Hand, foot and clothing *β/γ* monitor	Area source	IEC 60325, IEC 61560, ISO 7503-1, 2, 3, EN 61098
Floor monitor	Area source	EN 60325, (prEN 62363)
Laundry monitor	Area source	IEC 61256
Well-type *γ* counter	Point source / volume source	IEC 61562, ISO 11929-1, 2
γ spectrometer	Point source / volume source	IEC 61563, IEC 61275, IEC 62002, ISO 11929-3
α spectrometer	Area source

The International Committee for Radionuclide Metrology - ICRM

The International Committee for Radionuclide Metrology[5] is an association of radionuclide metrology laboratories whose membership is composed of delegates of these laboratories together with other scientists actively engaged in the study and applications of radioactivity. It explicitly aims at being an international forum for the dissemination of information on techniques, applications and data in the field of radionuclide metrology and measurement.

The Bylaws were adopted at the General Meeting in Gaithersburg, Maryland (USA) in 1997. The ICRM as a formal organization grew from efficient contacts among radionuclide metrologists who participated in the First International Summer School on Radionuclide Metrology in Hercig Novi, Yugoslavia in summer 1972.

ICRM activities are largely the responsibility of its working groups. Each group is guided by a coordinator who acts as a net worker for ideas, joint projects and communications and may organize conferences and workshops. There are now six working groups in the following thematic fields:

- Radionuclide Metrology Techniques
- Life Sciences
- Alpha-Particle Spectrometry
- Gamma-Ray Spectrometry
- Liquid Scintillation Techniques
- Low-Level Measurement Techniques
- Non-Neutron Nuclear Data

The (biennially) recently held 17th International Conference on Radionuclide Metrology and its Applications," had been hold in Bratislava in September 2009[6]. The conference papers will be published shortly in *Applied Radiation and Isotopes*. The next conference will be hold in September / October 2011 in Tsukuba, Japan, organized by the National Metrology Institute of Japan, Advanced Industrial Science and Technology (NMIJ/AIST).

The recent conference of the Low-Level Measurement Techniques ICRM working group - the 5th International Conference on Radionuclide Metrology – Low-Level Radioactivity Measurement Techniques ICRM-LLRMT'08 - was held in Braunschweig, Germany, in September 2008 (Arnold, Jerome, Hult, 2009).

All ICRM conferences and workshops are announced on the ICRM homepage. The participation in ICRM conferences and workshops is open to all scientists and persons who are interested in the topics.

Conclusions and perspectives

The metrological basis of radionuclide activity measurement has been well developed on an international high quality level since the last five decades under the scientifical and technological umbrella of the *Bureau International des Poids et Mesures* BIPM in the frame of the Consultative Committee for Ionising Radiation CCRI(II). More than 60 metrological institutes and laboratories operate high-level primary and secondary

---

[5] http://physics.nist.gov/Divisions/Div846/ICRM/
[6] http://www.icrm2009.sk/

standards for metrological radionuclide activity measurement. The International Reference System SIR at the BIPM coordinates key comparisons for all radionuclides of interest in radiation protection. The international infrastructure in radionuclide metrology supports the high-quality activity measurement instrumentation in radiation protection. In most Europen countries the traceability of activity measurement instruments used in operational radiation protection is ensured by traceable calibration or verification. The increasing application of emerging radionuclides in medicine, industry and science generates permanent developments in activity measurement instrumentation. The necessary methodical developments are challenging tasks both for radionuclide metrologists and radiation protection experts. In Europe, the research and development network in metrology is scientifically and financially supported by the European Metrology Research Programme EMRP[7]. Within this co-ordinated research programme joint research projects in all branches of metrology and also in activity measurements are carried out to increase and ensure the necessary high-quality scientific and technological basis of radionuclide activity measurement instrumentation.

Location and identification of radioactive materials on sea using airborne gamma-ray spectrometry

Nikkinen, Mika[1]; Kettunen, Markku[2]
[1] Radiation and Nuclear Safety Authority, P.O. Box 14, 00881 Helsinki, FINLAND[a]
[2] Finnish Defence Forces Research Centre, P.O. Box 5, 34111 Lakiala, FINLAND

Abstract
Considering the nuclear security, one of the threats is that a nuclear device or radiological explosive device is transported to the harbour over the sea. A ship can carry rather large radiological device and if it is detonated close to densely populated areas or economically or strategically important locations the consequences may be severe. Possible source term can also be a marine nuclear reactor release or underwater detonation of nuclear weapon. In these cases the detection of source term is based on identification of fission and activation products that are spread and diluted to a large volume of sea water. The mapping is based on same methodology that is applied to the detection of radioactive fall-out on the ground. As the water masses are constantly moving, the radioactive materials are also changing the location and this requires constant monitoring activity for long period of time. As part of security measures, these scenarios can be exercised by using airborne gamma ray measurement devices on the sea. Measurement over sea is actually very sensitive method as the background from natural radiation is close to zero and the detection capability is significantly better over the sea than over the land. The experience gained through these exercises show that also high-speed jet plane can be used in the identification tasks as we need only few seconds measurement time over the source. The detection system and search logic are illustrated in the presentation.

Introduction
Typical problem in the mobile on-site gamma-ray measurement is to be able to track the radioactive source location with high efficiency and still be able to characterize the source by identifying and quantifying the radioactive substances and their activity. In fact, location, detection, identification and quantification are competing with each other; good location accuracy requires high measurement resolution (i.e. short measurement time for individual gamma-ray spectra) and this reduces the possibility to detect, identify and quantify the radioactive source. Multiple level measurement

[a] Currently at Preparatory Commission for Nuclear Test-Ban-Treaty Organization, Vienna International Centre, P.O. Box 1200, 1400 Vienna, AUSTRIA

strategy can be used to ensure the detection and location power together with good quantification and identification capability.

This type of measurement capability is needed in case a large radiation source or it's activity is released in the environment and there arises need to locate and assess the risks related on source strength and type. This kind of situation is possible for example due to:

- Release of radiation due to use or testing of nuclear weapon
- Accidental release of radiation from nuclear reactor, medical isotope production or other kind of facility handling radioactive materials.
- Release of radiation due to malevolent use of radiation
- Radiation due lost or forgotten radioactive source

This paper is presenting the results of an exercise that was performed by Finnish Defence Forces by using a mobile radiation source (Cs-137, 3 GBq) in a ship on the Baltic Sea. This exercise was set up to study the detection of mobile source and possible radioactive contamination in the water due to release of radioactive material. The measurements were performed using a jet-plane with both medium volume NaI detector (6x4") and HPGe detector (70% relative efficiency). Typical cruising speed was 370-400 km/h and altitude above the water was 100 meters. Each NaI spectrum was collected with 1 second integration time and HPGe spectra with 2 seconds integration time. This method was developed to ensure quick response measurement in case of nuclear or radiation emergency [1].

Results and discussion

In real time measurements, it is important to show the results immediately for the analyst performing the measurement. This requires that a graphical display with capability to visualize the radiation levels. A spectrogram display as shown in the figure 1 has to be able to show the energy and location of the source so that the operational staff can react on finding. This is the spectrogram of NaI detector. This feature has been built in the gamma spectrum analysis software UniSampo [2].

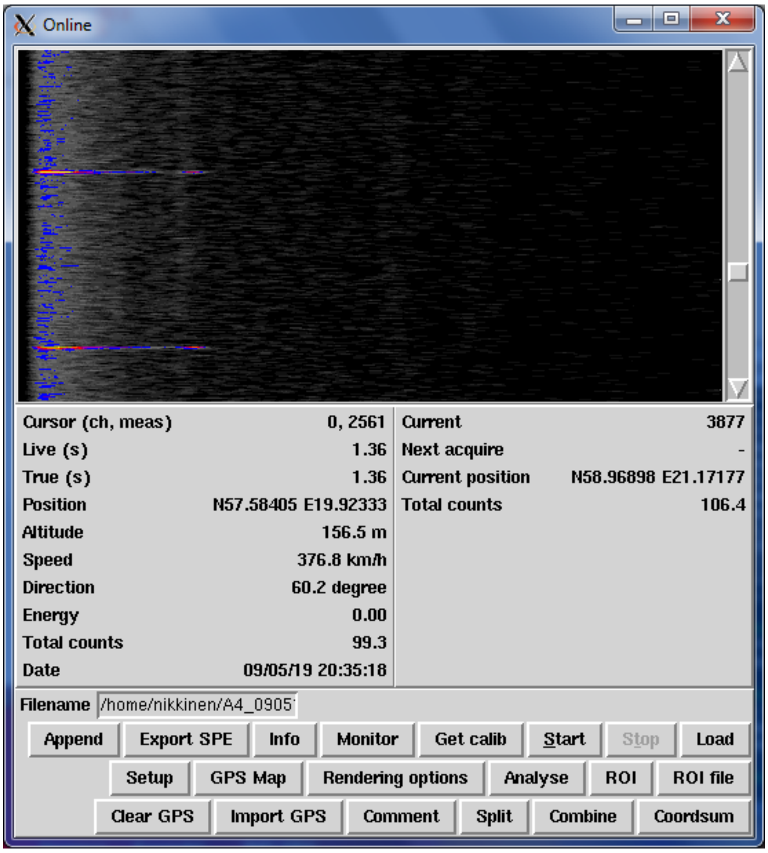

Fig. 1. Spectrogram display during the exercise (each horizontal pixel line represent one single spectrum, more intensive colour the pulses), high activity source is visible only in a few spectra. This view provides actual real-time detection and identification capability already during the flight.

Accurate post-processing is required to extract further information on source location and characteristics. It is possible also to lower the detection threshold using the post-processing. This is possible by combining the measurement points together and comparing the smoothed average with surrounding measurement points. In the measurements computer software GMLINT [3] has been used. The pulse rate of the background is used to calculate the critical limit in accordance with Currie [4]. As a result, it is possible to make a geographically referenced detection capability map as seen in figure 2 [5]. Possible source locations are highlighted in the processing window.

Number of corrections can be applied to the results:

– Distance between source and the detector (three dimensionally)
– Attenuation of the gamma rays in the air (gamma energy dependent)
– Attenuation of gamma rays in the body of the aircraft including angular response

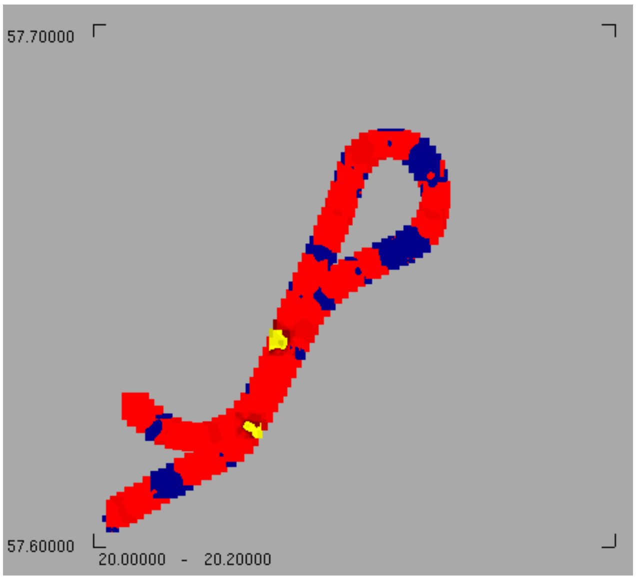

Fig. 2. Display of GMLINT software during the post-processing of data. Source location, uncertainty and critical limit can be displayed during the processing. This provides the end-user possibility to assess source locations and strengths. The yellow dot is showing the maximum source strength. As the ship was moving during the exercise the source was detected in two different locations.

More accurate information is available if HPGe detector information is combined with the analysis. In these kinds of measurements the background pulse-rate is relatively low and due to better energy resolution the pulses are concentrated on significantly more narrow energy window. As a result, the identification of the source is easier. Figure 3 shows one flight line and behaviour of pulse-rate for Cs-137 when by-passing the source during the exercise.

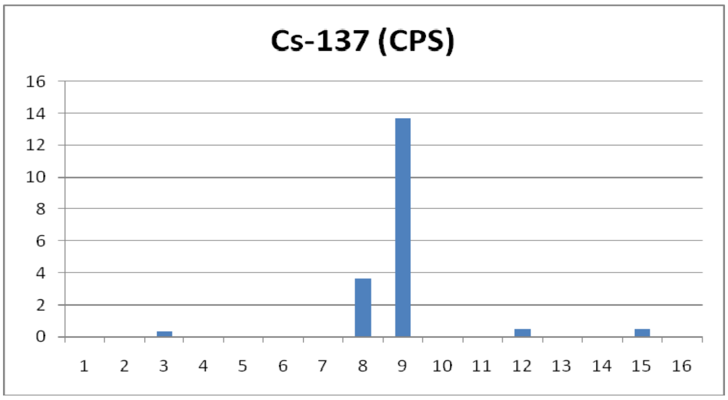

Fig. 3. Histogram display of HPGe detections, the maximum value is clearly detectable. Further analysis can be performed by calculating the weighted average to estimate the exact source location if when the gamma rays emitted are detected in more than one spectrum.

One additional question was where in the boat the source was located. As the size of the boat was rather large (218 meters long ship), it would be desirable to locate the source accurately during the over-flight. As the ship was moving, it was decided to bypass the ship by flying along the axis of the ship.

It is proposed to include also minimum and maximum source strength estimates to the automatic procedure. Maximum is the source strength if the measurement target is optimally located in the middle of integration time and the aircraft is flying exactly on the top of the source as shown in figure 4. Minimum would be if the source location maximum is in the end or beginning of integration time and the distance of the source is in the middle of measurement flight lines.

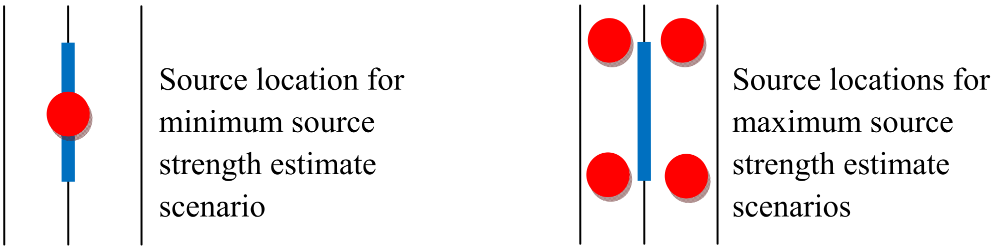

Fig. 4. Minimum and maximum estimates of the source strength. On the left side the source is right on the flight line (narrow line) and in the middle of integration line (thick line), this provides the minimum value for source strength. On the left side the possible source locations are in the end or begin of integration time and between the flight lines. This provides the maximum estimate for the source strength. All the source strength approximations should be between these two estimates.

Conclusions

As a conclusion the tools that are used for the radiation source detection and source location were working very well during the measurements. The flight team was able to locate the radioactive source carrying ship, to characterize the source type (open Cs-137 source) estimate the source activity. In this kind of measurement the uncertainties on source strength is large but the measurement team was able to give approximate source strength information in relatively good accuracy. It is also possible to calculate minimum and maximum source strength relative to source distance to the flight line.

Abstract

A generic EGSNRc-Monte Carlo model was developed for a whole body counter (WBC) with four NaI(Tl) detectors in a stretcher geometry - which is the setup both at Karlsruhe Institute of Technology (KIT) and at University Hospital of Cologne (UKK) – and the bottle phantoms previously used for their calibration. The main purpose of this work was to determine whether numerical calibrations can replace the ones based on measured spectra of known activity concentrations. Methods: Three main methods were developed and applied for the evaluation of measured spectra:

a) Simulation of nuclide decay and evaluation of total gross counts in a nuclide-specific region-of-interest (ROI), including the contribution of scattered photons

b) Simulation of nuclide decay and using these calibration spectra for a "full spectrum fit" to measured ones

c) Simulations of artificial "single energy" decays and deriving efficiency factors from a set of such simulations.

All methods were able to successfully replace the measured calibration spectra as proven at both institutions in a number of intercomparison exercises. A full set of "single energy" simulations offers a quick and flexible way to calculate efficiency factors for any nuclide without the need for further simulations or measurements. Moreover, Monte Carlo simulations offer the possibility to study the response of the counting system without the need of handling radioactive materials or relying on the properties of a real nuclide.

Introduction

Gamma spectrometry in whole body counters is used to detect and quantify radionuclides in man. This can be done as routine measure of incorporation monitoring or as means to assess doses after incidents. Further uses of whole body counting are measurements of the retention of pharmaceuticals labelled with radionuclides for medical diagnosis (ICRU 2003). All nuclides emitting gamma rays of sufficiently high energies (>100keV) with a significant emission probability (>3%) can be measured by in-vivo counting. Examples are fission or activation products such as ^{133}Ba, ^{137}Cs and

^{60}Co which are used in many nuclear applications or ^{99m}Tc, ^{201}Tl and ^{131}I from the field of nuclear medicine as well as naturally occurring ^{40}K.

Whole Body counters use an array of detectors placed around the person to be measured inside a shielding chamber. The person to be measured can either stand in front of the detectors, sit on a chair or lay on a bed. During the measurement the detectors may stay fixed or move around/along the patient (scanning mode). Detectors used for in-vivo counting are either scintillators such as NaI(Tl) or CsI(Tl) or semiconductor detectors like high purity germanium crystals (ICRU 2003). The activities of the identified nuclides can be calculated from the count rates in defined regions of the measured spectrum (ROI) using efficiency factors. The latter are classically determined from measurements of known activities in physical phantoms representing the human body. The phantoms used need to represent the properties of human body regarding scattering and absorption of radiation (ICRU 2003). Typically bottle phantoms filled with radionuclides diluted in water (e.g. BOMAB) or brick phantoms (e.g. IGOR) are used for calibration of whole body counters. Alternatively Monte-Carlo Methods can be used to simulate radiation transport during the measurement process. Such simulations can then be used to derive the efficiency factors. A Monte Carlo Code using the EGSNrc system (Kawrakow and Rogers 2000) was developed and applied to both installations. Several methods for the evaluation of simulated and measured calibration spectra have been tested and applied to both set ups. The results of this study will be presented in this paper.

Material and methods

The whole-body counters at Cologne-UKK and Karlsruhe-KIT

Both institutions, Karlsruhe Institute of Technology (KIT) and University Hospital of Cologne (UKK), operate whole body counters with a similar set up, referred to as "stretcher geometry". The person lays on a bed which is surrounded by four fixed NaI(Tl)-scintillation crystals facing the person. Figure 1 shows the KIT whole body counter during the measurement of a bottle phantom. The nuclides are identified and their activity is determined from the sum of the four spectra of the measurement. The position of the detectors is optimized such that the count rates in the sum of the four spectra are as independent from the distribution of the source inside the person measured as possible. Properties of the two installations are summarized in table 1.

Fig. 1. The KIT whole body counter. A bottle phantom representing a 70kg person is placed on the bed. Only the upper two detectors can be seen in this figure.

Table 1. Properties of the two whole body counters used in this study.

	KIT	UKK
Chamber shielding	15/25cm Steel + 1.5mm Lead	16cm Steel + 3mm Lead
Detectors Postions Orientation	20.3 x 10.2 cm (8 x 4''), Fa. Bicron 2 above, 2 below the bed tilted around person's body axis	12.7 x 10.2 cm (5x4''), Fa. Scionix 2 above, 2 below the bed Parallell to bed
Channels in spectrum	256	1024
Energy Range	0 – 2500keV	0- 2000keV
Routine Counting Time	300 s	450 s

The Bottle Phantoms

The bottle phantom consists of a set of 2-1 and 1-l water-filled Cautex bottles in which a known amount of the radionuclide is diluted. A number of human shape geometries ranging from 10 kg/70 cm to 100 kg/190 cm can be arranged with different numbers of bricks/bottles. The concentration of the radionuclide in each bottle/brick was the same, thus a homogenous distribution of the nuclide within the body is assumed. In man, this is found only for some nuclides, e.g. ^{40}K or isotopes of cesium.

The EGSNrc usercode "Flaschenphantom"

A usercode for the EGSNrc Monte Carlo system has been developed (Breustedt and Eschner 2010). The EGNSrc system consists of several FORTRAN subroutines (called egscode) that provide the mechanisms for the radiation transport calculation. The geometry of the problem to be simulated and the tallying (extraction of information) has to be programmed by the user and is then coupled with the egscode by a defined set of subroutines (Kawrakow and Rogers 2000). The usercode "Flaschenphantom" provides the general geometry of the whole body counter chamber, the bed and the four detectors. A set of "bottles" (simulated as columns of water, without the bottles themselves) can be placed at the stretcher. All information needed by the usercode can be specified via a plain-text input file. Thus the code is flexible and can easily be adapted to other whole-body counters of the stretcher type. A set of input files describing the series of bottle phantoms (10kg -100kg) in the UKK and KIT set ups (including information on detector resolution and spectrum output) has been developed. Via the inputfile the user has to enter the geometry to be simulated, the nuclide which is assumed to be homogenously distributed in the bottles and the number of decays to be simulated. For some nuclides all information required (photon energies and emission probability, normalized beta spectrum if available) has been collected in text files, which can be addressed by the user. In order to study the response of the whole body counters as a function of photon energy, some artificial "one line" nuclides with a hundred percent emission probability were defined. After finishing the simulations the code will provide 5 output files (plain text format) which contain the spectra of the four detectors and the sum of the four spectra. Other information about the simulation is provided in a separate plain text file. All spectra are normalized to counts per decay simulated. This unit is equivalent to counts per second per Becquerel to which measured spectra can be normalized. The resolution of the detectors is taken into account by a convolution of the simulated energy spectra with a Gaussian kernel of width according to photon energy. The parameters required for this Gaussian broadening can be determined from an observed FWHM vs. energy relation. Thus a direct comparison of measured and simulated spectra is possible, if the widths of the channels in the simulated spectra are chosen accordingly.

Methods for Evaluation of spectra

Three methods to assess the activities from the spectra have been applied ins this study. For each of the nuclides observed in the spectrum a dedicated region of interest ROI (usually centred around the full energy peak of the main emission line) was defined. Generally the count rate in the spectrum (or the parts thereof, ROI) is dependent on the activity of the nuclide measured. The proportionality factor eff(ROI $\leftarrow$ nuclide) is called efficiency.

$$Cps\ in\ ROI = eff\,(ROI \leftarrow nuclide) \cdot Acitivity$$

The classical approach in gamma spectrometry takes only the full energy counts into account by using the net peak area which is determined by subtracting a scatter background below the peak. In in-vivo counting applications the spectra measured have very low count rates. This imposes problems on the determination of the scatter background below the peak. We tried to avoid these by using all counts in a given ROI for the determination of the activity. The scatter contribution to this gross count rate is taken into account by calculating efficiency factors of the form eff($ROI_i \leftarrow nuclide_j$) which then describe the probability of observing a count in the ROI for nuclide i after one decay of nuclide j. For each pair of nuclide and ROI this factor needs to be determined from calibration spectra which contain only counts of this nuclide. This requires a calibration measurement or simulation for each nuclide to be assessed. For whole body counting only a few nuclides are expected thus the overall effort to calibrate the counter still remains feasible. If more than one nuclide is present the efficiency becomes a matrix and the vector of activities A_j can be calculated from the observed vector of count rates C_i in the ROIs by inverting this matrix.

$$\begin{pmatrix} Bq\,nuclide 1 \\ \vdots \\ Bq\,nuclide\,n \end{pmatrix} = \begin{pmatrix} eff\,(ROI\,1 \leftarrow nuclide\,1) & \cdots & eff\,(ROI\,1 \leftarrow nuclide\,n) \\ \vdots & \ddots & \vdots \\ eff\,(ROI\,n \leftarrow nuclide\,1) & \cdots & eff\,(ROI\,n \leftarrow nuclide\,n) \end{pmatrix}^{-1} \cdot \begin{pmatrix} cps\,in ROI\,1 \\ \vdots \\ cps\,in ROI\,n \end{pmatrix}$$

A shortfall of this matrix approach is that the assessed activities become dependent on each other due to the system of linear equations used to determine the activities. Nevertheless we used two methods for the Monte Carlo determination the elements of the efficiency matrix. One method (later referred to as “direct simulation”) is a complete simulation of the nuclide decay. The elements eff($ROI_i \leftarrow nuclide_j$) can then be calculated straightforward by integrating the simulated spectrum in the given ROI i. The second method (later referred to as “reference simulation” is based on simulations of artificial nuclides which emit only one energy with a 100 % probability per decay. Such nuclides were defined for 20, 40, . . . 1980 keV, 2000 keV. An example for the derivation of efficiency factors eff($ROI_i \leftarrow nuclide_j$) for real nuclides from the set of "reference simulations" is given in the results section.

A second approach for the determination of activities from the measured spectra (later referred to as "fitting method") is also based on calibration spectra obtained with one nuclide at a time. Here the whole range of the spectrum, normalised to cps/Bq, is used to determine the activity. A weighted sum of the calibration spectra for the nuclides identified is built. A least squares fit to the measured spectrum (normalized to cps) is used to determine the weighting factors A_i which then are the activities. A prerequisite for the fitting of reference spectra to the measured spectrum is that all use the same energy calibration. This is ensured by the quality assurance procedures used in both labs, e.g. in the daily QA at KIT a point source is measured and the amplification factors are adjusted to fit the measured peaks in defined channels. Deviations between the different geometries are apparent in the scatter part of the spectrum at low energies. Thus it is useful to introduce a lower energy limit for the optimisation. We usually use only counts above 100 keV in the fitting procedure. In this method the assessed activities are also dependent on each other due to the common fitting.

Results

Several simulations in different geometries and for different nuclides were run. The photons were followed down to 1 keV, electrons down to 10 keV in these simulations. Usually 10 million decays were simulated, providing reasonably good counting statistics in the spectra. Depending on the nuclides' decay schemes the simulation runs took only a few hours on a modern computer. Simulated and measured spectra are in a good agreement. The direct comparison of the simulation and measurement of a 70 kg bottle phantom filled with ^{131}I in the UKK counter is shown in figure 2.

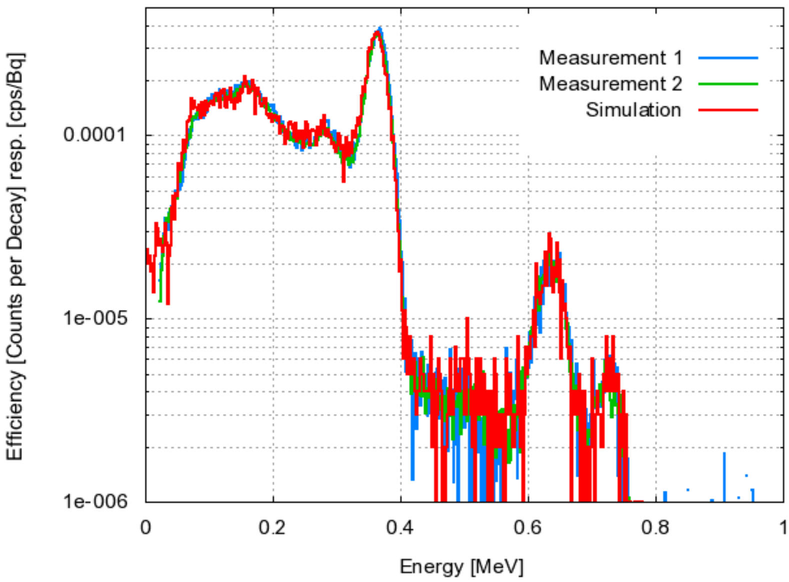

Fig. 2. Comparison of measured (blue, green) and simulated (red) spectrum of a 70 kg phantom filled with ^{131}I in the UKK whole body counter.

The only nuclide, where we observe deviations of measured and simulated spectra is ^{40}K. Here the spectra are in a good agreement above 250keV, below this energy the simulations underpredict the count rate in the spectra. The same effect could also be observed with another simulation code, MCNP5 (Brown 2002). Investigations on the reasons for these deviations are still in progress. Interestingly simulations with electron emissions only showed that the shape of the missing counts is that of a "Bremsstrahlung" spectrum for the electrons emitted by ^{40}K. If the electron emission in the simulations is artificially enhanced by a factor[1] of ~4.4, the simulated 40K spectra are in good agreement with the measured ones (Breustedt and Eschner 2010).

Efficiency factors eff(ROIi ← nuclidej) were calculated in the different geometries (10 kg – 100 kg) for several combinations of ROI and nuclides. The efficiency factors determined by the two methods "direct simulation" and "reference simulation" are in a good agreement with each other and with the ones derived from a series of measurements. For calculating the efficiency(ROI_k ← nuclide) from the set of "reference simulations" all of the simulated spectra are integrated in the same ROI and the results are assigned to the simulated energy. These values eff($ROI_k \leftarrow E_\gamma$) give the probability to observe one count in the ROI_k after the emission of one photon of E_γ in the phantom. An example of the resulting curve of 'efficiency in $ROI_{I\text{-}131}$ vs. emitted energy' is shown in Figure 3. $ROI_{I\text{-}131}$ is chosen from 316 – 411 keV centered around the ^{131}I line at 364 keV. The curves have a characteristic shape. For emitted energies below the ROI boundary, the efficiency values are zero. For emitted energies within the ROI high efficiency values are observed due to the photopeak being in the ROI. For higher energies only scatter events, which give lower efficiencies, are observed in the ROI.

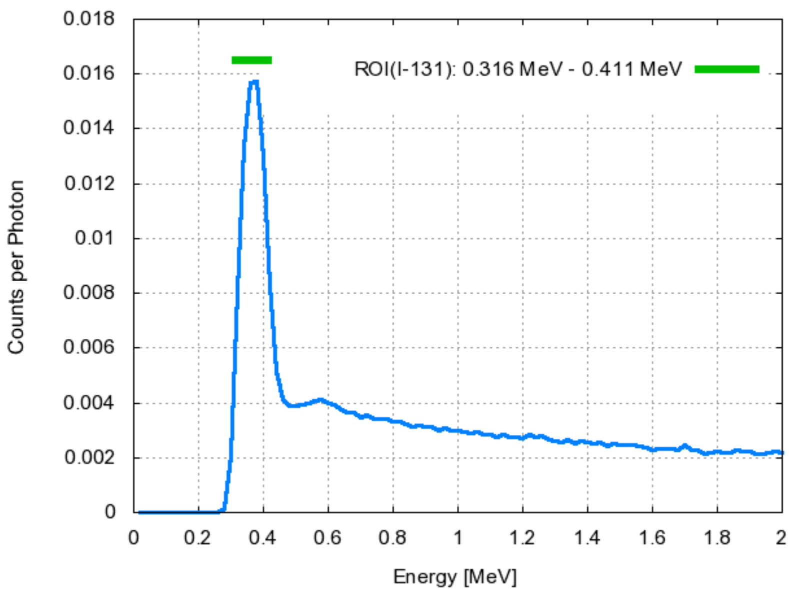

Fig. 3. Efficiency vs. energy curves (KIT counter) for ROI $_{I\text{-}131}$ centred around the peak at 364 keV. Here the ROI remains fixed and the efficiency for registering counts in this region of the spectrum after emission of a photon of a given energy is shown.

[1] Interestingly this factor is the same for both Monte Carlo systems EGSNrc and MCNP5.

Table 2. Calculation of efficiency from "Reference Simulations". Here the calculation of eff(ROI_{I-131} ← ^{58}Co), which gives the probability to observe one Count in ROI_{I-131} (from 316 – 411 keV) after the decay of one ^{58}Co nucleus in the phantom.

Energy [keV]	Emission Probability [%]	eff(ROI_{I-131} ← E_γ) [Counts per Photon]	contribution to eff(ROI_{I-131} ← ^{58}Co)
511	29,80	0.003876	0.001155
811	00,69	0.003329	0.003296
863	99,00	0.003131	0.000022
1674	00,52	0.002265	0.000012
		eff(ROI_{I-131} ← ^{58}Co) = 0.004485 **[cps/Bq]**	

Using the decay data of a nuclide the efficiency for the contribution of this nuclide to the count rate in a chosen ROI can then be calculated from such 'efficiency in ROI vs. emitted energy' curves. For each photon emitted by the nuclide its contribution to the efficiency is taken from the curve and summed up, weighted by the emission probabilities of the photons. The calculation of the nuclide specific efficiency factors from the curve shown in Figure 3 is shown in Table 2. Here eff(ROII-131 ← 58Co), which gives the probability to observe one count in ROII-131 (which again is centred around 364 keV, the main emission line of 131I) after one decay of an 58Co nucleus is calculated. Once a set of "reference simulations" is available for a given geometry, this method can be applied to derive efficiency factors for every nuclide. A contribution of Bremsstrahlung generated by emitted electrons is not taken into account. This may for some nuclides (e.g. 40K) lead to deviations. Nevertheless the efficiency factors eff(m, ROI ← nuclide) calculated with this method are consistent with the ones derived from direct simulations of the nuclide decay or from real measurements as can be seen in figure 3 which shows as example an plot of the "efficiency vs. mass" curve for 18F in the ROI which is centred around its main emission line at 511 keV. The mass dependency was parameterized by fitting a function of the type

$$eff\,(m, ROI \leftarrow nuclide) = a + b \cdot m^{-1} + c \cdot m$$

with free parameters a, b and c.

In the fitting procedure the main problem in the application of the simulated spectra was the underestimation of Bremsstrahlung counts in the spectrum of 40K. Thus the lower threshold needed to be raised as high as 250 keV in order to achieve good results for simulated spectra. If the 40K spectrum was replaced by a measured one, the lower threshold could by set down to 80 keV without any problems. Nevertheless the activities calculated by the application of simulated and measured spectra in the fitting method are in good agreement. The results were comparable to the ones calculated via ROI techniques.

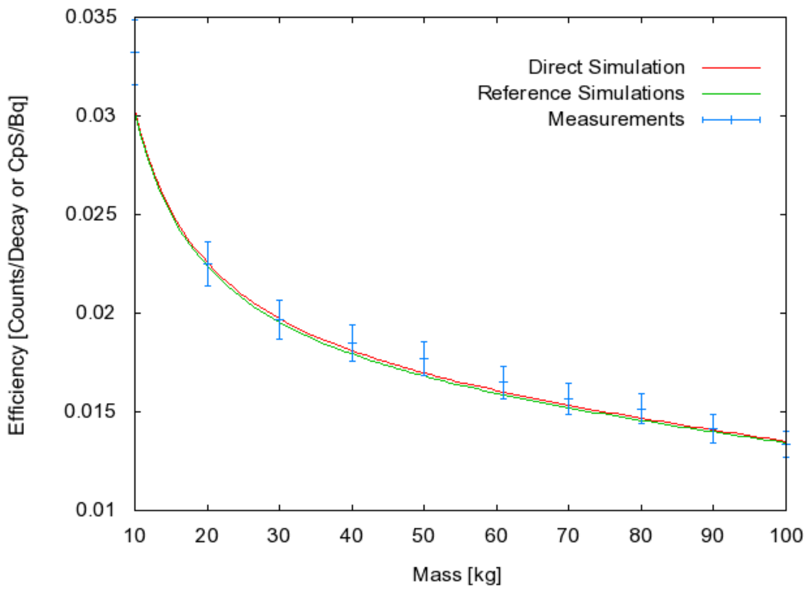

Fig. 4. Efficiency vs. mass curves for measurement of ^{18}F in a ROI centered around 511 keV. The lines show fits to efficiencies calculated from simulations (red: direct simulations; green: sets of reference simulations). Points show efficiencies derived from measured spectra.

Application example: Spectra from Intercomparison Exercises

Intercomparison exercises are one tool for quality assurance of in vivo measurement systems. The three methods described above were applied for the quantification of spectra during several intercomparison exercises. In these exercises, which are offered each year by the German federal office for radiation protection (Bundesamt für Strahlenschutz, BfS) (König et al. 2004), a brick phantom filled with activity (unknown to the participants) is measured by each participating institution. UKK and KIT participated regularly in the exercises of the last 10 years, which used the nuclides ^{133}Ba, ^{137}Cs, ^{60}Co and ^{40}K. All of the methods were able to quantify the reference activities within ±15%. As one example, the results for the KIT counter in the recent 2009 exercise are shown in table 3.

Table 3. Results of the 2009 intercomparison exercise at KIT. The activities calculated with the three approaches and the reference values provided by BfS are shown. The deviation from the reference values is given in brackets.

Nuclide	Reference Value [Bq]	Assessed Activity [Bq]		
		Direct Simulations of nuclide decay		Reference Simulations
		Fitting Method	ROI Method	ROI Method
K-40	2807	2605 (-7%)	2596 (-8%)	2631 (-6%)
Co-60	1176	1098 (-7%)	1045 (-11%)	1056 (-10%)
Cs-137	4332	3910 (-10%)	3895 (-10%)	3881 (-10%)
Ba-133	2564	2711 (+6%)	2403 (-6%)	2176 (-15%)

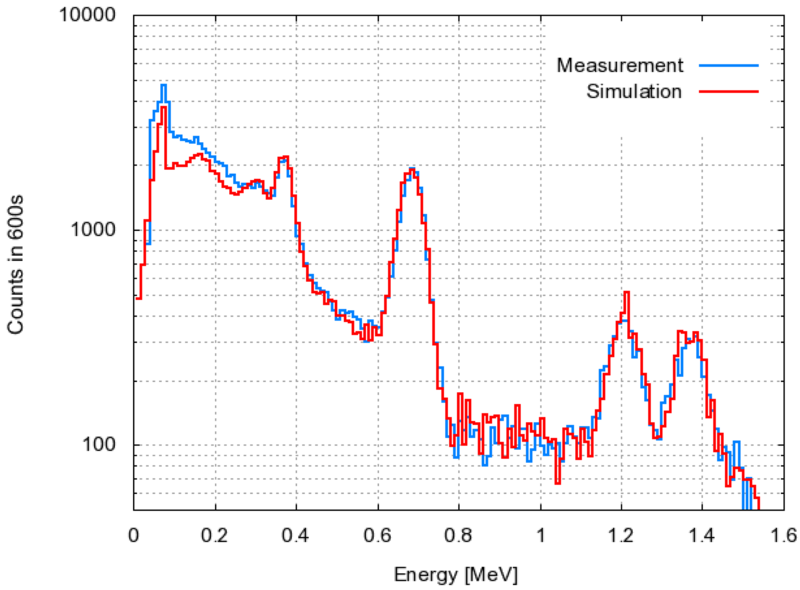

Fig. 5. Application of "fitting method" to spectrum of intercomparison exercise 2003 at KIT. The deviations below 250keV are due to Bremsstrahlung which is underestimated in the simulations. For the nuclide ^{40}K approximately half of the counts below 250 keV are due to Bremsstahlung.

Discussion and conclusions

None of the three methods we applied uses any algorithm to determine net peak areas. Only the gross counts in a Region of Interest need to be determined by an easy sum of counts in the according channels. This is an advantage especially in low count rate spectra as encountered in whole body applications, where net peak area algorithms may be hard to apply. The activities calculated are dependent on the other ones derived from the same measurement. This clearly is an disadvantage of the three methods and may lead to misinterpretations of the spectra. However, a large disagreement with activities derived from net peak areas algorithms has not been observed by us.

All Monte Carlo based methods were able to successfully replace the measured calibration spectra as proven at both institutions in a number of intercomparison exercises. The Monte Carlo Simulations offer the possibility to calibrate a whole body counter without the need of measuring activities. Thus single-nuclide spectra for the fitting method or the determination for efficiencies eff(ROI ← nuclide) become available for any nuclide needed. One problem observed by us is the improper simulation of Bremsstrahlung resulting from emitted electrons, which leads to an underestimation of low energy (< 250 keV) counts in the simulated spectra. This is observed for the nuclide ^{40}K which is always present in whole body counting. Studies to resolve this problem are currently done at KIT.

A full set of "single energy" simulations offers a quick and flexible way to calculate efficiency factors for any nuclide without the need for further simulations or measurements. Moreover, Monte Carlo simulations offer the possibility to study and evaluate the response of the counting system without the need of handling radioactive materials or relying on the properties of a real nuclide. A full calibration of the in-vivo counting system for using one of the three methods presented here may require a large amount of calibration spectra. But using Monte Carlo Simulations these spectra can be calculated without large effort in a rather short time.

New opportunities of radiation portal monitors with plastic detectors

Kagan, L.; Stavrov, A.
TSA Systems, Ltd., Longmont, Colorado, USA

I. Introduction

The prevention of unauthorized transportation of nuclear and radioactive materials through borders of the states demands the creation of a high quality system of the radiation control. As it is shown by the international experience, radiation portal monitors intended for the first stage of the control, i.e. the detection of a radioactive source in an object which crosses a control zone, create the basis of such a system. In highly sensitive gamma-neutron radiation monitors, the detection of gamma sources is provided by plastic detectors. Despite of a rather low cost of such detectors, the creation of systems of the border (customs) radiation control is rather expensive as the total number of radiation monitors is very high. It is enough to mention the Sheremetjevo-2 airport in Moscow and the Rotterdam sea port [1, 2].

A tendency has recently appeared to use the monitors based on essentially new detectors, providing not only detection of sources, but also their identification (the so-called spectroscopic radiation portal monitors). However, these are so expensive that can hardly replace traditional monitors with plastic detectors. So, it is very important to search for ways to increase their efficiency.

In the present paper the authors consider a possibility to increase the efficiency of traditional monitors with the use of additional lead collimators installed on both sides of each plastic detector.

The purpose of this research was not the elaboration of certain design recommendations of radiation portal monitors, but the analysis of the general relationships of the collimator influence on the basic monitor characteristics.

II. Results and discussion

II.1. Decrease of the measured natural gamma background

As known, radiation portal monitors with plastic detectors for gamma source detection use the traditional algorithm connecting a threshold of detection (minimum detectable signal **S**) with the background value **B**

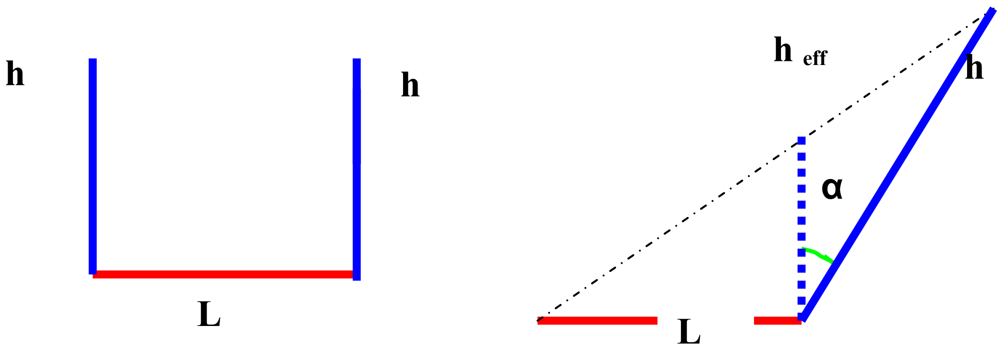
$$S = B + n \cdot \mathrm{sqrt}(B), \qquad (1)$$

where: **B** is value of the measured background;

sqrt (B) is the root-mean-square deviation of the background (so-called "sigma"),
n is the set number of "sigma" which defines both the false alarm rate, and the minimum detectable signal.

From the equation (1) it is clear, that a decrease of the background value measured by the given monitor should lead to a decrease of the minimum detectable signal other things being equal.

One of quite obvious technical decisions leading to a decrease of the measured gamma background is the use of a collimator installed on each plastic detector of the portal monitor. We have examined two versions of the lead collimator installation on the detector: collimator is perpendicular to the detector surface, and collimator is declined from the vertical by some angle (Fig. 1).



a) b)

Fig. 1. Versions of collimator installation on the detector (top view):
a) collimator of the length h is perpendicular to the detector (L is the detector width);
b) collimator of the length h is declined from the vertical by an angle α (h_{eff} is the effective length of collimator).

Experiments were carried out with a VM-250AG vehicle portal monitor [3]. A distance between pillars was 6 m, collimators were installed on all four plastic detectors, width of the detector was 152 mm, and collimator thickness was 10 mm.

As a result of simple geometrical considerations it is possible to obtain the following dependence:

$$B/B_0 = 1 - [\mathrm{arctg}\ (K \cdot h/L)]\ /90 \qquad (2)$$

where: B_0 is the natural background value without collimators;
B is the natural background value with collimators;
h is the collimator length, L is the detector width;
K is the numerical coefficient; its value can be found by calculations and experiments.

The equation (2) describes a version when the collimator is perpendicular to the detector surface (Fig. 1a). When the collimator is declined by an angle **α** from the vertical (Fig. 1b), it is necessary to use its effective length $\mathbf{h_{eff}}$ instead of the actual collimator length $\mathbf{h}$:

$$h_{eff} = (L \cdot h \cdot \cos\alpha)/(l + h \cdot \sin\alpha) \qquad (3)$$

Fig. 2 presents the calculated (by the equation (2)) and experimental data of relative background values when collimators of different lengths are installed perpendicular to the detector surface. As seen, the use of the collimator does significantly reduce the background value and, therefore, should result in a decrease of the minimum detectable activity (mass) of a radioactive source.

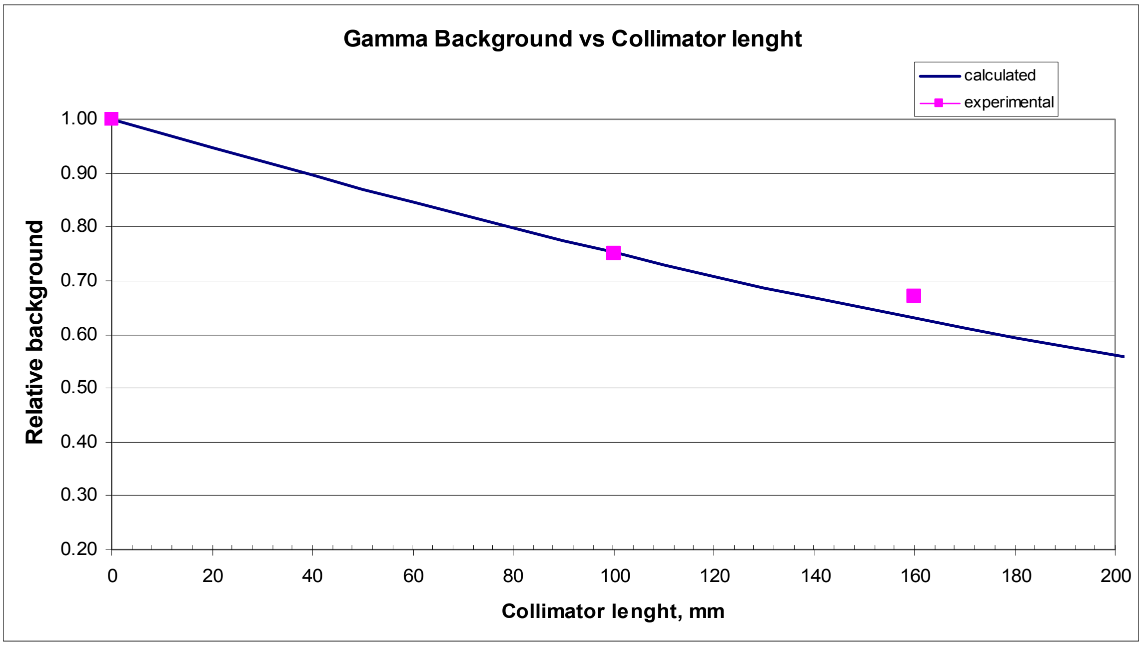


Fig. 2. Dependence of relative gamma background on collimator length (L=152 mm, K=0.625).

As known, when a vehicle is moving through the radiation portal monitor, the so-called "background suppression" effect, i.e. a decrease of recorded gamma background is observed. This effect is the cause of the fact that strong enough gamma sources which the monitor should detect easily become "invisible" [4]. Thus, a decrease of this effect also should promote the detection of weaker sources.

We have experimentally investigated the collimator influence on the "background suppression" effect by placing a truck between pillars of the portal monitor and measuring the gamma background values (Table 1). As seen from the data presented, the use of the collimator results in decreasing the " background suppression" effect both in absolute values (e.g. 90 cps instead of 160 cps for 160 mm collimator length), and in "sigma" values (2.9 instead of 4.3).

Table 1. Collimator influence on the background suppression caused by a truck inside of the radiation portal monitor.

Collimator length (alfa=0)	0 mm	100 mm	160 mm
Initial Background	1390 cps	1038 cps	933 cps
Backgr with truck	1230 cps	916 cps	843 cps
Backgr. suppression	-160 cps	-122 cps	-90 cps
Backgr. suppression	-4.3 sigma	-3.8 sigma	-2.9 sigma

II.2. Detection of the gamma sources.

The installation of a collimator results in two opposite effects. On the one hand, as it was stated above, there is a decrease of the natural gamma background measured by the monitor. On the other hand, the "field of view" of the detector is decreased and, as a consequence, the total time of a source exposition decreases too. Both of these effects depend directly on a ratio of the collimator and detector sizes. The efficiency of the collimator use is dependent on which of the effects is higher.

Let's consider the movement of a source with a speed of 2.2 km/s, in a distance of 3 m from the detector surface (a distance between the monitor pillars is 6 m). Fig.3 presents the experimental and calculated dependences of relative signal values on time without collimator and with collimator of 100 mm length. The Figure shows that the collimator installation causes a significant narrowing of the signal profile and, therefore, a decrease of the effective time of source exposition. If the collimator length is increased, the signal profile is even more narrowed.

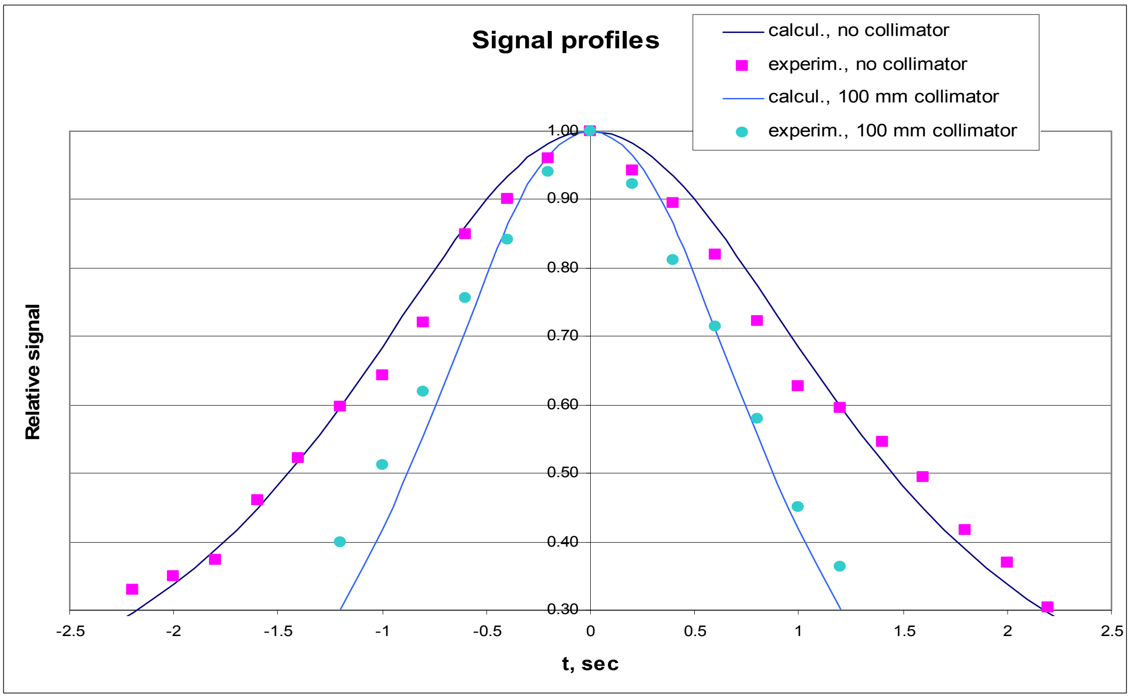

Fig. 3. Dependence of the signal profile on the collimator length.

It is possible to increase the source exposition time by changing an angle of the collimator declination (Fig.1), however, in this case the background also increases.

We estimated the results of mutual influence of these factors for collimators of different lengths installed under different angles Alfa to the vertical. The ratio of the maximum signal to the background "sigma" value was chosen as the studied parameter. The dependences obtained are presented in Fig. 4. As seen, the obvious maxima in the range of 20 degrees are observed for collimators of all the studied lengths.

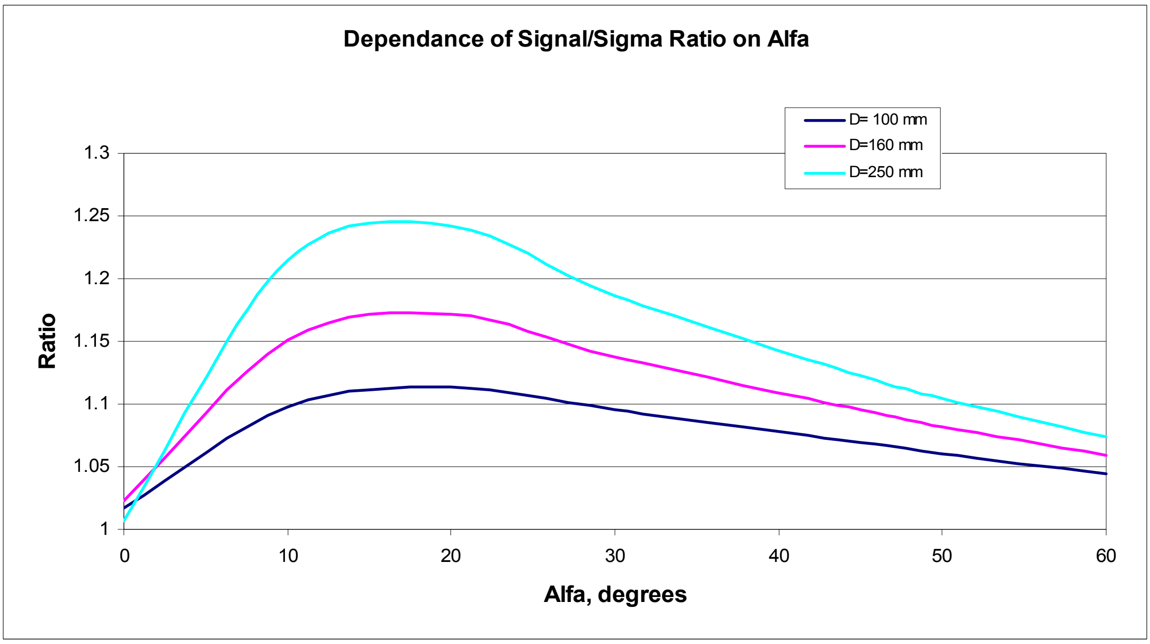

Fig. 4. Dependences of the signal/background ratio on the collimator declination angle Alfa for collimators of different lengths.

An increase in the signal/background ratio due to the collimator installation under an optimum angle results in an increase of the source detection probability. Dependences presented in Fig.5 testify that the collimator installation perpendicular to the detector surface (angle **α**=0) does not results in an increase of the source detection probability. However, the collimator installation at the optimum angle enables the monitor to detect a source (the detection probability is more than 90 %) which is practically not detectable without collimator (the detection probability is less than 60 %). Our calculations have shown that the collimator installation at the optimum angle results in a decrease of the minimum detectable signal by approximately 20 % (at the given detection probability).

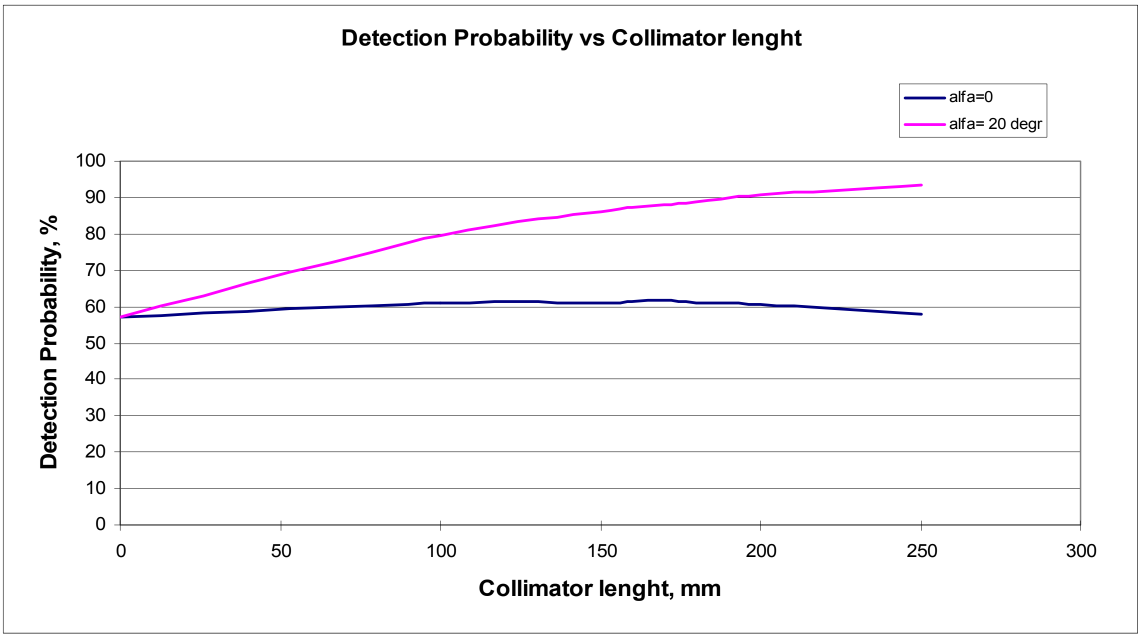

Fig. 5. Dependences of the source detection probability on the collimator length at different angles of the collimator declination to the vertical.

It is necessary to emphasize that the false alarm probability is the same for all the above cases as the alarm threshold (number of "sigma", equation (1)) was not changed in these calculations.

Conclusions

1. Installation of additional lead collimators on the plastic detectors of radiation portal monitors results in a decrease of the value of the measured gamma background. A decrease can reach 50% at collimator length of 250 mm.
2. Installation of the collimators causes as well a decrease of the detector "field of view" and, as a consequence, a narrowing of a signal profile; therefore, both the time of the source exposition and the probability of its detection decrease.
3. Installation of the collimators at some angle to the vertical results in an increase of the exposition time, however, the measured gamma background increases too. Calculations have shown that the maximum of the signal/background ratio for collimators of different lengths is observed at an angle of declination of 20 degrees.
4. Installation of the collimators at the optimum angle of 20 degrees provides an increase of the detection probability of the given source (or a decrease of the minimum detectable signal at the given detection probability) at the same false alarm probability.
5. We have paid the main attention to the collimator influence on **vehicle** portal monitors where the "field of view" of plastic detectors and the signal profile are of special importance. For **the pedestrian** portal monitors, a decrease of the measured gamma background can be more critical.
6. Additional advantages could be obtained with use of collimators of other shapes, for example, plate collimators [5].

Measurements and simulations of fission neutron spectra at the MEDAPP beam at FRM II and subsequent developments

Breitkreutz, Harald; Jungwirth, Michael; Schenk, Robert; Wagner, Franz M.; Petry, Winfried
Forschungsneutronenquelle Heinz Maier-Leibnitz (FRM II), Lichtenbergstr. 1, 85747 Garching bei München, GERMANY

Abstract

The neutron spectrum of the fission neutron beam of the MEDAPP facility at FRM II was simulated with MCNPX and transmission calculations. The simulations were verified by multiple foil activation using threshold reactions. The measured spectra were unfolded and equalisation calculations performed. The full flux of the beam was determined by three methods: a specially developed gold-waterbath-method; by the calculation on the basis of dose measurements in a water phantom; and by the combination of the results obtained by activation foils.

It was shown that the geometric and spectral shape of the beam are widely independent. Together with the measurement of the gamma spectrum of the beam, this paves the way for a dose-planning system for tumour therapy at FRM II and further developments like the construction of a new collimator to enhance geometrical beam shaping. An overview of these developments is given.

Introduction

The MEDAPP facility is located at the Forschungsneutronenquelle Heinz Maier-Leibnitz (FRM II) (Wagner 2008). See fig. 1 for an overview of the facility. It possesses a neutron beam consisting of mainly non-moderated fission neutrons. They originate from a pair of uranium plates containing 540 g U, 93% enriched in ^{235}U, with an effective area of 15x15 cm², fed by thermal neutrons from the reactor core. The plates are positioned in contact to the entrance of the beam tube SR10. At the exit of SR10, thermal neutrons are captured by a boron filter. The beam quality (spectrum and neutron-to-gamma ratio) can be adjusted using filters of lead and polyethylene. Geometrical shaping is achieved by means of a multi-leaf collimator (MLC). For the tumour therapy, only one well-defined beam quality is used. Besides, numerous other biological and technical applications are possible.

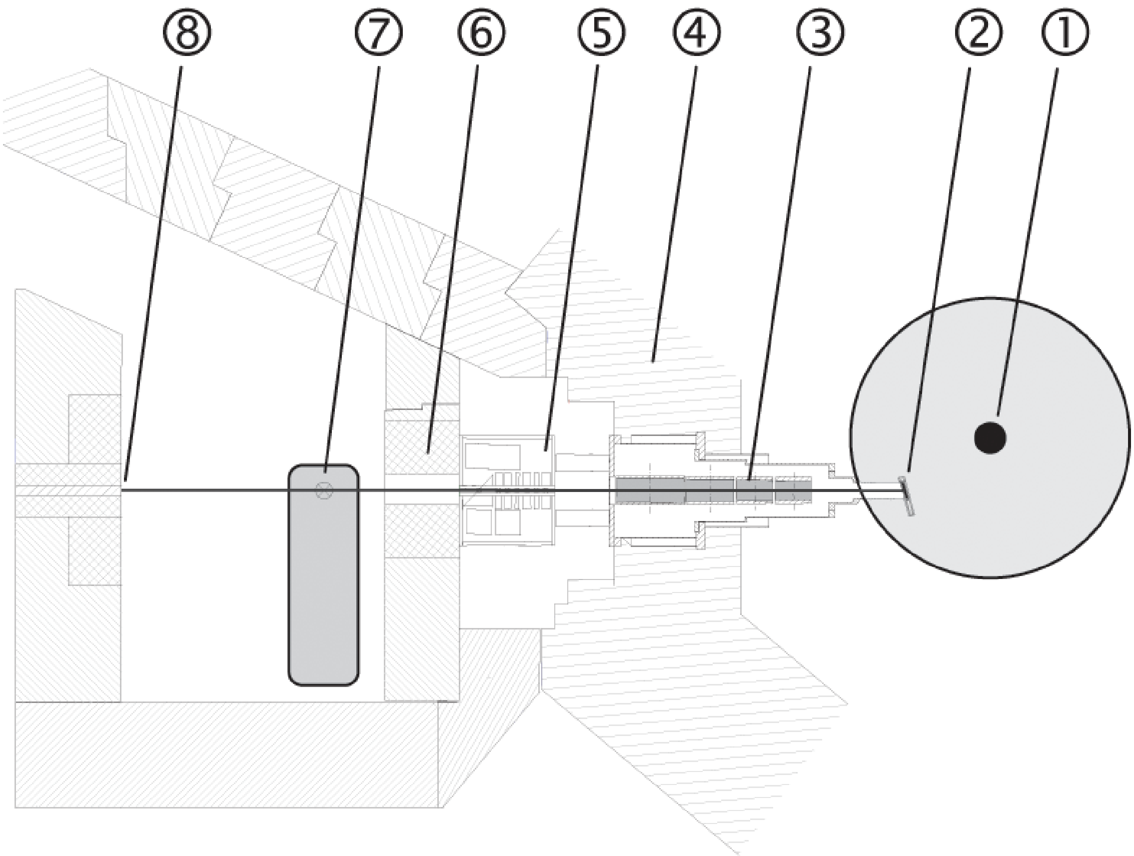

Fig 1. The MEDAPP facility. 1: Reactor core of FRM II inside a heavy water tank; 2: Converter plates; 3: Beam tube with shutters; 4: Biological shield (reactor pool wall); 5: Filter bench; 6: MLC; 7: Patient's position (SSD = 592cm); 8: Beam dump.

By now, the dose distribution is determined by measurements in a water phantom and results are transferred to the actual application at the patient. This delivers a sufficient accuracy for the irradiation of tumours situated near to the surface, although in the age of fast computers and modern simulation codes, a more precise-to-plan application is desirable. To develop such a dose planning system, five essential parameters of the beam must be known: Neutron spectrum and flux, gamma spectrum and flux and the correlations between the geometric position and those four items.

In a series of simulations and measurements, all parameters and correlations were determined. This paper mainly deals with the identification of the neutron spectrum, the neutron flux and the geometric correlations. In addition, an overview on the measurement of the gamma spectrum and a discussion on current developments based on these findings is given.

Neutron beam quality

Simulations

Prior to the measurements, simulations were carried out to be able to plan measurements more precisely and to lay the foundation for the unfolding of the spectra and the equalisation calculations. MCNP4C was used initially, later calculations were conducted using MCNPX, version 2.6.0. There was already a detailed model of the reactor core available which was used to calculate the first part of the simulation, from the reactor core to the converter and further on to the entrance of the beam tube. The spectrum at this point was analysed and it was shown that it fully matches a reactor spectrum consisting of a Maxwellian distribution of thermal neutrons, an 1/E-distribution for intermediate energies, and the Watt spectrum for fission neutrons.

From thereon, the simulation was continued using RSSA files which were modified as described in (Breitkreutz 2007) using the program "ModRSSA" which was developed especially for this purpose. Using the technique of cell flagging, it could be shown that due to the collimation and a SSD (source skin distance) of nearly 6 m, the contribution of scattered particles to the resulting spectrum at the position of the patient is insignificant. It was therefore possible to calculate much more detailed spectra by means of straightforward transmission calculations applied to the spectrum at the entrance of the beam tube.

Due to the limited statistics that were achievable using RSSA files, it was not possible to extract the geometric-spectral correlations mentioned above in detail. However, there was no indication that such a correlation exists in an extent relevant for tumour therapy. As a consequence of this, the problem of the large source area and its projection onto the target could be solved by a straight-forward geometric approach, realised in a program called "ausleuchtung". This program calculates the geometric shape of the beam, i.e. the total neutron flux dependent on the geometric position in the treatment room, by summing up all visible source points (silhouettes / shadow image approach).

Measurements

The measurements consisted of three parts, namely the verification of the spectrum using threshold activation foils, the determination of the total neutron flux by a bath method, and the verification of the shadow image assumption used in "ausleuchtung", i.e. the determination of the beam profile after the MLC. (Breitkreutz 2008)

To measure the fission neutron spectrum, a total of 19 reactions with threshold energies ranging from 0.17 MeV, ^{103}Rh (n,n') ^{103m}Rh, to 12.40 MeV, ^{58}Ni (n,2n) ^{57}Ni, were used, with most reactions starting below 3.5 MeV. This high number of different reactions was possible due to the high intensity of the beam and barely no disturbing underground from thermal neutrons. After activation, the resulting radioactive isotopes were identified using a HPGe detector.

The total neutron flux density was determined using three different techniques: It was calculated from the activation foils with supplemental (n,γ)-reactions in combination with equalisation calculations below. Second, as the neutron spectrum was known, the fast flux could be calculated from depth dose measurements using the twin chamber method in a 200-l-water phantom (PTW-Freiburg). Third, the total flux was measured in the same water phantom in which gold foils were arranged in equidistant positions throughout its volume. This technique is similar to the well-known $MnSO_4$ bath method, but avoids handling large amounts of radioactive fluids and allows well to distinguish the contributions from thermal and epithermal neutrons. The horizontal beam was guided in the middle of the bath via an empty closed aluminium tube. The efflux from the bath was also determined using gold foils on its surfaces. This set-up is shown in fig. 2. The activation was again determined using a HPGe.

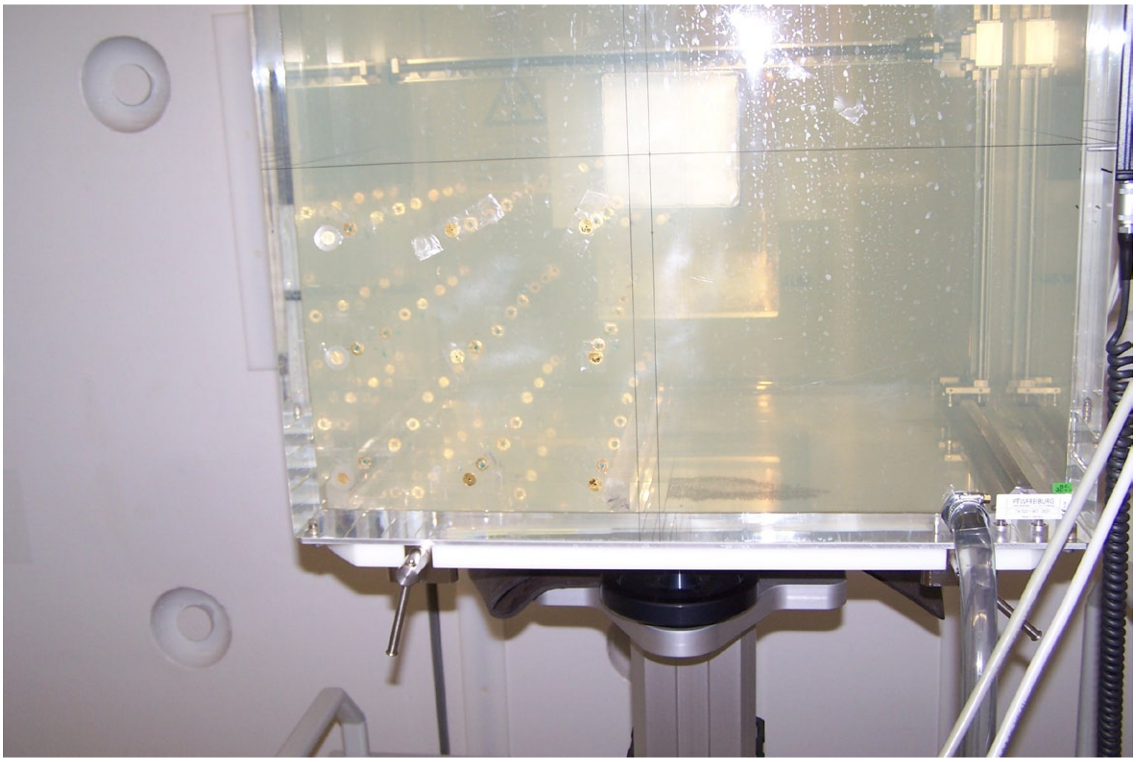

Fig 2. Measurement of the total flux by use of equally distributed gold foils in a big water bath. For symmetry reasons, it was sufficient to arrange about 150 foils in one quadrant around the beam.

To determine the correctness of the shadow image approach, a 1D flux profile was recorded using indium wires. The reaction ^{115}In (n,n') ^{115m}In has a threshold energy of 0.35 MeV. Of course, spectral changes can not be captured completely in this way, but it can be assumed that a significant spectral change goes hand in hand with a change of the flux above the threshold energy. Therefore, if the beam profile simulation and the 1D measurement agree well, it can be concluded that the spectral-geometric correlation is insignificant above this threshold. MCNPX calculations support this assumption.

As an additional verification, spectra at various positions in various depths inside a PE phantom were measured and simulated. It could be shown that the fission spectrum is hardened with increasing depth, though not significantly within the first five centimetres, and a thermal neutron flux in the same order of magnitude as the fast neutron flux builds up.

Equalisation calculations

Due to the low information density contained in the activation foil measurements and the high uncertainty in some of the cross sections for the fast reactions, it is hardly possible to unfold the spectrum from these measurements without any prior knowledge. Therefore spectra from transmission calculations and MCNPX simulations were used as start spectra. It turned out that the classic unfolding codes like MSANDB tended to converge to solutions that could not be explained by the materials in and the geometry of the beam. In fact, this behaviour could be suppressed when some measured reactions were excluded, but this approach is not easy to justify and, hence, was not followed up. Instead, equalisation calculations using MSITER were conducted. These calculations roughly follow the procedure required by DIN 1319-4, even though the (co-) variances of cross section uncertainties are not taken into account.

Neutron results

All three flux measurements described above delivered a total neutron flux of 3.2(1)·10^8 n/(s cm²). The simulated neutron spectrum was essentially confirmed; only with slight adjustments above 5 MeV and in the intermediate range between thermal and epithermal neutrons, where. the MCNPX simulation showed large statistical errors.

The mean energy of the spectrum was determined to be 1.9(1) MeV, slightly lower than the 2.0 MeV of a pure fission spectrum. The final spectrum is shown in fig. 3.

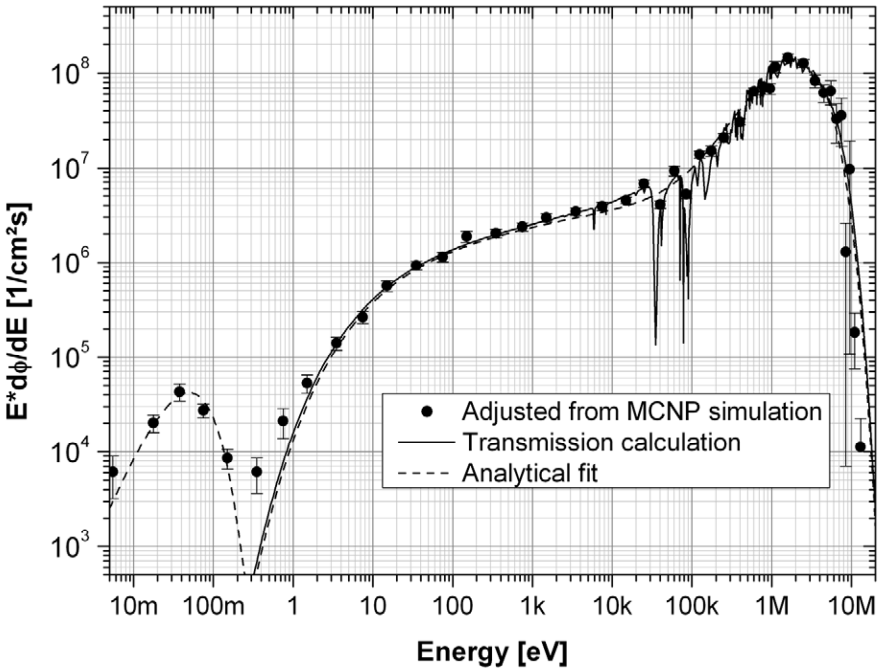

Fig 3. Neutron spectrum of MEDAPP at the patient's position. The small thermal peak results from scattering in the MLC which is not included in the transmission calculation. Due to the low resolution of the MCNP simulation (43 energy groups), the resonances from lead (filters) and aluminium (covers) clearly show up only in the transmission calculation.

Gamma beam quality

Simulation

A simulation of the gamma part of the beam was not fully possible until support for delayed gamma emission was added in MCNPX 2.6. Before, only the prompt gammas emitted during fission as well as on capture events in neutron-absorbing structure materials and the related Compton part could be simulated. With MCNPX 2.6, the delayed gammas emitted by fission products and activations due to neutron capture reactions were taken into account by means of an approach with 25 energy groups. Essentially the same models as for the older neutronic simulations were used for the simulation.

However, in the case of gamma radiation it was hardly possible to achieve satisfactory statistics by the original simulation approach using RSSA files at the beam tube entrance. To overcome this deficiency, the program "autospect" was developed. It is similar to "ModRSSA" but features some kind of peak detection routine as the complex gamma spectrum can not be fitted with a closed expression as easily as the neutron spectrum. "Autospect" starts to acquire the particles stored in the RSSA file with a high number of energy groups. It then detects peaks in this group structure by the unsteadiness of the statistic error and starts condensing the remaining energy groups until a specified level of statistics is reached. In this way, an inhomogeneous group structure is produced with sharp peaks and wider ranges in-between, all with an acceptable statistic error. With the spectrum gathered by "autospect", the simulation was continued at the entrance of the beam tube and brought further on to the patient's position. Fig. 4 shows the spectrum as determined by "autospect" and a transmission calculation to the patients position. Some important peaks like the 1779 keV ^{28}Al decay peak are missing as they are hidden in the coarse delayed gamma group structure mentioned above.

The measurements described below were simulated apart. For this, a MCNPX model of the detector was created.

Measurements

The measurement of the gamma spectrum proved to be a far higher cradle than the neutron spectrum. Due to the inevitable fission neutrons and the high intensity of the beam, the spectrum could not be measured directly in the therapy beam with a gamma detector (Jungwirth 2009).

Two measurements were conducted to determine the gamma spectrum: First, a measurement on the beam axis at very low reactor power (approximately 50 kW instead of 20 MW) with a 5" NaI using additional attenuators. At full reactor power, only scattered photons were measured under a defined angle apart of the direct beam using the 5" NaI detector and, for better resolution at lower energies, a HPGe detector. A special collimator was constructed for the latter measurement.

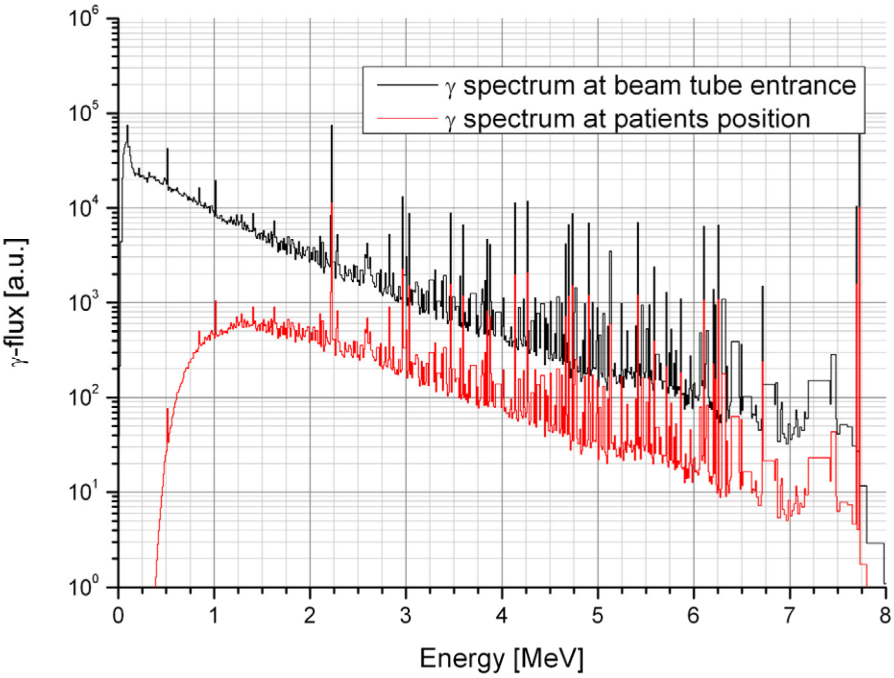

Fig 4. Gamma-spectrum determined by "autospect" and spectrum at the patients position calculated by transmission calculation.

Fig. 5 shows a measured gamma spectrum on the beam axis with partially closed shutters, i.e. with about 20 cm iron in the beam. In this case, all major peaks from fig. 4 can easily be identified, except decay peaks that were not included as line emission but within the 25 energy group structure in the simulation.

The total gamma flux was determined similarly to the neutron flux determination by evaluation of a depth dose curve in a water phantom in comparison to a simulated one. Of course, in this case a good knowledge of the spectrum is required, too.

Results

The simulated detector showed a drastic underestimation of the Compton spectrum. Peak efficiencies were ok (±4%). As a result of this, all measured spectra showed an increasing deviation in the high energy range starting from about 3.5 MeV up to the measured maximum of 10 MeV (or, in other words, an underestimation of the low energy part). Moreover, the depth dose curve showed deviations in depths larger than 5 cm, also pointing towards an overestimation of the high energy part in the simulations.

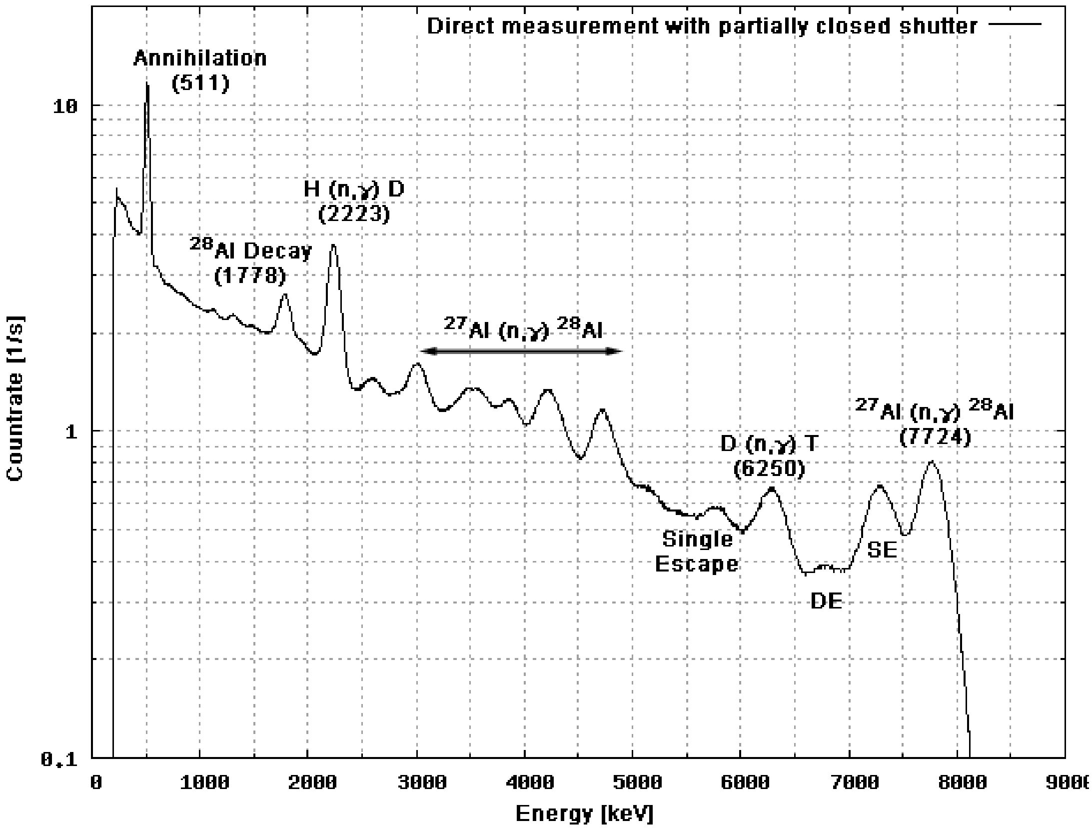

Fig 5. Measured gamma spectrum directly in the beam with partially closed shutters.

The mean energy of the gamma part of the beam is about 2.4 MeV, the total gamma flux 3.7(1) · 10^8 γ/s cm². As explained before, the accuracy of the total flux assignation depends on the correctness of the assumed spectral shape which is not the case here to the full extent. Therefore the total flux was determined from the first three depth dose points only. The uncertainty of the number given above is therefore by trend higher than quoted here. We are currently investigating the reasons for the deviations in the spectrum.

The spectral-geometric correlation has not been measured yet. However, results from simulations again suggest that there is no significant correlation.

Further Developments

A new MLC

As the current design of the beam collimator is not optimal regarding the large penumbra around the main beam, a new collimator is currently being constructed with improved field shaping and thereby increased radiation protection for the healthy tissue of the patient.

Based on the verified shadow image approach, a program "ausleuchtung" (see sec. 2.1) was developed which can be used to simulate the geometric shape of the beam depending on the collimator setting within seconds. With its help, the construction of the new collimator was optimised towards steep beam intensity edges for small fields as they are predominantly needed for irradiations of the head and neck (Schenk 2009).

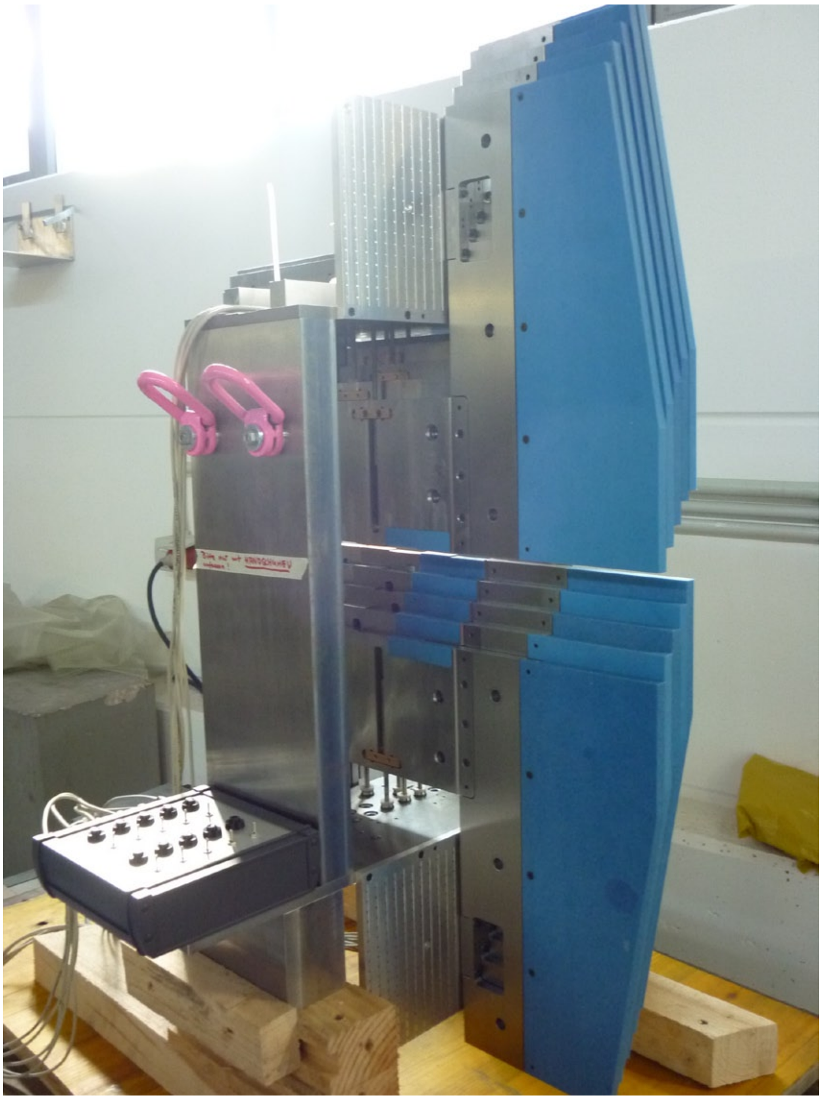

Fig 6. Prototype of a new collimator for MEDAPP.

Using the measured neutron and gamma spectra, the shielding and self-shielding against activation of the collimator is being optimised, yielding an increased radiation protection for the staff of MEDAPP. The collimator is electronically driven so that the collimator can be closed automatically and the medical staff is not exposed to the activated metal parts of the MLC.

Towards a dose planning system

For the development of a dose planning system, it is essential to know all the beam parameters mentioned in the introduction. As soon as the remaining discrepancies with the gamma spectrum are solved, all these parameters are known. In fact, spectral uncertainties play a minor role in the medical treatment because the photon component of the beam contributes only about 10 % to the total RBE-dose.

By now, based on the approach of "ausleuchtung" and MCNPX, a program was developed which utilises all the findings described above to simulate 3D depth dose distributions in a water phantom in a reasonable amount of time (some hours). The errors which were introduced to the depth dose curve by all the measures like denying all spectral-geometric correlations and the adjustments made by neglecting scattered particles in the beam tube are assumed to be negligible compared to other uncertainties like the exact elemental composition of the patient's tissue or cross section uncertainties for fast reactions.

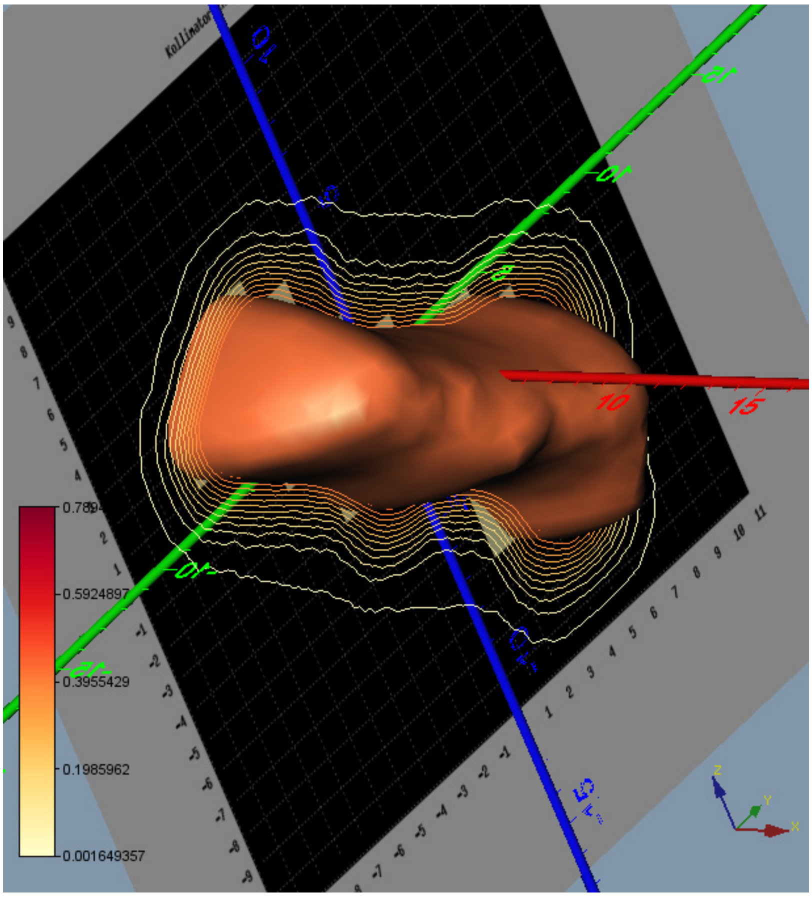

Fig 7. Example of a water phantom dose plan for MEDAPP: 2D and 3D iso-doses for a certain MLC setting (background image). The beam is entering along the red x-axis from behind through the MLC image.

Conclusions

The measurement of the neutron and the gamma spectrum and the determination of the spectral-geometric correlations have laid the foundation for the development of a dose planning system and a number of other programs. The radiation protection of the patient will be brought a good step forward when the dose planning system is eventually realised. The enhancements in radiation protection by the construction of a new collimator, which is optimised towards field shaping, again is mainly for the benefit of the patient. The staff profits from the enhanced activation self-shielding of the new collimator and more precisely calculable activation after long-term irradiations when the facility is used for technical applications.

Abstract

The Radiation Protection Department at the Technical University Eindhoven has developed the operational need for an ionizing radiation monitoring instrument mapping real-time radiation emanated by industrial processes into the environment and workplace. Available instruments are energy consumptive, static and labor intensive in data collecting so this feasibility study will investigate an alternative. The aim of this feasibility study is to design a device collecting dosimetric data in a more economical and ergonomically manner. The end product is a modular, energy efficient wireless radiation sensor which constitutes automatically a flexible, secure and failsafe network with multiple modules. A module consists of a ZigBee protocol based transceiver capable of forming several types of network topologies and a MDA300CA sensor board interconnected with a custom-made ionizing radiation sensor. The radiation sensor is constructed using a widely used PIN-photodiode sensitive to photon energies ranging from 35 keV till 1173 keV. The received data streams are easily viewed and interpreted using an open-source PostgreSQL database. The wireless radiation sensor network is a real-time monitoring instrument which can be implemented in existing organizations and expanded on in several ways using commercially available components.

Introduction

For radiation protection of workers and environment a source oriented approach is indispensable. For such an approach to be effective, operational area monitoring is very helpful. Traditionally, area monitoring is done with handheld survey monitors or by fixed area monitors. The latter monitors are sometimes equipped with local or remote alarm indications. If source conditions in a workplace are relatively stable, periodic manual surveys are usually quite adequate. However, in situations like ours of strongly fluctuating source strengths or variable locations, real time monitoring is often desired.

Eindhoven University of Technology hosts a 30 MeV proton cyclotron, mainly used for large scale radionuclide production and radionuclide processing facilities. In all stages of production and processing there has been a growing need to monitor radiation levels in more detail in workplaces. Until now this has been done by a wired network of area monitors (wall mounted GM tubes) and by many small scale active and passive dosemeters. We found the wired network to be inflexible and expensive; small standalone dosemeters fit our needs much better, but require of lot of manual work and manual data processing.

Therefore, we strive for an area monitoring system that is networked and flexible. The main goal of this study is to investigate the feasibility of a cost-effective modular area monitoring system, consisting of wireless sensors.

Material and methods

The system we designed has modules with ZigBee protocol based transceivers from Crossbow Technologies, capable of forming several types of network topologies and a MDA300CA data acquisition board with a custom made radiation detector. The detector was constructed using a widely used PIN-photodiode, capable of detecting photon energies ranging from 35 keV to 1332 keV.

Some properties like sensitivity, linearity and efficiency of the PIN-photodiode were investigated by using different calibration sources. Especially efficiency at low photonic energies was expected to be increased so filtration might be a crucial aspect (*C-R. Chen et al., 1993, R.H. Olser et al., 1991*). Calibration has been done with secondary standard calibrated Cs-137 sources with different activities (*P.W. Cattaneo, 1991*).

ZigBee

The ZigBee Alliance uses an energy efficient protocol IEEE 802.15.4 for wireless transmitting data (*P. Baronti et al.*, *2007*) and distinguishes three different devices. The *ZigBee coordinator (ZC)* is the most capable device. This coordinator forms the root of the network tree and might bridge to other networks. There is only one ZigBee coordinator in each network since it is the device that started the network originally. It is able to store information about the network, including acting as the Trust Centre & Repository for security keys. The *ZigBee Router (ZR)* runs application functions and is acting as an intermediate router, passing on data from other devices. The *ZigBee End Device (ZED)* contains just enough functionality to talk to the parent node (either the coordinator or a router); it cannot relay data from other devices. This relationship allows the node to be asleep a significant amount of time, combined with efficient use of memory, therefore giving long battery life.

In our experiments the integration of a ZigBee transceiver module, an experimental board (MDA300CA), the sensor and electronics and electromagnetically shielded wiring operates as a ZR or ZED, all powered by two LR6 (AA) batteries. The signals coming from the detector are sent to an internal counter in the microprocessor. This value is then stored, time-stamped and combined with data from other sensors and finally transmitted to the nearest module using the 2.4 GHz open band so the data collected by the sensory node in this network is eventually transmitted to the base node. There is no interference between other protocols, like 802.11a/b/g (WiFi), using the 2.4 GHz open band frequency. A ZigBee transceiver combined with an USB-connected programming board (MIB400) acts as a ZC.

The sensor

The sensor used is a daylight filtered PIN-photodiode (OSRAM BPW34FS) with a designed sensitivity range of 780 nm and 1100 nm. This semiconductor is commonly used for measuring infrared photons or X-rays but is also quite suitable for detecting photons in a range between 35 keV and 1173 keV.

A PIN-photodiode consists of three layers where the intrinsic (I) high resistance layer is important for detecting photon energies higher than 10 eV (*C-R. Chen et al., 1993*). The intrinsic layer reduces the leakage current between the P-N-junctions and also acts as an active volume for high energy photons and secondary electrons originated in the active volume or surrounding materials. Undiscriminated and unfiltered, the efficiency of a PIN-photodiode steeply increases at 10 keV and shows a decline until 10 MeV as seen in figure 1 (no filter).

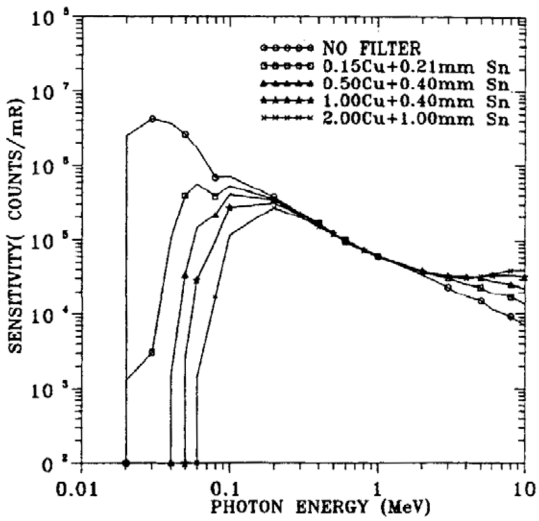

Fig. 1. Calculated sensitivities (in counts/mR) for several filter thicknesses (C-R. Chen et al., 1993).

We have limited our measurements between 35 keV and 2 MeV. Sensitivity and efficiency has been investigated by using several calibrated radioactive sources; Am-241, Ba-133, Cs-137, Mn-54, Co-60 and Na-22.

The electronic design

The used design is based on a PIN-photodiode (OSRAM BPW34FS) (*B. Denmark, 2003*). Major concern is noise reduction, therefore at the end of the amplification chain a discriminator cuts off the signal at low energies causing effects like reducing sensitivity as seen in figure 2.

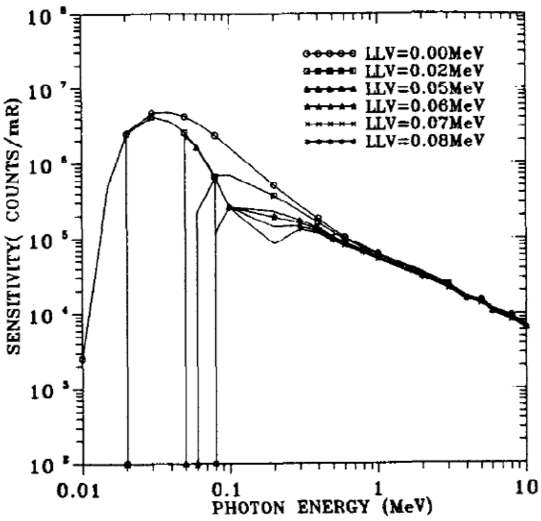

Fig. 2. Sensitivity curves with different settings of discrimination level (*C-R. Chen et al., 1993*).

The PIN-photodiode has a spectral range of sensitivity between 780 and 1100 nm. Exclusion of electromagnetic interference and daylight is achieved by a metal casing. The PIN-photodiode is embedded in the print so its angle sensitiveness is maximized.

In beneficially deploying this network power consumption of the sensor electronics had to be reduced. The energy consumption of the detector was about 80-90% of the total energy consumption of a node. The detector electronics consumes about 7 mA in active mode, for the greater part due to amplification electronics (4x MAX4475). The amplification electronics can be set in standby mode using an external digital pulse. Using this standby mode the power consumption of the detector electronics is about 0,001 mA.

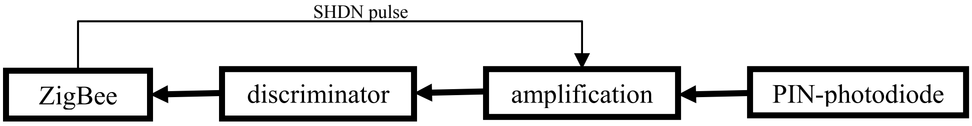

Fig. 3. Schematic view of the detector electronics.

The voltage ripple created in the PIN photodiode enters a four stage amplification line as seen in figure 3. After final amplification the pulse height is cut off with a pulse height discriminator so the pulse resembles a square wave. These square waves are used as input for the counter in the transceivers' microprocessor (ATMEL ATmega1281). To reduce power consumption the shutdown mode of the amplification chips (4x MAX4475) are routed to the transceiver module. This enables development of future measuring algorithms.

For valid representation of the collected data it is necessary to calibrate the detector. The calibration has been done with secondary standard calibrated Cs-137 sources with different activities. Using an Am-241 source (490 MBq) and the calibration installation of the Radiation Protection Service of the University of Technology Eindhoven the linearity of the detector has been investigated by verifying the inverse square law. The measured data are stored in a provided open source SQL database (PostGreSQL) for further analysis.

Results

The discrimination level setting has a strong influence on the detector efficiency for photon energies up to several hundreds keV as seen in figure 4. There is an optimum between noise reduction and the low energy cut-off level. This reduces sensitivity and flattens the efficiency curve. Therefore sensor filtration was not required like in figure 1. Our prototype is capable of measuring photon energies from 35 keV, using I-125 seeds, up to 1173 keV, using a Co-60 source.

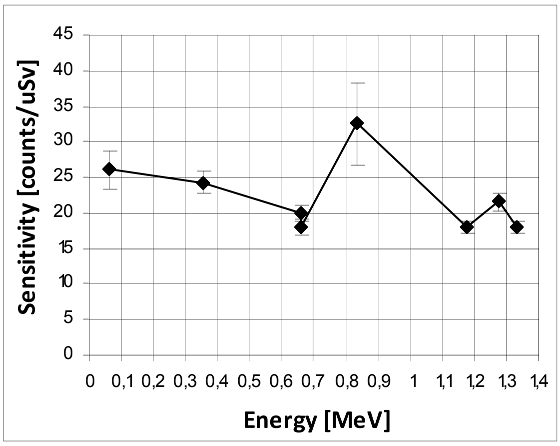

Fig. 4. Sensitivity of BPW34FS_no_filter using a set of calibration sources.

The measured sensitivity of the detector is about 20-25 counts per microSv.

The discriminator voltage is Vcc dependent. Battery voltage should not be below 2.3 V to prevent signal loss.

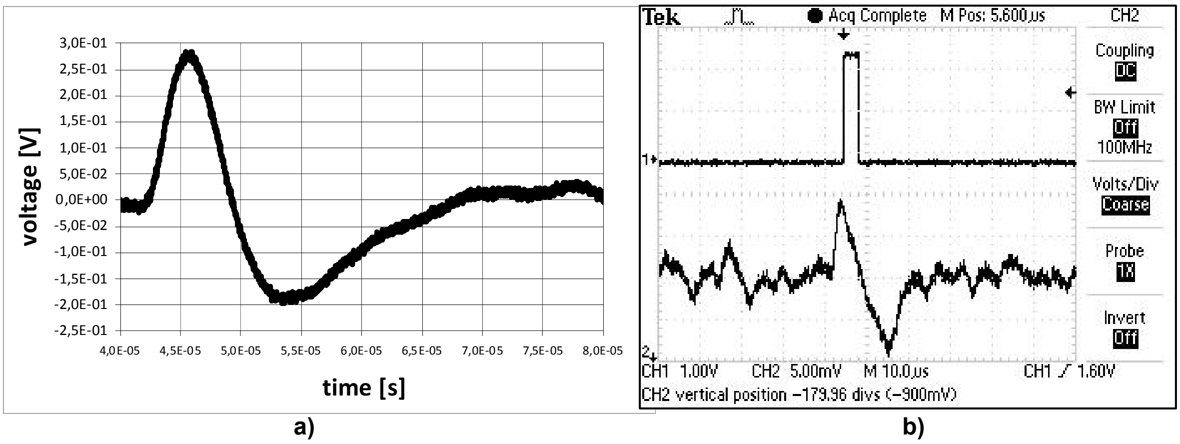

Fig. 5. a) Non-discriminated pulse created using a Cs-137 source and b) X-ray photon pulse converted into a square wave.

The pulse width varies between 5 and 25 microseconds and increases with higher photon energies as seen in figures 5a en 5b. The internal counter is capable of detecting these short pulses so the transceiver can send every second a time-stamped data packet with the amount of counted pulses.

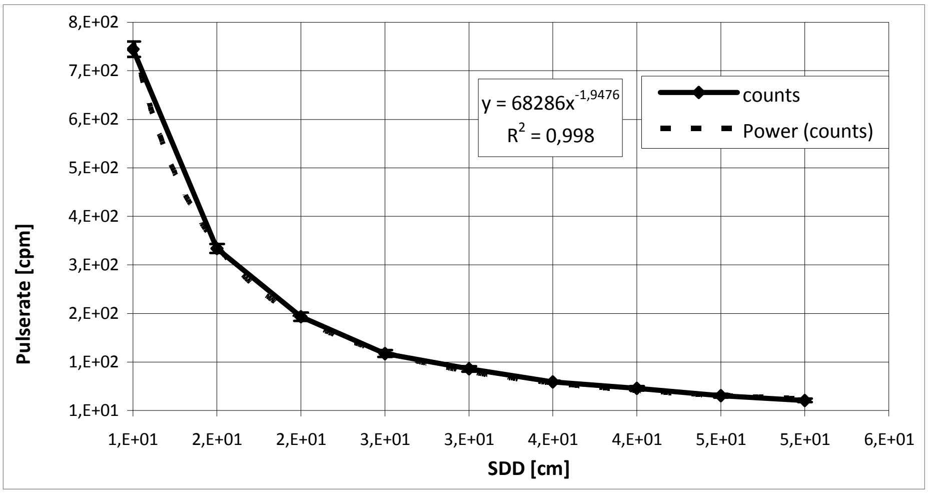

Fig. 7. Measured linearity of BPW34FS_no_filter using Am-241.

The linearity of the detector node has been tested using Am-241 (490 MBq). The pulserate measured in counts per minute follows the inverse square law indicated by figure 7.

Discussion

The first prototype with one gateway, one repeating node and one detector node was developed and tested successfully. The concept has good prospects for use in small to medium sized installations. Nevertheless, a complete wireless radiation sensor network has not been tested yet. In future detector nodes the node programs have to be modified so the frequency of emitting packets is reduced to a data packet every minute. This will also reduce power consumption.

Lowering the temperature of the PIN-photodiode by applying a Peltier element on the back of the PIN-photodiode could reduce noise by a factor 10 (*Z. Bian et al., 1985*).

For further sensitivity maximization a scintillation crystal can be mounted on the sensitive sides of the diode (*E. Fioretto et al., 2000*) or several PIN-photodiodes connected in series acting as one detector (*A. Sertap Kavasoglu et al., 2008*). The detector has not been tested in high frequency pulsed radiation fields.

The cost of a complete network system depends on the mapping detail degree, the size of the location, the signal attenuation between nodes, all in all, the amount of nodes. The cost of a detector node depends on further development of the hardware, like miniaturization of detector design, sensitization of the sensor and integration of detector and transceiver module in one design, and further development of software like data processing alarm algorithms, node programming and a comprehensible end-user software interface.

Conclusions

The development of a low cost reliable radiation detector is feasible. This study showed good sensitivity, efficiency and linearity of the detector. The wireless radiation sensor network is a real-time area monitoring instrument which can be implemented in existing organizations and workplaces. The wireless radiation sensor network can be expanded in several ways using commercially available components. Using a flexible wireless sensor platform creates a foundation for future applications determining activities in facilities for mapping radiation fields.

Results of model calculations and algorithm development related to a 3D silicon detector dosimetric telescope

Hirn, Attila
Hungarian Academy of Sciences KFKI Atomic Energy Research Institute, HUNGARY

Abstract

One of the many risks of long-duration space flights is the excessive exposure to cosmic radiation. The dose equivalent in orbit may be two orders of magnitude higher than that under the shield of Earth's atmosphere. In order to determine the dose equivalent on board different spacecrafts, the development of a 3D silicon detector telescope got underway in the Hungarian Academy of Sciences KFKI Atomic Energy Research Institute several years ago.

In the course of my doctoral research I was taking part in the R&D activities related to the instrument, such as designing the measurement system, developing the electronic system, reconciling the scientific, the electronic and the mechanical considerations of the development, working out the algorithms of the on-board software as well as coordinating, controlling and managing the development (Hirn 2009a). The present paper addresses two important issues of my work: the method of determining in almost real time the time intervals of the South Atlantic Anomaly (SAA) crossings of the International Space Station (ISS) and the calculations performed in relation with the anisotropy of the cosmic radiation field in low Earth orbit in order to compare the performances of 1D and 3D telescopes on board ISS. To switch between the SAA and non-SAA spectra I developed an algorithm, which has been tested with model time spectra generated from time spectra measured by the DOSTEL 1D telescope. I calculated the parameter of the algorithm such that the probability of false switching was less than 10^{-3}. With model calculations I also analyzed the effects of the angular dependence of the geomagnetic cut-off, the shielding of the Earth and the East-West asymmetry of the trapped particles on the measured deposited energy spectra. The results have shown that in case of the untrapped radiation the differences in the spectra could be attributed only to the shielding effect of the Earth. As for the trapped radiation a more pronounced directionality was obtained.

Introduction

Due to the lack of shielding provided by the atmosphere of our planet, the dose rates measured on the International Space Station (ISS, at an altitude of ~340 km) are about two orders of magnitude higher than those from cosmic origin measured on the Earth's surface. Since dose equivalent, which characterizes the stochastic biological effects of the radiation, was defined in terms of a LET (linear energy transfer)-dependent quality factor, determining the LET spectrum and the quality factor of the cosmic radiation is necessary. For this reason, the development of a 3D silicon detector telescope (TriTel) started in the KFKI Atomic Energy Research Institute (AEKI) several years ago. The instrument comprises three mutually orthogonal, fully depleted PIPS detector pairs that are connected as AND gate in coincidence and has almost uniform sensitivity in 4π. A big advantage of TriTel, either as a stand-alone instrument or when operated together with the Pille thermoluminescent dosimeter system (Feher et al. 1981), is the capability of determining not only the absorbed dose but the LET spectrum and the average quality factor of the cosmic radiation as well (Pazmandi et al. 2006). From the absorbed dose and the quality factor the dose equivalent can be also determined.

Anisotropy of the cosmic radiation in low Earth orbit

The galactic cosmic radiation (GCR) in the near-Earth free space is approximately isotropic. However, because of the shielding effect of the Earth's magnetic field and the Earth itself, there is a lower limit on the energy of primary cosmic ray particles to enter given points in low Earth orbit from different directions (geomagnetic cut-off, Lemaître, Vallarta 1933). The solar component of the cosmic radiation also shows significant anisotropy. Its intensity on board ISS is usually negligible compared to GCR. However, its contribution to the radiation environment may be significant during solar particle events. My work did not address the anisotropy of the solar component.

Even at lower altitudes, due to a shift (~500 km) and tilt (~11°) of the geomagnetic axis compared to the Earth's rotational axis, the magnetic field is not symmetrical in relation to the rotational axis. Therefore in the region between South Africa and South America the inner radiation belt protrudes into lower altitudes (2-300 km). This designated region is called the South Atlantic Anomaly (Stassinopoulos, Staffer, 2007). The International Space Station passes the SAA in two time windows a day and in 2-3 consecutive orbits in a time window. The time elapsed between two time windows is approximately 8 and 16 hours respectively. When travelling through the SAA, astronauts are exposed to trapped radiation of the inner Van Allen belt, which shows a pronounced directionality. Although only about 5% of the mission time on board ISS is spent in the SAA, the astronauts may collect more than 50% of their total dose during this short time period (Apathy et al. 2007).

In case of ISS, which has usually an airplane-like attitude, i.e. the attitude is stabilized in the local vertical reference frame (ESA 2006), the anisotropies in the radiation field, such as the effect of the Earth's shadow, the angular dependence of the geomagnetic transmission factors and the East–West asymmetry in the SAA, might not be ignored in dosimetric measurements, unlike in case of Space Shuttle flights where, due to the changing orientation of the spacecraft, anisotropies usually tend to be averaged out (Badhwar et al. 1999). 1D telescopes used for dosimetry have strong directional sensitivity and therefore they might either under- or overestimate the dose equivalent. The application of 3D telescopes with three, mutually orthogonal axes improves significantly the measuring precision of the instrument.

A number of papers addressed the models of the anisotropic radiation environment on board ISS. The results of the calculations presented in (Wilson et al.

2006) have shown that the addition of the angular dependence of both the trapped protons and GCR transmission factors considerably increases the usefulness of the basic cosmic radiation models. Time resolved measurements performed with Liulin type silicon detector instruments on board ISS were used to evaluate the adequacy of the environmental revised models. The comparison has shown that further corrections are needed (Wilson et al. 2007). Nealy et al. presented validation of their revised environmental models in which they compared the results of the calculations with that of the measurements carried out with several passive and active detectors on board ISS. Albeit the agreement was found to be fairly good, they suggested further improvement of the models (Nealy et al. 2007).

Material and methods

The SAA switching algorithm

After a signal coming from a detector has been processed and digitized, the content of the appropriate channel in the active deposited energy spectrum is incremented. In order to collect the SAA and non-SAA spectra separately, it is necessary to switch automatically between them, i.e. to make the SAA spectra active when the ISS entered the SAA and the non-SAA spectra active when it leaves the anomaly. The algorithm for performing this procedure was developed based on the results of the measurements carried out with DOSTEL in different shielding configurations (Burmeister et al. 2000). The effectiveness of the method was tested with model time spectra calculated from the time spectra obtained by DOSTEL after taking into account the differences in the telescope geometry. Depending on the parameter of the algorithm and the expected number of counts, the switching between the SAA and non-SAA spectra might take place due to the statistics of the measurement. In order to determine the probability of this "false switching", statistical uncertainty was added to the calculated spectra by means of a pseudo-random number generator (Hirn 2009b).

Modelling the anisotropy of the GCR at low Earth orbit

In my calculations it is assumed that the 3D telescope is installed outside the wall and shielded by the space station from the nadir direction (Fig. 1). The x-axis of the telescope points along the orbital velocity vector, the z-axis toward the nadir direction, and the y-axis completes the right-handed coordinate system. Calculations are performed for ISS orientation with zero pitch, roll and yaw angles. Free-space GCR spectra for protons and alpha particles were obtained with the FLUX module of the CREME96 model (heavier ions were not included in the calculations).

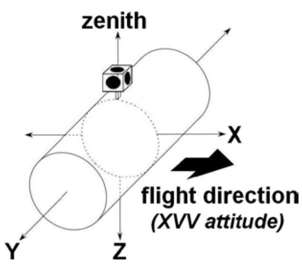

Fig. 1. Orientation and position of the telescopes.

The GTRN module of CREME96 can be used for evaluating geomagnetic shielding but only in a vertical cut-off approximation (Tylka et al. 1997). In order to determine the directional distribution of the geomagnetic cut-off rigidity, the expression developed by Stoermer for characterizing the interaction of a charged particle with a dipole magnetic field was used (Stoermer 1937)

$$R = \frac{C_D \cos^4 \lambda_M}{r_D^{\,2}\left(1+\sqrt{1-\cos^3 \lambda_M \sin\zeta \sin\psi}\right)^2} \qquad \text{Eq. 1.}$$

where R is the directional cut-off rigidity in GV, λ_M is the magnetic latitude, r_D is the distance from the magnetic dipole centre in Earth radii, ζ is the zenith angle, ψ is the azimuth angle measured clockwise from the magnetic north and C_D is a constant which is directly proportional to the dipole moment, and has a value of 59.6 GV for the 2000 IGRF (International Geomagnetic Reference Field) dipole. Geographical coordinates of the ISS as a function of the time were provided by the coordinate generator package included in ESA's Space Environment Information System (SPENVIS 2003; Heynderickx et al. 1996). The magnetic coordinates λ_M and r_D were obtained after coordinate transformations. At the altitude of the ISS the magnetic field of the Earth can be well approximated by the eccentric dipole model. The parameters of the coordinate transformations i.e. the colatitude (θ_N) and the azimuth (φ_N) of the point of intersection of the geomagnetic axis with the Earth's surface in the northern hemisphere in the centred dipole model as well as the translation in the x, y and z directions (η^*, ζ^* and ξ^*, respectively) are shown in Table 1.

Table 1. Parameters of the coordinate transformation.

Parameter	Value	Reference field model
θ_N	79.54°	IGRF 2000
φ_N	288.43°	IGRF 2000
η^*	–0.06308 R_{Earth}	IGRF 2000
ζ^*	0.04713 R_{Earth}	IGRF 2000
ξ^*	0.03149 R_{Earth}	IGRF 2000

Stoermer's expression does not account for the presence of the solid Earth. Since the details of how exactly the Earth's umbral shadow changes with altitude is still unknown (Smart et al. 2000, 2006), for the sake of simplicity, the Earth was considered as a solid sphere. At the altitude of the ISS the solid angle occulted by the Earth is 1.4π. The cut-off distributions as a function of the particle's energy and the angle of incidence were calculated in the reference frame fixed to the given telescope axis. The angle of incidence was discretized with a discretization step of 5°. With knowledge of the free-space GCR spectrum and the cut-off distribution, the LEO GCR spectrum was determined. To estimate the deposited energy spectra the FLUKA Monte Carlo transport code developed by the Italian National Institute for Nuclear Physics (INFN) and the European Organisation for Nuclear Research (CERN) was used (Ferrari et al. 2005; Battistoni et al. 2007). The geometry was simplified to two 300-micrometer-thick silicon detectors at a distance of 8.9 mm with an active area of 222 mm^2 and an aluminium slab representing an effective shielding. Concerning the aluminium slab two different thicknesses were chosen:

– 0.5 mm of aluminium in front of the detectors (mechanical constraints);
– 74 mm (20 g/cm^2) of Al in the direction of the ISS.

Particles were generated from behind the slab. The deposited energy spectra were calculated with the DETECT card in coincidence mode. The minimum total energy to be scored in one event in the measuring detector region, as well as the coincidence threshold was 70 keV. Below this value the contribution of charged particles to the coincidence spectra is negligible (Hirn et al. 2007).

Modelling the anisotropy in the SAA

In the Earth's magnetic field charged particles are moving in spiral paths around the geomagnetic field lines bouncing back and forth between the mirror points. The SAA is also close to a mirror point where the pitch angle with respect to the magnetic field vector approaches and recedes from 90°. The proton flux is therefore maximized in the plane normal to the local magnetic field. Protons arriving from the west have trajectories with gyration about a point located above the reference observational point and hence they encounter less residual atmosphere than protons arriving from the east. This results in an asymmetry, where at a given point the flux of protons coming from the west is higher than the flux of protons coming from the east (Badavi et al. 2006). Although, there exist models (Watts et al. 1989; Badhwar, Konradi 1989) that are capable of predicting the directional flux of the charged particles, most of the cosmic radiation models that have been used for describing the cosmic radiation field are omnidirectional, including the "de-facto" standard AP8 and AE8 trapped proton and electron models.

Directionality of the proton flux then can be expressed as follows

$$\frac{J(\theta,\psi)}{J_{4\pi}} = F_N \exp\left[\frac{-(\pi/2-\theta)^2}{2\sigma_\theta^2}\right] \exp\left[\frac{r_g \cos I \cos\psi}{d_s}\right] \qquad \text{Eq. 2.}$$

where J is the vector flux, $J_{4\pi}$ is the omnidirectional proton flux provided by the AP-8 trapped proton models implemented in SPENVIS, θ and ψ are the pitch and azimuth angles respectively, d_s is the ionospheric scale height, I is the magnetic dip angle, r_g is the proton gyro-radius in km, σ_θ is the standard deviation of the pitch angle and F_N is a normalization factor (Kern 1994). To get a rough estimation of the directionality of trapped particles, calculations were performed with the positional version of the 'radiation sources and effects' package of SPENVIS. In the calculations, one single SAA transit was considered. The orbit was tailored to pass through near the centre of the SAA (centred near 29.4° S, 45.6° W in 2010).

Results

Performance of the SAA switching algorithm on model time spectra

Since the number of counts measured with TriTel depends on several factors (e.g. altitude, solar activity, shielding configuration), it might considerably change during a mission or from one mission to another. Therefore the switching algorithm developed is based not only on the absolute value of the number of counts but on its relative change as well. The switching between the SAA and the non-SAA spectra takes place in real time. Passage through the anomaly is indicated by an SAA flag, its value outside SAA is 0 (the measured counts contribute to the non-SAA spectra). The number of counts in consecutive 60-second-long time intervals is registered in the time spectra. In case the relative change in the sum of the time channels of the x-, y- and z-axis exceeds a predefined δ value, the SAA flag changes to 1 and the number of counts starts to be registered in the SAA spectra. TriTel switches back to the non-SAA spectra (value of the SAA flag is 0) only if the number of counts decreases below the value registered at the time of the previous switch (Hirn 2009b).

From the calculations the value of δ at which the probability of false switching is less than 10^{-3} was found to be 0.34 and 0.25 for the spectra generated from the measurements with DOSTEL during the STS-84 mission and in the Matroshka-1 experiment, respectively. The difference in the two values can be attributed to the fact that during the STS-84 mission DOSTEL was inside the Space Shuttle, while in the Matroshka-1 experiment it was located outside the wall of the ISS. Therefore, in the former case, due to the smaller number of counts and so the higher standard deviation, the relative difference between the numbers of counts in two neighbouring time channels might be more significant. Since the number of SAA peaks in the model time spectra has shown weak statistics, no detailed statistical analysis has been performed on the maximum value of δ (δ has a nearly uniform distribution between 0.3 and 0.8).

In the view of the above I proposed $\delta = 0.35$. Fig. 2 shows the performance of the algorithm applied for the model time spectra generated from the STS-84 measurements of DOSTEL for this case.

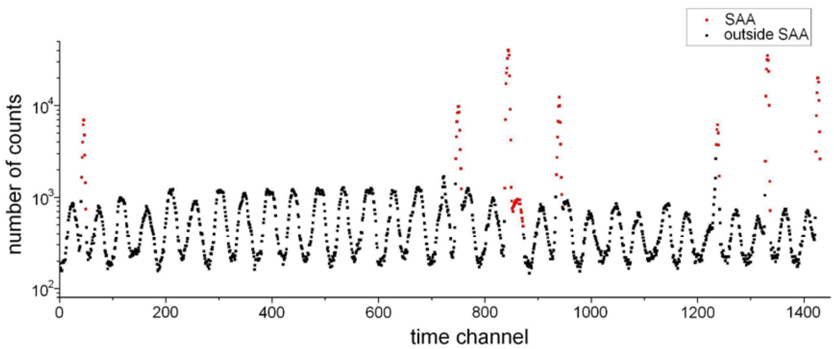

Fig. 2. A sample from the results of the SAA-switching algorithm applied to the model time spectra.

Effects of the anisotropy of untrapped GCR particles on the model calculations

The cut-off distributions for 0°, 20°, 40°, and 60° angles of incidence are shown in Fig. 3 in the case of a telescope axis pointing toward the geographical zenith direction. Below 10 GV, the four curves are practically identical. The contribution to this low cut-off region comes from segments of the orbit when the ISS is passing at higher latitudes where the change in the geomagnetic cut-off due to the change in the zenith and azimuth angles is not so significant. However, the differences in the curves above 10 GV originate from the zenith dependence of the cut-off at latitudes that are close to the geomagnetic equator.

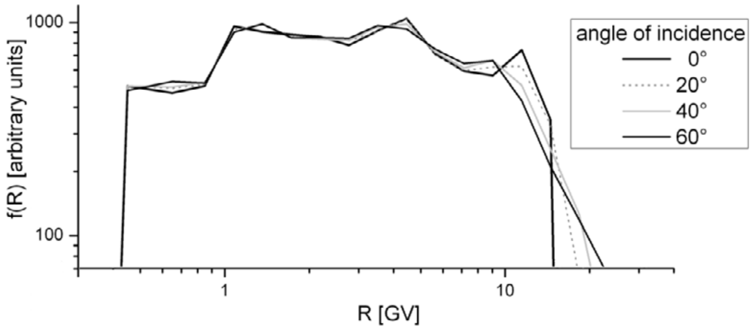

Fig. 3. Cut-off distribution for different angles of incidence for a telescope pointing towards the geographical zenith direction.

As for the total deposited energy spectra, the spectra in the x- and y-directions were found to be the same due to symmetry reasons and, in spite of the planar geometry of the detectors, no difference could be seen in the zenith direction either. Because of the planar geometry of the silicon detectors, the absorbed dose measured can be significantly higher for non-relativistic particles incident perpendicularly to the axis of the detector than for particles with normal incidence to the effective surface of the detector. Since the nadir, from which direction the radiation is considerably shielded by the Earth, is perpendicular to the axes of the x- and y-telescopes, the contribution of these higher energy deposits is lower in the total deposited energy spectra in the x- and y-directions. However, the lower cut-off values in the zenith direction have the opposite effect. In order to interpret the results in more details and determine the significance of the effects described above, further calculations are needed. The effects of the anisotropy of the galactic cosmic rays in LEO arise in the coincidence spectra and so in the calculated LET spectra, as well (Fig. 4).

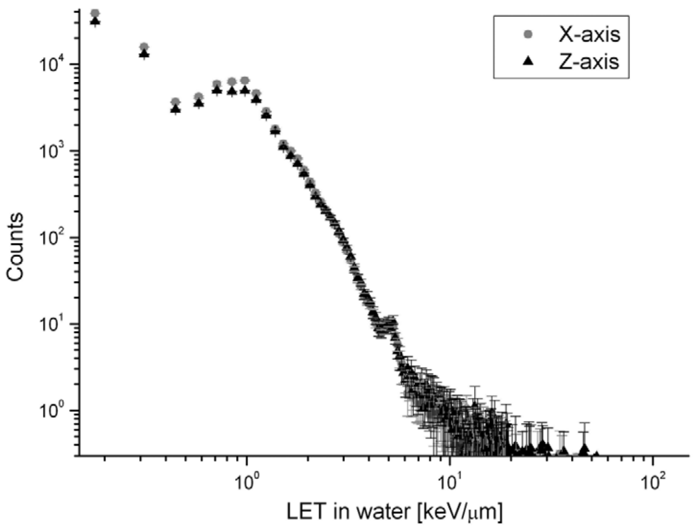

Fig. 4. LET spectra of protons and alpha particles determined from the coincidence spectra in the X and Z directions (the Y coincidence spectrum was found to be identical with the X spectrum; therefore it is not indicated in figure).

Contrary to the total deposited energy spectra, the number of counts in the LET spectra in the x- and y-directions is significantly higher than in the z-direction. The fact, that in case of the z-axis, 50% of the field of view is occulted by the Earth, while this ratio is only 30% in case of the x- and y-axis, might result in this effect (because the altitude of the spacecraft is 340 km, a considerable part of the particles coming from the –z directions can give a contribution to the coincidence spectra of the x- and y-axis).

Since only protons and alpha particles were considered in the calculations and the uncertainties in the number of counts related to the energy deposit of particles with a LET value higher than 10 keV/μm in water was high, no significant difference could be observed in the calculated quality factors. In order to study the differences in the quality factors, ions heavier than alpha-particles shall be included in the calculations as well (Hirn 2010).

Effects of the anisotropy of trapped particles in the SAA on the model calculations

The integral fluxes of trapped protons that can enter the sensitive volume of the detector are plotted in Fig. 5 as a function of the magnetic pitch angle. The fluxes were determined in seven distinct positions in the section of the orbit of the ISS crossing the SAA. Inside the SAA, protons arrive from directions within 10–15° of the plane perpendicular to the geomagnetic field line. Even if we take into account that the geographical and geomagnetic axis do not coincide, the velocity vectors of the trapped protons lie outside the field of view of the z-telescope. Therefore, these particles will contribute only to the coincidence spectra in the x- and y-directions but not the z-direction (Hirn 2010). A more quantitative description of the directionality of the trapped radiation can be performed by analyzing Eq. 2.

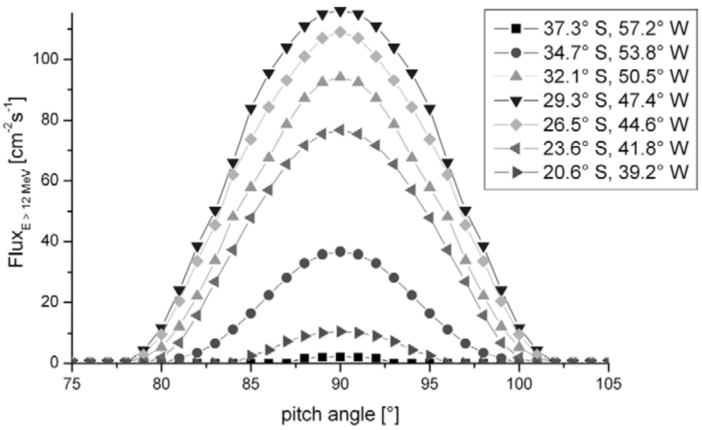

Fig. 5. The integral flux of trapped protons as a function of the pitch angle inside the SAA.

Discussion

The optimal value of the δ parameter of the SAA switching algorithm for a given experiment can be determined only after the first measurement data has been evaluated. However, the fine-tuning of the parameter is necessary. In the knowledge of the time spectra the effects of the time-shifts and the false switching might be corrected during the on-ground evaluation of spectra.

The calculations presented in the paper show that the effects of the directionality of the geomagnetic cut-off are negligible compared to that of the Earth's shadow when integrated over the orbit. In order to demonstrate the effects of the anisotropy of the untrapped radiation in the measured dose equivalents and quality factors, it will be necessary to take into consideration heavier ions as well. The trapped protons inside the SAA evidence an even more pronounced anisotropy. The velocity vectors of the trapped protons lie outside the field of view of a telescope pointing toward the zenith direction. However, with a 3D telescope, the LET spectrum of the trapped radiation can be studied as well. The author wishes to acknowledge the services provided by SPENVIS and CREME96 hereby.

Conclusions

In this paper only the anisotropy of the radiation field outside the ISS was addressed. Inside the space station, due to the complexity of the shielding distribution, simulating the deposited energy spectra is even more complicated; hence, 3D measurements on board the space station should be performed. In the light of the above, three different versions of the TriTel 3D telescope are being developed at AEKI. One version, in the framework of the European SURE project, will perform measurements on-board the Columbus module of the ISS, one in cooperation with the Institute of Biomedical Problems on-board the Russian segment of the ISS and finally another version will measure the LET spectra and the dose on board the ESEO satellite in the near future.

Sequential separation of alpha and beta emitters from natural samples by mixed solvent anion exchange and their subsequent determination

Rozmaric Macefat, Martina
Rudjer Boskovic Institute, CROATIA

Abstract

Determination of alpha and beta radionuclides in environmental samples, food and drinking water is important from the aspect of human health and environmental protection. Low level activities determination of pure alpha and beta emitters in natural samples, prior to detection and quantitative determination, requires isolation of radionuclide from the sample and simultaneous separation from interfering elements. The extraction chromatography is mostly used method in last decade. However, due to chemical and mechanical stability and low price, ion exchangers are a good alternative to expensive extraction chromatographic resins because they don't lose their capacity with multiple usage, whereas resins do. It is very important, for the ion exchanger to be applicable in the separation, that its capacity is not a limiting factor (ion exchange must not be a dominant mechanism of bounding). This work will show that anion exchangers in nitric form, in combination with alcohol solution of nitric acid, can be used for separation of all kinds of cations. The effect of dielectric properties of solutions on the bounding strength of particular cations to anion exchangers in nitric form, its effect on exchanger selectivity conversion for Ca, Sr, Y, Pb, Th, U, Am and Pu from HNO_3 solutions in methanol, ethanol and acetone, as well as the separation possibility of various cations, based on changes in solution properties, will be presented. The effect of change in dielectric constant on the bounding strength of certain cations to the exchanger will be shown in temperature range from -50 to 20°C, and how it can be used in cation separation. For quantitative determination of certain isotopes, already existing methods have been modified (LSC, Cherenkov counting, alpha and gamma spectrometry, ICP MS). Finally, simple and rapid methods, which are used in daily Laboratory work, have been developed for isolation and quantitative determination of $^{89,90}Sr$, ^{210}Pb, and other isotopes.

Optically stimulated luminescence in salt tested against thermally stimulated luminescence in LiF and ambient survey measurements in a ^{137}Cs contaminated village in Belarus

Abstract

Ordinary household salt (NaCl) have previously been investigated in the laboratory and has exhibited several promising properties for dosimetry, e.g. a linear dose response down to a few mGy and a low detection limit. In an attempt to test NaCl as a dosemeter outside the laboratory, we here report the first results from the use of NaCl as a dosemeter under normal environmental conditions, both indoor and outdoor. For this purpose, special dosemeter kits, each containing two chips of LiF and 2×10 mg of NaCl were designed. During the summers of 2008 and 2009 the dosemeter kits were positioned pair wise inside and outside the outer walls of 17 houses located in a village which was highly contaminated by ^{137}Cs from Chernobyl, in the Gomel region (Belarus). After 2.5 – 3 months the dosemeters were collected and read out using thermoluminescence (TL) and optically stimulated luminescence (OSL), respectively. The estimated dose rates from the two dosemeter systems were then compared for each kit and in addition, the dose rate at positioning and collection of the dosemeters was measured using a hand-held ambient dose survey meter (GR-110) based on a 5.0 x 3.8 x 3.8 cm^3 NaI(Tl)-detector.

The radiation level in the village was found to be highly inhomogeneous, even within the gardens around the houses. On average, the radiation level around the houses was 3 – 8 times higher compared to a normal background dose rate (0.10 µSv h^{-1}). Despite the relatively low signals, a strong correlation was observed between the results of the salt dosemeters and the portable NaI(Tl)-detector (r^2 = 0.89), but the correlation between NaCl and LiF was weaker (r^2 = 0.64). The repeated study in 2009 confirmed the potential for ordinary cheap household salt as a tool for retrospective dose estimates.

Introduction

In order to estimate radiation absorbed doses to the general public after an event that involves unwanted exposure of ionising radiation, several retrospective methods have been suggested, see e.g. (ICRU, 2002; Alexander et al. 2007). The Medical Radiation Physics group in Malmö has especially focused on optically stimulated luminescence (OSL) of household salt (NaCl) as a tool for retrospective dosimetry. The dosimetric properties of different brands of household salt have been investigated in the laboratory (Bernhardsson et al. 2009; Christiansson et al. 2008a; Christiansson et al. 2008b) and several promising properties for dosimetry have been found. The next step is now to test salt as a dosemeter *in situ*, under normal environmental conditions and during extended periods of time. This has been done in an environment that has been affected by a major surface contamination of anthropogenic radionuclides, mimicking a situation in which the dosemeters are aimed to be used in the future, after e.g. radiological and nuclear accidents as well as after antagonistic use of radiation and radioactive substances.

The Vetka district in the Gomel region (Belarus) was found to be an area that fulfils these conditions where one of the villages, Svetilovichi, was one of the most contaminated settlements outside the 30 km zone after the Chernobyl catastrophe. Parts of this district were decontaminated in 1986 – 1987, but not the village of Svetilovichi. The people living in this village were advised to relocate to areas with less contamination, but most of the inhabitants decided to stay instead of abandon their homes and village. However, in 1991 a more systematic decontamination was carried out in the village (roads and outside public buildings, i.e. kindergartens and the hospital). Thereafter, in 1999, and as part of the IAEA regional project RER/9/059 (Andersson K.G. et al. 2001), Svetilovichi was selected as a village for practicing and improving the existing techniques of decontamination. New equipment was bought and experts on decontamination were training the personnel at the federal state company Polesye (Gomel) who is specialized in cleaning contaminated buildings. Up till 2006, about 50 houses and gardens have been decontaminated according to the program and today, all of the most heavily contaminated houses have been decontaminated.

During the summers of 2008 and 2009, measurements of the gamma radiation level in the village of Svetilovichi were carried out by the Medical Physics group in Malmö (Lund University, Sweden) in cooperation with the Chernobyl Committee (Minsk, Belarus) and the federal state company Polesye (Gomel, Belarus). One of the aims of the project was to investigate household salt as an optically stimulated dosimeter (OSLD) when used in a contaminated environment.

Material and methods

The village of Svetilovichi is situated in eastern Belarus (Latitude: 52°47'43.76"N; Longitude: 31°19"11.88"E), between Gomel (Gomel region, Belarus) and Novozybkov (Bryansk region, Russia). Due to heavy rainout of the passing plume of the Chernobyl release, the Gomel region received an average ^{137}Cs surface deposition of 154 kBq m^{-2} [Drozdovitch V. et al. 2007]. Since 1990s, individual effective dose estimates of the internal and external exposure have been carried out in a number of the nearby villages, on the Russian side of the border, see e.g. (Thornberg C. et al. 2001; Thornberg C. et al. 2005; Bernhardsson C. et al. 2008).

Assemblying and positioning the dosemeters

To investigate the radiation level in some of the decontaminated and non-decontaminated houses in Svetilovichi, between 5 and 14 dosemeter kits were placed inside- and outside each of the houses described in Table 1. Each dosemeter kit contained two chips of LiF (TLD100, Harshaw) and two sections (about 10 mg each) of NaCl (Falksalt fint bergsalt, Hansson and Möhring, Halmstad, Sweden), a regular seasoning salt in Sweden. The TL-chips and the salt were placed between two 4 mm thick sheets of PMMA, thus forming a dosemeter kit with two different luminescent materials. Before the dosemeter kits were put together, during the night before the distribution, the salt was exposed to sunlight (bleached) in order to empty the stored dose information. To avoid further bleaching of the luminescence signal, all dosemeter kits were covered with light-tight black tape. Another precaution was to place the dosemeter kits in plastic bags filled with silica gel, to protect the dosimetric material from rain and moist during the varying outdoor weather conditions.

Table 1. Description of the houses and the extent of countermeasures carried out at each dwelling. Fifty-six dosemeters were used at houses 1-7 in 2008 and 69 dosemeters at houses 8-17 in 2009. The thickness of the outer walls on the wooden houses was about 0.2 – 0.3 m and 0.5 m on the brick houses.

[a] Decontamination of a building includes; cleaning of roofs and walls using high-pressure water as well as removal of the top soil layer (10 cm depth) from the house wall and 2 m out and replacing it with sand. Highly contaminated roofs were removed and replaced with new ones.
[b] Walls on houses made from bricks were not cleaned.

The investigated houses were all documented by Polesye and had a known history from the owners. In this way, only houses built after 1986 and where no major changes of the constructions (after 1986) had been carried out, were selected for the measurements. The dosemeter kits were fixed firmly on both the inside- and outside of the walls of the houses, in opposite positions on the wall where it was possible and about 1 m above the floor level. Rooms that were most frequently used e.g. living room, bedroom and kitchen were prioritised for the indoor measurements. The ambient dose rate at the position of the dosemeters was registered with a handheld 3.8×3.8×5 cm^3 NaI(Tl)-detector (GR-110, Exploranium, Canada). These measurements were repeated when the dosemeters were collected approximately 2.5 months later and a mean value of the two measurements was used as a reference value to the dosemeter readings. To compare the absorbed doses to the dosemeter kits with the readings of the GR-110 instrument, a general calibration coefficient (free in air using a ^{137}Cs source; SMM, Department of Emergency Preparedness and Environmental Monitoring, certificate No:06-08S01) of 1.15 nSv/h cps^{-1} has been used.

Read-out procedure

The dosemeters were distributed, at 56 positions in 2008 and 69 positions in 2009, during the last week of May and were re-collected in the middle of August. They were immediately transported back to Sweden and shortly after that, the LiF chips were read-out in a TL–reader (Toledo, Vinten Instruments Ltd., England) at Sahlgrenska University Hospital in Göteborg. To assess the signal in the salt, it was optically stimulated by blue light (λ = 470±30 nm) at the Medical Radiation Physics department in Malmö, using a TL/OSL-DA-15 reader (Risø National Laboratory, Roskilde, Denmark). The net OSL signal was defined as the registered luminescence during the first 2 s subtracted by the average luminescence after 10-12 s, 20-22 s and 31-33 s of stimulation. In order to convert the net OSL signal to an absorbed dose a pre determined calibration coefficient ($c_{specific}$ = 313 counts mg^{-1} mGy^{-1}) for this particular brand of salt was used (Bernhardsson et al. 2009). It should be noted that $c_{specific}$ is determined for a specific brand of salt, from a single jar, and then generalised to hold for all salt jars of the same brand, thereby assuming that the salt in all jars are identical. To account for changes between individual dosemeters and salts taken from different jars, there are other means of calibration that can be used. One approach is to use the single-aliquot-regenerative-dose (SAR) protocol (Murray et al. 1998) where successively increasing doses, in the range of the dose to be determined, are given to the salt after the read out. This approach was however impossible to carry out at the time of the readouts in 2008 and 2009 and hence the protocol and calibration coefficients described by Bernhardsson et al. (2009) have been used.

A correction for the additional dose originating from the exposure during transportation from Svetilovichi and storage before read-out has been carried out. To estimate the magnitude of this dose, ambient survey meters were used at various positions along the travel route from Belarus and the final destinations (the laboratories in Malmö and Göteborg, Sweden, respectively). From these measurements an average background dose rate was calculated and subtracted from the total dose accumulated during the probing time.

Results and discussion

The average dose rate during transportation and storage was determined to 0.10 µSv h^{-1}. The total dose accumulated during transit and storage varied individually and has hence been subtracted from the total dose registered by each dosemeter. Unfortunately, the dose to the TLDs used in 2009 was not possible to retrieve due to problems with the TLD-reader and therefore, the OSLD to TLD comparison was not achievable that year.

In Fig. 1 is the absorbed dose as determined by NaCl and LiF plotted as a function of the corresponding dose obtained from the handheld NaI(Tl)-detector at the position of the luminescent dosemeters. In spite of the low detector signals there is a fairly good correlation between the dosemeters and the radiation protection instrument. However, the OSLDs exhibit on average, a 15% higher absorbed dose than the TLDs. This might indicate a too small signal background subtraction of the NaCl batches, or a too high signal background subtraction of the LiF-chips. It could also be a consequence of sensitivity changes in the LiF-chips during the measuring period. Another explanation could be that anomalous fading of the signal is more rapid in the specific LiF-chips used, compared to NaCl, at least during the first 2 – 3 months.

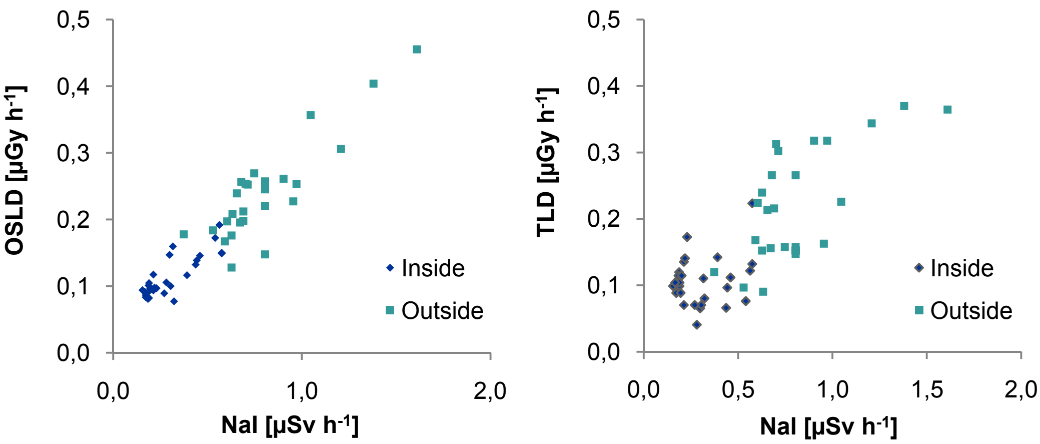

Figure 1. Absorbed dose in OSLD and TLD as a function of the dose registered by GR-110 (average of measurement at outset and pickup of the kits). Included in the figures are measurements from 56 dosemeter kits (positions) in 7 houses, during the summer of 2008. Different colours have been used to distinguish between dosemeters positioned inside and outside the buildings.

Generally, the dose rates indoor were rather low, comparable to the normal background radiation level in many European countries. Outside the houses the average dose rate was 3 – 8 times higher compared to the indoor values. The pair-wise correlation between the results of the 3 measurements in terms of Pearsons's r^2 was higher for the outdoor measurements compared to those inside. Nevertheless, there was a moderately or a strong correlation between all of the investigated dosemeters (Table 2). The correlation was strongest between the OSLDs and GR-110, which may partly reflect the similar responses between these two detectors for the photon energies studied. It is however apparent that some of the specific LiF chips used in this study exhibited a rather low sensitivity and this in turn may have adversity influenced the detection limit (0.01 mGy, as specified by the manufacturer).

Table 2. Covariance matrix (r^2-values), for the three dosemeters tested in the survey in 2008.

	OSLD	TLD	GR-110
OSLD	1	0.64	0.89
TLD	-	1	0.65
GR-110	-	-	1

The dose rates measured with the OSLDs, plotted as a function of the correspondingly dose rates of GR-110, in the years 2008 and 2009, is shown in Fig. 2. There is a noticeable difference in the linear relationship between the two years, with:

$$OSLD_{2008} = 0.24 \cdot NaI + 0.04 \qquad \text{Eq. 1}$$

$$OSLD_{2009} = 0.40 \cdot NaI + 0.10 \qquad \text{Eq. 2}$$

Even though it was not the same houses that were investigated, the dose response in the salt should not be affected by this factor. The ranges in the registered doses are similar in both years but the slope and intercept of the lines are significantly different (Eq. 1 and Eq. 2).

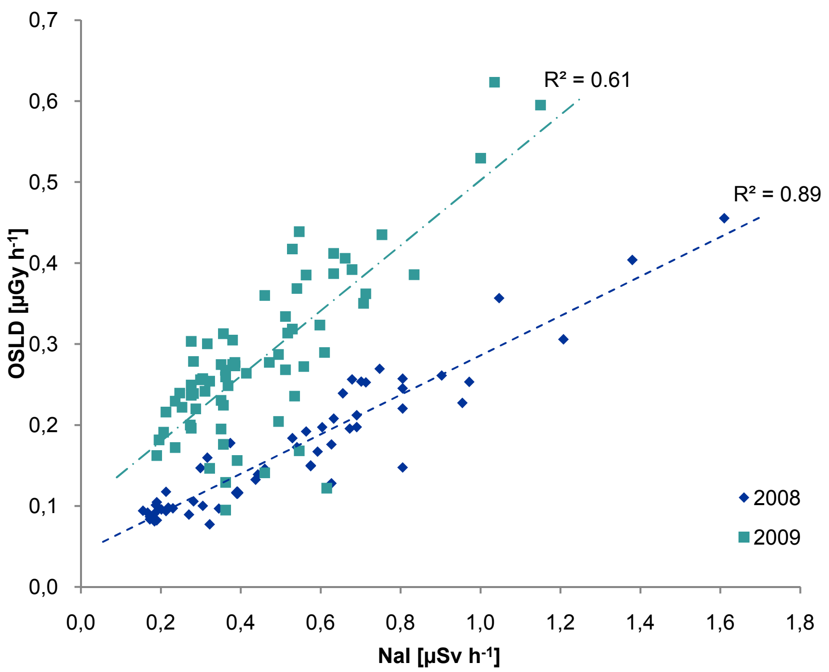

Figure 2. Absorbed dose rate as measure by the salt dosemeters in 2008 and 2009 as a function of the dose rate as measured with GR-110 at the position of the dosemeters.

The sensitivity is about twice as high in the salt used in 2009 compared to 2008, despite the fact that they are from the same brand of salt. The reason for this diversity is that the particular salts used were taken from different jars. The jar of salt used the first year was packed in December 2006 and the salt used in 2009 was packed in March

2009. Hence, the salts were probably extracted from different salt layers within the same, or different, mines and possibly mixed with salt from other deposits before it was packed and distributed. Changes in these fractions will accordingly change the properties of the salt as a dosemeter.

Another observation is that the salt used in 2009 appears to have a slightly weaker correlation to the GR-110 reading, compared to the salt used in 2008. One factor that influences this is the distribution of grain sizes within a particular package of salt. Large grains will generally give less luminescence per absorbed dose compared to small grains, at a given weight. Since the salt was not sieved (fractionated due to grain size), this might be one of the major factors for the discrepancy found in the OSLD measurements in 2008 and 2009 caused by using two different jars of salt.

Conclusions

Even though the study was carried out with pre-manufactured dosemeter kits, the salt demonstrates a promising potential as a tool for retrospective dose reconstructions. The salt in the dosemeter kits exhibits a good or a strong correlation to measurements carried out using a radiation protection instrument and TLDs. The repeated survey increases the confidence in salt as an OSLD, despite the fact that the measuring conditions were slightly different during the two different years.

Small changes to the experimental set-up by changing a few factors can further increase the usefulness of salt as a dosemeter. One of these is to sieve the salt before the read-out, thereby making the salt more homogenous and thus, minimising the risk of analysing inefficiently used grains. Another one is to use individual calibrations of each dosemeter, e.g. by the use of the SAR-protocol. One benefit with this approach is that changes in the sensitivity between two different jars of salt, from the same brand, will be incorporated in the calibration. Another benefit is that almost every salt on the worlds market becomes available as a potential dosemeter.

Visualization of hot particles in lung of radionuclide associated with emergency preparedness by means of clinical gamma cameras

Hansson, Mats; Rääf, Christopher

Medical Radiation Physics, Department of Clinical Science Malmö, Lund University, Malmö University Hospital, SWEDEN

Abstract

In a situation when radionuclides accidentally or deliberately are dispersed in the environment and individuals have been internally contaminated there is an urgent need for localization of the radionuclide in affected individuals. The aim of this study is to examine the possibilities to visualize hot particles of radionuclides with gamma energies close to and beyond the upper level of the pulse height analysers (PHA) of clinical gamma camera systems. The aim is also to examine the possibilities to visualize hot particles of pure β-emitters with a clinical gamma camera. An anthropomorphic phantom was used to mimic uptakes in the lung region of three different radionuclides associated with emergency preparedness ^{60}Co ^{137}Cs and ^{90}Sr/^{90}Y (0.8, 0.16 and 2.2 MBq respectively). The radionuclides were located in or outside the right lobe of the lung insert. The conclusion of this study is that point sources, mimicking a hot particle of a given radionuclide can clearly be visualized even in cases when the primary gamma photon energy exceeds the upper limit of the PHA. This study indicates also that point sources of pure β-emitters can be visualized. Hence gamma camera systems can be useful for rapid assessment of inhaled hot particles in connection with radiological and nuclear accident.

Introduction

There are a number of radionuclides of special concern within the emergency preparedness; for instance ^{60}Co, ^{137}Cs and ^{90}Sr/^{90}Y, which are frequently used in hospitals, in the industry and at research laboratories. In addition to these sources, nuclear power plants generate airborne aerosols and surface contamination of ^{60}Co as a result of neutron activation of stable cobalt in construction materials, which can accidently be ingested or inhaled by workers (D. W. Whillans, W. J. Chase and W. H. Wolodarsky 2007). Another source of radionuclides in nuclear power plants is fission products of ^{235}U such as ^{137}Cs and ^{90}Sr/^{90}Y. These radionuclides are generally not dispersed to the surroundings except in cases of severe nuclear reactor accidents, such as the Chernobyl accident in 1986. Other potential exposure pathways to humans are transportation accidents or releases in connection with terrorist activities where radionuclides are involved (ICRP 96, 2003). In previous mention scenarios there is a need for methods to rapidly screen suspected intakes of e.g. ^{60}Co and ^{137}Cs in individuals by means of in-vivo measurements. Potential resources that are useful in case of nuclear and radiological emergencies must be explored. Equipment and personnel connected to radiological work at general hospitals are one such resource. Clinical gamma camera imaging systems, which are available in many hospitals, would be a valuable addition to the capacity of emergency measurements.

Wallström et al., (1998) examined the possibility to use a gamma camera for visualizing of ^{137}Cs in man by using bottle phantoms. The major part of the work was performed with a gamma camera consisting of a NaI(Tl)-detector with a crystal thickness of 1.2 cm. The limitations with many gamma camera systems are that some radionuclides associated with emergency preparedness scenarios emit gamma photons with energies beyond the upper level of the energy window of the PHA. Therefore, imaging of organ uptakes of the high energy photon emitters must be deduced by detection of scattered radiation. A previous study using a Siemens MultiSPECT 2 with various acquisition settings for imaging of ^{46}Sc and ^{60}Co in the lungs and abdomen were carried out at our department (Hansson et al., 2008).

The aim of this work is to evaluate the possibility to use clinical gamma camera systems for visualization of the presence of radionuclides associated with emergency preparedness in the lungs, also in cases where the primary photon energies exceed the normal operative range of the PHA. In addition to gamma emitters associated with emergency preparedness (e.g. ^{60}Co and ^{137}Cs) we aim to evaluate the possibility to visualise presence of pure beta-emitters (^{90}Sr/^{90}Y) by the detection of bremsstrahlung.

Material and methods

Gamma camera systems and imaging of high energy gamma quanta

Two gamma camera imaging systems have been used in this study, the principal measurements being carried out on a Siemens MultiSPECT 2 (Siemens, Erlangen, Germany), The MultiSPECT 2 is a dual-head imaging system with NaI(Tl)-detectors having a field-of-view of 53.3x38.7 cm^2 and a crystal thickness of 0.95 cm. Complementary pilot measurements have been carried out on a Symbia SPECT-CT (Siemens, Erlangen, Germany) which is a SPECT-system equipped with an low dose CT. The point source of the radionuclide was placed on the right lung lobe close to the heart compartment or inside the same lung compartment of the phantom (Fig 1). The first alternative was used when the physical size of the holder of the point source did not allow it to pass in to the inside of the lung compartment. When exploring the MultiSPECT 2 capability to visualise lung uptakes of point sources, the entire energy window, 45-535 keV, of the PHA was used. High energy collimator was used in connection with the MultiSPECT 2 measurements. The matrix size of the SPECT image was 128x128 and filtered back projection reconstruction algorithm was used. For the Symbia SPECT-CT an energy window of 100-300 keV was used, together with a medium energy collimator. The matrix size of the image was 64x64 and here an iterative reconstruction algorithm was used.

Phantom characteristics

An anthropomorphic phantom (Alderson-phantom, RSD 2008) specifically designed for calibration of imaging systems within nuclear medicine has been used in this study. The phantom is composed of different materials with attenuating properties comparable to human tissues. Phantom inserts shaped as human internal organs, such as lungs, liver and heart, can be filled with various radioactive solutions of known activity to simulate different organ uptakes. By supplying additional human tissue equivalent material on the anterior of the phantom torso, three different body sizes can be simulated. The body sizes are; *i.*) average male 74 kg, (personal communication Helen Kelly, RDS) *ii.*) large male more than 74 kg and *iii.*) large female more than 74 kg. Only the "average male" phantom was used in this study.

Fig 1. Left frame: The Alderson phantom positioned on the patient couch of the MultiSPECT 2 gamma camera. Right frame: The lung insert of the Alderson phantom with a point source on the outside.

Radionuclides

Three key radionuclides associated with the emergency preparedness scenarios as mentioned before were used in this study. The photon energies emitted by these radionuclides was 661.6 keV (^{137}Cs) and 1132 keV and 1332.5 keV, respectively (^{60}Co). The possibility to visualize uptakes of pure β-emitters in the lung has also been investigated using a commonly occurring β-emitters ^{90}Sr/^{90}Y ($E_{\beta,Average}$=0.196 MeV / $E_{\beta,Average}$=0.934 MeV). For the ^{90}Sr/^{90}Y the radiation detected by the gamma camera consists of the bremsstrahlung originating from the interaction between the high-energy β-particles within the tissue material. In Table 2 the investigated radionuclides and some of their properties are summarised.

Table 2. Strength of the point sources used simulating hot particles. ^{90}Sr was in equilibrium with the daughter ^{90}Y that emits the *β*-p.

Radionuclide	$T_{1/2}$ [year]	Main energy [keV]	γ-yield [%]	Activity [kBq]
^{60}Co	5.3	1173/1332	100/100	800
^{137}Cs	30	662	85	160
^{90}Sr /^{90}Y	29/0,0073	196/934 (average β-energy)	100/100	2200

Results and discussion

Visualisation of lung uptakes for different radionuclides

Fig 1-3 show images (matrix 256*256) obtained with the MultiSPECT 2 visualise ^{60}Co, ^{137}Cs and $^{90}Sr/^{90}Y$ in the Alderson phantom. An increased intensity at the position of the sources is clearly seen in all images compared to the background. The obvious disadvantage with planar gamma camera imaging in this case is the lack of correlation of the point source and the anatomy in the image. It could be a help to use so called landmarks in form of ^{57}Co sources of low activity placed on well defined points on the thorax of the internal contaminated person in the measuring situation. In fig 1 the image representing a hot particle in the lung containing ^{60}Co appears as a cloud with no distinct delimitation. Such an image may be of limited help in an emergency situation, but with another levelling of the SPECT image the area of the cloud can be reduced and become somewhat more guiding in terms of localisation of the particle. The general problem is that the high gamma energy (1173 keV/1332 keV) emitted from ^{60}Co is more than twice that of the ULD at 535 keV of the MultiSPECT 2.

Fig 4-6 show images (matrix 64*64) obtained with the Symbia SPECT-CT visualising hot particles of ^{60}Co, ^{137}Cs and $^{90}Sr/^{90}Y$, respectively, in the Alderson phantom. The obvious advantage with fused SPECT-CT imaging compared to planar gamma camera image is the possibility to correlate the point source to a specific point in the anatomy. The correlation between the point source in the anatomy is not only given in one dimension but in three dimensions. N.B. that the image layers of the SPECT and CT are morphed at the coronal plane of the phantom.

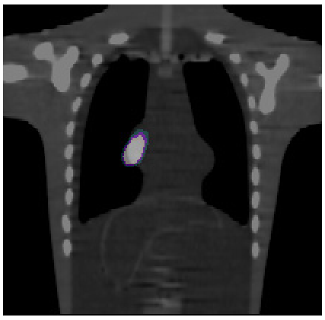

Fig 5. ^{137}Cs, 160 kBq, point source positioned on the right lung.

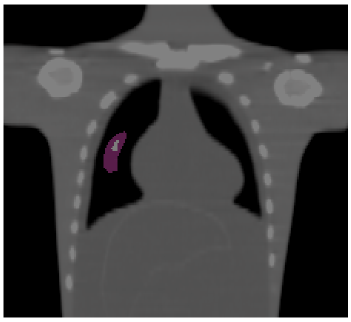

Fig 6. ^{90}Sr/^{90}Y, 2200 kBq, point source positioned in the right lung.

Conclusions

The conclusion of these pilot studies can be summarised as follows;

- Lung uptakes of a point source with gamma energy high above (^{60}Co) the ULD appear as a cloud with no clear delimitation by planar gamma camera and as a point with distinct delimitation by SPECT-CT imaging system.
- Lung uptakes of a point source with gamma energy close to or right above (^{137}Cs) the ULD can be visualized as a point with distinct delimitation both by planar gamma camera and by SPECT-CT imaging system.
- Lung uptakes of a point source of a pure beta-emitter (^{90}Sr/^{90}Y) can clearly be visualized as a point with distinct delimitation both by planar gamma camera and by SPECT-CT imaging system. In fact, the bremsstrahlung of ^{90}Sr/^{90}Y is more clearly delineates the hot particle in the planar image than do the scattered ^{60}Co radiation.

Our study thus indicates that clinical gamma cameras and SPECT-CT can be a useful instrument for visualisation of human lung contents of gamma emitting hot particle normally associated with emergency preparedness scenarios, and for pure β-emitting radionuclides as well. Future work is to examine which settings of the SPECT-CT are optimum for visualisation of high photon energy emitting sources in the inhalation tracts, and the detection limit in terms of activity for which the source can be visualised in an image at given acquisition times.

Whole-body counters for measurement of internal contamination in Finland

Huikari, Jussi; Pusa, Sauli; Muikku, Maarit
STUK – Radiation and Nuclear Safety Authority, P.O. Box 14, 00881 Helsinki, FINLAND

Abstract

STUK - Radiation and Nuclear Safety Authority - has two whole body counters for measurement of internal contamination. Both counters use high purity germanium detectors. The stationary system is installed inside a 50-ton iron room. The new mobile unit is built on a truck chassis. Both counters are used to assess the internal exposure of radiation workers and that of the Finnish public in general. Up to now, information of the location of the internal contamination has not been available due to measurement geometry in the mobile unit.

For this reason, a project was started to design and build a new counter in order to obtain location information and to improve detection efficiency. Monte Carlo simulations exploiting MCNPX were used together with voxel phantoms to guide the design process. The mobile unit can also be mobilised in emergency situations and it provides a fast and reliable method for both screening and dose assessment purposes. The need for assessing internal radiation doses in emergency situations is evident and has been demonstrated after the accidents e.g. in Brasil and Ukraine. This paper describes a design for the new mobile counter and presents calculated predictions of detection limits and efficiency.

Introduction

Assessment of internal radiation doses can be done using results from direct measurement of people or indirectly by excreta measurements. Estimations can also be made using air concentration data or activity concentrations in food stuffs combined with consumption data. By experience from occupational contamination cases we have noticed that air concentration data tends to give too low an estimate of the intake as well as estimates done from dietary data. In principle, the dietary data gives estimate for the whole population. However, individual differences are significant, depending on how much each individual uses wild-caught fish or wild berries or mushrooms. Therefore, the need for reliable measurements is obvious. The aim of measurements is to determine the intake of radioactive substances. The internal radiation dose is then assessed using metabolic and dosimetric models. *In-vivo* measurements are used to assess the internal exposure of radiation workers as well as the exposure of the public. In cases with high internal contamination, the purpose of measurements is to help in deciding if medical treatment or other types of measurement for more exact dosimetry is needed. In situations with prolonged exposure repeated measurements are recommended. In emergency situations direct measurements should be done as soon as possible after an alert to give support for decision making and to reassure the general public.

Equipment

STUK has obtained a new mobile whole-body counter for measurement of internal contamination (Figure 1). The unit has been built on standard Volvo FE 42R truck. The carrossery is insulated and equipped with air conditioning, along with electric and diesel heaters which makes all year usage comfortable. The monitoring unit uses 230 V AC. This external power is backed up by a UPS system consisting of a powerful sine wave inverter, a sophisticated battery charger, a high speed AC transfer switch and AC distribution in a single light weight and compact enclosure. A battery pack (24 V/400 Ah) has been added in order to maintain measuring devices 24 hours in case of loss of the external mains. This battery pack is also charged by the alternator of the truck when the engine is running.

Figure 1. A new mobile whole-body counter.

The whole-body monitor inside the carossery consists of two HPGe detectors and Dspec Pro digital electronics from Ortec (Ortec 2005). The present geometry used is a modified chair with a shadow-shield made of lead to reduce background in detectors (Figure 2). The detector set-up consists of a coaxial p-type HPGe-detector with a 90% efficiency and a GAMMA-X detector which is a coaxial n-type HPGe having an efficiency of 80%. The former detector is placed in the middle of the chair for whole-body measurements and the latter is placed closer to the upper body, providing the possibility to detect iodine accumulated in the thyroid, for example. The GAMMA-X has an ultra thin entrance window made of beryllium, providing good efficiency also for low energy γ -rays. The detectors are surrounded by a 5 cm thick lead shield. The typical time used in a routine measurement is 1000 s. Background is determined using the background phantom consisting of 14 pieces of 5 kg sugar bags. If needed the measurement distance can be adjusted by moving the detectors and the lead shield up or down.

Figure 2. The present measurement set-up in the mobile unit. The modified chair is made of lead. The white shadow shield is also made of lead from "waist" down. Upper part is made of steel covering the detectors and supporting them.

The stationary whole-body counter is shown in Figure 3 below. This chamber is built of old steel in order to avoid background radiation (often tiny amounts of ^{60}Co) from freshly rolled sheets. This indoor unit, usually called Ironroom, uses scanning bed geometry, detectors being positioned in a fixed location surrounding the person. The detectors presently in use are two HPGe (both 80 % crystals) above the person and one 28% crystal under the bed. In addition, two NaI detectors are installed above and two below the bed. The analysis program provides also the total count rate versus location graph. However, as the detectors are not collimated, only a modest spatial resolution can be achieved.

Figure 3. Inner view of the Ironroom. The indoor whole body counter uses HPGe and NaI detectors, some of which are visible above the person being measured.

The background phantom used in Ironroom is made of plastic containers filled with sugar. The containers include pieces for thorax, arms, legs, head and neck. The neck part can be replaced with a thyroid phantom.

Method

The efficiency calibration for both units is performed using the adult St. Petersburg whole-body phantom (Kovtun 2000) with ^{60}Co, ^{137}Cs, ^{40}K and ^{152}Eu rods (energy range 122-1460 keV). Figure 4 shows the efficiency calibration for a mobile unit. Both calculated and measured curves are shown. In addition, three St. Petersburg thyroid phantoms with ^{133}Ba capsules are available: adult, teenager (14 years old) and child (6 years old). Barium is used to imitate ^{131}I as its gamma energies are in the same energy range. The body burden of adult persons is determined roughly from knees to nose in the mobile unit. The Ironroom measures whole person. The whole-body phantoms from 12 kg to 110 kg corresponding ages from two-year old to adult were used to obtain the correction to the efficiency due to the size of the measured person. The correction factor ranges from 1.4 (12 kg) via 0.9 (90 kg) to 1 (110 kg).

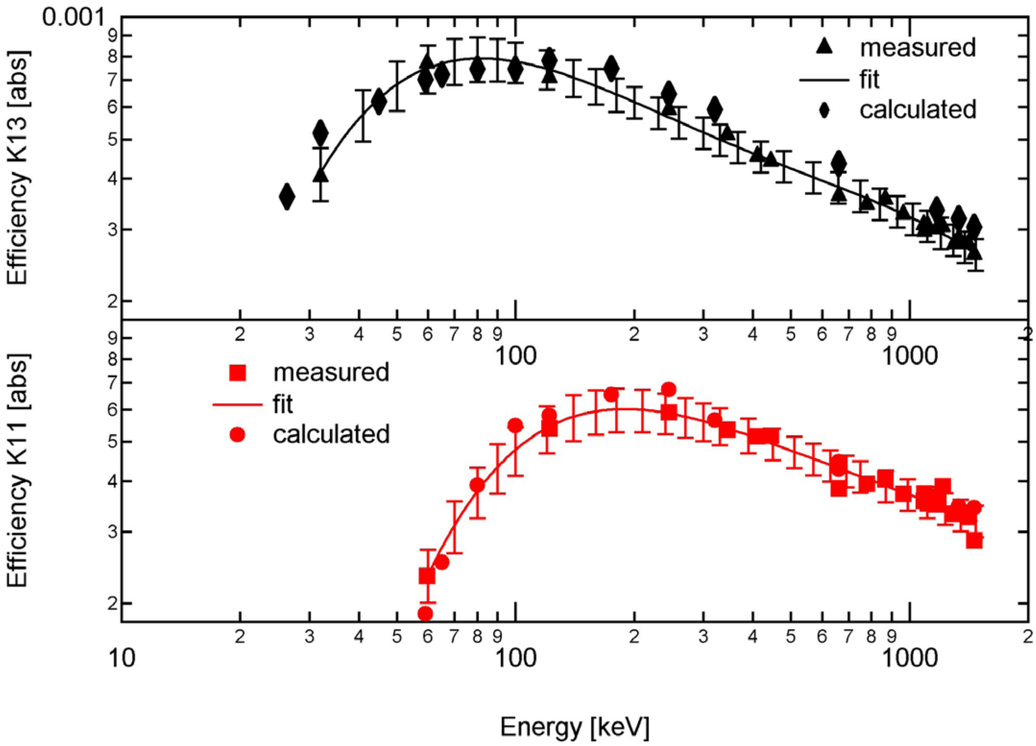

Figure 4. Efficiency curves for the p-type HPGe (K11, lower) and n-type GAMMA-X HPGe (K13, upper) detectors.

The uncertainty on the absolute γ-efficiency is 10 % for γ-rays >200 keV and goes up to 15 % towards lower energies. The final uncertainty on the activity measured will be determined by adding quadratically the statistical uncertainty of the identified γ-peak and that of the efficiency. For the most of the cases, uncertainties on the branching ratios and half-lives of the nuclei are so small that they can be neglected. The minimum detectable activities (MDAs) (Moilanen 2007) for the most commonly detected artificial nuclei, ^{137}Cs and ^{60}Co have been determined to be of the order of 100 Bq. MDAs are roughly factor of two smaller in Ironroom. The minimum detectable activities for the most of the common radionuclides found in nuclear power plants, industry or radiopharmacy are sufficient from the point of view of radiation protection. As the MDA depends on the background level it should be determined when the background changes. In emergency situations the MDAs can be higher due to the higher background from the environment. However, as the MDA increases as a function of square root of background rate, the equipment will be able to handle it. *In-vivo* monitoring can also be used to follow prolonged exposure e.g. after a nuclear or radiological accident. Presently, the efficiency calibration assumes that the radionuclides are homogenously distributed in human body.

Mathematical calibrations and new set-up

STUK has launched the project in order to upgrade the measuring units. The main goal of the project is to obtain better treatment for the radionuclides that are not homogenously distributed in the body, for instance freshly inhaled radionuclides in the emergency situations. Other goals are to improve ergonomics for the person being measured and to gain more information about the location of the contamination in the body in the cases where intake path is not known. In addition, lower detection limits for some specific nuclei (like ^{241}Am, ^{123}I) which emit only low energy (<200 keV) gamma rays will be necessary to achieve. To begin with, Monte Carlo simulations will be used with voxel phantoms. The code selected is MCNPX (Monte Carlo N-Particle eXtended, Pelowitz 2005).

The simulations were started by reproducing the calibration for the present set-up where good measurements are available (Figure 4). For a new set-up, different possibilities were considered and ordinary chair geometry was chosen for a further study (Figure 5).

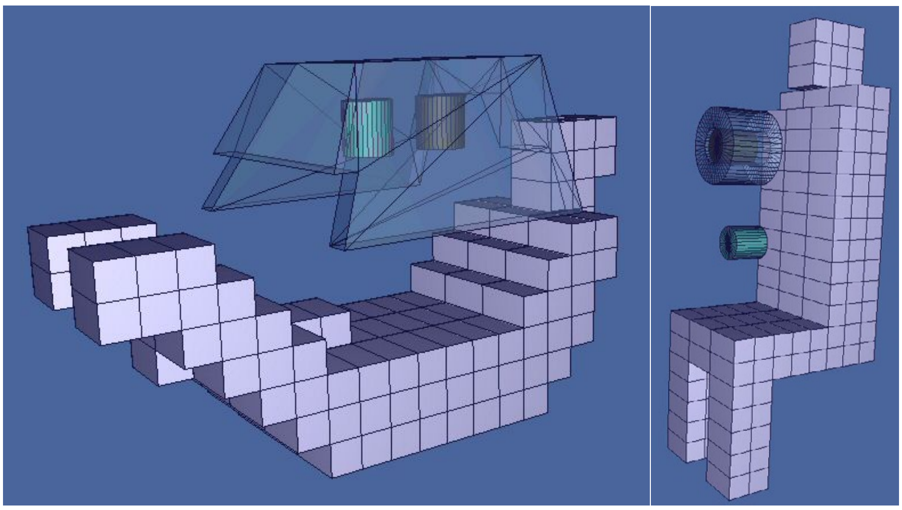

Figure 5. Models for MCNPX simulations. The present mobile unit set-up is on left and the new set-up is shown on the right. Transparent part is the lead made background shield. In the new set-up, shield of the lower detector is removed from the picture.

The background shield will be made of lead (not shown in Figure 5). There will be 5 cm of lead at the back, top and bottom and front side is open for a measurement. Cylindrical collimators around detector crystals can be moved along the axis, allowing fine tuning of the spatial resolution.

Figure 6 below presents calculated detection efficiency for a present and a new set-up in mobile unit. The overall efficiency with the new set-up will be better by a factor of 1.7 as the detectors can be closer. However, the detection efficiency will improve only for the region below the detectors. This can be compensated by using the sum spectrum for species like ^{137}Cs, which is known to be evenly distributed. For non-even distributions localisation of the activity can be done by comparing the measured two spectra. As can be seen in Figure 6, spatial resolution will be just enough to determine whether the activity is in lungs only or whether it has already been transferred further, for instance to liver as ^{60}Co would do.

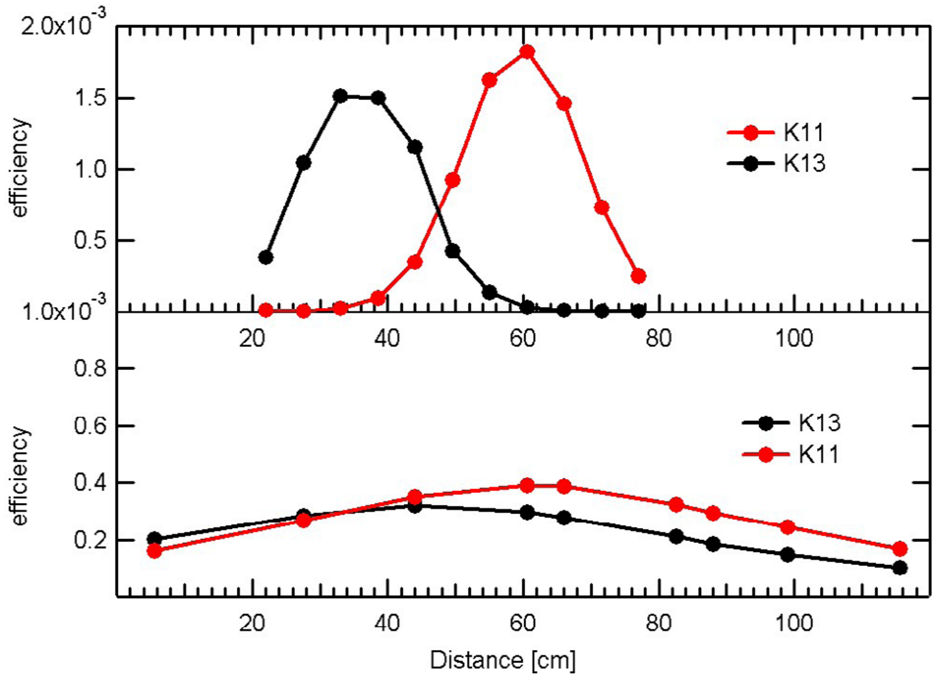

Figure 6. MCNPX simulation results for a polyetylene brick phantom. Each point has been calculated by placing 30 cm long cylinder of ^{137}Cs in different locations perpendicular to longitudinal axis of the phantom. The top curve displays the new set-up and the lower is for the present one.

Conclusions

In-vivo measurements are used to assess the internal exposure of radiation workers as well as the exposure of the public. The whole-body counters in STUK fulfil the requirements defined by the dose registration limits of radiation workers. In emergency situations it will be necessary to perform also direct measurements on people for reassurance of the public even if such measurements would not be necessary from a strictly radiation protection point of view. The new measurement unit will provide fast and reliable method for both screening and dose assessment purposes. The gamma ray detection efficiency for the whole energy range will be greatly increased. A significant improvement will be the new feature of localisation of the internal contamination. In addition, it will give more precise information about possible ^{131}I accumulation in the thyroid. The new set-up presented above will be studied further in STUK. Calibrations with well defined calibration phantoms need to be performed before commissioning.

Abstract

Chest wall thickness is a major quantity for the calibration of lung counting detector systems. A method for the determination of chest wall thickness of anthropometric voxel models is introduced and applied. The computer-aided method was compared successfully with mechanical measurements and found valid within small error ranges. This method allows the generation of three-dimensional, colour-coded profiles for visualisation of tissue thicknesses overlying an organ of interest. Furthermore Monte Carlo simulations of lung counting scenarios involving two germanium detectors were performed to show the performance of the method with a selection of voxel models.

Introduction

Chest wall thickness – an important counting efficiency calibration parameter for *in vivo* measurements

The detector efficiency for *in vivo* measurements of low energy photon emitters in the thorax (e.g. lung or liver) depends strongly on chest wall thickness (CWT). Hence, CWT is an important calibration parameter for counting efficiency. Systematic errors for the determination of counting efficiency can be reduced if the accuracy of the estimation of CWT can be improved.

The first challenge is a clear definition of CWT. For lung counting, the distance from the anterior skin surface of the thorax to the pleura (thin skin surrounding the lung) can be taken as a definition for CWT. However, this distance is not constant throughout the chest, but CWT can be averaged in the region that is covered by the detector. Consequently, position and size of detectors are important parameters for this definition.

Sumerling and Quant (1982) suggested a standard geometry for placing two scintillation detectors, one on the left, and one on the right side of the anterior chest. The centre of the detector was positioned in the intercostal space of the second and third rib. They performed ultrasound measurements on each side in the area of a circle with the detector's diameter to determine CWT.

Physical phantoms are used for calibrating counting efficiency. For example, the LLNL Torso Phantom (Griffith *et al.* 1978) has a set of overlays that can additionally be put onto the chest for the determination of counting efficiency. This way, counting efficiency can be described as a function of CWT.

Chest wall thickness of anthropometric voxel models

Anthropometric voxel models are increasingly used to calculate counting efficiencies for *in vivo* measurement systems numerically with radiation transport simulations based on Monte Carlo methods. An MCNPX (Hendricks *et al.* 2005) based Monte Carlo simulation environment for the partial body counter at KIT has been developed and validated (Hegenbart *et al.* 2009). Simulations can help to investigate counting efficiencies of radionuclides incorporated in arbitrary organs that might not be available in the laboratory's inventory. Thus, sensitive parameters can be identified which is helpful to develop strategies to reduce systematic errors of classical counting efficiency calibration.

Using voxel models can in principle help to represent an individual better than an ordinary physical calibration phantom, especially, if the model is customisable. Several novel techniques have been developed and allow generating customised anthropometric voxel models. The generation of customised voxel models for better representation of individuals should be based on biometric data of the individual. Hence, there is a demand to develop methods for measuring biometric data of voxel models in virtual reality. Those methods need to be comparable to conventional methods in reality. A previous example for this was the measurement of chest circumferences and cup sizes of a series of female voxel models (Hegenbart *et al.* 2008).

Since CWT is a sensitive biometric parameter for counting efficiency, it is meaningful to develop a method to determine the CWT of anthropometric voxel models.

Material and methods

Determination of CWT of voxel models

The determination of the CWT of anthropometric voxel models is based on measuring and averaging distances of body surface (skin) voxels to voxels of the target organ, i.e. the lung in case of lung counting.

The method is inspired by the determination of CWT with ultrasound, as for example presented by Sumerling and Quant (1982). The surface voxels are chosen according to a given detector diameter and its position and alignment onto the chest. The voxels lie in a cylindrical projection of the diameter of the detector along its axis onto the body surface. Starting from the surface voxels, the shortest distance – often perpendicular to the surface – to the nearest voxel of the organ of interest is determined. Depending on detector diameter and voxel resolution, hundreds to thousands of surface voxels are selected. Single distances x_i for each voxel are stored in a list.

The arithmetic mean can be calculated with the distances x_i from the list. Moreover, after defining a linear attenuation coefficient – suitable for the concerned tissue and photon energy – the *effective* CWT (Dean 1973, Kramer and Hauck 1997) can be calculated.

$$CWT_{eff} = -\frac{1}{\mu}\ln\left[\frac{1}{n}\sum_{i=1}^{n} e^{-\mu x_i}\right]$$

CWT_{eff}: effective chest wall thickness (mm)

n: number of list entries

x_i: distance i (mm)

μ: linear attenuation coefficient (mm^{-1})

The effective CWT takes the exponential attenuation law into account. Short distances are given higher weight, since photons can pass through them more likely. The higher the photon energy considered for the attenuation coefficient, the closer the effective CWT gets to the arithmetic mean. For photon energies starting from 60 keV, the effective CWT can be approximated with the arithmetic mean (Kramer 1999).

The introduced method for determination of the CWT of voxel models is integrated in the in-house developed software Voxel2MCNP (Hegenbart 2009). This software is able to generate and visualise *in vivo* measurement scenarios and furthermore to prepare and evaluate MCNP(X) Monte Carlo simulations with voxel models. The viewer of the software allows the generation of three-dimensional, colour-coded illustrations of the local distribution of the tissue thickness, i.e. a CWT-profile of a voxel model. This information can be used for optimisation of detector position and helps judging if a voxel model keeps a reasonable anatomy after customisation.

Validation of the method

The *in vivo* Measurement Laboratory (IVM) at KIT has a copy of the LLNL Torso Phantom (Griffith *et al.* 1978). The thicknesses were measured mechanically with a calliper within 14 cm diameter from the centre of the three concentric markings on the chest cover and on each overlay defining the detector position for lung and liver measurements. The physical phantom was compared with the voxel model of KIT's LLNL Torso Phantom, which was generated from computed tomography (CT) images performed at the Vincentius Kliniken of Karlsruhe by Prof. Dr. J. Lehmann and his team. The CT images were segmented and successfully used to validate Monte Carlo simulation of an *in vivo* measurement scenario (Hegenbart *et al.* 2009).

The mechanically measured data were compared to the corresponding CWT data obtained from the computer method from the voxel model. Furthermore, a comparison with effective CWT values from literature (Taylor 1997) was performed.

Monte Carlo simulations

Monte Carlo simulations of lung counting scenarios have been performed to investigate the relationship of voxel model's CWT and the corresponding counting efficiency. The voxel models used in this investigation were the

- MEET Man (Sachse *et al.* 1996) and Voxelman (Zubal *et al.* 1994) with organ density and material data from ICRP 89 (ICRP 2002),
- in-house developed voxel models of the LLNL-Phantom without and with four overlays with measured organ densities and materials specified by the manufacturer,

- LLNL-Phantom of the EURADOS Intercomparison on Monte Carlo modelling (Broggio 2009),
- ICRP Adult Male (ICRP 2009), and
- Godwin (Zankl *et al.* 2005) and Frank (Petoussi-Henss 2002) of HMGU.

With these voxel models *in vivo* counting scenarios were generated involving ^{241}Am-photon-emissions (Schötzig and Schrader 2000) homogeneously distributed in all lung voxels. The voxel models lie in supine position on a model of the examination table of KIT's partial body counter. In this scenario two detectors were placed on the chest using the validated model of the *in vivo* Measurement Laboratory's Canberra XtRa HPGe detector with a diameter of 7.5 cm (Marzocchi *et al.* 2009). The detector was inclined by 25° in order to be parallel to the skin surface of the chest with about 1 to 2 mm distance. The detector axis was centred on the third rib, 7 cm away from the centre of the sternum. This setup was symmetrical for one detector on the left and on the right side.

The CWTs (arithmetic means) of these voxel models have been determined with the above introduced method considering the detectors' positions and diameters. A CWT profile was generated for all phantoms.

MCNPX 2.6 (Hendricks *et al.* 2008) was used to simulate 10 million photon histories for each voxel model. The voxel model syntax for the MCNPX-input-file was generated with Voxel2MCNP according to recommendations by Taranenko *et al.* (2005). The code was run in MCNPX's mode p (photon transport only). The electron transport mode was skipped, because no significant differences were found in test calculations. Thus, it was possible to save computer time. The cross-section library PLIB=04p for photons and ELIB=03e for electrons were used.

MCNPX's F8 tallies were assigned to the active HPGe-crystal volumes. The counting efficiency was calculated in the energy range from 57.5 keV to 61.5 keV, which is about +/-1.5 FWHM. The net counting efficiency was determined subtracting the background with the trapezoidal rule from the full absorption peak of the 59.5 keV gamma line of ^{241}Am. Results from both detectors were summed up.

Results and discussion

Validation of the method

Table 1 shows a comparison of mechanically measured CWT values and calculated values from the corresponding voxel models. Both columns show the effective CWT with μ/ρ=0.93 cm^{2}g^{-1} for polyurethane tissue equivalent material with a muscle/adipose ratio of 50/50 for the overlays and μ/ρ=1.13 cm^{2}g^{-1} for 100% muscle for the chest cover, respectively, both at 17 keV (NIST 2009). The comparison of effective CWT values was preferred. The first reason for this was, to have a more strict comparison, which takes variances stronger into account. The second reason was, to make a comparison with literature values.

The values are in agreement with a maximum deviation of 1.0 mm. The values for the chest cover show the largest deviations. This is can be explained by the comparably large variances of the single measurements. 2σ-errors were estimated for the calliper measuring (0.1 mm) and for position inaccuracies (0.95 mm) on the voxel model. The method for determination of effective CWT of voxel models can be taken as valid, considering an error of roughly 1 mm.

Most measured and calculated values lie in the range of values reported in the literature. Some phantom values are smaller than those reported by Taylor (1997). The investigated LLNL phantom at KIT is a third-generation, commercial version and might not be comparable with the second generation investigated by Taylor (1997). Manufacturer's specifications are unknown.

Table 1. Effective CWT of the mechanical measurements in the three concentric markings (liver, left and right lung) of the LLNL phantom of the phantom compared with the calculated values of the corresponding voxel model (Gün 2010). The obtained values are faced to literature values (average and range) from five laboratories, which owned the second generation of the LLNL phantom (Taylor 1997).

Configuration (concentric marking)	CWT_{eff} (mm) of phantom	CWT_{eff} (mm) of voxel model	Absolute deviation (mm)	Literature average values (range) (mm)
Chest cover (left lung)	15.4	16.2	0.8	16.4 (15.6-17.2)
Overlay B1 (left lung)	6.1	6.1	<0.1	6.6 (5.4-8.9)
Overlay B2 (left lung)	12.1	12.5	0.4	12.6 (11.2-14.5)
Overlay B3 (left lung)	17.2	17.3	0.1	17.6 (16.4-19.0
Overlay B4 (left lung)	24.0	24.2	0.2	24.7 (24.2-26.1)
Chest cover (right lung)	14.0	15.0	1.0	14.6 (13.3-15.0)
Overlay B1 (right lung)	6.3	6.5	0.2	7.0 (6.0-9.0)
Overlay B2 (right lung)	12.3	12.1	0.2	12.7 (10.8-13.8)
Overlay B3 (right lung)	17.0	17.4	0.4	17.9 (17.4-19.6)
Overlay B4 (right lung)	24.8	25.3	0.5	25.6 (24.8-27.2)
Chest cover (liver)	13.6	13.2	0.4	14.1 (12.9-15.2)
Overlay B1 (liver)	6.2	6.2	<0.1	6.8 (4.4-9.9)
Overlay B2 (liver)	11.2	11.1	0.1	11.8 (9.5-14.4)
Overlay B3 (liver)	16.4	16.3	0.1	18.1 (16.4-20.6)
Overlay B4 (liver)	24.5	24.4	0.1	24.7 (23.7-27.3)

CWT profiles

Figure 1 shows colour-coded CWT profiles (skin-pleura distance) of a selection of three voxel models. The profile of KIT's LLNL voxel model shows strong asymmetric shading due to the position of the heart, which covers partly the left lung lobe. This uncovers some limits of the LLNL phantom's anatomy in terms of realism. The other two models exhibit just a slight asymmetry. The ICRP Adult Male's chest wall is coloured partly in dark red, because he is less obese compared to the MEETMan. The red zones are suitable for placing detectors in order to get high count rates. Notable are local CWT minima near the second rib and at the lower end of the lung lobes. Such coloured profiles can be generated for every organ (e.g. the liver).

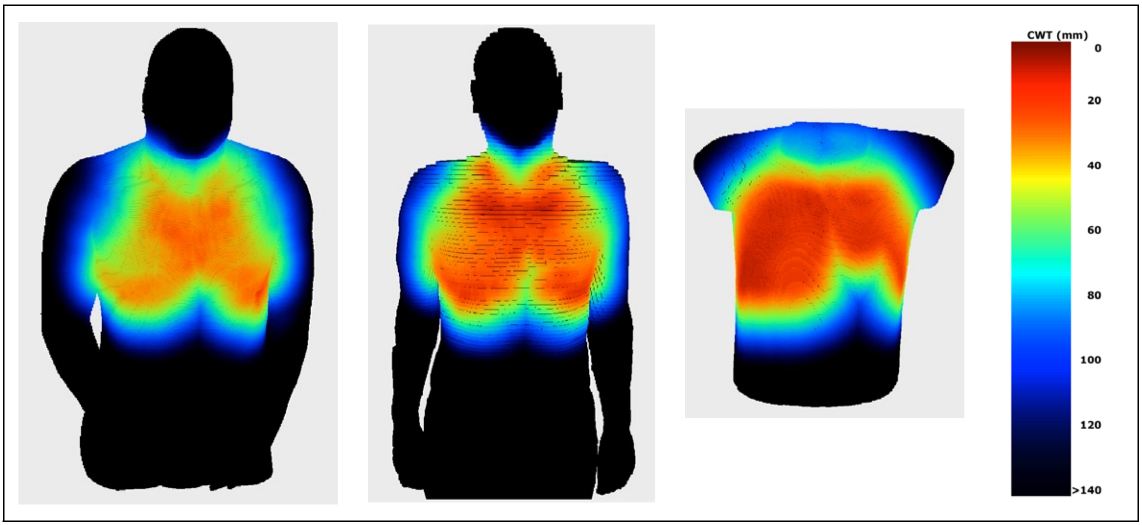

Fig. 1. CWT profiles of the MEETMan (left), the ICRP Adult Male (middle) and KIT's voxel model of the LLNL Phantom without overlay (right). Deep red colour indicates a small CWT (see legend, right). Larger CWT are indicated with the transition to shades of green. Dark-blue and black areas are not meaningful, since the distance to the lungs is too high and angles are not perpendicular to the skin surface anymore.

Monte Carlo simulations

Figure 2 shows the summary of the results. The left and the right detector's counting efficiencies for a ^{241}Am-lung-counting scenario were summed and plotted over the determined CWT (arithmetic mean of left and right) for each voxel model. Similar to routine *in vivo* measurements, the KIT's five LLNL voxel models were used to determine an exponential calibration curve. As a first approximation, the exponential calibration curve is suitable for most voxel models, except the ICRP Adult Male and Godwin. Their counting efficiencies are considerably higher. Yet unknown, the responsible parameters for the observed higher efficiencies need further investigation. The EURADOS LLNL voxel models P0 and P4 lie on the curve as expected. Since air cavities under the chest cover of these models were not considered, CWTs are higher and hence, counting efficiencies are lower compared to the corresponding KIT LLNL models. Two resolutions of the MEETMan were also investigated and compared. The plot shows that CWT and efficiency differ only slightly within the error bars.

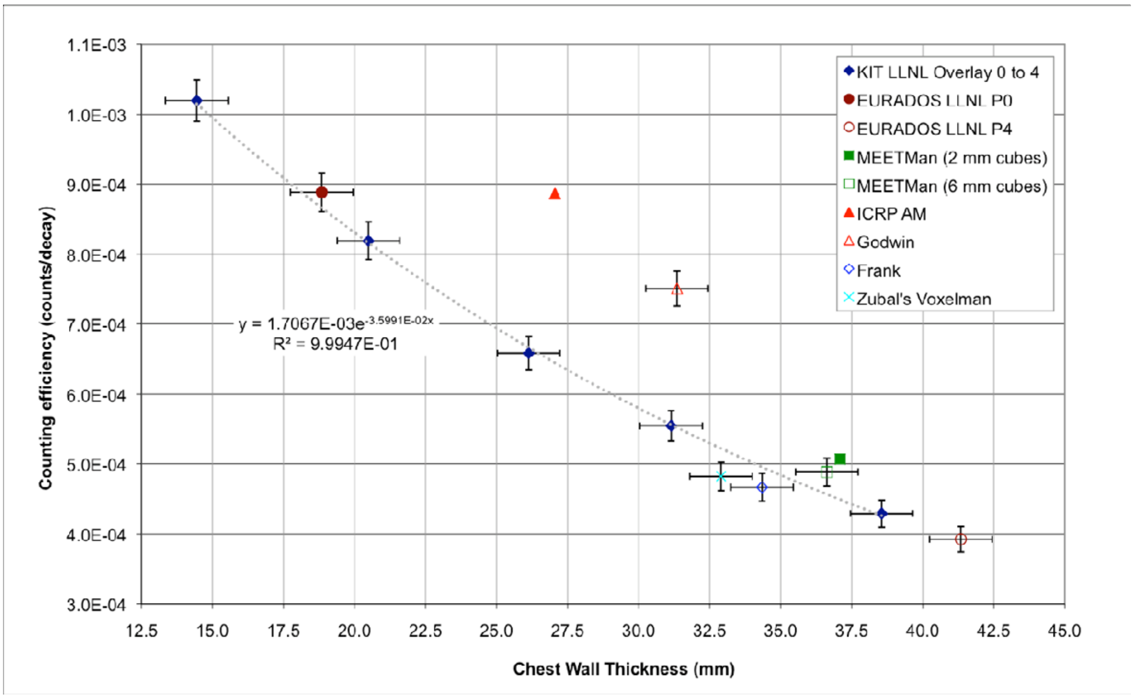

Fig. 2. Lung counting efficiencies calculated with MCNPX plotted against the determined CWT of various voxel models. An exponential fit (dotted gray line) was performed with Microsoft's Excel with data from the five KIT LLNL models (solid diamonds). The formula and the R2-coefficient are given in the plot. The horizontal and vertical error bars indicate the error (2σ) of the CWT and the net counting efficiency in the ROI (2σ).

Conclusions

The authors presented and validated a method for determination of CWT of anthropometric voxel model with an error of about 1 mm.

This method can also be used to generate colour-coded, three-dimensional CWT-profiles. The profiles are helpful for verifying the realism of anatomy of voxel models, i.e. models of man-made phantoms or customised/adapted models. Furthermore, it gives useful information for detector positioning.

An exponential calibration curve depending on CWT was generated from KIT's LLNL voxel models for a typical ^{241}Am-lung counting setup with germanium detectors. As a first approximation, the curve can be used for counting efficiency calculation for most voxel models considered in this investigation. The ICRP Adult Male and Godwin show that there are other important parameters that play a role in the determination of lung counting efficiency. Thinkable is another important quantity in the assessment of thoracic deposits of nuclides emitting low energy photons: the composition of the tissue in the anterior chest wall, i.e. the fraction of muscle, adipose and bone tissue. Next steps will involve the development of algorithms, which determine such fractions in voxel models.

Acknowledgements

The authors would like to thank Mr. Olaf Marzocchi of KIT for providing the HPGe detector model.

Abstract

Some Actinides like Americium are bone-seekers, and according to their biokinetics are retained in the skeleton after an intake. Because of the radiosensitivity of red-marrow and endosteum cells, the assessment of the bone activity is an important matter to take into account. *In vivo* counting of bone seekers is usually performed at the skull or at the knee, since the attenuation of radiation is here limited.

The USTUR (U.S. Transuranium and Uranium Registries) disposes of a unique physical phantom containing the left half of the skeleton of a donor significantly contaminated by ^{241}Am. The left leg phantom, containing bones from hip to foot, embedded in muscle equivalent plastic, has an activity of 1026 Bq. This phantom was measured in three European *in vivo* facilities and one Canadian laboratory; Monte Carlo (MC) simulations were also performed to assess the reliability of numerical calibration based on voxel phantoms.

Using different Germanium detectors the same efficiency pattern was found by participants, when counting positions were comparable. A sharp increase of counting efficiency is found at the patella level, about 10 times higher than at other locations, at this level a 5 cm displacement of detectors can result in 50% change in efficiency. Measurements on each side of the leg show a significantly different efficiency pattern.

A voxel phantom was build after acquisition of 234 CT scan images and used to simulate the measurements. Despite the gross feature of the efficiency pattern is reproduced by MC simulations, discrepancies larger than 50% have been found for some measurements. Several factors can explain these discrepancies: difficulties in building the voxel model and in reproducing the measurement conditions, uncertainty about the total activity and the activity distribution in bones.

Based on this study recommendations will be given to ensure reliable measurements, the efficiency obtained in this study will also be compared with other relevant data.

Advanced Monitorin In Mixed Radiation Area – AMIRA

Saphymo GmbH, GERMANY

Advanced Monitoring In Mixed Radiation Area – AMIRA

AMIRA is the result of a research project in cooperation with the Radiobiological Institute of the University of Munich, a workgroup of the University of Saarland and Saphymo GmbH. An active, universal applicable dosimeter for radiation protection has been developed providing precise neutron and photon measurements within mixed unidentified radiation fields. AMIRA uses a miniaturized tissue equivalent proportional counter tube (TEPC), simulating a microscopic volume of 1 µm diameter. Using a microscopic detector offers the advantage that for each event of energy deposition not only the proportion of dose but also the lineal energy, the micro dosimetric analogon of the LET, can be determined. This allows assigning to each individual event the correct quality factor for the determination of the equivalent dose. Thus, a separate indication of neutrons and photons is not really required for radiation protection applications although it is principally possible.

The energy response of most conventional instruments is often varying by a factor of 10. Measuring results of PTB Braunschweig – Germany and IRSN Cadarache – France prove an extremely high energy response within the entire measuring range.

The latest version of the measurement device is based on reduced size and weight, disposes of an economized MCA with more than four decades dynamic measurement range and suppresses microphonic effects. The software saves the LET spectrum, calculates and saves the total dose according to ICRP60 as well as the neutron/photon dose by LET separation. Due to the small, compact construction it could be achieved for the first time to make use of the TEPC technology for applications everywhere where there is occupational exposition. Examples can be found with aircrew dosimetry or in the complete spectrum of the nuclear fuel cycle for the determination of the personal dose and dose rate.

Introduction

The exact measuring of the exposure rate gains more and more importance due to growing activities of human beings within radiation exposed areas (i.e. aviation, astronautics, medicine, nuclear techniques, etc.). People are mostly confronted with mixed radiation exposure composed of charged particles, neutron and photon rays. Therefore, at workplaces being subject to radiation exposure dosimeters for measurement of radiation, dose rate and environmental surveillance are applied.

Common dosimeters using semiconductor detectors cannot determine the correct proportion of neutrons and photons of the equivalent dose, although especially the neutron exposition is known to have a quite high injury potential to humans. This results from the great variety of interacting processes and their distinctive dependence from material composition and neutron energy. Further, the high and energy depending RBW (relative biological effectivity) requires the discrimination of neutrons and photons with most of the detector conceptions.

This fact as well as the growing interest in active electronic dosimeters providing lower detection limits as passive equipment, more flexibility in use and real-time monitoring features (e.g. alarm function) generated the motivation for the development of a new personal dosimeter. While official dosimetry is still exclusively applying passive detectors the in-plant use of electronic dosimeters for monitoring tasks is increasing. It is expected that the passive dosimeters will be replaced by electronic units in the medium term.

Along with the described AMIRA development the correct measurement of neutron radiation using a personal dosimeter based on the Tissue Equivalent Proportional Counter (TEPC) technology should be realized. Neutrons and photons within mixed unknown radiation fields should be accurately detected using an active handy measuring device.

Material and methods

The most important challenges with respect to this project were the reduction of mass and size of a sufficiently sensitive TEPC, the improvement of the gas booster's long-term stability as well as the elimination or reduction of the sensitivity against acoustic noise and shock (microphony) which is inherent to all TEPCs. Additionally, a miniaturization of all required electronic components and the reduction of power consumption should help to optimize the use of the new instrument as personal dose meter.

Apart of the detector the measuring system also includes a high-voltage supply, a charge sensitive pre-amplifier, a 4 decade multi channel analyzer, a display, PC-interface and power supply (rechargeable batteries). All components are designed for minimum power consumption.

Based on a tissue equivalent proportional counter (TEPC) with a simple geometry and modular design a plastic (A150) is used which due to its interaction with neutrons simulates the characteristics respectively the features of a biological tissue with a microscopic volume of 1µm diameter. The Radiobiological Institute of the University of Munich (SBI) already proved the basic technical feasibility of such detectors.

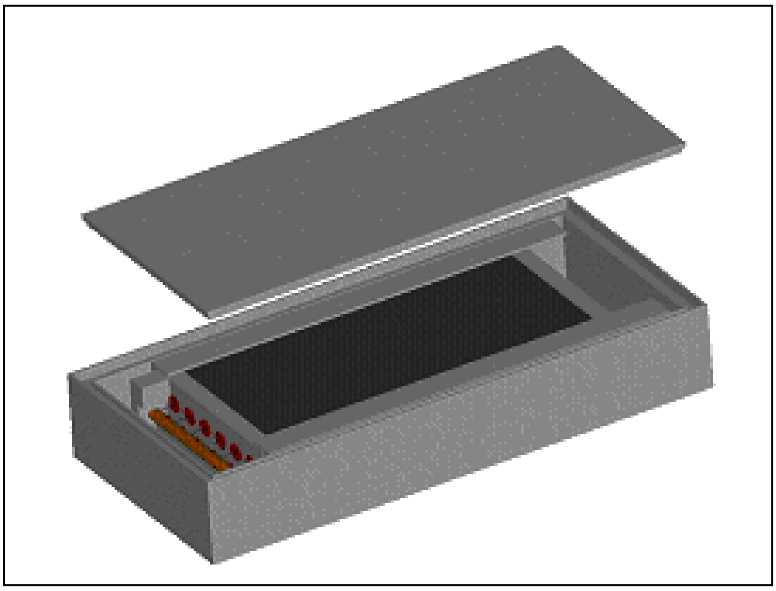

Fig. 1. Miniaturized multi-element TEPC (Tissue Equivalent Proportional Counter).

Within applications in the radiation protection area tissue equivalent micro dosimetric proportional counters offer the great advantage that they are simulating the energy deposition within the tissue - that means the so called lineal energy - the micro dosimetric analogon to the LET (= linear energy transfer) is determined for each individual event of energy deposition. This measuring method is therefore able to allocate a quality factor to each given radiation contribution. It therefore allows giving evidence about the biological radiation effect within mixed radiation fields (determination of equivalent dose).

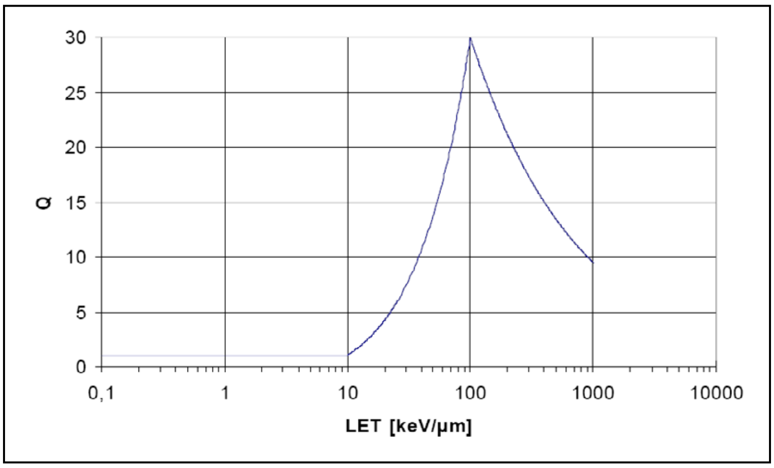

Fig. 2. Quality factor Q as function of LET L [1].

Equivalent dose and dose rate are calculated in a five second interval and displayed. Determination of absorbed dose contributions of neutron and photon radiation is not required as the different radiation components are automatically evaluated according to the respective LET. Analogous to each measured impulse a weighting factor Q according to ICRP 60 is assigned to allow to indicate the result using the measuring categories $H_p(10)$ respectively $H^*(10)$. Fig. 3 shows the LET spectrum of Cs-137.

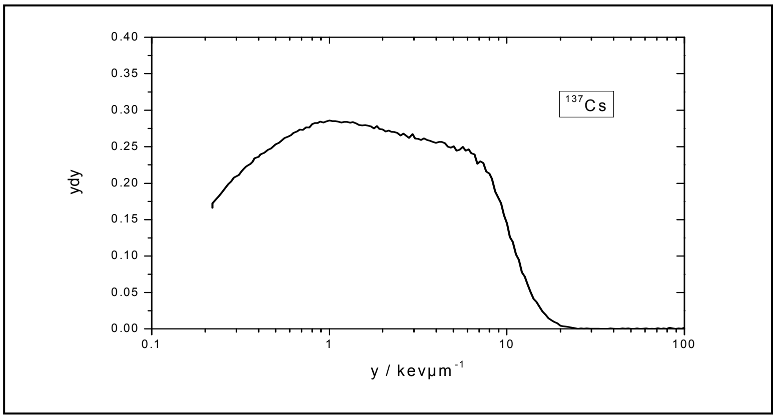

Fig. 3. LET spectrum for Cs-137.

An alarm function with simply settable dose rate thresholds is available. The accumulated event spectrum can be downloaded to a PC and can then be displayed and analysed in detail.

Fig. 4 shows a block diagram of the miniaturized electronics. The signal received from the TEPC reaches the pre-amplifier as a negative slope. This charge sensitive component is acting as trans-impedance amplifier and is adjusted to an optimal signal-noise-ratio. Subsequently, the signal is sampled by a fast high resolution ADC and transferred to a micro processor which registers the pulses using digital filter algorithms.

For dose meter configuration and data download the instrument provides an integrated RS-232 interface. The software running on PC also allows displaying the spectra of lineal energies – almost in real-time.

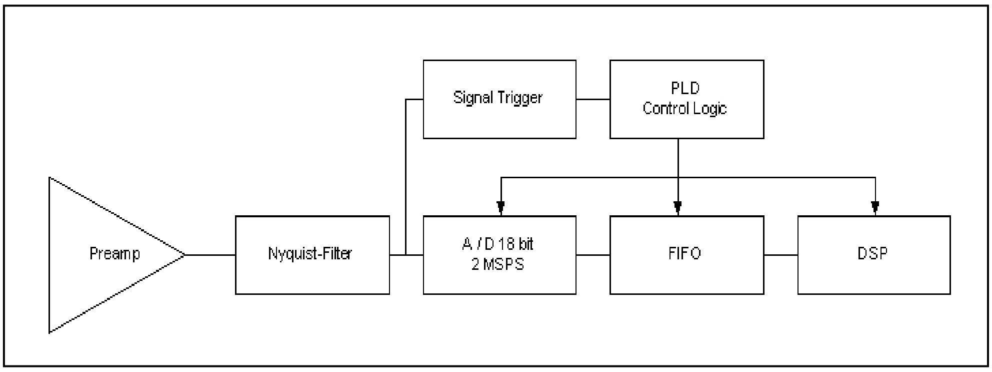

Fig. 5. Block diagram of the signal unit.

Results

Since the energy of neutron fields spreads over several decades the measuring technique is faced with a big challenge. The energy dependency of most of the commercially available measuring equipment is varying up to a factor 10 about this range. Fig. 5 is demonstrating that the new TEPC-design concept features an extremely high energy response across the entire field.

Simple method to determine ^{234}U and ^{238}U in water using alpha spectrometry

Vesterbacka, Pia; Pöllänen, Roy
STUK – Radiation and Nuclear Safety Authority, Laippatie 4, 00880 Helsinki, FINLAND

Abstract
A simple method was developed to determine the activity concentration of ^{234}U and ^{238}U in water using alpha spectrometry. The method is based on rapid evaporation of water, mounting the residue into a vacuum chamber of an alpha spectrometer, alpha particle counting and subsequent spectrum analysis using a novel analysis program known as Adam. The method was compared to liquid scintillation spectrometry and alpha spectrometry with radiochemical sample processing. Consistent results were obtained.

Introduction
In a nuclear or radiation emergency or in nuclear security there is a need for rapid and simple off-line and on-line analysis methods to detect radionuclide threat agents in water. Efficient tools are necessary especially when screening the samples with low and medium activity concentrations. Simplified methods have recently been developed for example for liquid samples (Semkow et al., 2009), swipe samples (Ihantola, 2009) and air filters (Pöllänen and Siiskonen, 2006). Nevertheless, there still room to develop the methods.

Radiochemical sample processing is often prerequisite for successful measurements in alpha spectrometry. However, the processing may be too tedious and time-consuming especially in the case when the analysis results must be obtained rapidly. In addition, operations in the field pose special requirements although the processing is typically performed in a fixed laboratory.

In the simple and rapid off-line method investigated here, water samples were evaporated and the residues were counted as such using alpha spectrometry, i.e. without further radiochemical sample processing. A novel spectrum analysis tool known as Adam (Advanced deconvolution of alpha multiplets) was used to unfold the alpha spectra. The results were compared to those obtained by scintillation spectrometry and alpha spectrometry with radiochemical sample processing. The main focus was put on the congruity of the results obtained using different methods.

Material and methods

Simplified method for alpha spectrometry

Eleven drilled well water samples were selected for the study. An aliquote of 15 ml was evaporated in Teflon container to stainless disc under IR lamp. After evaporation the alpha particles were counted in an alpha spectrometer (AlphaAnalyst, Canberra) for one week (Fig. 1). The samples were measured from shelf one, where the distance from the semiconductor (PIPS, Canberra) detector is 2 mm. The area of the detector was 450 mm^2.

After evaporation, the walls of the Teflon container were rinsed using 1M HCl acid to determine the influence of possible adsorption. The activity concentration of rinsing acid was determined using liquid scintillation spectrometry (Quantulus 1220, Perkin Elmer), and the final results were corrected accordingly.

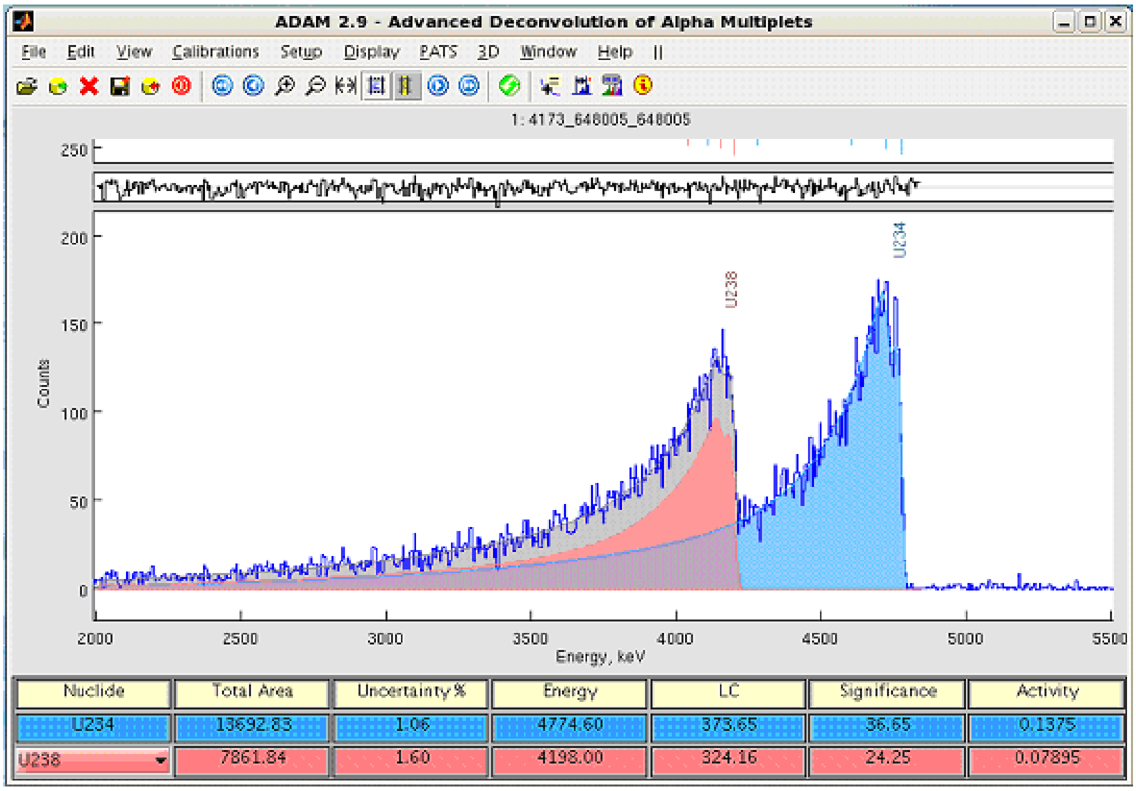

Fig. 1. Screen snapshot of an alpha spectrum from evaporated residue (sample ID 4173 in Figs. 2 and 3). The families of the peaks of ^{238}U and ^{234}U were fitted using Adam. All peaks are assumed to have the same shape. ^{234}U was not taken into account in the fitting. Reduced residual is shown at the top.

Gross alpha analysis

Sum activity concentrations were determined by liquid scintillation method (Salonen 1993, Salonen and Hukkanen 1997). The measurements were performed to screen the level of occurrence of the long-lived alpha-particle emitting (^{238}U and ^{234}U, ^{226}Ra and ^{210}Po) radionuclides in water. The samples (38 mL) were prepared by evaporating water into dryness with a freeze-dryer in a Teflon-coated polyethylene vial. The residues were dissolved in small amount of HCl acid and then scintillation cocktail Ultima Gold AB was added. The sample was counted one month after the sample preparation. During that time ^{226}Ra attains equilibrium with ^{222}Rn and its short-lived daughters. Gross alpha and beta are determined with a low-background liquid scintillation spectrometer (Quantulus 1220, Perkin Elmer).

Radiochemical uranium determination

Radiochemical processing of the samples was performed to determine the activity concentrations and ratios of uranium isotopes (Sill and Williams 1981, Sill 1987). The water samples were concentrated by applying iron scavenging. The precipitate was dissolved in concentrated HCl. Uranium was separated from other radionuclides by ion exchange method (using Dowex 1x8, 50/100 mesh). Uranium was co-precipitating with CeF3 for the alpha counting (AlfaAnalyst, Canberra). Minimum detectable activity was 2.0 mBq for one litre water sample and 180 hour counting. ^{232}U was used as a chemical yield tracer.

Spectrum unfolding using Adam

Adam is a spectrum analysis tool for alpha spectrometry (Toivonen et al., 2009). The peaks of a nuclide are treated as a family of individual peaks with energies and yields obtained from a nuclide library. Because of the omission of radioelement separation there may be a number of peaks of different radionuclides present in the spectra.

In the fitting the peaks of each radionuclide are treated as a group which enables efficient spectrum unfolding even in the case of complex alpha spectra. The shape of the peaks of the nuclides used in the analysis was same. Convolution of a Gaussian distribution with low-energy side double exponential tail is used in the fitting. The energy region considered in the analyses was 2–8 MeV. In the measurements the number of the channels was 1024 (5.9 keV per channel).

Uncertainty estimation

The activity uncertainty of the ^{232}U tracer used in the radiochemical analyses was 5%. The uncertainty for the geometrical detection efficicency used in the simple method was estimated to be 10%. The uncertainty (Δf) of the $^{234}U/^{238}U$ ratio between the simple method and the radiochemical determination was calculated according to the following formula

$$\Delta f = \sqrt{\left(\frac{\Delta x}{y}\right)^2 + \left(\frac{x \times \Delta y}{y^2}\right)^2} \times f\,, \qquad (1)$$

where Δx is the uncertainty of $^{234}U/^{238}U$ ratio in the simple method, Δy is the uncertainty of $^{234}U/^{238}U$ ratio in the radiochemical determination and f is the abovementioned isotopic ratio between the simple method and the radiochemical determination.

Results

The correlation between the activity concentrations obtained by the simple method to those determined by liquid scintillation method and radiochemical analyses was good (Fig. 2). The calculated correlation coefficients between the rapid method and gross alpha determination and radiochemical analyses were 0.98 and 0.99, respectively. For the method developed here the adsorption onto the walls of the evaporation container was on the average 8% (range 5–14%).

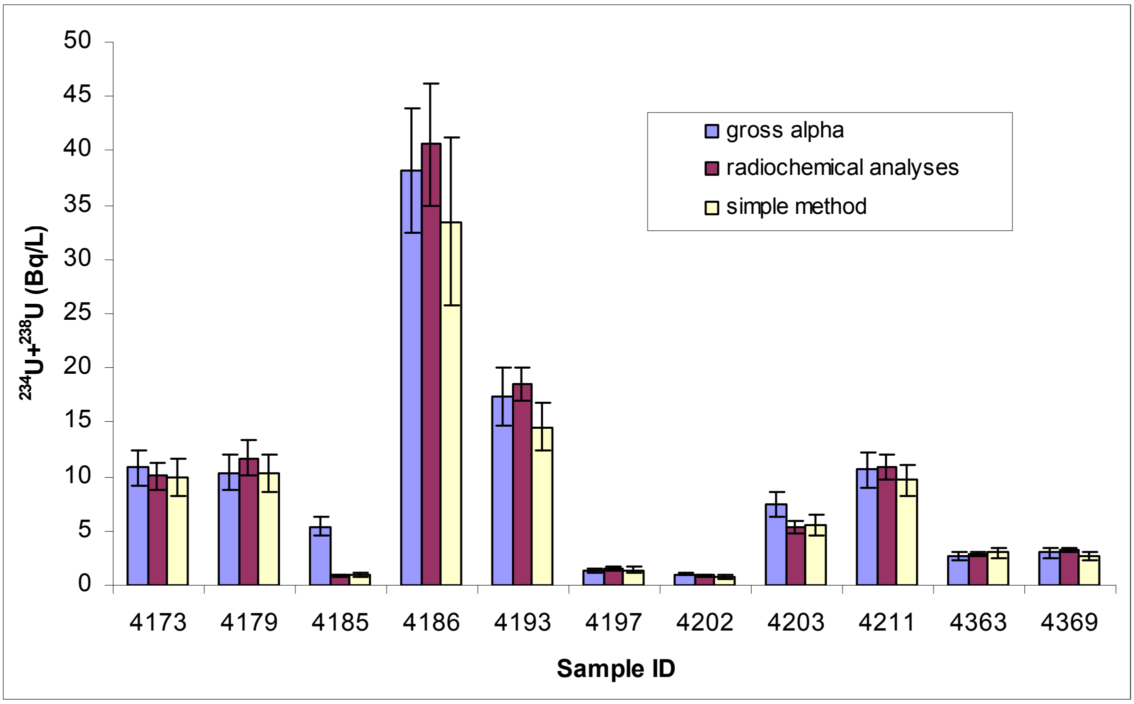

Fig. 2. Total activity concentration of uranium (^{234}U + ^{238}U) obtained from gross alpha determination, radiochemical sample processing and the rapid evaporation method developed here. Numbers in the x-axis refer to the sample identification number.

U isotope ratios obtained by the rapid method developed here and those obtained by radiochemical analyses were close to each other (Fig. 3). The difference was 10% on the average.

The presence on ^{226}Ra (main peak alpha energy 4784 keV is only 10 keV larger than that of ^{234}U) must be taken into account to unfold the spectra correctly. Among the 11 samples considered here there were three samples that contained notable amounts of ^{226}Ra (Fig. 4). Radium contribution was accounted for in the present analysis.

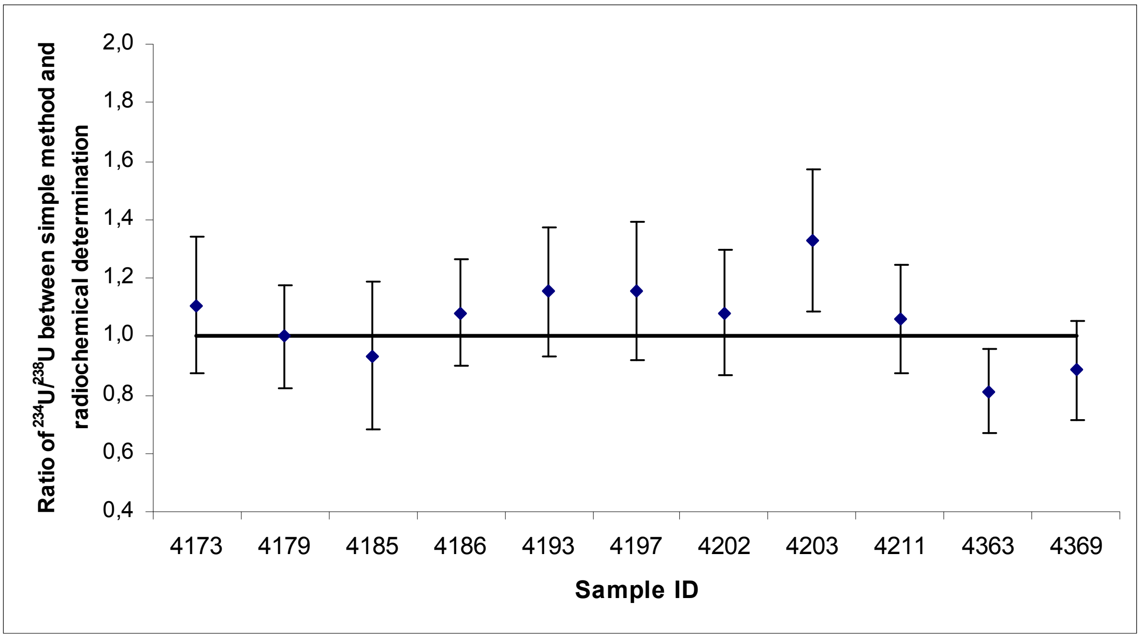

Fig. 3. ^{234}U/^{238}U activity ratio for different samples determined by alpha spectrometry with radiochemical sample processing relative to that of the simple analysis method developed here. Error bars refer to 2σ uncertainty and the numbers in the x-axis refer to the sample identification code.

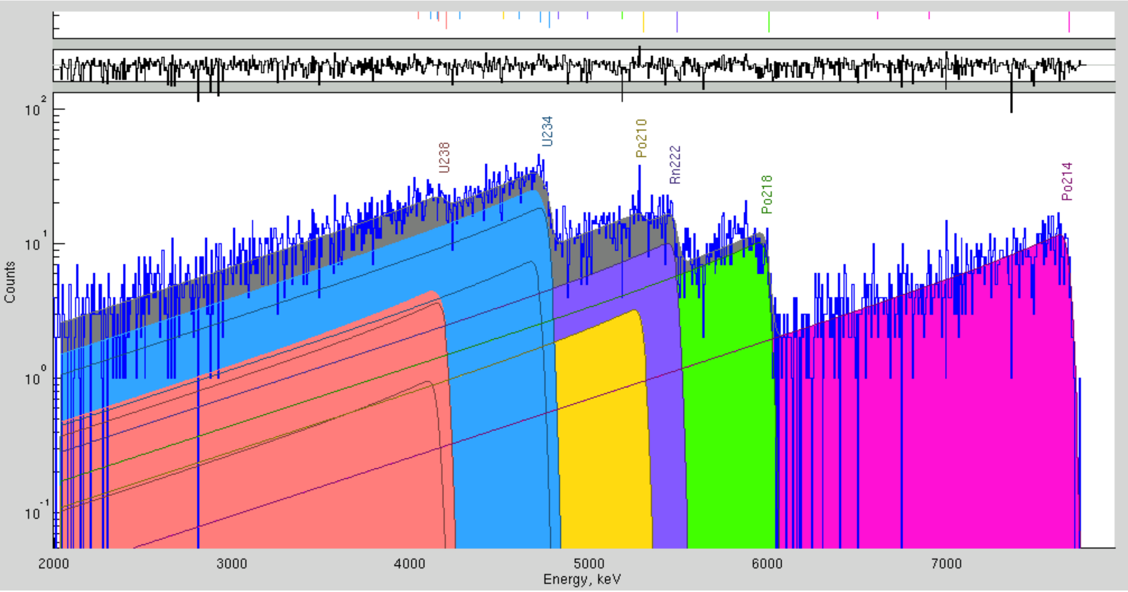

Fig. 4. Alpha particle energy spectrum from the sample 4185 (see Figs. 3 and 4) containing notable amounts of radon and its progeny (^{218}Po, ^{214}Po and ^{210}Po). Here (in this figure), the contribution of ^{226}Ra is not taken into account in the fitting.

Discussion and conclusions

Simplified sample manipulation with sophisticated analysis methods is advantageous when obtaining the results rapidly is of importance. However, straightforward water evaporation cannot entirely replace the radiochemical sample processing. This is because peak broadening in the alpha spectrum, caused by the absorption of the alpha particles in the evaporation residues, makes spectrum analysis challenging and, thus, influences the identification of the radionuclides. Too thick residues may even prohibit the analysis and since no radioelement separation is performed for the source, unequivocal nuclide identification may sometimes be impossible.

Despite of the drawbacks mentioned above the method developed here has many advantages: The sample manipulation is simpler, more rapid and inexpensive compared with radiochemical processing. If the samples could be counted without major sample manipulation (or using only minor processing) it gives the possibility to redirect resources in a laboratory towards sophisticated data analysis. This does not require expensive investment for the laboratory facilities. In addition, the information from several alpha-particle emitting radionuclides can be obtained in only one measurement.

In the present paper it was shown that simple and rapid water sample processing gave comparable results to those obtained with radiochemical processing and gross alpha analysis. The method gave information on all alpha-particle emitting radionuclides present in a water sample. Although the spectrum analysis software Adam is currently under evaluation it worked well and was capable to unfold complex alpha spectra reliably. Using the method presented here the sample preparation is simple and availability of the results is fast.

Abstract

The introduction of new and more beneficial diagnostic procedures combining CT and PET or SPECT is related to a rapid growth of medical exposures. The European collaborative project MADEIRA (Minimizing Activity and Dose with Enhanced Image Quality by Radiopharmaceutical Administration) within the 7th EURATOM FP aims to improve 3D nuclear medical imaging in terms of increase of spatial and temporal resolution and also of reduction of the radiation exposure. The project is organized in 5 work packages, which are identified as: WP1 assessment of clinical data, WP2 PET magnifier probe development, WP3 physics-based image processing; WP4 biokinetic and dosimetric modelling; WP5 training and dissemination activities. In particular in WP1 quantitative biokinetic data were collected in patients after administration of 18F-choline and those data were used to develop detailed compartmental models and to evaluate the internal dose to the patient. Moreover, the biokinetic models were used as a basis to define more efficient protocols for data collection (WP4). The collected tomographic images were used to test different reconstruction algorithms (WP3) including some newly developed ones for which a patent is pending. In addition a special phantom for checking image quality in nuclear medicine imaging was designed and also for this a patent is pending. WP2 deals with the construction of a PET insert probe. The different modules of the probe have been developed and their performances monitored, and the probe prototype is going to be tested in clinical conditions with the use of the developed reconstruction methods. Finally, training and dissemination activities include the organization of two training courses (Milano, November 2008; Malmö November 2009), and the Malmö Conference on Medical Imaging (June 2009) as well as the tutoring of graduate and doctoral students and young post-doctoral researchers.

^{177g}Lu produced with high specific activity by deuteron irradiation for metabolic radiotherapy

Bonardi, Mauro L.[1]; **Manenti, Simone**[1]; **Groppi, Flavia**[1]; **Gini, Luigi**[2]
[1] Università degli Studi di Milano & INFN of Milano, L.A.S.A. Laboratory, Physics Department, ITALY
[2] INFN of Milano, L.A.S.A. Laboratory, ITALY

Abstract

Nowadays metabolic radiotherapy is in constant progress and there is a range of new radionuclides (RNs) and radiopharmaceutical compounds on the market. Although the production of RNs is improved, often it is not possible to achieve high AS, even in NCA conditions, and sometimes long-lived radionuclidic impurities are co-produced.

^{177g}Lu (t1/2 = 6.734 d, β-emission 100 %, $E_{\beta- \, max}$ = 489.3 keV and E_{γ}= 208.4 keV) is one of the therapeutic γ emitting RNs, which is starting to find several applications in nuclear medicine, especially for metabolic radiotherapy of cancer and radioimmuno-therapy, thanks to its favorable decay characteristics (half-life of the order of few days, relative low energy of negatrons and gamma emission suitable for detection). Presently, the production of ^{177}Lu is carried out mainly in thermal nuclear reactor either in carried added (CA) form by direct neutron capture reaction ^{176}Lu(n,γ)^{177}Lu on enriched ^{176}Lu target, or by neutron capture reaction on enriched ^{176}Yb target, followed by negatron decay. This second method produces a high specific activity (AS) no-carrier-added (NCA) radionuclide, since ^{177}Yb decays to the ground state ^{177g}Lu only.

We started to study an alternative method for the production of ^{177}Lu by the deuteron activation of natural or enriched Yb targets. In order to optimize the irradiation conditions, the thin target yields were experimentally determinated in the energy range from the threshold up to 19 MeV. The thick target yields were measured in order to compare with the production yield by neutron activation route. The contamination from the long-lived metastable level was evaluated too. Moreover a suitable radiochemical separation of Lu radioisotopes from Yb target and from the contaminants was pointed out.

High-grade radiochemical analyses act as a basis for good assessment in radiation protection

Vesterbacka, Pia; Vartti, Vesa-Pekka; Heikkinen, Tarja; Ikäheimonen, Tarja K.
STUK – Radiation and Nuclear Safety Authority, Laippatie 4, 00880 Helsinki, FINLAND

Abstract
High-level risk assessment is mostly based on results of qualitative and accurate radioactivity measurements. Accreditation is one of the most effective tools to maintain high quality in the laboratory. This means, for example, proficiency of the personnel, documented working procedures, validated methods, participating in intercomparisons, maintenance of measuring equipment, workable laboratory information management system and continuous improvement of the working practices in the laboratory. By maintaining quality system and accredited determination methods STUK assures high-grade quality in radiochemical analyses that are used as basic data of doses in risk assessment in radiation protection work.

Introduction
High-level risk assessment is mostly based on results of qualitative and accurate radioactivity measurements. In future, the need for knowledge of low doses increases and raises requirements for research infrastructure and quality management in laboratory. It means documented working practices, traceability of the results, method validation, active participating in intercomparisons, good professional skills of personnel, stability of measurement equipment, proper data management, uncertainty estimations, plan of action in case of errors and continuous improvement of working practices. It also creates the need for accredited determination methods.

At STUK, development of a uniform and modern quality system started in 1997. Accreditation of laboratory processes was awarded by FINAS (The Finnish Accreditation Service) in 1999 and was renewed twice in 2003 and 2007 according to the European Standard EN ISO/IEC 17025. The accreditation field is “Test of radiation safety and related environmental sampling”. Fields of testing in radiochemical analyses are both artificial and natural radionuclides. Other fields of testing are gammaspectrometric analyses, direct measurements of people, airborne ^{222}Rn concentrations, chromosome analyses, sampling for control of radioactivity and method for local laboratories (NaI(Tl) detector).

STUK’s radiochemical analyses are carried out at two different locations, in the main office in Helsinki, and in the regional laboratory in Rovaniemi, in northern Finland. The facilities comprise a total of 50 laboratory rooms for pre-treatment of samples, radiochemical and biological treatment and analysis of samples as well as measuring rooms.

Radiochemical analyses are made from foodstuffs, all kinds of environmental samples, swipe and urine samples. ^{3}H and ^{222}Rn are determined without radiochemical separation using direct measurement by liquid scintillation spectrometry. Ion chromatographic extraction is used in ^{89,90}Sr and ^{210}Pb separation and ion exchange in ^{239,240}Pu, ^{238}Pu, ^{241}Am, ^{234}U, ^{235}U, and ^{238}U separation. ^{210}Po is determined via spontaneous deposition onto silver disk and measured using alpha spectrometry. Low-background proportional counter is used with ^{89,90}Sr measurements, liquid scintillation spectrometry with ^{90}Sr and ^{210}Pb measurements and alpha spectrometry with measurement of actinides. The radiochemical analyses are validated and their quality is maintained by participating regularly in intercomparison exercises and professional tests. All data from samples and measurements are stored either in LIMS or LINSSI databases in order to maintain traceability of the results.

By maintaining quality system and accredited determination methods STUK assures high-grade quality in radiochemical analyses that are used as basic data of doses in risk assessment in radiation protection work.

Analyses methods

Radiochemical determination demands nearly always digestion of the sample and elemental separation. Elemental separation is done because of the interference of other elements. Radiochemical analyses are made from all samples that can be digested into liquid form. Sample types analysed are environmental samples (e.g. sediments, soil, mushroom, various berries, lichen, moss, water), drinking water and food samples, excretion samples (urine), swipe samples and industrial products. Summary for the detection limits for radionuclides ^{90}Sr, ^{239,240}Pu, ^{3}H, ^{222}Rn, ^{226}Ra, ^{228}Ra, ^{234,235,238}U, ^{210}Pb, ^{210}Po, gross alpha and gross beta are given in Table 1.

Artificial radionuclides

Strontium (^{89,90}Sr)

Strontium separation from interfering nuclides is performed with extraction chromatographic resin, Sr resin (Triskem International) and measured either with low-background proportional counter (Risø or LB770 Berthold) or liquid scintillation counter (Quantulus). Proportional counter is used if both ^{89}Sr and ^{90}Sr are to be measured, liquid scintillation counter is used if only ^{90}Sr is to be measured. In proportional counter method the strontium is precipitated after Sr separation as a carbonate onto filter paper, and ^{89}Sr and ^{90}Sr together with its ingrowing daughter nuclide ^{90}Y are measured as soon as possible. After a minimum of 18 days, the ingrowth daughter nuclide ^{90}Y is separated together with stable Y from Sr and measured few times in a couple days. ^{90}Sr is calculated from the ^{90}Y measurements and ^{89}Sr from the first measurement by subtracting the ^{90}Sr contribution. In liquid scintillation method the ^{90}Sr is measured together with its ingrowth daughter ^{90}Y after a minimum of 18 days from the Sr separation (Fig. 1 (B)). The chemical yield is determined with inactive Sr and Y carriers. The efficiency in proportional counting is typically 40-50% and in liquid scintillation counting ~200%.

Plutonium ($^{239,240}Pu$)

The routine method for separation of plutonium is based on ion exchange with Dowex 1x4 anion exchange resin. Radioactive tracer ^{242}Pu is added and the sample is brought into solution either by wet ashing or microwave digestion. The sample is introduced into ion exchange column (Dowex 1x4, 50-100 mesh, in NO_3^- -form) in 8 M HNO_3, washed with 8 M HNO_3 and concentrated HCl, and the Pu fraction is eluted with conc. HCl + 1 M NH_4I solution. The plutonium is electrodeposited on stainless steel disc and counted with an alpha spectrometer. The chemical yield is determined with the radioactive tracer ^{242}Pu. The counting efficiency is approximately 35-40%.

Tritium (^3H)

Tritium measurements are made from water, urine and swipe samples. Water and urine samples are distilled for purification. Aliquote from a distilled sample is taken and UltimaGold uLLT scintillation cocktail is added to the 20-ml plastic scintillation vials. In Figure 1, the tritium spectrum of a water sample is presented. Swipe samples are measured with no pre-treatment. Pori-Vuoltee-groundwater is used for a background sample. Counting efficiency is determined measuring also a ^3H standard sample in every sample sequence. Activity concentration of tritium is determined with a low-background liquid scintillation spectrometer 1220 Quantulus.

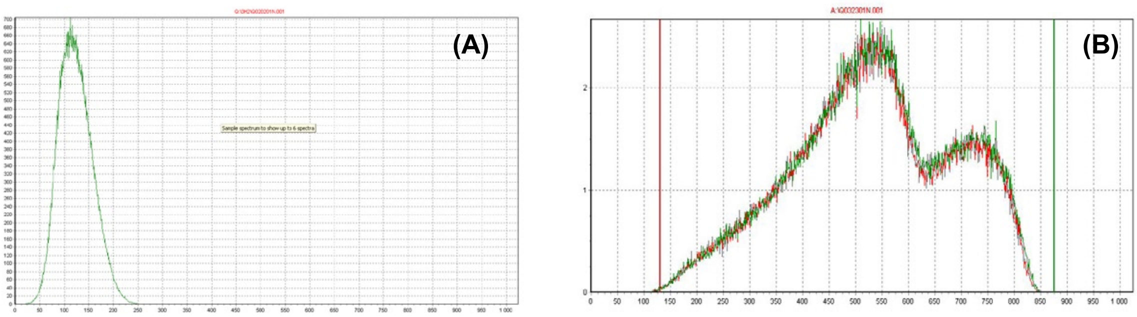

Fig. 1. Tritium spectrum of water sample (A). Strontium-90 spectra together with its ingrowth daughter ^{90}Y measured with Quantulus 1220 liquid scintillation spectrometer (B).

Natural radionuclides

Gross alpha and beta

The gross alpha and beta measurements are performed mainly in order to screen for the level of occurrence of the long-lived alpha-emitting (^{238}U and ^{234}U, ^{226}Ra and ^{210}Po) and beta-emitting (^{40}K, ^{210}Pb and ^{228}Ra) radionuclides in water. The sample (38ml) is prepared by evaporating water into dryness with a freeze-dryer in a teflon-coated polyethylene vial. The residue is dissolved in small amount of HCl acid and then scintillation cocktail Ultima Gold AB is added. The sample is counted one month after the sample preparation. During that time ^{226}Ra attains equilibrium with ^{222}Rn and its short-lived daughters. Gross alpha and beta are determined with a low-background liquid scintillation spectrometer 1220 Quantulus. An example of the gross alpha spectra of a drilled well water sample is given in Figure 2(A).

Radon (^{222}Rn)

Radon is measured in a homogeneous solution with a liquid scintillation spectrometer 1414 Guardian. The sample is prepared by adding 10 ml of water into a glass vial (equipped with a cap containing an aluminium foil) pre-filled with liquid scintillation cocktail Ultima Gold XR. The concentration of ^{222}Rn is calculated from the alpha spectrum in the window which covers the most part of the alpha peaks. The alpha counting efficiency of radon in the selected alpha window is 268%±3%.

Radium (226Ra) and Radium (228Ra)

^{226}Ra activity is calculated from the gross alpha spectrum on the basis of the counts measured in window set on the area of the ^{214}Po peak. This will give quite accurate results to ^{226}Ra because no other natural or artificial radionuclide has alpha emissions in the same energy range >7.5 MeV. The counting efficiency of ^{214}Po (and thus of ^{226}Ra) in the selected window is 86±3%. ^{228}Ra is determined via its daughter nuclide ^{228}Ac using gamma spectrometric measurement.

Uranium (^{238}U, ^{234}U and ^{235}U) and Thorium (^{232}Th, ^{230}Th and ^{228}Th)

Uranium and thorium are analysed by a radiochemical method. It allows the accurate determination of each uranium and thorium isotope separately. The water sample is concentrated by applying iron scavenging and the iron precipitate is dissolved in concentrated HCl. The other environmental samples are digested by either wet ashing or microwave digestion. Uranium and thorium are then separated from other radionuclides by ion exchange method (by using Dowex 1x8, 50/100 mesh). Uranium and thorium are coprecipitated with CeF_3 for the alpha measurement. The sample is counted with AlfaAnalyst spectrometer (Canberra). ^{232}U is used as a chemical yield tracer in the uranium analysis and ^{229}Th in the thorium analysis.

Lead (^{210}Pb) and polonium (^{210}Po)

^{210}Pb and ^{210}Po concentrations were determined using spontaneous deposition of ^{210}Po on silver disk and alpha spectrometric measurement (AlphaAnalyst) of the ^{210}Po activity (Fig. 2 (B)). The solution, remaining from the ^{210}Po deposition, is stored at least for 200 days to allow the in-growth of ^{210}Po which is a daughter product of ^{210}Pb. The second ^{210}Po deposition is then carried out and its ^{210}Po activity is counted. The final ^{210}Po result is calculated using the results from these two depositions. The ^{210}Pb result is calculated from the second ^{210}Po deposition. ^{209}Po and ^{208}Po are used as chemical yield tracers. Lead can also be determined using extraction chromatography. ^{210}Pb is separated from other radionuclides by Triskem´s Sr-resin. The sample is counted after a 30-day period during which ^{210}Bi attains nearly 100% equilibrium with ^{210}Pb. The result is then calculated from ^{210}Bi and ^{210}Pb together. Inactive lead is used for yield determination.

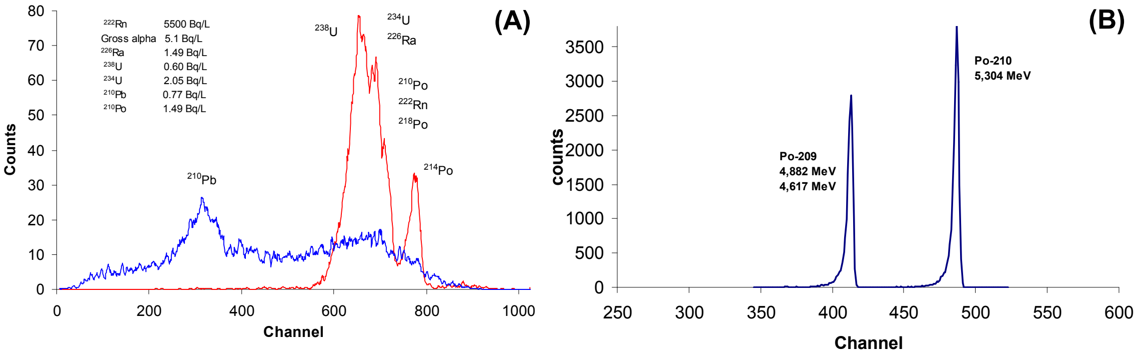

Fig. 2. The alpha and beta spectra of the Quantulus from a drinking water sample with different radionuclide contents (A). Alpha spectrum of ^{209}Po and ^{210}Po isotopes measured with Alpha Analyst (Canberra). ^{209}Po is used as tracer (B).

Table 1. The minimum detection limits for radionuclides ^{90}Sr, ^{239,240}Pu, ^{3}H, ^{222}Rn, ^{226}Ra, ^{228}Ra, ^{234,235,238}U, ^{210}Pb, ^{210}Po, gross alpha and gross beta at 95% confidence level. The amount of samples used in analyses depends on material. In this table MDA is calculated for the sample amount given in the table.

Nuclide	Equipment used in the measurement	Examples from amount of sample used in analysis (L, kg)	Counting time (h)	MDA (Bq/sample)
^{90}Sr	Quantulus 1220, proportional counter	30 L	15	0.005
^{239,240}Pu	AlphaAnalyst (Canberra)	100 L	60	0.0005
^{3}H	Quantulus 1220	0.008 L	10	0.008
^{222}Rn	Guardian 1414	0.01 L	1	0.0017
^{226}Ra	Guardian 1414, Quantulus 1220	0.04 L	3	0.00004
^{228}Ra	HPGe detector (Ortec, Canberra)	2 L	16	0.14
^{238}U	AlphaAnalyst (Canberra)	1 L, kg	180	0.002

Quality control in radiochemical laboratory

Good laboratory practices carried out at STUK in analytical work for radiochemical and gammaspectrometric analyses are described in detail in publication Ikäheimonen et. al 2006. A short summary of these practices is described here. Concerning radioactivity determinations there are only few international standards available. Therefore, almost always the methods used are laboratory-developed methods.

Proficiency of personnel and working practices

Proficiency of the personnel must be on a level where everybody knows what he is doing and why. Skilful laboratory personnel know what things can affect the result. Working with environmental samples with low radioactivity levels implies that the analysts must be qualified and aware of good laboratory practices. Especially, attention needs to be paid on contamination. This means that glassware and equipment are classified for different purposes according to the activity concentration of the sample. Also separate rooms are organized for pre-treatment of the sample, analyses and measuring equipment. In a laboratory with good working practices all instructions are found in written form in laboratory manuals.

Measurement rooms

STUK has four laboratory rooms for low-background alpha and beta measurements. The rooms are constructed of a special concrete containing an extremely low amount of natural radioactive elements and are equipped with a special air ventilation system. Measuring equipment is separated according to the measured radionuclide and activity concentration of the sample. Monitoring of temperature and humidity in the measurement rooms is arranged and all data is stored for further evaluation. The measurement rooms are equipped with uninterruptible power supplies (UPS) and outside backup generator to assure continuous power supply.

Equipment stability

STUK has a large number of high-quality measurement equipment used for radiochemical analyses. The equipment are three alpha spectrometer systems from Canberra (AlphaAnalyst), three Guardian 1414 liquid scintillation spectrometers, three Quantulus 1220 liquid scintillation spectrometers and three proportional counters (Fig. 3).

Confidence in the performance of equipment is maintained by regular calibrations and service, routine checks and control charts. Additionally, for good flow of information regular instrument meetings, four times per year, are arranged. In the meetings, all changes in operations of the equipment are documented. Equipment is operated only by authorized personnel. Up-to-date instructions on the use and maintenance of equipment are found in equipment manuals. All significant information from software and item of equipment is documented.

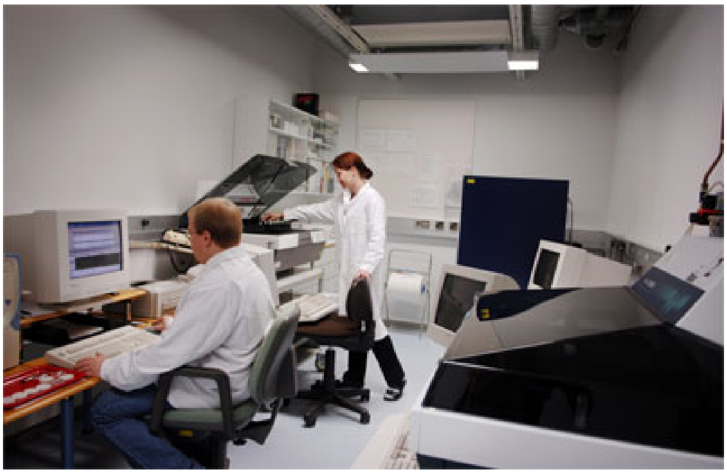

Fig. 3. Activity concentrations of tritium, Rn-222, C-14 and Sr-90 are determined using Guardian 1414 liquid scintillation spectrometer.

Regular calibrations

Standard 17025 requires that the calibration programmes are established for the equipment having significant effect on the results. At STUK the equipment used for radioactivity measurements are calibrated regularly. For all the analysis methods the interval for calibration is determined. For example, ^{222}Rn determination is calibrated between 3 to 5 years and ^{89,90}Sr between 5 to 7 years. Calibration procedure and the results are documented as closed circuit technical documents (TecDocs). With methods where internal standard is used as tracer, no regular calibrations of equipment are needed e.g. Pu. In these cases the activity of the tracer used is controlled regularly. The results are documented as a TecDoc in order to attain traceability of the results.

Control measurements

The laboratory needs to maintain confidence on its calibration status. This is done by making control measurements using blank samples, background and reference samples and internal measurements of the equipment (alpha spectrometer) indicating that calibrations are valid during activity measurement. All measurements are done regularly and the results are documented in x-cards (Fig. 4).

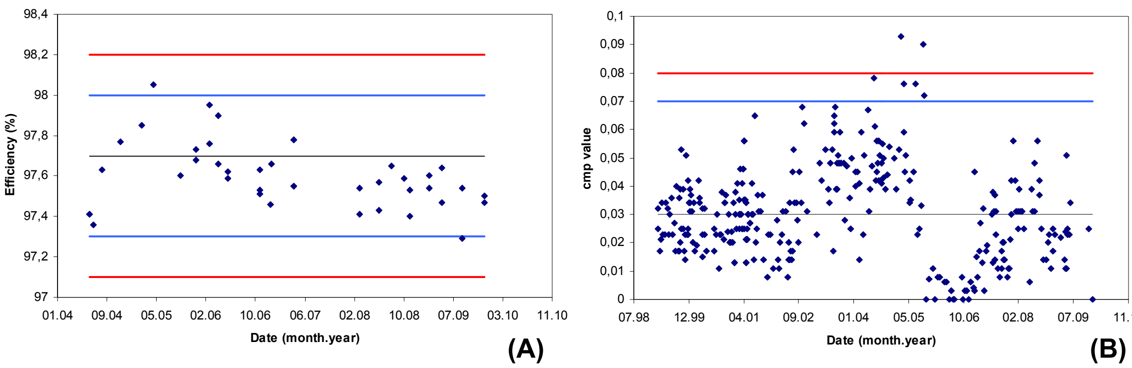

Fig. 4. Regular C-14 measurements of the reference sample (A) and background measurements from gross alpha determination (B) using Quantulus 1220 liquid scintillation spectrometer. Blue line presents the alarm level and red line the action level.

Regular maintenances

Confidence in the performance of equipment is maintained by regular service which is done by authorized personnel. Typically, measurement equipment is maintained once a year.

Intercomparisons

The laboratory takes regularly part in internal and international intercomparison exercises or proficiency tests. These are good tools to assure high quality of analyses and also excellent tools for analysis development. STUK participates in 5 to 10 international intercomparisons per year (Fig. 5). Additionally, internal intercomparisons are arranged to ensure convergent results and personnel competence.

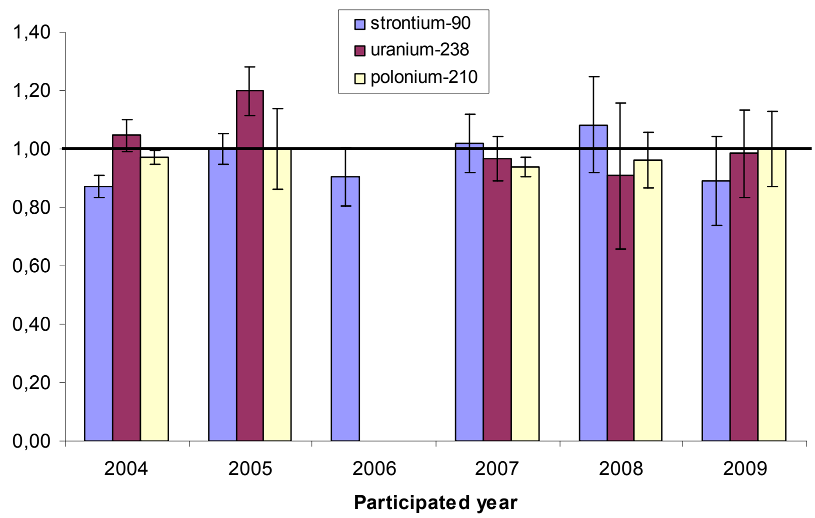

Fig. 5. Intercomparison results for ^{90}Sr and ^{238}U in 2004 – 2009. Analyzed samples were urine, lake water, sea water, drinking water, spinach and milk power.

Laboratory information management system

A uniform Laboratory Information Management Systems, LIMS and LINSSI, are used for data management, follow-up samples and chemicals, and analysis flow control. The system is password-protected and access is given only for authorized persons. The system helps the management of laboratory work, data management, traceability of the results, reporting and quality assurance in the laboratory. In the future, the same system will manage also the equipment used with radioactivity determinations.

Development of laboratory work and analyses methods

The most important issues in accredited laboratory are continuous improvement of laboratory work and analyses methods as well as the whole quality management system. New analyses methods are first tested, then validated and taken in use if they are found eligible for the analysis. Validation procedure is planned and all work tasks are documented as closed circuit technical documents (TecDocs). The laboratory work is enhanced by self-assessments, external and internal audits, various customer surveys and regular meetings with customers.

Conclusions

Radiochemical analyses are demanding analyses and demand proficiency of the whole personnel, well documented working procedures and properly controlled equipment. Validation of a new analysis method is a long procedure and requires a careful plan before the actual work can begin. In routine work, attention is needed on regular control measurements and contamination in order to maintain high quality of the analyses and measurement equipment. Workable laboratory information management systems provide an effective tool for evaluation of control measurements.

Accreditation is an excellent way to bring clarity in the routine work and regular external assessors improve the continuous maintenance of laboratory work. Laboratory work can be continuously improved by self-assessments, internal audits and customer surveys or regular meetings with customers.

Condition of liver, and iron and plutonium content

Mussalo-Rauhamaa, Helena[1]; Jaakkola, Timo[2]; Miettinen, Jorma K.[2]; Laiho, Kaino[3]

[2] University of Helsinki, Department of Radiochemistry, FINLAND
[3] University of Helsinki, Department of Forensic Medicine, FINLAND

Abstract
Plutonium and iron share a common metabolism in transportation and accumulation in human body. This was also supported by this study, where the accumulation of plutonium and iron in liver was investigated. The $^{239,240}Pu$ and iron contents in liver correlated positively (Rs = 0.378) in healthy livers, but not in livers having pathological changes. In contrast to iron content , the plutonium content of fatty degenerated or cirrhotic livers was significantly lower than that in normal livers. This difference suggests that plutonium and iron are not similarly accumulated or excreted in fatty degenerated and cirrhotic livers. The plutonium contents in lung and bone of these persons did not differ from the average values of the same age group, which may suggest that plutonium is excreted from the liver cells mainly by feces, instead of having been recirculated.

$^{240}Pu/^{239}Pu$ ratio in peat, lichen and air filter samples contaminated by global nuclear test fallout, the Chernobyl accident and other nuclear events

Salminen, Susanna[1]; Paatero, Jussi[2]
[1] Laboratory of Radiochemistry, University of Helsinki, FINLAND
[2] Finnish Meteorological Institute, FINLAND

Abstract

The $^{238}Pu/^{239+240}Pu$ activity ratio by alpha spectrometry is a useful method for separating the influences from nuclear weapons testing and the Chernobyl fallout. However, $^{238}Pu/^{239+240}Pu$ activity ratios in global nuclear test fallout and weapons-grade Pu are nowadays so similar, that it is difficult to reliably distinguish the two Pu sources by using this activity ratio. Besides, the activity concentration of ^{238}Pu is usually relatively low compared to ^{239}Pu and ^{240}Pu in environmental samples, leading to high uncertainties in $^{238}Pu/^{239+240}Pu$ activity ratio. As a complementary method for alpha spectrometry, ICP-MS provides the tool for identifying the origin of the Pu from global fallout or weapons-grade Pu, since the $^{240}Pu/^{239}Pu$ mass ratio is clearly different in Pu from nuclear weapons testing and weapons-grade Pu.

$^{238}Pu/^{239+240}Pu$ and $^{241}Pu/^{239+240}Pu$ activity ratios have been determined for peat and lichen samples collected in Finland immediately after the Chernobyl accident in 1986, air filter samples collected in Sodankylä in 1963 and air filter samples collected in Astana, Kazakhstan, in 2002. The Pu activity ratios indicated contamination from global nuclear test fallout in air filters from Sodankylä, and in peat and lichen samples Pu has been deposited from global fallout and the Chernobyl accident. $^{238}Pu/^{239+240}Pu$ activity ratio in air filters from Astana corresponded with the ratio in nuclear fuel of high burnup. In this study, a more exact estimation about the origin of Pu in these different types of samples from Finland and Kazakhstan was sought by determining their $^{240}Pu/^{239}Pu$ mass ratios.

The membrane filters used for alpha counting were decomposed and the resulting solutions containing Pu were purified with extraction chromatography. Mass concentration of ^{239}Pu and ^{240}Pu in the samples was determined by quadrupole ICP-MS. Results from $^{240}Pu/^{239}Pu$ mass ratio determinations for the investigated samples will be presented in detail in the poster.

Sensitivity of the standard and Fpg-modified comet assay for the estimation of DNA damage in peripheral blood lymphocytes after exposure to gamma rays

Garaj-Vrhovac, Vera[1]; Gajski Goran[1]; Miljanić Saveta[2]

[1] Institute for Medical Research and Occupational Health, Mutagenesis Unit, CROATIA

[2] Ruđer Bošković Institute, Laboratory for Radiation Chemistry and Dosimetry, CROATIA

Abstract

The comet assay is a rapid and sensitive technique for measuring DNA damage. This assay detects single and double stranded breaks, sites of incomplete repair, alkali labile sites, DNA-DNA and DNA-protein cross-links. In addition, particular enzymes such as formamidopyrimidine glycosilase (Fpg) can be used for detection of oxidative damage at the level of DNA molecule by cleavage of 8-oxodG, FaPyGua, FaPyAde and other ring-opened purines caused by reactive oxygen species (ROS). The aim of this study was to test the sensitivity of both standard alkaline and Fpg-modified comet assay and to detect the type of DNA damage caused by gamma rays. In that manner, human lymphocytes were exposed to gamma radiation doses of 0.1 Gy and 4 Gy *in vitro*. With the standard assay increase in DNA damage was noticed for both exposure doses but it was significant only at higher dose of 4 Gy whereas at lower dose there were no statistically significant increase in neither of the standard comet assay parameters. Fpg-modified protocol showed significant increase in all the parameters measured for both exposure doses indicating that the modified version is capable of detecting wider scale of DNA damage induced by gamma radiation. In addition, with modified protocol it is possible to detect ROS mediated DNA damage, thus significant increase in modified comet parameters in comparison to the standard ones suggests that gamma radiation did induce oxidative damage in DNA molecule. Correlation between different protocols of the comet assay suggests that Fpg-modified version is more sensitive to gamma radiation by virtue of measuring oxidative DNA damage in addition to the basal DNA strand breaks. Results obtained lead to the conclusion that gamma rays affects DNA molecule by ROS that are the most frequent product of gamma radiation. Additionally, human lymphocytes proved to be sensitive to ionizing radiation depending on the radiation dose and are suitable biomarkers for this type of research.

Introduction

Ionizing radiation is nowadays omnipresent in human lives because of the increasing development of technology, industry and medicine. People live and work near nuclear facilities and places of testing nuclear weapon and also use nuclear (gamma) radiation in medical purposes. In each case, human organism bears the strong genotoxic effect making the structure of the DNA molecule unstable and causing the genesis of many changes in it (Mettler and Voelz 2002). The damage of the genetic material caused by ionizing radiation is one of the best precondition indicators for development of malign diseases such as breast, gall-bladder or thyroid cancer (Cooke and Evans 2006). Gamma radiation affects the DNA structure directly, causing strand breaks, or indirectly causing cleavage of the water molecules and damaging the DNA molecule by reactive oxygen species (ROS) (Ito et al. 2007). These changes can be examined in human lymphocytes using different cytogenetic techniques.

The comet assay is a rapid, simple, visual and sensitive technique for measuring and analyzing DNA damage at the single cell level (Fairbairn et al. 1995, Faust et al. 2003, Møller 2006, Olive 1999, Singh 1988). This technique can be performed at the level of individual cells and requires a small number of cells per sample. Single cells can be used *in vivo* and *in vitro* as well as in biomonitoring of population exposed to radiation or chemical mutagens (Faust et al. 2003, Garaj-Vrhovac et al. 2002). The comet assay detects single and double stranded breaks at the level of DNA molecule, sites of incomplete repair, alkali labile sites, DNA-DNA and DNA-protein cross-links. Besides, the comet assay can be used for detection of the level of the DNA fragmentation in apoptosis (Collins 2004, Husseini et al. 2005, Olive 1999, Piperakis et al. 1999). Particular enzymes such as formamidopyrimidine glycosilase can be used for detection of oxidative damage at the level of the DNA molecule caused by ROS (Collins et al. 1993, Speit et al. 2003).

The aim of this study was to detect the type of DNA damage caused by ionizing radiation. For that purpose human peripheral blood lymphocytes were exposed to gamma radiation doses of 0.1 Gy and 4 Gy *in vitro.* Considering that, two forms of the comet assay, standard alkaline and Fpg-modified were used.

Material and methods

Blood sampling

The study was performed on peripheral blood samples obtained from a healthy female non-smoking donor (age 24 years). The donor was not exposed to ionizing radiation, vaccinated or used medicals for a year before blood sampling. Whole venous blood was collected under sterile conditions in heparinised vacutainer tubes (Becton Dickinson, Franklin Lakes, NJ, USA) containing lithium heparin as anticoagulant. After collection, blood was divided into a large number of samples. All experiments were conducted on peripheral blood lymphocytes cultivated at 37ºC in an atmosphere of 5% CO_2 in air.

Exposure conditions

The whole blood samples were irradiated with gamma radiation on the ice. As a source of radiation Gammacell 220 (Ruđer Bošković Institute, Zagreb, Croatia) was used. Vacutainers (volume 5 cm^3) containing blood samples were exposed to radiation doses defined as doses in the water, but irradiation was performed in the air. Samples were irradiated with radiation doses of 0.1 Gy and 4 Gy that is equal to radiation periods of 32.3 s and 23 min and 9 s at the temperature of 21°C. Significance of the absorbed dose was 3% (Miljanic et al. 1994). To get homogenate samples, they were stirred after irradiation, cooled to 4°C, transported to the laboratory on ice and processed as quickly as possible.

Alkaline comet assay

The comet assay was carried out under alkaline conditions, basically as described by Singh et al. (1988). Fully frosted slides were covered with 1% normal melting point (NMP) agarose (Sigma, St Louis, Mo, USA). After solidification, the gel was scraped off the slide. The slides were then coated with 0.6% NMP agarose. When this layer had solidified a second layer containing the whole blood sample mixed with 0.5% low melting point (LMP) agarose (Sigma) was placed on the slides. After 10 min of solidification on ice, the slides were covered with 0.5% LMP agarose. The slides were then immersed for 1 h in ice-cold freshly prepared lysis solution [2.5 M NaCl, 100 mM disodium EDTA, 10 mM Tris–HCl, 1% sodium sarcosinate (Sigma), pH 10] with 1% Triton X-100 (Sigma) and 10% dimethyl sulfoxide (Kemika, Zagreb, Croatia) added fresh to lyse cells and allow DNA unfolding. The slides were then placed on a horizontal gel electrophoresis tank, facing the anode. The unit was filled with fresh electrophoresis buffer (300 mM NaOH, 1 mM disodium EDTA, pH 13.0) and the slides were placed in this alkaline buffer for 20 min to allow DNA unwinding and expression of alkali-labile sites. Denaturation and electrophoresis were performed at 4°C under dim light. Electrophoresis was carried out for 20 min at 25 V (300 mA). After electrophoresis the slides were rinsed gently three times with neutralization buffer (0.4 M Tris–HCl, pH 7.5) to remove excess alkali and detergents. Each slide was stained with ethidium bromide (20 µg/ml) and covered with a coverslip. The slides were then stored in sealed boxes at 4°C until analysis.

Fpg-modified comet assay

The analysis of oxidized purines was performed using an Fpg FLARE™ assay kit (Trevigen Inc, Gaithersburg, Maryland, USA) with some modification (Comet Assay interest group website: http://cometassay.com/). Within the kit the manufacturer provided all the reagents used. Fully-frosted microscopic slides were prepared. Each slide was covered with 1% normal melting point (NMP) agarose (Sigma). After solidification, the gel was scraped off the slide. The slides were then coated with 0.6% NMP agarose. A low melting point (LMP) agarose was melted and stabilized in a water bath at 37 °C. For each sample and control, 5 µl of cell homogenate was mixed with 100 µl of LMP agarose (provided with the FLARE™ assay kit) and placed on the slides. After 10 min of solidification on ice, the slides were covered with 0.5% LMP agarose. The slides were then immersed in a pre-chilled lysis solution (provided with the FLARE™ assay kit) and kept in a refrigerator at 2 °C for 60 min. Followed the immersion in the FLARE™ buffer, three times for 15 min. After lysis, the slides were treated with 100 µl of Fpg enzyme (1:500 in REC dilution buffer). The enzyme was diluted right before use. Control slides were treated with 100 µl of REC dilution buffer only. The slides were placed horizontally in a humidity chamber at 37 °C for 30 min.

All slides were then immersed in an alkali solution (0.3 M NaOH, 1 mM Na_2EDTA; pH 12.1) for 40 min. Followed electrophoresis in a pre-chilled alkali solution (0.3 M NaOH, 1 mM Na_2EDTA; pH 12.1) at 1 V/cm for 20 min. After electrophoresis, the slides were rinsed gently three times with neutralization buffer (0.4 M Tris–HCl, pH 7.5) to remove excess alkali and detergents. Each slide was stained with ethidium bromide (20 µg/ml) and covered with a coverslip. Slides were stored at 4°C in sealed boxes until analysis.

Comet capture and analysis

A total of one hundred randomly captured comets from each slide were examined at 250x magnification using an epifluorescence microscope (Zeiss, Oberkochen, Germany) connected through a black and white camera to an image analysis system (Comet Assay II; Perceptive Instruments Ltd., Haverhill, Suffolk, UK). The analysis did not include the edges and damaged parts of the gel as well as debris, superimposed comets, and comets without distinct head (“clouds”, “hedgehogs”, or “ghost cells”). To quantify DNA damage, the following comet parameters were evaluated: tail length, tail intensity (percentage of DNA in tail), and tail moment. Differences in the tail length, tail intensity and tail moment between samples obtained with standard alkaline comet assay and Fpg-modified comet assay were considered as oxidative DNA damage in a single cell.

Statistical analysis

The various parameters measured in the exposed and control groups were evaluated using Statistica 5.0 package (StaSoft, Tulsa, Okla, USA). Each sample was characterized for the extent of DNA damage by considering the mean ± SE (standard error of the mean), median and range of the comet parameters. In order to normalize the distribution and to equalize the variances, a logarithmic transformation of data was applied. Multiple comparisons between groups were done by means of ANOVA on log-transformed data. Post-hoc analysis of differences was done by Scheffé test. The level of statistical significance was set at $P<0.05$.

Results

Results of the standard alkaline comet assay are presented in the Figure 2A. These results showed statistically significant increase of the mean values for all three parameters of the standard comet assay ($P<0.05$) in the sample irradiated with the dose of 4 Gy in contrast to control sample and sample irradiated with the dose of 0.1 Gy. Sample irradiated with the dose of 0.1 Gy showed slightly increased values for all parameters measured but there were no significant differences in compare to the corresponding control. Results of the Fpg-modified comet assay are presented in the Figure 2B. These results showed statistically significant increase in all three parameters of modified comet assay ($P<0.05$) for both irradiation doses in compare to the control sample. Generally, the mean values of all three Fpg-modified comet assay parameters were significantly higher than of the standard comet assay. These findings suggest that the Fpg-modified comet assay is more sensitive to gamma irradiation than the standard alkaline comet assay.

Discussion

Our goal was to test the sensitivity of the standard alkaline and Fpg-modified version of comet assay after exposure to different doses of gamma radiation. This type of radiation is a potent carcinogen mainly due to it potential as oxidative-induced damage agent. It produces variety of primary lesions in DNA such as single and double strand breaks, DNA-DNA and DNA-protein cross-links, alkali-labile sites and damage to purine and pyrimidine bases as well as oxidize bases and abasic sites (Cadet et al. 1999, Đurinec et al. 2006, Garaj-Vrhovac and Zeljezic 2004, Sudprasert et al. 2006).

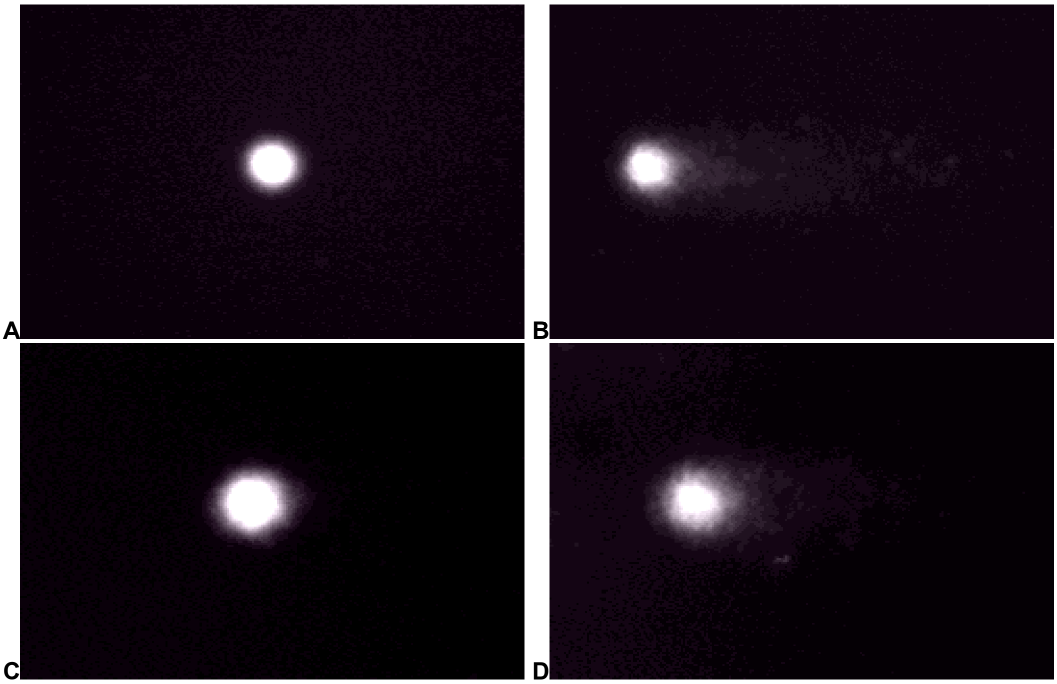

Fig. 1. Comet assay microphotographs represent undamaged lymphocyte from the un-exposed sample (A). Image (B) represents damaged lymphocyte that has comet appearance. Fpg-modified comet assay microphotographs represent undamaged lymphocyte from the un-exposed sample (C). Image (D) represents damaged lymphocyte that has comet appearance. Cells were stained with ethidium bromide. Cells were photographed under the fluorescent microscope using a 60x objective equipped with a 515 nm to 560 nm excitation filters and a 590 nm barrier filter.

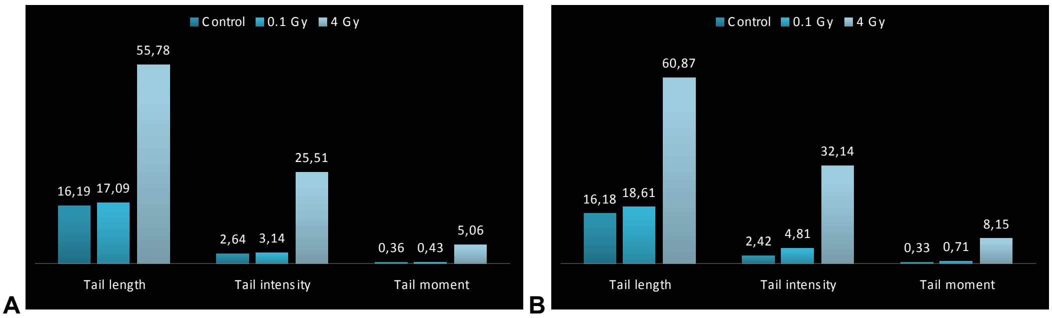

Fig. 2. Parameters of the alkaline comet assay (A) and Fpg-modified comet assay (B) (tail length, tail intensity and tail moment), in human peripheral blood lymphocytes exposed to 0.1 Gy and 4 Gy gamma irradiation.

Both protocols used in this study showed genotoxic effect of gamma rays on DNA molecule of human peripheral blood lymphocytes *in vitro*. With the standard alkaline comet assay increase in DNA damage was noticed in both exposure doses but it was significant only at higher dose of 4 Gy whereas at lower dose there were no statistically significant increase in neither of the standard comet assay parameters. Usage of the Fpg-modified protocol showed significant increase in all the parameters measured at both exposure doses indicating that the modified version of this assay is capable to detect wider scale of DNA damage induced by gamma irradiation. In addition, with modified protocol it is possible to detect ROS mediated DNA damage, thus significant increase in modified comet parameters in comparison to the standard one suggests that gamma radiation did induce oxidative damage in DNA molecule *in vitro*.

Some of the previous studies also showed that the Fpg-modified version of the comet assay is more sensitive for detection of DNA damage than the standard alkaline one (Domijan et al. 2006, Fracasso et al. 2006, Husseini et al. 2005, Garaj-Vrhovac et al. 2002, Rössler et al. 2006). According to that fact, scientists revealed that using the standard alkaline comet assay it is possible to detect damages at radiation doses from 5 cGy to 10 cGy and in some adapted experimental conditions (*e.g.* addition of the Fpg enzyme) it is possible to detect damages even at radiation doses of 0.6 cGy (Dusinska and Collins 1996, Malyapa et al. 1998, Verbeek et al. 2007). The additional reason why the Fpg-modified comet assay is more sensitive than the standard alkaline one is that the Fpg enzyme helps to detect oxidative damage of the DNA molecule by cleavage of 8-oxodG, FaPyGua, FaPyAde and other ring-opened purines (Karakaya et al. 1997).

Conclusions

In this study correlation between different protocols of the comet assay was made suggesting that Fpg-modified version is more sensitive to gamma radiation by virtue of measuring oxidative DNA damage in addition to basal DNA strand breaks. Results obtained lead to the conclusion that gamma radiation affects the DNA molecule by ROS that are most frequent product of the gamma radiation effect. Human peripheral blood lymphocytes proved to be sensitive to ionizing radiation depending on the radiation dose and are suitable biomarkers for this type of research.

Gamma spectrometric sample measurements at STUK laboratories

Klemola, Seppo; Leppänen Ari-Pekka; Mattila Aleksi; Renvall Tommi
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

In this paper, the facilities and applications for gamma spectrometric sample measurements at the Finnish Radiation and Nuclear Safety Authority (STUK) will be presented. The Department of Research and Environmental Surveillance has 15 HPGe spectrometers operated in specially constructed counting rooms. The software for the spectrum analysis and detector calibration are the key components of the accredited method. Integrated Laboratory Information Management System (LIMS) databases offer tools to manage the large amount of data involved in spectrum analyses.

Applications of STUK's gamma spectrometry include surveillance of environmental radioactivity in Finland, radioecological studies of both natural and artificial radionuclides and contracted services to industry and trade and for various organisations and institutes. STUK's laboratory is also one of the Radionuclide Laboratories certified by the Comprehensive Nuclear Test Ban Treaty Organisation (CTBTO). One of the tasks of the Department is to maintain measurement standards for radioactivity determinations.

Introduction

Finnish Radiation and Nuclear Safety Authority (STUK) has more than 40 years of experience in gamma spectrometric analysis of environmental samples.

Since 1999, the method of gamma spectrometric sample measurements has been accredited according to the Standard EN ISO/IEC 17025. The method of analysis of environmental samples, biological samples and foodstuffs is two-graded: 1) measurements of ^{137}Cs, ^{134}Cs, ^{131}I, ^{40}K and natural decay series of U and Th, 2) advanced analysis of all radionuclides emitting gamma-rays in energy range of 30 keV-2700 keV. The accreditation has been renewed in 2003 and 2007.

More than 4 000 samples are analysed annually in the Department of Research and Environmental Surveillance, and more than 500 additional quality control measurements are performed.

Laboratories and equipment

The sample measurements are carried out in three separate counting rooms; two of them are located in Helsinki and one in Rovaniemi, in the premises of the Regional

Laboratory of Northern Finland. The Helsinki counting rooms are constructed from selected concrete and mortar materials where the abundance of natural radionuclides is low. In addition, the rooms are equipped with special air conditioning in order to decrease background radiation due to indoor radon, and also to prevent contamination of the laboratory during an incidence of fallout. Continuous monitoring of temperature, humidity, air pressure and ambient radon is arranged in order to evaluate changes in detector background and in operation of the measurement equipment. The measurement rooms are equipped with uninterruptible power supplies (UPS) and a reserve power generator (Fig 1.).

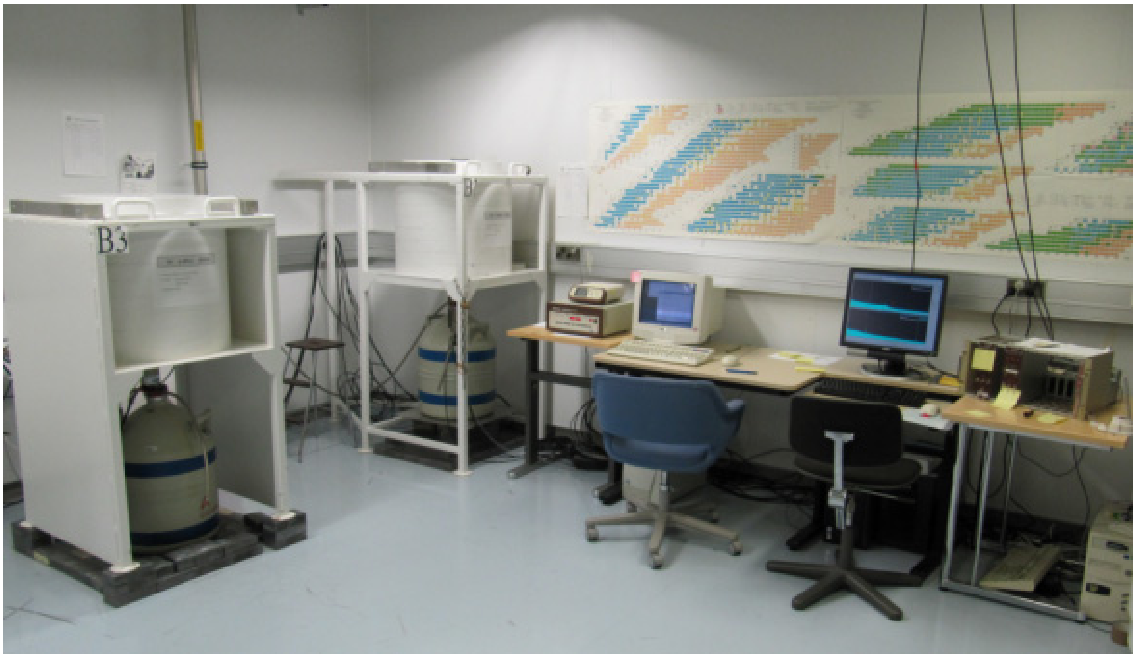

Fig. 1. One of the gamma spectrometry laboratories in the Research and Environmental Surveillance department. HPGe detectors are installed in heavy lead shields.

Currently there are altogether 14 low-background, high-resolution spectrometers at STUK laboratories for sample measurements (Table 1). In addition, two high-resolution spectrometers are employed for environmental monitoring sample measurements at sampling stations. The p-type HPGe detectors are of coaxial design with vertical cryostats. The relative efficiencies of the detectors range from 33% to 90% and energy resolution from 1.6 keV to 2.1 keV at 1.33 MeV. The detectors are installed in 12-14 cm thick lead background shields which are lined on the inside with cadmium and copper. The electronics of the spectrometers are either conventional NIM-modules or all digital stand-alone units. Measurement control and spectrum analysis are performed at a local microcomputer or on any network computer with the proper software installed. Lowest reachable detection limit is a few mBq/sample.

The laboratories in Helsinki use liquid nitrogen for cooling of spectrometers. The supply of nitrogen is arranged with vacuum insulated pipelines from a storage tank outside the building. All the detectors at Rovaniemi laboratory are electrically cooled.

Table 1. HPGe spectrometers for sample measurements at STUK laboratories.

Detector code	Manufacturer and model	Relative efficiency %	Energy resolution keV at 1.33 MeV	Purchase year
G1	ORTEC GEM-35185	33	1.76	1985

For sample measurements there are three standard measurement geometries at the laboratory. Two of them are simple cylindrical plastic beakers with diameters of 42 mm and 74 mm, correspondingly. The height of beakers is 26 mm, and the volumes are 35 and 105 ml, correspondingly. The third beaker in use is a standard 0.5-l Marinelli beaker (Fig. 2.).

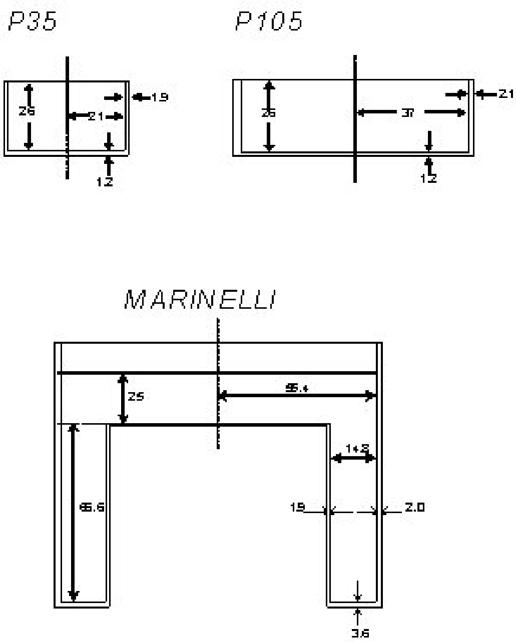

Fig. 2. Three standard measurement geometries for sample measurements at STUK.

All the beakers are measured right on top of the detector end-cap. The efficiency calibrations for other measuring geometries, densities or sample matrices can be obtained using a semi-empirical computer method developed to transfer full-energy peak efficiency to other geometries for the same detector (Ugletveit et al. 1989, Aaltonen et al. 1994).

The experimental efficiency calibrations of the detectors have been obtained with both separate single-line nuclides in water solution and multinuclide standard sources. The following nuclides have been used: ^{40}K, ^{51}Cr, ^{57}Co, ^{60}Co, ^{65}Zn, ^{88}Y, ^{109}Cd, ^{113}Sn, ^{137}Cs, ^{203}Hg, ^{210}Pb and ^{241}Am.

Analysis software and databases

In the early 1980s STUK developed a spectrum analysis programme especially for the analysis of low-level environmental sample measurements. The original GAMMA-83 code was written in Fortran language and run in a mainframe computer (Sinkko 1981, Sinkko and Aaltonen 1985). In the late 1980s, the code was ported to microcomputers and MS-DOS operating system. A MS-Windows version of the programme was written in 1997. This version introduced several new features, e.g. interactive user interface, evaluation of detection limits for selected nuclides, various optional output files.

GAMMA-99 programme searches peaks, evaluates their area and, after subtracting the background, calculates activity concentrations for identified nuclides. The varying heights and densities of the samples and the effect of true coincidence summing are taken into account in calculating the results. The program can be operated either in interactive or automatic mode. The updated master nuclide library has at present 139 nuclides and 1027 gamma lines, including decay data for calculation of coincidence summing corrections.

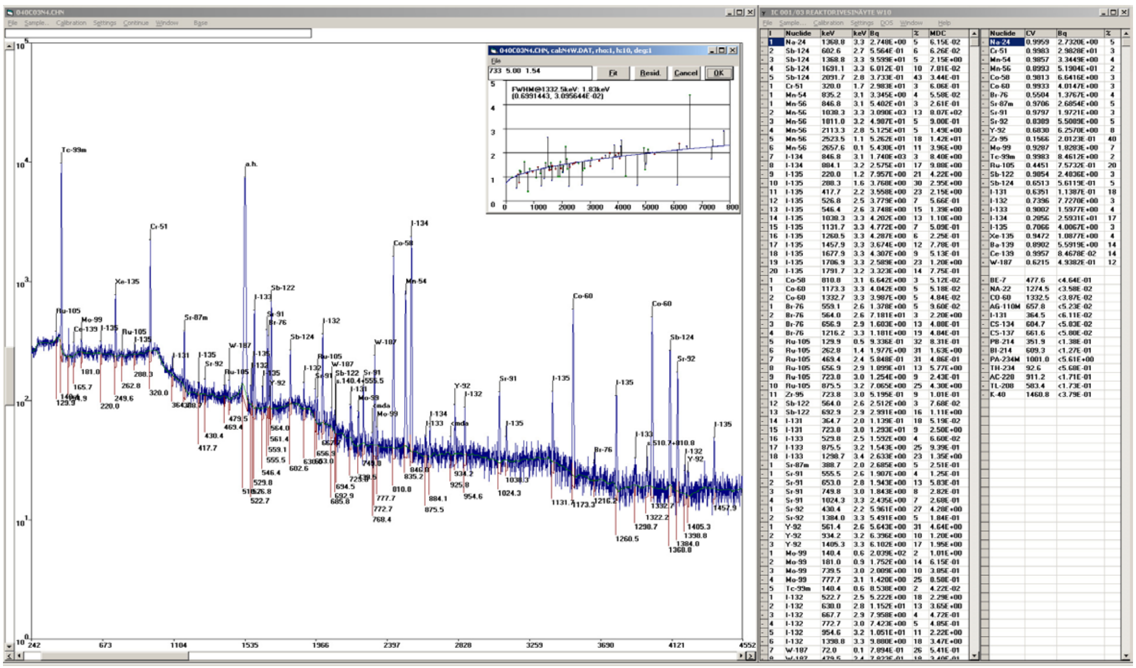

Fig. 3. GAMMA-99 user interface; spectrum, result and energy resolution views.

Recently, the laboratory has implemented and validated a new analysing software package, Unisampo/Shaman. UniSampo is the newest member of the Sampo family of gamma-ray spectrum analysis programs. UniSampo carries out the first part of the analysis, i.e. determination of the peak energies and intensities with the corresponding uncertainty estimates (Aarnio et al. 2001) .Peak analysis results from UniSampo are the input for Shaman programme which is a rule-based expert system for qualitative and quantitative radionuclide identification. Shaman utilizes a reference library with 3 648 radionuclides and 80 062 gamma lines extracted from the ENSDF and NUDAT databases. The programme takes into account e.g. true coincidence summing and is capable of identifying also sum peaks, escape peaks, and X-ray peaks (Aarnio et al. 1995, Ala-Heikkilä et al. 1995).

In 2004, uniform Laboratory Information Management System (LIMS) software was taken into use at the analytical laboratories at STUK. All analytical data, including basic information on sampling and samples, raw measuring data and results, are stored in the database.

In 2010 especially for gamma spectrometry designed database, LINSSI, will be integrated into the LIMS system. LINSSI (Linux System for Spectral Information) is a MySQL database that covers the whole production chain from sample preparation to final analysis results. Also full control of calibrations and their histories is supported, providing complete traceability of the results. As a database system specifically designed for gamma spectroscopy, LINSSI allows for more comprehensive recording of various quantities related to a spectral analysis than LIMS. LINSSI is being developed in collaboration with STUK, Helsinki University of Technology and Health Canada (Aarnio 2006).

Quality assurance

Confidence in the performance of equipment is maintained by regular calibration and servicing, routine checks and control charts. The most important control charts, background, energy resolution and detection efficiency, are based on regular QC measurements. Computerised techniques record the performance characteristics of spectrometers and software. These include peak widths and positions, which are evaluated during the spectrum analysis of every sample measurement, thus decreasing the frequency of regular QC measurements. The obtained values are recorded in a log file.

Corresponding warning limits and action limits are set, taking into account the different characteristics of spectrometers. The acceptance criteria in the charts are normally set as warning limits of 2σ and an action limit of 3σ above and below the long-term average data. However, with low-level measurements the differing behaviour of various background components requires careful consideration. While count rates of the peaks due to ^{40}K and cosmic background can be considered as stable, the count rates from daughter nuclides of ambient radon might vary either periodically or irregularly. ^{210}Pb in detector material and shielding is a special source of background, since it decays at a constant rate and can even be calculated for the future. Each of these components might require separate update frequency, also taking into account the contribution of the background to the total uncertainty of a particular result.

The dominant uncertainty contributions in gamma-ray spectrometry of environmental samples are usually those of count rate, full-energy peak efficiency and source-detector geometry. In special circumstances other sources of uncertainty will have a major contribution. Examples of these are the same or higher background count rate of a nuclide compared to sample activity, low energy gamma-rays from high density samples, and cascade-summing correction of the poorly-defined decay scheme of a rarely analysed nuclide (Ikäheimonen et al. 2006).

Successful participation in proficiency tests and inter-laboratory comparisons is highlighted as the best way of proving good quality. Since it is not possible to have exercises for all the gamma-emitting nuclides, it is important to show quality of the analyses of a few nuclides representing a variety of situations, especially including the wide range of gamma-ray energies.

To test and demonstrate proficiency also for short-lived nuclides, STUK co-organizes intercomparisons of reactor water analysis. The nuclear power plant coolant water samples are taken and prepared by NPPs and delivered promptly to the participating laboratories. Since all the participants get their sample within a few hours, it is possible to analyse and compare results of nuclides with half-lives shorter than one hour (Klemola 2008).

Applications

Applications of gamma spectrometry at STUK include surveillance of environmental radioactivity in Finland, radioecological studies of both natural and artificial radionuclides, contracted services for industry and trade and for various organisations and institutes. These applications provide a wide variety of sample types to be analysed including air, deposition, water, milk, foodstuffs, biota, sediments, swipe samples, building materials and various export products.

Since 2003, STUK has been one of the radionuclide laboratories certified by the CTBTO (Comprehensive Nuclear Test Ban Treaty Organisation) to support the network of radionuclide air sampling stations. These laboratories perform additional analysis of a suspect air filter samples to verify presence or absence of fission or activation products. Radionuclide laboratories also analyze samples from stations as a part of network quality control program. The main requirements for the CTBTO certification are quality system, documented procedures for sample analysis and good quality of analytical results. Certified laboratories are required to participate in proficiency test exercises organised by the CTBTO.

One of the tasks of the gamma spectrometry laboratory is to maintain measurement standards which ensure the traceability and accuracy of activity measurements of gamma-emitting radionuclides. Measurement standards are accurate spectrometers with traceable calibration, validated methods, or radiation sources. STUK is a member in a network for ionising radiation standard laboratories and participates in the activities of International Committee for Radionuclide Metrology (ICRM) and its Gamma-Ray Spectrometry Working Group.

Gamma spectrometry gives also support to radiation and nuclear safety authorities at STUK performing analyses for dosimetry, metrology, inspections, NPP radiation safety, safeguards and quality assurance. Gamma spectrometry is the most efficient method also for emergency preparedness, which presents a special challenge for the maintenance and development of software and equipment and also personnel competence for rapid response.

When is *in situ* gamma spectrometry motivated?

Boson, Jonas; Nylén, Torbjörn; Ramebäck, Henrik
Swedish Defence Research Agency, FOI, SWEDEN

Abstract

In situ gamma-ray spectrometry has since the introduction of portable germanium detectors been a widely used method for the assessment of radionuclide ground deposition activity levels. It is, however, a method that is most often associated with fairly large and poorly known uncertainties. A large part of the combined uncertainty originates from the source characterization, e.g. soil density and activity depth profile. In order to reduce this uncertainty soil sampling and subsequent laboratory analysis is often needed. The more samples collected for this characterization, the lower uncertainty in the *in situ* measurement result. However, if a large enough number of soil samples are collected, the uncertainty in the ground deposition activity measure directly obtainable from soil sample measurements will surpass the uncertainty of the *in situ* measurement. This will then render the *in situ* measurement superfluous. In this work we have considered *in situ* gamma ray spectrometry from a decision-maker-point-of-view; at which uncertainty level is *in situ* gamma ray spectrometry fit-for-purpose, and at which uncertainty level are laboratory measurements of soil samples preferable.

Review of modern application of gamma-beta spectrometer – radiometer MKGB-01 "RADEK"

Finkel, Felix
Scientific and Technical Center "Radek" ltd., RUSSIAN FEDERATION

Review of a modern application of spectrometer- radiometer of gamma-beta-radiation MKGB-01 "RADEK"

In the year 2001 STC "RADEK" Ltd. company produced spectrometer- radiometer of gamma-beta-radiation MKGB-01 "RADEK". Since then the device is widely used by various scientific and educational institutions, certification authority, research laboratories and organizations of nuclear fuel cycles. Apart its common use as a measuring instrument of activities of γ-radiating radionuclides in samples of ground, vegetation, water, foodstuff, materials of construction and other substances, it was also applied as a basis for the construction of unique spectrometric units.

Thus, the Railway Service Institute uses MKGB-01 as a measurement instrument of radionuclide contamination of railway acres and roads. On basis of MKGB-01 the underwater gamma-radiation spectrometer was developed for Geologic Institute, allowing the radioactivity measurement of bottom silt with the moving of detector along the bottom. The same spectrometer was also produced for the Federal Security Guard Service of Russian Federation for installation on boats patrolling water area.

The special place in radioactivity measurement of radionuclides belongs to spectrometry of body radiation. So the SEG-10P was developed as a modification of MKGB-01. It is completely implemented in the form of armchair and allows to measure the activity of incorporate γ- emitting radionuclides. The apparatus is used by nuclear power plants and medical centres.

In 2006 in the Russian Centre of Emergency and Radiation Medicine the expert spectrometric unit for human radiation measurement was constructed and put into operation. It is completely composed of analyzers of MKGB-01 spectrometer (14 pieces) and different types of detectors (scintillation and semiconductor detector). The unit is presented by steel chamber with 4x2x2 meters dimensions edged by lead, cadmium and copper. The chamber is provided by scanning operation.

Due to STUK Finland has about 50 devices of such kind.

Introduction

Nuclear-physical analysis methods of samples are widely used in various fields of science and technology. It provides an opportunity to resolve the tasks in such spheres as medicine, ecology, geologic intelligence, atomic industry, etc. To study the radionuclide composition of samples, among others, gamma- and beta spectrometric methods of analysis are used.

In the beginning of 2001 the company STC “RADEK” manufactured a spectrometer-radiometer of gamma and beta radiation MKGB-01 “RADEK”. Since that moment this device is widely used in different scientific, educational organizations, centers of certification, research laboratories and enterprises of NFC (Nuclear Fuel Cycle). Besides the standard use of this device by way of mean of measuring of γ and β radiating radionuclides activities in samples of ground, vegetation, water, foodstuffs, constructing materials and other substances, a unique spectrometric complexes are also constructed on its base.

Review

Thus, the institute of railway transport (VNIIZhT, Russia, Moscow), uses MKGB-01 by way of mean of measuring of radionuclide contamination of railroad track right of way and of automobile roads[1]. This complex is called “Main gamma-spectrometer of high sensivity (MGSHS)” and is placed in laboratory rail car of VNIIZhT. High sensitivity of gamma-spectrometer is determinated by a large volume of scintillator.

Constructively the spectrometer MGSHS consists of two DSU (detection and selection unit with 2 detectors each); unit for summing signals; four analog-digital converters (ADC) MD-129; three high-voltage power supplies; low-voltage power supply and PC. Functionally and programly the complex allows to use a signal from GPS - receiver, to turn on the alarm signal (bleeper, light, etc.), means of objective control, etc. Each DSU has 2 detectors in it on the base of crystals NaI(Tl) with size 100x200 and a PMT-49 (Photomultiplier Tubes) for registration of external gamma-radiation, and a stabilization unit based on beta-gamma coincidence (detector on the basis of scintillating plastic and PMT-85 for stabilization, source of ionizing radiation on the base of ^{60}Co with activity less than the minimum significant).

Conducted in 2007 the induction and performance tests on the known contaminated territories showed, that during the correlation of graphs of ^{137}Cs density contamination measurements, performed with an interval of 17 years, paying respect to the decay and migration of radionuclide correction, the discrepancy doesn’t exceed 20%. At this moment the spectrometer is used in laboratory rail car, belonging to VNIIZhT [1].

Also an underwater gamma spectrometer on the basis of MKGB-01 is developed for geological institute, which allows to measure the radioactivity level of bottomset beds through the aid of the detector moving along the bottom. The spectrometer consists of a detector towed on bottom and of an onboard analytical complex. The full consist of the complex includes: a sealed shock-proof sleeve with an obstacles bypass system “Eel”, containing a scintillation gamma-radiation detector with crystal CsJ(Tl) with size 80×80 mm; an analytical unit, containing an analog-digital converter board (ADC); power supplies and amplifiers (Fig.1); control PC with appropriate software; armored towing - connecting cable [2].

To stabilize and to control the amplification, a reference source of ^{113}Sn mounted in the detector sleeve was used, which allowed to change operatively the amplifying coefficient depending on the involving facts. The spectrometer is calibrated in the measurement units of specific activities on the volumetric, saturated for gamma-radiation state standard norms. Estimated minimum detected activity with the exposure time of 30 seconds is as follows for ^{137}Cs - 4 Bq/kg, ^{226}Ra - 10 Bq/kg, ^{232}Th - 7 Bq/kg, ^{40}K - 90 Bq/kg. The working depth of spectrometer sleeve immersion - 500 meters, and by towing with speed 3–4 knots, using 600 meters of a tow cable-hemp – to 200 meters. By towing the underwater gamma-spectrometer the exposition set of each spectrum was about 30 seconds. The towing speed – 3 knots. Thus, in average each single spectrum corresponds to 50 meters of profile.

Fig. 1.

An example of underwater use of spectrometer MKGB-01 in geological purposes is the charting of ferromanganese nodules fields (FMK) in the gulf of Finland of Baltic sea. It’s well known that FMK of marginal and inland seas sorb intensively the ^{226}Ra and are largely enriched with it. At the same time the accumulation of ^{137}Cs by nodules is insignificantly to the aleuropelite precipitations, which are intensively accumulating ^{137}Cs in zones, related to the impact of the Chernobyl disaster. These provisions give a theoretical basis of FMK fields charting by means of underwater gamma-spectrometry. Conducted in the gulf of Finland the experimental-methodological works have confirmed the assumptions made above. It can be stated a fairly reliable charting method of FMK fields on the ratio ^{226}Ra/^{137}Cs. Besides it the underwater gamma-spectrometry directly on the activity of ^{137}Cs, and also on the ratio ^{137}Cs/^{40}K and ^{226}Ra, ^{232}Th/^{40}K in many cases allows to separate and to chart the fields of aleuropelite sediments, of sands and boulder-pebble material.

Another successful example of underwater gamma-spectrometer use in geoenvironmental purposes was its application for radiogeochemical situation study in bottom sediments on the mass burial areas of PDUO (potentially dangerous underwater objects), representing the container landfills, containing radioactive waste, or single large objects, containing large quantities of radioactive substances. The researches of four burial plots showed, that by one of the profiles, passing close to two sunken ships with radioactive substances and containers landfill, an extended anomalous zone with ^{137}Cs activity up 1500 Bq/kg was detected. In a container burial area with radioactive waste, a local anomaly with length about 100 meters with ^{137}Cs activity in the maximum of 80 Bq/kg was also detected by another profile. Besides, in different sectors, the ^{137}Cs anomaly with activity from 40 to 60 Bq/kg were allocated by several profiles. It should be noted, that all the identified anomalies are located in the distribution area of aleuropelite precipitations, which, as known, sorb intensively ^{137}Cs. Cesium background activity for the entire area was vastly negligible and ranged from values below the MDA (minimum detectable activity) to 7 Bq/kg.

Thus, the towed underwater spectrometric complex MKGB-01 proved to be quite suitable for solving problems of ^{137}Cs areal distribution study in bottom sediments and of local pollution identification in bottom sediments, associated with specific objects [2].

The same spectrometer was created by order of Federal Security Guard Service of the Russian Federation (FSGS RF) for installation on boats, patrolling the water areas.

A special place in the measurement of radionuclide activity is occupied by spectrometry of human radiation. In this field a spectrometer of human radiation SEG-10P is developped, it's a modification of MKGB-01. It is designed as a chair with console module on the anvil, aimed at the geometric center of the chair (Fig.2).

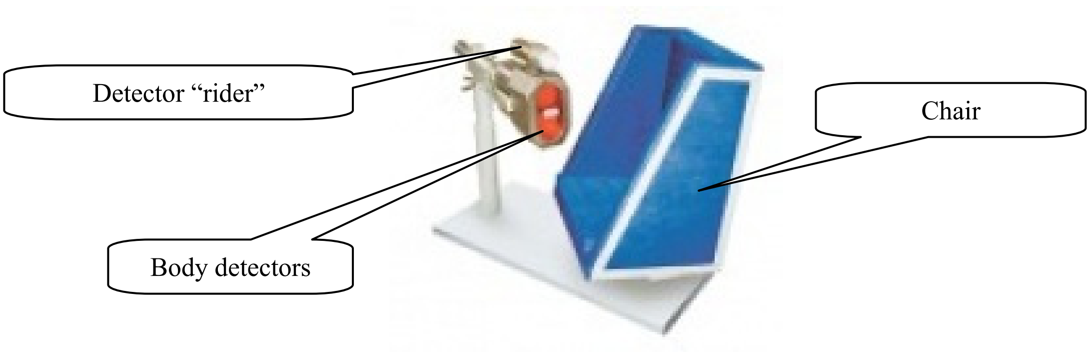

Fig. 2.

The module consists of two body detectors and so-called detector "rider", and allows to evaluate the activity of incorporated γ- radiating radionuclides in human body, lungs and thyroid. The spectrometer calibration is made by means of unified phantoms UF-02T (body) and FSZ-04T (thyroid). The phantoms are made of rectangular polyethylene blocks with bulk 1 kg with openings for placing the rod sources of radioactive material. The spectrometer is widely used on nuclear power plants and in medical centers.

In 2006 in the center of emergency and radiation medicine in Saint-Petersburg an expert low-background spectrometric complex of high sensitivity "SICh-E" for measuring human radiation was manufactured and was put into operation. In fact it's a totality of low-background spectrometers of human radiation and consists of 28 different spectrometric tracts (scintillation and semiconducting), based on electronic modules of spectrometer-radiometer MKGB-01 (14 two-channel analyzers MD-198, Fig.6). The low background of spectrometer is provided by its construction, which represents a steel chamber with size 4x2x2 meters, plated from the inside by lead, cadmium and copper (Fig.3,4,5).

Fig. 3. Chamber of spectrometer of human radiation inside view.

Fig. 4. Detectors view inside the chamber without couch.

Fig. 5. Detectors view inside the chamber with couch and with phantom.

Fig. 6. View of 14 analyzers MD-198 from the front side in the control cabinet.

The complex is intended for expert surveys of the content of incorporated radionuclides of persons, exposed to the radiation in various accidents and incidents, of nuclear technology cycle factory staff during the current and periodic monitoring of internal irradiation, and also of people, living in the radioactively contaminated areas [3]. The works performed on the spectrometer:

– identification of radionuclide composition and measurement in the linear longitudinal scanning mode of low activity levels of gamma - radiating radionuclides throughout the human body in minimum dependence from the character of their distribution in organism and from variations of examined body anthropometric parameters (the contingent of examined people – adults and children from 5 y.o.);
– identification of radionuclide composition and gamma – radiating radionuclides activity measurement in particular human organs: lungs, thyroid, liver, reins, etc.;
– measurement of ^{90}Sr radionuclide content in bones by the bremsstrahlung spectrum as in skeleton entirely, and in separate skeleton parts (in frontal bone, shin bone, etc.);
– measurement of content in the lightweight transuranic radionuclides with low photon radiation energy: plutonium, americium, etc., and also of gamma-radiating radionuclides content with energy less than 300 keV;
– research of radionuclides metabolism in human body in the estimation of parameters;
– research of homeostasis (on potassium metabolism by measuring the ^{40}K radionuclide activity in human body).

The widespread use of MKGB-01 is not limited only by RF. Thanks to STUK (Radiation and Nuclear Safety Authority) Finland has about 50 such devices. Since the mid 1980's in local laboratories of Finland from 6 to 20 counters Mini-Assay were used for evaluation the specific and radioactive substances volumetric activity in foodstuffs and of radon in potable water. The counters showed the total intensity of gamma radiation in samples, and when they began to fail, STUK started to develop a modernization plan of radiometric control equipment. Thus, a new equipment was purchased – gamma-spectrometer MKGB-01, which is used for radionuclide evaluation in samples. The spectrometer consists of a detector Nal(Tl) with size 63×63, located in a lead protection with thickness 60 mm, computational electronics and of a gamma radiation spectrums processing program. Two measurement geometries are used – Marinelly container with volume 1l for liquids and cylindrical cuvette with volume 320 ml for solid foodstuffs. The minimum detectable specific activities of ^{137}Cs with measuring time - 1000 sec. in laboratory - 50 and 30 Bq/kg for cuvette with volume 320 ml and Marinelly container, respectively. The spectrometer is calibrated for samples density from 0,2 to 2,0 g/cm^3 [4].

Referring to the scientific-research sphere of application of spectrometer MKGB-01, it's necessary to mention its use in the maquette of device, which realizes the method of KX-gamma coincidences, created in the ionizing radiation measurements department of D.I. Mendeleev Institute for Metrology (VNIIM). The activity evaluation results, obtained on this maquette, enable to recommend it for inclusion in the primary standard of RF [5].

Another example of MKGB-01 use in the research activity can be the Nephrology Department of Saint-Petersburg Medical University, where spectrometer MKGB-01 is used as an equipment for reins function study. For this, a so-called parameter GFV (glomerular filtration velocity) is evaluated. A patient is injected by a certain amount of radioactive medication (DTPA ^{99m}Tc) with known (measured in syringe on the spectrometer) activity, then after some time the blood of the patient is sampled, centrifuged and the activity in blood plasma is measured, some time later the blood is sampled, centrifuged again and the activity is measured again too. Then, according to the given algorithm, a so-called clearance is evaluated, with the help of which the reins function is studied.

Thereby, the gamma-beta spectrometer MKGB-01 have found a wide application in various applied and scientific problems, and, therefore, the realization of this project can be considered as successful.

Abstract

Dose rate monitoring networks equipped with Geiger-Müller or proportional counters can provide an alarm with sensitivity to approximately 0.1 µSv/h increase over the ambient background. For airborne activity the 0.1 µSv/h increase translates to activity concentrations in the kBq/m^3 range. Better sensitivity and nuclide identification can be achieved by gamma spectrometers with sufficient energy resolution.

$LaBr_3$ scintillators provide a good energy resolution of about 2.5 % at 662 keV enabling the separation of I-131 (364.9 keV) and Pb-214 (351.9 keV) lines. The detectors are large enough to yield an adequate sensitivity, making them suitable for dose rate monitoring network applications. Major drawbacks of $LaBr_3$ detectors are the radioactive impurities in the material and the gain variation as a function of temperature. A fitting algorithm based on the La-138 and K-40 multiplet at 1430-1470 keV was developed to stabilize the detector. With fully automatic software controlling the $LaBr_3$ spectrometer during data acquisition the system gain is stable and provides environmental spectra of excellent quality. The same fitting algorithm is also applied to the analysis of the whole spectrum.

Spectrometers have recently been installed around the Finnish nuclear power plants. They send measurements to a central database at STUK headquarters over a secure wireless TETRA network at ten minute intervals. The spectra are automatically analyzed and checked for the presence of small signatures of man-made activity. Airborne or fallout nuclide activity concentrations and the dose rate are calculated from the spectra. The detection limit for I-131 is roughly 40 Bq/m^3. In comparison, an activity concentration of 1700 Bq/m^3, yielding an increase of 0.1 µSv/h in the dose rate, would be needed to create an alarm in the Geiger-Müller monitors.

In summary, the $LaBr_3$ spectrometer system now in operational use in Finland, is an excellent enhancement to the country-wide radiation monitoring network providing nuclide identification with high sensitivity.

Introduction

The Finnish ambient dose rate monitoring network consists of 255 monitoring stations. The network covers the whole country, with several stations around the Finnish nuclear power plants in Olkiluoto and Loviisa. Ambient dose rate at the station is monitored with three independent Geiger-Müller counters, with two identical counters for low dose rate and one counter for high dose rate. Instrumentation also includes a rain sensor. The measurement data from the stations is sent in ten minute intervals to the Radiation and Nuclear Safety Authority (STUK) headquarters to form a real-time picture of the dose rates. An increase in dose rate over a predefined limit, verified by the three independent Geiger-Müller counters at the station, generates an alarm at the regional Emergency Response Centres in addition to alerting STUK's duty officer.

The Geiger-Müller counters of the monitoring network can discern about 0.02 µSv/h change in the ambient dose rate. With the natural background in Finland varying between 0.05 µSv/h - 0.30 µSv/h, the alarm limit has been set to 0.4 µSv/h. In addition to a fixed alarm limit, a station-specific comparison of the latest dose rate value to a smoothed background over the last 7 d measurements is used to detect anomalous cases of concern. The alarm level is set to a 0.1 µSv/h increase over the average. For I-131, an air concentration of 1700 Bq/m^3 is needed to raise the dose rate by 0.1 µSv/h. Countermeasures, however, are needed already at the concentration levels of 1000 Bq/m^3 of I-131. Another drawback is the fact that Geiger-Müller counters do not provide identification information on the possible radionuclides responsible for an increased dose rate. An illustrative case is a weather-related increase in the radon progeny concentration of the surface air leading to elevated dose rate. Discerning these cases with natural origin reliably and promptly from events that might require further action can be a challenge to network operators, if spectroscopic measurements are not available.

The Finnish dose rate monitoring network was updated in 2005-2007. The prospects of adding spectrometric instrumentation to achieve better detection limits and nuclide identification was envisaged, but the NaI scintillators considered at the time did not provide sufficient energy resolution for e.g. resolving the I-131 gamma line at 364.9 keV photon energy from the Pb-214 radon progeny gamma line at 351.9 keV. Despite the lack of suitable spectrometers the monitoring station structure was designed to be flexible, with several interface options for adding new instrumentation.

Recently, a new scintillator material $LaBr_3$, has emerged as a viable alternative. The Cerium-doped $LaBr_3$ presents a scintillation photon output higher than NaI(Tl), (63,000 photons/MeV) at a wavelength suited for a photocathode. In addition, the crystals have an excellent energy resolution and are available at sizes suitable for gamma spectrometric measurements (Dorenbos et al. 2004, van Loef et al. 2001, Pani et al. 2007). The energy resolution of $LaBr_3$ scintillators is 2.5-2.9 % at 662 keV, whereas the resolution of NaI scintillators is 6-7 %. The operational lifetime of a $LaBr_3$ scintillator coupled with a suitable photomultiplier tube and related signal processing electronics is estimated to be several years.

$LaBr_3$ scintillators also exhibit problematic characteristics that need to be considered when designing a measurement system. The $LaBr_3$ material contains radioactive La-138 and Ac-227 impurities, which contribute to the background complicating the analysis of the spectrum. La-138 in particular has a disturbing impact on the detection limits due to the increase of spectral baseline. In addition, the gain variation of the detector and the coupled photomultiplier tube may be of several percentages depending on the temperature and the detector orientation in terrestrial magnetic field.

Despite these complications, the overall performance of $LaBr_3$ scintillators is good enough for continuous environmental monitoring applications. In this paper, we show how the problems related to $LaBr_3$ material and gain instability have been overcome. We discuss how these detectors have been added to a geographically sparse monitoring network and show that automatic analysis procedures can be applied to process the environmental spectra from $LaBr_3$ scintillators.

Material and methods

Measurement setup and data processing

The $LaBr_3$ scintillators installed to the Finnish dose rate monitoring network utilize Saint-Gobain BrilLanCe 380 crystals with a height and diameter of 1.5 inches. The detector, including Hamatsu photomultiplier tube (R6231-100) is connected to a Princeton Gamma-Tech Instruments MCA2500 multi-channel analyser (MCA). The MCA2500 is connected via an ethernet interface, allowing cable lenghts up to 100m without a separate signal amplifier. This is an advantage for the typical monitoring station installation, where the central unit is located indoors and the sensors stand outside at some distance from nearby buildings.

The detector and the MCA are housed inside a weather resistant and insulated casing. The casing insulation has been tested in the expected outside temperature range of -30 C° … +30 C° to keep the detector and the MCA unit inside a manufacturer specified operational temperature range of 0 °C ... +50 °C, while preventing the condensation of humidity on the electronic components. The aluminium casing has a wall thickness of 1.5 mm at the scintillator end, not preventing the detection of low energy gamma radiation.

The monitoring station central unit is running on an embedded Linux computer. The Intel PXA255 computer has no moving parts ensuring long life time, with the open Linux software architecture offering software vendor independence and flexibility, including monitoring station software updates with user scripts and installation of additional programs written with C/C++ programming language. The control unit has several interfaces for external equipment and sensors, such as the ethernet connection used to interface with the $LaBr_3$ detector's MCA.

Individual stations communicate via a TETRA-based, closed government radio network called VIRVE (Fig 1). The VIRVE network is mainly used by law enforcement authorities and rescue services to relay voice communications, but the TETRA network also supports TCP/IP protocol and text messaging, with both services utilized by the radiation monitoring network stations to relay measurement data. The setup allows for two-way communication enabling remote management and software updates.

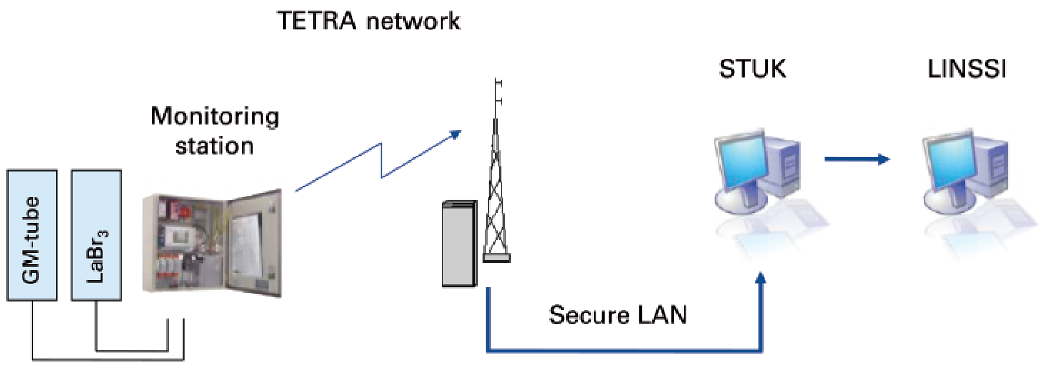

Fig. 1. Architecture of the Finnish radiation monitoring network.

The $LaBr_3$ detectors are operated in the same data acquisition mode as the Geiger-Müller counters, with a spectrum reading interval of ten minutes. The MCA conversion gain is set to 2048 channels, with the energy range extending up to 3200 keV. After a spectrum is read, it is processed at the monitoring station by a specialized multiplet fitting algorithm *mufi*. The purpose of the *mufi* algorithm is to stabilize the energy calibration against gain fluctuations induced by changes in external temperature. The program analyses the position of the La-138/K-40 multiplet at the photon energy region of 1430 keV - 1470 keV. If the multiplet peak positions have moved from their nominal values, *mufi* returns the channel shift, which is converted to a change in the amplifier gain. A new gain setting is then sent to the MCA unit to keep the energy calibration stable.

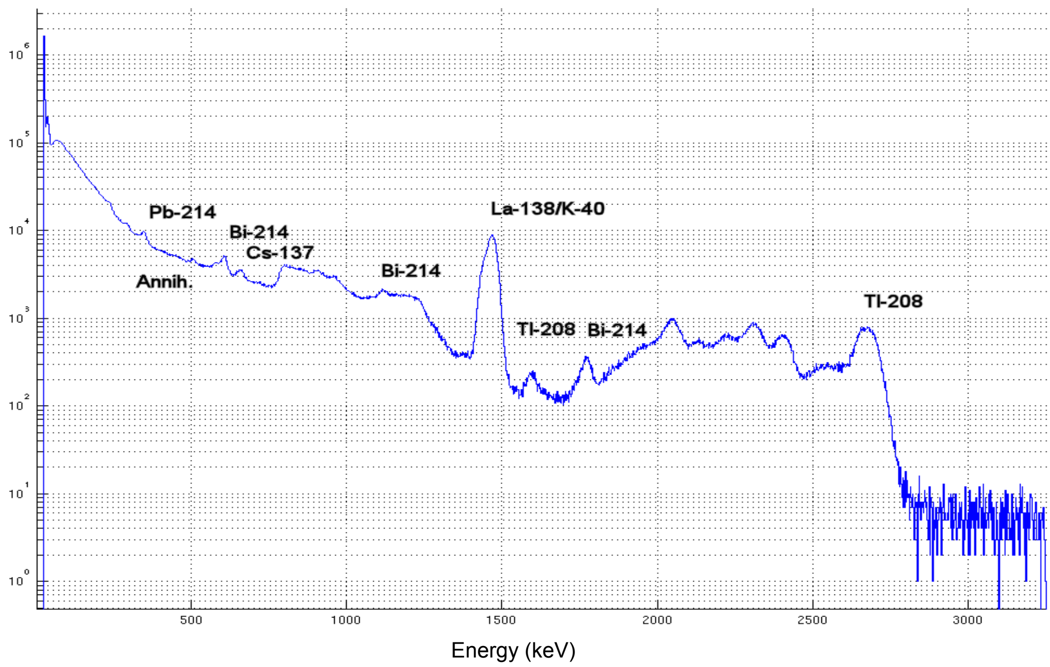

Fig. 2. A spectrum of the background radiation measured with the $LaBr_3$ detector. The La-138/K-40 multiplet is used to stabilize the energy calibration against gain fluctuations induced by changes in temperature. Measurement time was 24 h.

The spectral data and the *mufi* analysis results are then send from the monitoring station to a central server at STUK and stored to a gamma spectrometry database *Linssi* (Aarnio et al. 2006). A summation spectrum with a length of 60 min is formed from the individual 10 min spectra. These are automatically analyzed by a second multiplet fitting algorithm *jmufi*, which analyses predefined spectral regions for the presence of interesting gamma peaks. The *jmufi* software provides nuclide identification and count rates, detection limits and error estimates for the various quantities. In addition to nuclide identification, dose rates are calculated from the 10 min spectra to compare with the the Geiger-Müller counter values. The *jmufi* program and the dose rate calculation method are discussed in detail in Toivonen, 2008. A spectrum of the background radiation integrated over a 24 h measuring period is shown in fig. 2. Several radon progeny related peaks are apparent in the spectrum, with the La-138/K40 multiplet peak being the most prominent feature.

As of spring 2010, 19 monitoring stations have been equipped with $LaBr_3$ detectors. Most of these spectrometric stations are situated around the Finnish nuclear power plant sites in Olkiluoto and Loviisa (Fig 3.). Installations will continue with few additional $LaBr_3$ spectrometers during the year 2010.

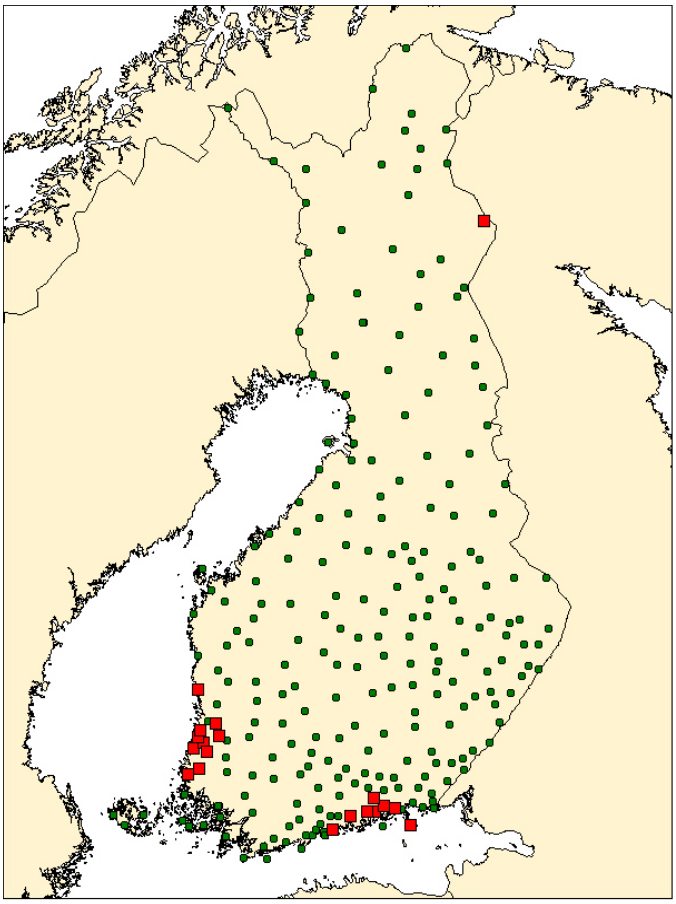

Fig. 3. Ambient dose rate monitoring network. Stations with $LaBr_3$ detectors are shown with red squares.

Conversion of detector count rates to activity concentrations

The nuclide specific count rates recorded at the spectrometers need to be converted to more general quantities. For a dose rate monitoring network, two distinct cases are of interest. In the first case, the radioactive nuclides are airborne and the nuclide specific air concentrations (Bq/m^3) need be derived from the respective count rates. In the second case, the radioactive nuclides are deposited on the ground and the interesting quantity is the fallout (Bq/m^2). The efficiency curves relating the nuclide-specific count rates to the different concentrations are also needed to estimate the detection limits (contamination level) which would generate the alarm. To this end, we have developed a semi-empirical method to derive the peak efficiency calibrations for the two different cases outlined above. We have derived equations for the efficiency curves of extended source geometries, utilizing a point source peak efficiency curve at a fixed source-detector distance.

The point source peak efficiencies can be easily measured with a selection of well calibrated sources at some finite source-detector distance *r*. From this data, the point source efficiency at an arbitrary distance is calculated. For airborne radioactivity one needs to consider the $1/r^2$ counting geometry dependance and the absorption of the radiation in air. The angular dependence can be neglected in the present case as the $LaBr_3$ crystals with equal height and diameter have only a small directional sensitivity. Finally, the point efficiency is integrated over the involved space to give the peak efficiency curve for the volume source. A similar approach is used to derive the peak efficiency curve for the fallout. A more detailed discussion of the method is given by Toivonen et al. 2009.

We obtained the experimental point source efficiency data at five different photon energies with a detector-source distance of 5 m. The experimental data set was supplemented by Monte Carlo calculations at different photon energies to yield a point efficiency curve over the whole energy region of interest. Fig. 4 shows the efficiency curve for the volume concentration, together with a scaled point source efficiency curve. With the calculated efficiency curves the nuclide specific count rates can be converted to corresponding air concentrations and fallout.

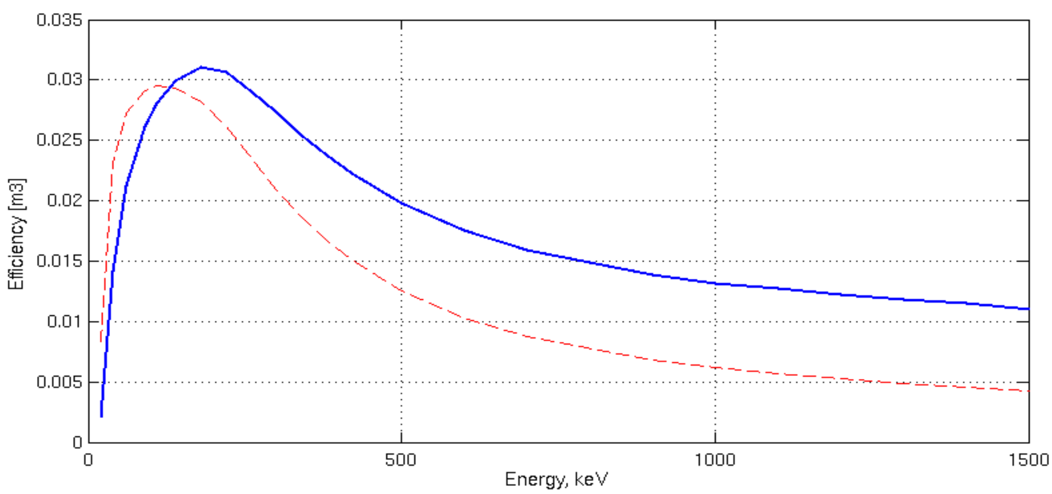

Fig. 4. Efficiency curve for the air concentration. The dashed line is provided for the reference; it is the shape of the point source efficiency at 5 m, multiplied by a factor of 10,000

Results

After deriving the efficiency curves for the relevant source geometries we proceed to discuss the detection limits of nuclides and compare the situation with a monitoring station equipped solely with Geiger-Müller counters. One of the most important benchmark nuclides is I-131 due its relevance in nuclear power plant accident scenarios, where significant amounts can be released into the atmosphere. Then the dose delivered to the thyroid gland by the inhaled or ingested iodine is of high concern.

Using *jmufi*, the main gamma line of I-131 at 364.9 keV photon energy is well separated from the Pb-214 radon progeny gamma line at 351.9 keV in the $LaBr_3$ spectra. As discussed before, an activity concentration of 1700 Bq/m^3 of I-131 in the air would increase the dose rate by 0.1 μSv/h, triggering an alarm at the Geiger-Müller counters of the Finnish monitoring network. For $LaBr_3$ detector, with typical background count rates and a 10 min measurement, the decision limit (Lc) for I-131 at risk level of 10^{-6} (type I error with $k\alpha = 4.75$) yields to approximately 30 Bq/m^3 using the derived peak efficiency shown in fig. 4. The MDA (Ld) is 40 Bq/m^3 at risk level of 5 % (type II error), which is a factor of 40 smaller compared to the alarm level of Geiger-Müller counter.

For Cs-137, in a 10 min measurement, the decision limit is approximately 26 Bq/m^3 and MDA (Ld) is 35 Bq/m^3.

Table 1 summarizes the detection limits of some nuclides in a 10 min measurement with the $LaBr_3$ detector. For a comparison, the activity concentration increasing the dose rate by 0.1 μSv/h is given. For many of the nuclides the $LaBr_3$ detection limits are better by a factor of 30-100.

Table 1. The $LaBr_3$ spectrometer detection limits for airborne nuclides. For a comparison, the alarm limit (increase of 0.1 μSv/h in the dose rate) for the Geiger-Müller counter is also given.

Nuclide	Gamma energy (keV)	LaBr3 Detection limit (Bq/m^3)	GM-tube alarm limit (Bq/m^3)
Am-241	59.5	200	33000
Co-60	1332	20	250
Cs-137	662	30	1100
I-123	159	50	4000

Discussion

The value of nuclide specific information in addition to dose rate is well demonstrated by an event in Olkiluoto area in November, 2009. At a late evening of 22nd of November starting 23:00 UTC, the dose rate at some of the monitoring stations near the Olkiluoto nuclear power plant site started to rise (Fig.4). The values did not at any time during the event cross the alarm limits. However, the change was noticed at a very early stage and an investigative action was taken. Although the rain sensors and weather data of the monitoring stations indicated a rain shower passing over the area, suggesting radon progenies related event, it was not possible to confirm this conclusively from the dose rate data only. The dose rate reached the peak values at 00:10 UTC on the 23rd of November, with a dose rate of 0.20 μSv/h measured at Eurajoki monitoring station.

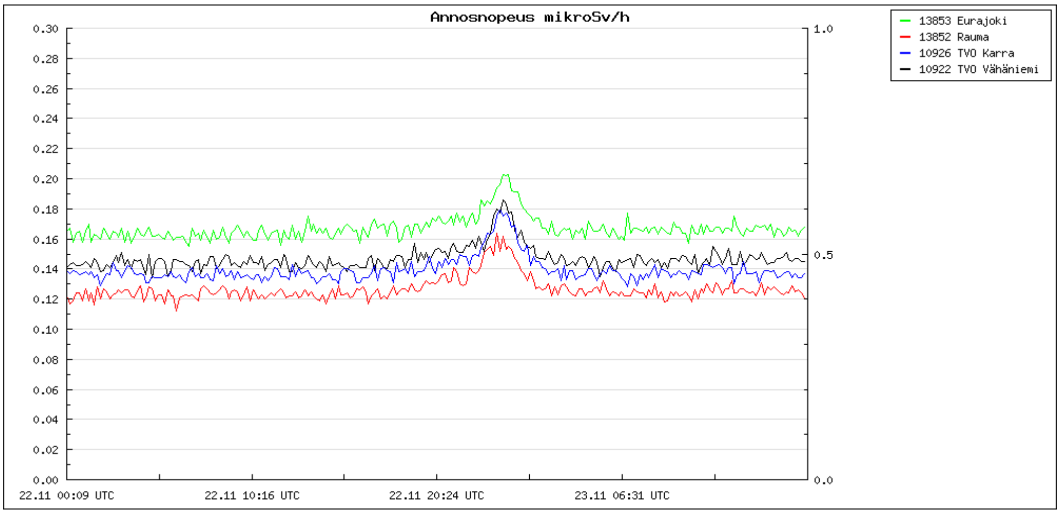

Fig. 4. Dose rates from four monitoring stations around Olkiluoto between 12:00 UTC 22.11.2009 - 12:00 UTC 23.11.2009.

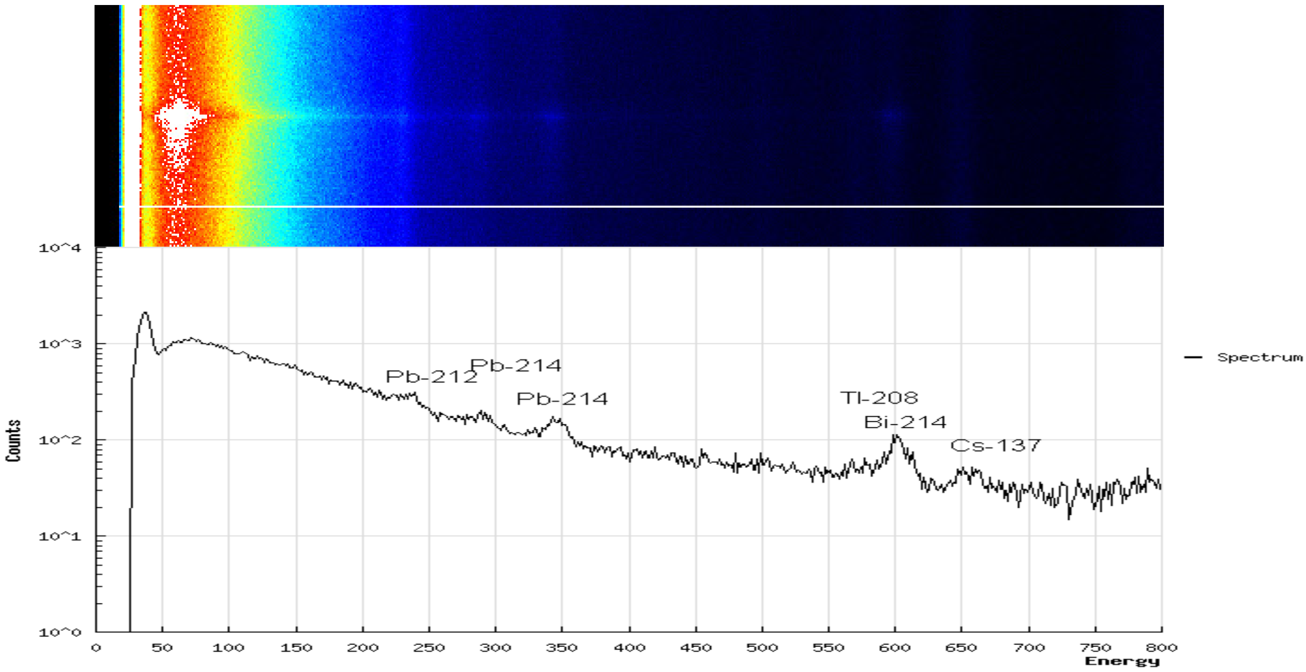

Fig. 5. Waterfall plot of the $LaBr_3$ spectra from Eurajoki monitoring station between 12:00 UTC 22.11.2009 - 12:00 UTC 23.11.2009. The energy scale (x-axis) is from 10 keV to 700 keV, while the y-axis is time. Increase in the intensity of several radon progeny related peaks is observed around midnight. A spectrum recorded at 23:40 UTC shows that the prominent peaks are related to radon progenies.

At that time, the spectra of the $LaBr_3$ detector installed at the Eurajoki station were investigated, and increase in radon progenies was immediately confirmed to be the culprit for the dose rate rise. A waterfall plot of the spectra between 12:00 UTC 22.11.2009 - 12:00 UTC 23.11.2009, shown in fig. 5, reveal several radon progeny related gamma peaks gaining in intensity starting at 22.30 UTC. A single spectrum measured at 23:40 UTC shows that the most prominent peaks can be associated with Pb-212, Pb214 and Tl-208. The waterfall plot clearly shows how the rise and decay in the intensity of these peaks closely follows the dose rate curve. Even though the event did not generate an alarm in the dose rate monitoring network, as the radon-related events almost never because the typical dose increase is below 0.1 µSv/h, the value of $LaBr_3$ scintillators is clearly demonstrated. With the spectroscopic information at hand, the network operator was quickly able to verify the origin of the dose rate increase and confirm the non-alarming nature of the event.

Conclusions

The Finnish dose rate monitoring network has been equipped with 19 $LaBr_3$ spectrometers. These spectrometers have been installed to monitoring stations near the nuclear power plants. This fully automated $LaBr_3$ spectrometer subnetwork provides environmental spectra of excellent quality. Nuclide-specific activity concentrations can be derived from the measured gamma peak count rates. The detection limits for many nuclides are better by a factor of 30-100 compared with the standard Geiger-Müller counters of the monitoring network.

Sample screening to locate active particles with position-sensitive alpha detector

Ihantola, Sakari; Outola, Iisa; Peräjärvi, Kari; Pöllänen, Roy; Toivonen, Harri; Turunen, Jani
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

In order to speed up the analysis of collected samples, new sample screening techniques are required both in nuclear safeguards and nuclear forensics. One promising approach is using a position-sensitive alpha detector. In this work, screening is performed with a Double-Sided Silicon Strip Detector (DSSSD) supported with a novel analysis algorithm. The method is shown to accurately locate the most active particles from a sample containing multiple micrometer-sized particles consisting of weapons-grade plutonium. In addition to the particle locations, the DSSSD also gives the alpha spectrum that can be used to perform a preliminary isotope analysis. Compiling isotope and location information allows further assay methods to be focused only on the spots containing the key isotopes.

Introduction

Analysis of samples containing potentially radioactive particles is a complicated, multi-phased process. Typically, the samples are first screened in order to select the most probable spots. Thereafter, more time-consuming destructive assay methods, such as mass spectrometry, can be used to investigate the selected spots in detail. In increasing the throughput of the analysis without losing any interesting particles, the accuracy of the screening method has a crucial role. In addition to speed and accuracy, it is often essential that the method used is non-destructive to ensure that the sample stays intact for possible subsequent analyses.

Traditional gamma spectrometry is often very inefficient for detecting small amounts of heavy alpha-active isotopes. The gamma yields of such isotopes are typically orders of magnitude smaller than the alpha yields, or the emitted photons have too low energies to be measured. These properties also apply to many isotopes of plutonium and uranium that are of particular interest in nuclear safeguards and nuclear forensics. Thus, to ensure that these isotopes are not ignored during the screening, the screening method cannot only rely on gamma spectrometry but the emitted alphas must be detected as well.

In this work, a new screening method for particles emitting alpha radiation is presented. The particles are located with a position-sensitive Double-Sided Silicon Strip

Detector (DSSSD) and novel software. The performance of the method is investigated by analysing a sample containing multiple micrometer-sized particles from a nuclear bomb. The results are also compared with autoradiography performed to the same sample.

Measurement

The sample analyzed in this work contained pieces of an actinide particle on a filter. The original particle, containing ^{241}Am and ^{239,240}Pu, was isolated from a soil sample collected from Thule, Greenland (Roos et al., 2010) near the location where a US bomber carrying thermonuclear weapons crashed in 1968 (see Eriksson 2002 and references therein). Following chemical treatments with nitric acid and other reagents broke the particle down into several smaller particles. These smaller particles were collected on a filter paper with a pore size of 0.45 µm. All particles in the sample were too small to be visible with the naked eye. To image the sample, it was measured for a few days with the same autoradiography method as in Pöllänen et al. 2004. The autoradiography image obtained is shown in Fig. 1. As can be seen from the image, there are several particles in the sample, two of them having a significantly higher activity than the others.

The measurement of the sample was performed with the alpha-gamma coincidence setup of Particle And Non-Destructive Analysis (PANDA) testbed (Turunen et. al 2010). This setup contains a broad-energy HPGe gamma detector and a position-sensitive alpha detector connected to an event-mode data acquisition system. However, in this work, only the data from the alpha detector were utilized. The alpha detector in PANDA is a Double-Sided Silicon Strip Detector, consisting of 32 active strips in x and y directions. The width of each stripe is 2 mm, and thus, the stripes generate a 64×64-mm² grid consisting of pixels with a size of 2×2 mm². The typical energy resolution of this type of detectors for alphas from ^{241}Am is 55 keV (Micron 2010).

For the measurement, the sample was set inside the measurement chamber of PANDA, and the pressure inside the chamber was pumped to less than 10^{-5} mbar. The surface of the sample matrix was parallel to the alpha detector, and the distance from the detector to the sample was 3.5 ± 0.5 mm. The sample was located approximately at the centre line of the DSSSD. The sample was measured for one week, and the number of accepted alpha hits used in the analysis was about 33 000.

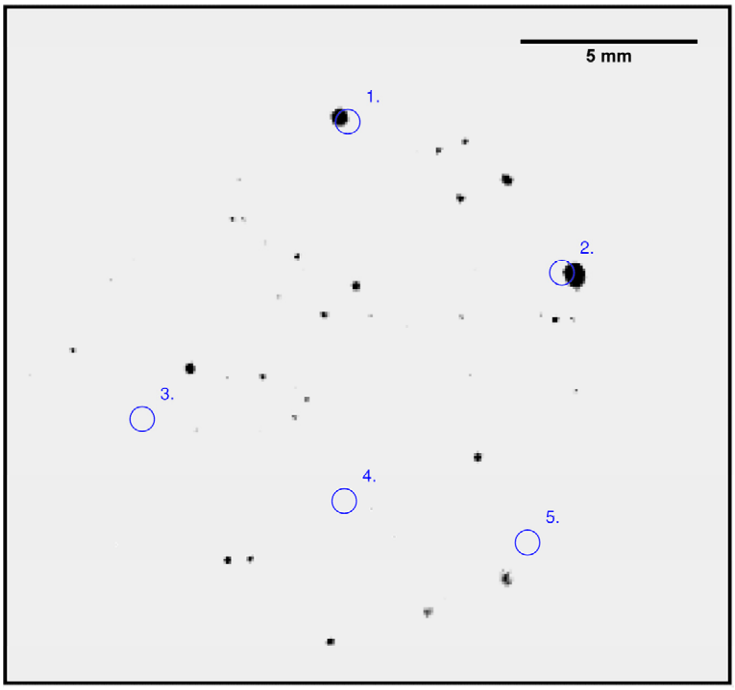

Fig. 1. Autoradiography image of the sample. The blue circles refer to the particle locations obtained with automated analysis (see Table 1) .

Methods

Let us assume that the DSSSD detects every alpha particle hitting the front surface of the detector. In this case, the absolute detection efficiency of each pixel (ε_{abs}) only depends on the solid angle of the pixel (Ω) seen from the source location:

$$\varepsilon_{\text{abs}} = \Omega/(4\pi).$$

For a rectangular pixel, Ω can be analytically calculated with the following equation

$$\begin{aligned}
\Omega = {} & \arctan\left(\frac{(x_2-x_p)(y_2-y_p)}{z_p\left[(x_2-x_p)^2+(y_2-y_p)^2+z_p^2\right]^{1/2}}\right) \\
& -\arctan\left(\frac{(x_1-x_p)(y_2-y_p)}{z_p\left[(x_1-x_p)^2+(y_2-y_p)^2+z_p^2\right]^{1/2}}\right) \\
& -\arctan\left(\frac{(x_2-x_p)(y_1-y_p)}{z_p\left[(x_2-x_p)^2+(y_1-y_p)^2+z_p^2\right]^{1/2}}\right) \\
& +\arctan\left(\frac{(x_1-x_p)(y_1-y_p)}{z_p\left[(x_1-x_p)^2+(y_1-y_p)^2+z_p^2\right]^{1/2}}\right)
\end{aligned}$$

where (x_p, y_p, z_p) is the location of the source and $(x_1, y_1, 0)$ $(x_2, y_2, 0)$ locations of the opposite corners of the pixel (Gotoh et al. 1971). If the location of the source and number of alphas emitted (C) are known, an estimate for the number of alphas detected with one pixel can be calculated as

$$c = C\Omega(x_p, y_p, z_p)/(4\pi).$$

The location and activity of a particle can be determined by finding the parameters that maximize the probability of the detected counts to be produced by the model. Due to the small pixel size of the DSSSD and the low activity of the sample, the number of counts on many pixels is small. Thus, the number of counts does not follow Gaussian statistics, and only properties of the Poisson distribution can be used.

Results

Fig. 2 shows the measured hitmap (counts per pixel). As can be seen from the figure, without further analysis, only one particle can be clearly detected from the raw data. However, by analysing the spectrum with the software designed, the detected hitmap can be explained with five point sources. The parameters of the particles that explain best the shape of the hitmap are shown in Table 1. Fig. 3 shows a hitmap that was simulated by using a set of particle positions and activities obtained from the fit. Comparison of Fig. 2 and Fig. 3 reveals that the simulated hitmap resembles the measured one.

The locations of the fitted particles are also shown in Fig. 1 together with the autoradiography image of the sample. This figure reveals that the automated analysis of the DSSSD data successfully located two particles. The other particles found are not real but describe the shapes in the hitmap generated by multiple small particles close to each other.

Since DSSSD also has a relatively good energy resolution, the measurement produces not only the alpha hitmap but also the alpha spectrum of each pixel. Fig. 4 shows an alpha spectrum obtained by summing the spectra from the pixels near the active particles in the sample. This spectrum already reveals that the particles in the sample probably contain ^{241}Am and ^{239}Pu or ^{240}Pu. If more detailed information of the isotopes is required, the spectrum could be deconvoluted with Adam (see Vesterbacka et al. 2010).

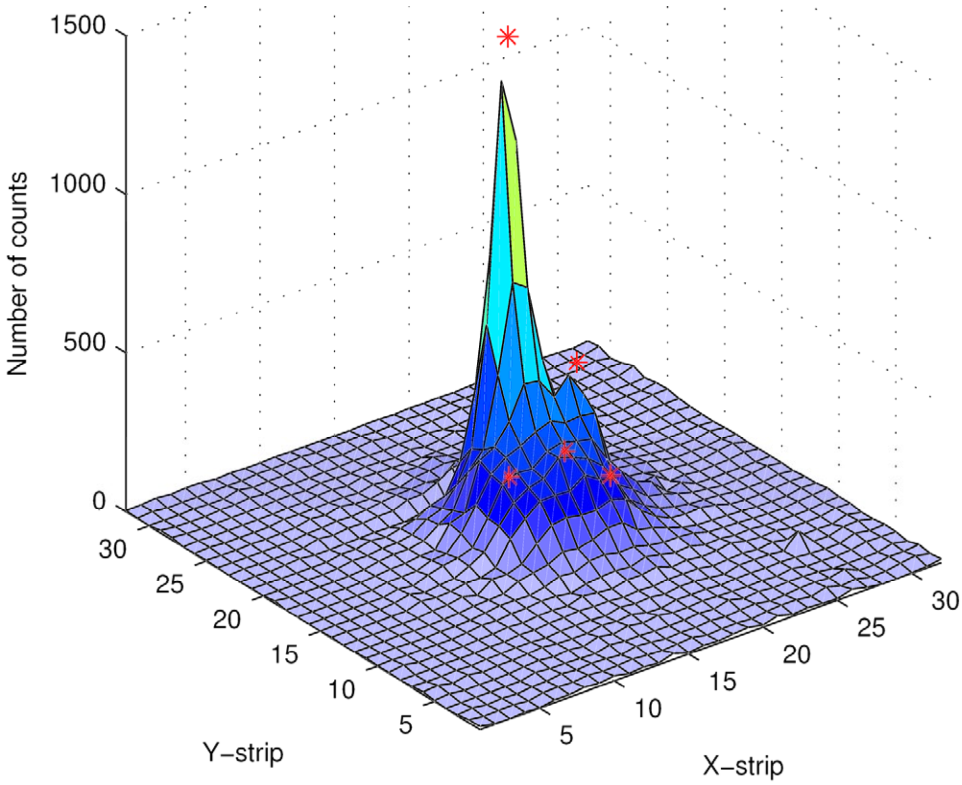

Fig. 2. Measured hitmap and locations of the fitted particles.

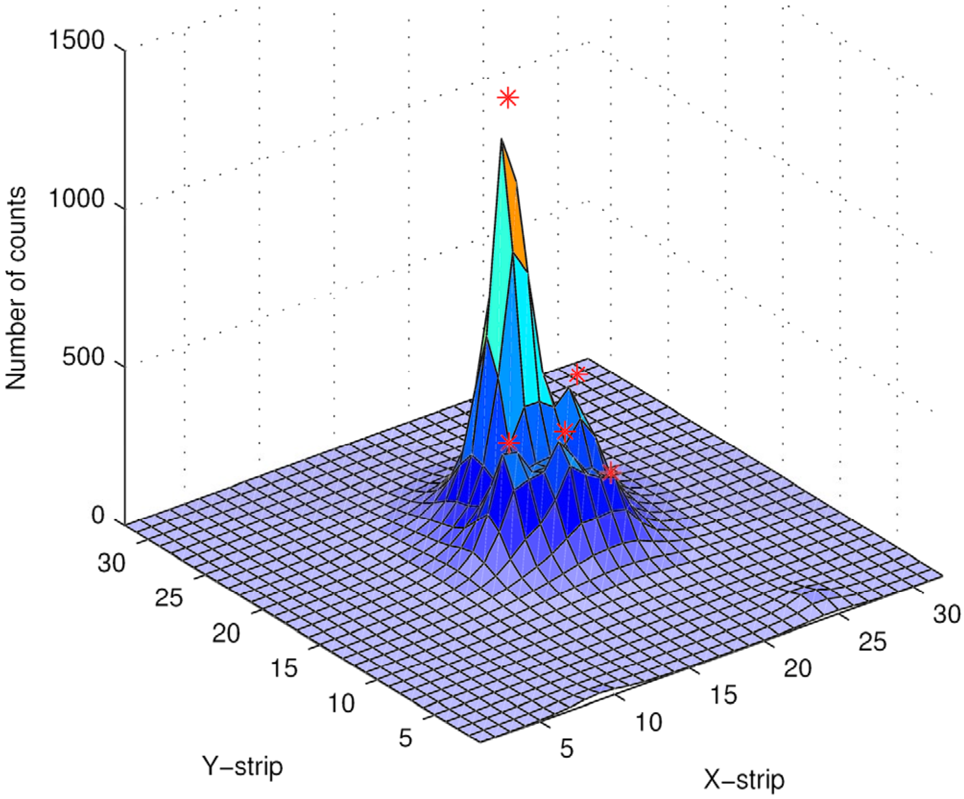

Fig. 3. Simulated hitmap and locations of the fitted particles.

Table 1. Parameters for the fitted particles. The origin of the coordinate system is located at the centre of the detector.

Particle ID	Number of alphas, C	X-coordinate, x_p (mm)	Y-coordinate, y_p (mm)
1	39884	6.8	1.7
2	10151	2.4	7.6
3	9970	-1.3	-4.4
4	9094	-3.8	1.3
5	5086	-5.1	6.4

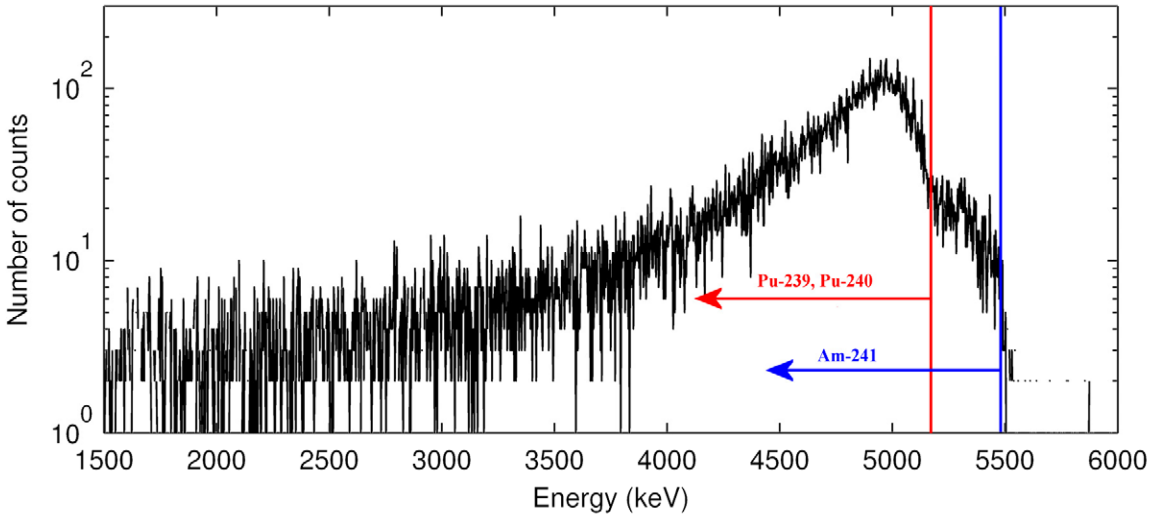

Fig. 4. Summed alpha spectrum from the pixels near the active particles.

Discussion and conclusions

Our research clearly showed that a Double-Sided Silicon Strip Detector can be used to locate alpha-active particles with very low activity. From the analysed sample, the method was able find one particle having a significantly higher activity than the other particles in the same sample. In addition, it was clearly shown that this one particle cannot explain all counts detected but the sample must contain multiple particles. The locations of the other particles given by the analysis software are not as precise but can still be used to determine the most interesting spots for more comprehensive analysis.

Compared to traditional autoradiography, DSSSD has several advantages for sample screening. First, DSSSD does not only give the locations of the particles but also accurate estimates for their activities. Second, the particle locations from the measured data are obtained fully automatically. Third, even though the pixels of the DSSSD are typically very large compared to the pixels in autoradiography images, preliminary tests have shown that with a dedicated location algorithm, the particles can easily be located with an accuracy of less than the pixel size (here 2×2 mm²).

Fourth, unlike in autoradiography, DSSSD also measures the alpha spectrum that can be used to find out the isotopes of the particles. Comparing the alpha spectra of different pixels, even differences in the isotope composition between the particles can be detected. To determine the isotope compositions of the particles, the data from the gamma detector in PANDA can be utilized as well. For example, generating an alpha hitmap only of those counts in coincidence with 59.5 keV gammas from ^{241}Am may be very helpful in locating particles containing plutonium.

On the other hand, using DSSSD to locate particles has also some limitations compared to autoradiography. The greatest disadvantage of DSSSD is the relatively large pixel size that makes it impossible to distinguish particles close to each other. In addition, since DSSSD can only be operated in a high vacuum and each strip of the detector must be read individually, the measurement system is fairly complex. However, there are already similar detectors on the market with a pixel size as small as 400×400 μm² (Micron 2010). Therefore, the locations could be determined with significantly higher accuracy than what is presented in this work.

Abstract

The Finnish Radiation and Nuclear Safety Authority, STUK, is conducting research on non-destructive sample analysis. One of the main tools used for this research is called PANDA (Particles And Non-Destructive Analysis).

Rather than just being a device tailored for a specific use, PANDA is more like a development platform. It has two vacuum chambers; the first is for loading and changing the samples and the second for the measurements. The currently operational measurement set-up consists of an HPGe detector to detect gamma radiation and a Double-Sided Silicon Strip Detector (DSSSD) to detect alpha particles. These detectors are placed face to face in PANDA's measurement position 1 (MP1). Samples are transported from the loading chamber and placed in the middle of these detectors using a linear feedthrough. The distance between the HPGe and DSSSD is about 8 mm. This setup allows simultaneous alpha-particle screening of large-area samples (around 40 cm^2), position-sensitive alpha-gamma and gamma-alpha coincidence studies and various half-life investigations. For example, alpha-gamma coincidence technique provides nearly background-free gamma spectra of alpha-decaying nuclides.

After the sample is screened in MP1, it can be transported to the measurement position 2 (MP2) where the interesting parts of the sample can be further investigated. At first, MP2 will host a single small-area (10 mm^2) silicon drift detector that has superior energy resolution as compared to the detectors of MP1. The main focus of MP2 will be in detecting conversion electrons, alpha particles and X-rays.

The data of MP1 are recorded in event mode, i.e. all events are timestamped. The resulting binary event files are then converted to xml-format and transferred to a database. Various analysis algorithms are currently being developed to facilitate the analysis process. The performance of PANDA is presented through the measurement and analysis of various environmental samples.

Introduction

A novel device for non-destructive sample analysis has been designed and built [1, 2]. This device is called PANDA (Particles And Non-Destructive Analysis). PANDA broadens measurements and analysis prospects of radioactive samples by applying techniques and instruments typical of basic research. These are, for example, double-sided silicon strip detectors, event mode data acquisition and software-based coincidences.

PANDA

PANDA is not only a measurement setup but rather a development platform to study different methods to measure and analyze radioactive samples. Two vacuum chambers are installed side by side on an aluminium pedestal (Fig. 1). The chambers are connected to each other with a gate valve. One chamber is for loading the samples and the other for making the measurements. The samples are transported from the loading chamber to the measurement chamber with a linear feedthrough.

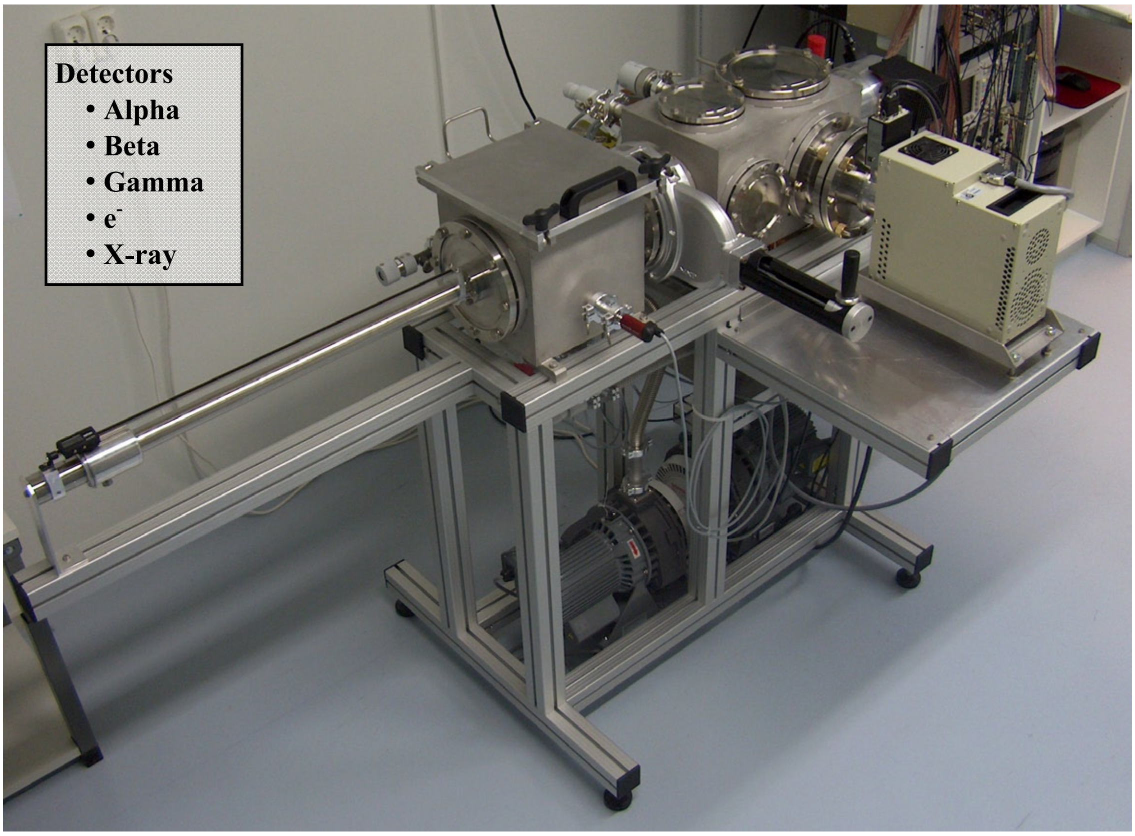

Fig. 1. The PANDA measurement setup.

The measurement chamber has two measurement positions. Measurement position 1 (MP1) is primarily meant for screening of large-area samples such as air filters. It hosts a High Purity Germanium (HPGe) detector and a Double-Sided Silicon Strip Detector (DSSSD) facing each other. The HPGe is used to detect photons and the DSSSD is intended for alpha particles. The samples are transported with the linear feedthrough between the two detectors, see Fig. 2. The source-to-detector distance can be adjusted from a few millimetres to a few centimetres to fit different sample types.

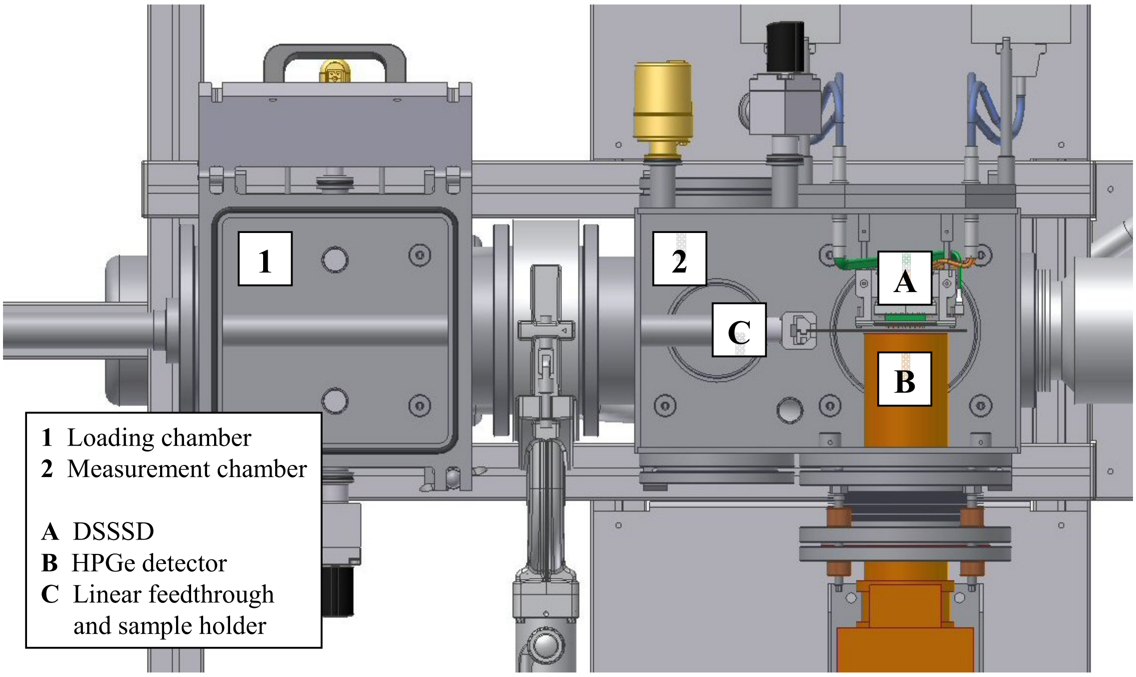

Fig. 2. Top view of PANDA's vacuum chambers.

The position sensitive DSSSD is used to locate interesting radioactive particles. It has 32 front and 32 back strips. Each strip is 2 mm wide and 64 mm long, so the active area of the DSSSD is 64 x 64 mm^2. It can be considered as 1024 individual pixels with a pixel size of 2 x 2 mm^2. After the location and partial analysis of the particles in MP1, the further analyses can be continued in measurement position 2 (MP2). It is devoted to the studies of individual radioactive particles and chemically processed samples. The first version of MP2 has a small silicon drift detector that can be used to detect conversion electrons, alpha particles and X-rays. This detector has an excellent energy resolution, about four times better for low energy photons as compared to the HPGe of MP1. Later on, MP2 will be expanded to include two or more detectors.

PANDA records data in event mode and the events are timestamped. This provides a lot of flexibility and additional possibilities to the data analysis. It enables, for example, to create alpha-gated gamma spectra that are nearly free of background [1]. Analysis of such spectra is simplified, since all gamma peaks are created by the alpha-decaying nuclides. In the near future similar gating can be done to beta-emitting radionuclides as well. This will be done by adding a third detector to MP1. The data are stored to a database and various analysis algorithms are being developed to further improve and intensify the analysis sequence.

Air filter measurement with PANDA

For performance evaluation, PANDA is tested with different kinds of samples. For initial tests, a measurement with an air sample was carried out (Fig. 3). The following results are taken from [2]. The air sample was collected to a Fluoropore filter with a small commercial sampler. The collection time was 2.2 h and the total air flow through the filter was 12.7 m^3. The measurement with PANDA was started 0.5 h after the sample collection ended. The total acquisition time was 3 d 5 h.

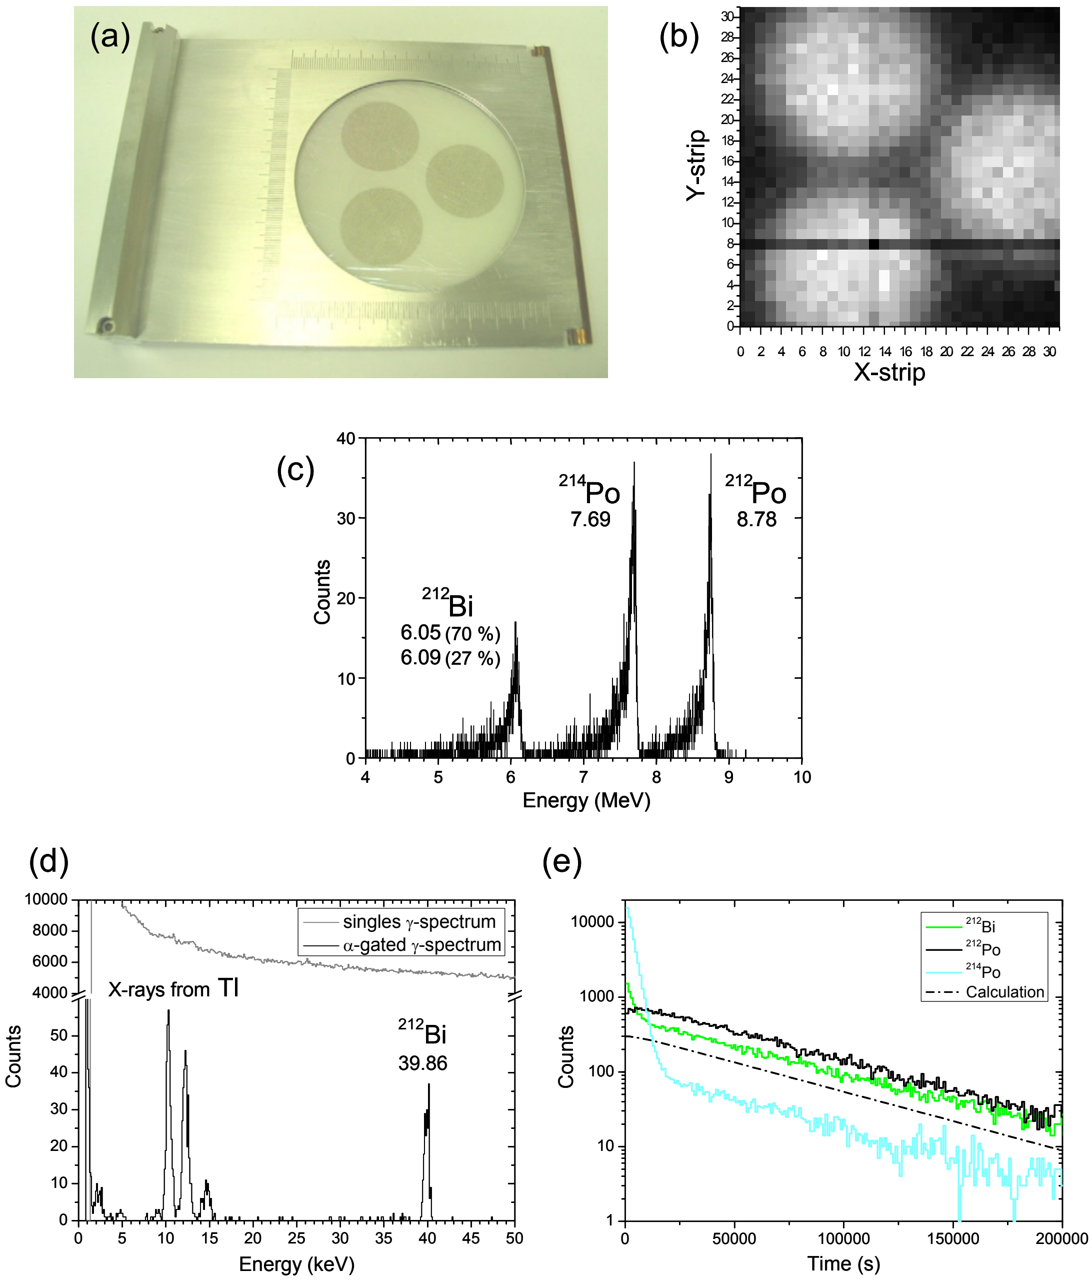

Fig. 3. An air sample measurement made with PANDA. (a) Air filter installed to a sample holder. (b) XY-hitmap of the DSSSD. (c) Alpha spectrum from a single strip. The alpha peaks are from radon daughters ^{212}Bi, ^{214}Po and ^{212}Po. (d) Conventional gamma spectrum and an alpha-gated gamma spectrum made using data from ^{212}Bi alphas. (e) Time behaviour of ^{212}Bi, ^{212}Po and ^{214}Po activity and a theoretical curve showing the shape of the ^{212}Bi and ^{212}Po. Figures 3b-e are taken from [2].

The air filter installed to a sample holder is presented in Fig. 3a. There is a 0.5 µm Mylar foil in front of the filter to protect the DSSSD from contamination. Figure 3b shows an alpha XY-hitmap recorded by the DSSSD. The highest alpha particle count rate is in the brightest pixels. An alpha spectrum of a single strip is shown in Fig. 3c. Three significant alpha peaks belonging to radon daughters ^{212}Bi, ^{214}Po and ^{212}Po are clearly visible.

Figure 3d presents both the singles and the ^{212}Bi alpha-gated gamma spectrum. The alpha gate drastically reduces the background. In the alpha-gated gamma spectrum the 39.9 keV gamma peak related to ^{212}Bi alpha decay and Tl X-rays are easily visible.

With the timestamp data it is possible to study the time behaviour of interesting nuclides in the samples. The time behaviour of ^{212}Bi, ^{212}Po and ^{214}Po activities are shown in Fig. 3e. The graphs are made by gating the timestamp data with the three energy regions where the alpha peaks are located, see Fig. 3c. In the present case, the tailing of the two peaks with the highest energy corrupt the data from the peaks below them. The shape of the time behaviour of ^{212}Po agrees well with the calculated curve since it is not affected by other nuclides. The shape of the calculated curve comes from ^{212}Pb which is the grandmother nuclide of ^{212}Po. Note that since ^{212}Pb is a beta decaying nuclide it is therefore not directly visible in the recorded alpha spectrum. The count rate in the ^{214}Po region is initially dominated by genuine ^{214}Po counts (effective half-life 26.8 min). Later, tailing effects from the ^{212}Po peak (effective half-life 10.64 h) takes over. The ^{212}Bi count rate initially shows contributions from the ^{214}Po peak tails which quickly decay off and show the genuine ^{212}Bi count rate (with a very little fraction attributable to ^{212}Po tailing counts). The flat cap of the ^{212}Po count rate, however, shows the delay in reaching the equilibrium between ^{212}Pb -> ^{212}Bi -> ^{212}Po.

Impactor sample measurements with PANDA

The second sample used here to demonstrate PANDA's abilities is a sample from air monitoring of Thorium with a Berner low-pressure impactor. Figure 4 presents three different measurements of the same sample. In Fig. 4a there is an image of the sample made using autoradiography technique. As seen, the sample consists of 26 active spots that form a spiral shape (diameter ~ 23-28 mm, distance between consecutive spots ~ 3 mm). The same number of spots in the same formation is also clearly visible to the naked eye just by looking at the sample's surface.

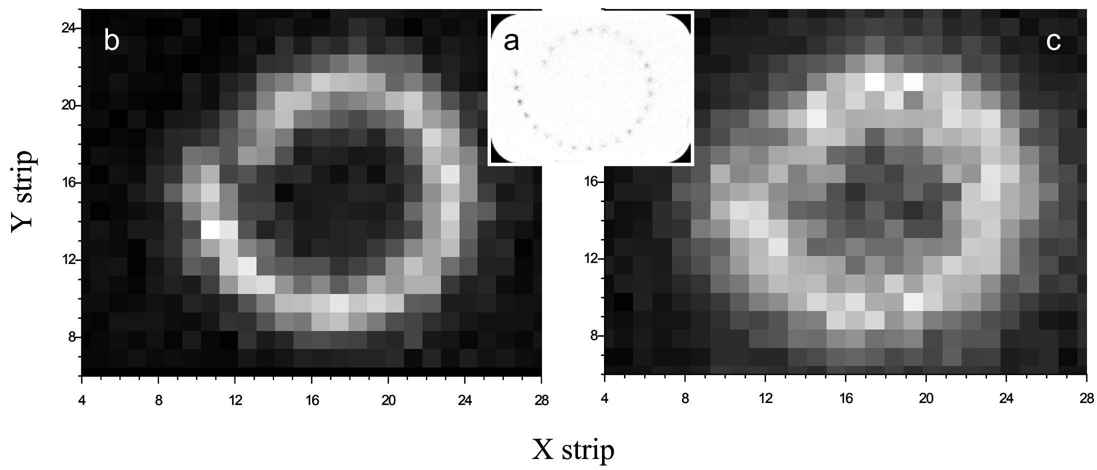

Fig. 4. Impactor sample. (a) Measured with autoradiography technique. (b) XY-hitmap of the DSSSD when sdd is 3 mm. (c) XY-hitmap of the DSSSD when sdd is 4 mm.

Figures 4b and 4c show two alpha particle hitmaps measured using PANDA's DSSSD. The source-to-detector distances (sdd) used were 3 mm and 4 mm, respectively. These hitmaps show only a portion of the DSSSD that is close to the size of the imaging plate shown in Fig. 4a.

As can be seen from the two hitmaps in Fig. 4, the quality of the image obtained with the DSSSD is strongly depended on the source-to-detector distance. There are limitations to how close to the detectors the samples can be installed in PANDA and, at the moment, 3 mm is close to the minimum. Also, since the pixel size (2 mm * 2 mm) in the DSSSD is quite large, it is very difficult to distinguish particles located only a few millimetres apart. When comparing Fig. 4b and 4c, it is clear that even one millimetre in the source-to-detector distance can make a great difference. More about finding and locating particles are discussed in Ihantola et al. [3].

Discussion

With the alpha-gamma coincidence technique, it is possible to reduce the background to nearly zero and improve the detection limits greatly. For example, PANDA is able to detect and locate a particle containing 10^{-9} g of $^{239,240}Pu$ in a few minutes [1]. Notice that the interesting alpha region for Pu and U is between 4 to 6 MeV and, as shown, the contribution of the radon daughters to the alpha spectra is mainly at energies above 6 MeV.

Using the DSSSD in a close geometry instead of a single large area silicon detector reduces the evenly distributed, naturally occurring alpha background significantly. This is because it is possible to use only the pixels right above an interesting spot of the sample in the analysis, i.e., the background recorded by these pixels is only a fraction of the background recorded by the entire detector [1].

As demonstrated, PANDA is a measurement setup that can, for example, greatly improve the analysis of air samples in Certified Laboratories. However, the sampling and subsequent sample preparation must be non-destructive, similar to the sample treatment at Cinderella-type air sampling stations [4].

Acknowledgements

The authors would like to thank Rudolf Engelbrecht, Seibersdorf Labor GmbH and Erich Hrnecek, EC JRC ITU for providing us the impactor sample.

Application of the MKGB-01 spectrometer-radiometer in the KX-gamma coincidences setup at the D. I. Mendeleyev Institute for Metrology

Moiseev, Nikolay; Tereshchenko, Evgeny
D.I. Mendeleyev Institute for Metrology (VNIIM), Saint-Petersburg, RUSSIAN FEDERATION

Abstract

The prototype of setup that implements of KX-gamma coincidences technique developed at the ionizing radiation department of the D.I. Mendeleyev Institute for Metrology is described. The basic element of setup is MKGB-01 spectrometer-radiometer (STC "Radek"). MKGB-01 units - NaI(Tl) crystals of 100 µm x 40 mm and 80 x 80 mm are used for photon radiation detection. The standard set of “CAMAC” units is used as a secondary electronic part. Original design multi-channel counting system is used for counting rate measurements. The main metrological characteristics of the setup model were determined: a long-term stability, background, dead time, resolution time.

Using the described setup the electron-capture radionuclides ^{54}Mn, ^{57}Co, ^{65}Zn, ^{88}Y, ^{139}Ce activity was measured. The combined uncertainty (K=2) of activity was estimated in the range 0,5-1,0 %. Using KX-KX coincidences technique ^{125}I activity was measured with combined uncertainty of 1,0 % (K=2). The results obtained are in good coincidence with international comparisons results.

The main result of investigations is a conception of a new KX-gamma coincidence setup based of the MKGB-01 serial spectrometer-radiometer. A number of requirements for the secondary electronic units have been declared, a device for source positioning has been designed and an achievable uncertainty of the KX-gamma coincidence method has been evaluated. The supplementary investigation for determination of possibility to use the MKGB-01 spectrometer-radiometer for realization in beta-gamma coincidence technique.

Introduction

The photon sources based on ^{54}Mn, ^{57}Co, ^{65}Zn, ^{88}Y, ^{139}Ce and ^{125}I radionuclides are used for spectrometers calibration, applied in radio-ecological measurements. Moreover, ^{125}I based sources are applying in nuclear medicine. These radionuclide disintegrates via electron capture (1) which is accompanied by characteristic radiation from the K, L shells, etc., and the excited state of daughter atom without delay becomes stable with gamma radiation emission (accompanied by the conversion characteristic radiation). The positron emission can also be present.

The main problem is the activity measurement of radionuclides in covered sources, when it is impossible to use beta-gamma coincidence methods (2). X-ray and γ-radiation coincidence method is practically the only method to measure radionuclides activity directly in the covered source.

In our opinion, the most appropriate, is the coincidences of KX and γ-radiation. The detector with thin crystal and Be entrance window was used for KX-radiation, and detector with large crystal and Al entrance window for γ-radiation. The crystals design provides registration mainly only one type of radiation in each detector, and the entrance windows construction excludes registration of KX-KX and KX-LX coincidences. The ^{125}I activity was measured by KX-KX coincidences method using two thin crystals NaI(Tl) (3).

Materials and methods

STC «Radek» produces spectrometer-radiometer MKGB-01, equiped by several detecting units of different type. In the ionizing radiation department at the D. I. Mendeleyev Institute for Metrology a prototype of setup for realisation of KX–γ и KX-KX coincidences method based on this commercially available device has been constructed.

The detecting units based on NaI(Tl) crystals 100 mkm*40 mm and 80*80 mm respectively were used for registration of KX and γ-radiation. For realization of KX-KX coincidences method two NaI(Tl) crystals, 40 mm diameter and 100 mkm thickness were used. Background radiation was shield by using 10 mm thickness lead screen. The prototype block-diagram is shown on Fig.1.

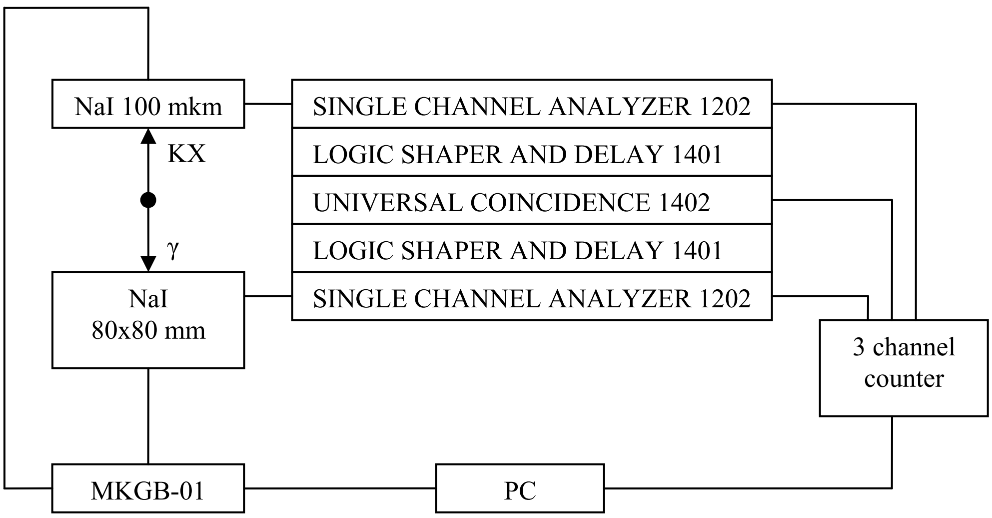

Fig.1. Prototype of setup block-diagram.

The control of spectrometer operating modes (PMT high voltage, preamplifier gain factors and etc.) was carried out using the MKGB-01 firmware.
The registration system is created using set of CAMAC module and consist of single-channel analyzer, pulse shaper and coincidence unit. X-rays, gamma-rays and coincidence counting rates are measured using original design multichannel counting system.

Before making the measurements the main characteristics of the measurement system were determined. These characteristics are following:

Warming time is the time interval, after which the device readings satisfy the requirement:

$$\left|N_i - \bar{N}\right| \leq 3 \cdot S(\bar{N})$$

Where N_i is the device reading of the i-th measurement; $\bar{N}$ is the mean value of the device readings calculated as a result of m measurements performed two hours after the device has been turned on; $S(\bar{N})$ is the standard deviation of the mean value calculated by equation:

$$S(\bar{N}) = \sqrt{\frac{\sum (Ni - \bar{N})}{\sum (m-1)}}$$

Reproducibility after turning off is the relative deviation of the device reading after it has been turned off and turned on again at the unchanging (invariable, constant, permanent) irradiation field:

$$R = \frac{\left|N_i - N_j\right|}{N_i} \cdot 100\%\,,$$

where N_i and N_j are the device readings before and after turning off.

Instability during the working day is the maximum deviation of detector readings from the mean value during the working day:

$$D = \frac{\max\left|N_i - \bar{N}\right|}{\bar{N}} \cdot 100\%$$

Temperature dependence of sensitivity is the variation of device readings when the environment temperature is changing :

$$k(t) = \frac{N(t) - N(t_o)}{t - t_o} \cdot 100\%\,,$$

where $N(t)$ is the device reading when the environment temperature is t°C; $N(t_o)$ is the device reading when the environment temperature is t_o°C.

"Dead"time of the devices was determined using the "two sources technique":

- gamma or X-ray source was placed at a fixed point to provide the device counting rate of about 10^4 s^{-1}, the counting rate N_1 was measured;
- device and source remained immovable, the other source was placed in a position providing to make the counting rate $N_{12} \sim 2N_1$, then the counting rate N_{12} was measured;
- counting rate N_2 with the first source moved out was measured.

The "dead" time value τ was calculated by equation :

$$\tau = \frac{1}{N_{12}}\{1 - \sqrt{\frac{(N_{12} - N_1)(N_{12} - N2)}{N_1 N_2}}\}$$

The following results were obtained for the described prototype.

For X-ray channel:

- warming time is less than 30 min;
- reproducibility after turning off does not exceed 0.1 %;
- instability during the working day does not exceed 0.1%;
- temperature dependence of the sensitivity is 0.05%/°C;
- "dead" time $\tau = 1.21 \pm 0.01$ μs for first KX-detector
- "dead" time $\tau = 1.44 \pm 0.02$ μs for second KX-detector

For gamma-ray channel:

- warming time is less than 30 min;
- reproducibility after turning off does not exceed 0.1 %;
- instability during the working day does not exceed 0.1%;
- temperature dependence of the sensitivity is 0.05%/°C;
- "dead" time $\tau = 2.42 \pm 0.02$ μs.

The coincidence system resolving time τ_p was measured using a pulse generator and is equal 0,514, 1,004 and 2,018 μs for 1402 unit modes «½», «1» and «2» respectively. These τ_p values provided the random coincidence contribution less than 10% of coincidence counting rate.

The final result - activity value was calculated according to Campion (4) and Brian (5) equations.

Measurement modes selection.

The setup operating modes were the follow:

- The source-detector distance in any cases should minimize of summary events probability.
- The KX-channel energy «window» is configured to register the KX-radiation only. In γ-channel the integral operating mode with lower threshold higher than KX-radiation energy is used. It is accepted, that the KX-radiation registration efficiency by γ-detector is close to zero.
- The γ-channel lower threshold for ^{54}Mn and ^{88}Y activity measuring is adjusted above 255 keV to avoid coincidence registration with back scattered radiation.
- The γ-channel lower threshold for ^{65}Zn activity measuring is adjusted above 511 keV to avoid coincidence registration with annihilation radiation.
- The γ-channel lower threshold for ^{57}Co and ^{139}Ce activity measuring is adjusted in energy 80 keV and 100 keV respectively.
- For measuring ^{125}I activity in both KX-channels, the integral operating mode with lower threshold higher than the radiation emission peak (≥15 keV) is used.

Derivation of measurement equations

In general the measurement equations system for electron-capture radionuclide accompanied by internal conversion of γ–transition (^{125}I, for example), taking into account the summary events in each channel, will be follows:

$$\begin{cases} N_1 = N_0 \cdot (\varepsilon_{\gamma 1} I_\gamma + \varepsilon_{kx1}(I_{ec} + I_{ic}) - \varepsilon_{\gamma 1} I_\gamma \varepsilon_{kx1} I_{ec} - \varepsilon_{kx1}^2 I_{ec} I_{ic}) \\ N_2 = N_0 \cdot (\varepsilon_{\gamma 2} I_\gamma + \varepsilon_{kx2}(I_{ec} + I_{ic}) - \varepsilon_{\gamma 2} I_\gamma \varepsilon_{kx2} I_{ec} - \varepsilon_{kx2}^2 I_{ec} I_{ic}) \\ N_c = N_0 \cdot (\varepsilon_{\gamma 1} I_\gamma \varepsilon_{kx2} I_{ec} + \varepsilon_{\gamma 2} I_\gamma \varepsilon_{kx1} I_{ec} + 2\varepsilon_{kx1} I_{ec} \varepsilon_{kx2} I_{ic}) \end{cases} \qquad (1)$$

Where: $N_1; N_2; N_c$ - pulse counting rates in γ-channel, KX channel and in coincidence channel, $\varepsilon_{\gamma 1}; \varepsilon_{\gamma 2}; \varepsilon_{kx1}; \varepsilon_{kx2}$ - efficiencies of γ and KX-detector to γ and KX-radiation; I_γ - emission probability of γ-radiation, $I_{ec} = P_k \omega_k$ - emission probability of KX-radiation due to electron capture, $I_{ic} = (\alpha_k \omega_k)/(1+\alpha_t)$ - emission probability of KX-radiation due to internal conversion. The coincidences with LX – radiation are not considered for reasons described above.

In conditions of summary events low probability ($\varepsilon_{\gamma 1}; \varepsilon_{\gamma 2}; \varepsilon_{kx1}; \varepsilon_{kx2}$<5%) the equations (1) are simplified to (2).

$$\begin{cases} N_1 = N_0 \cdot (\varepsilon_{\gamma 1} I_\gamma + \varepsilon_{kx1}(I_{ec} + I_{ic})) \\ N_2 = N_0 \cdot (\varepsilon_{\gamma 2} I_\gamma + \varepsilon_{kx2}(I_{ec} + I_{ic})) \\ N_c = N_0 \cdot (\varepsilon_{\gamma 1} I_\gamma \varepsilon_{kx2} I_{ec} + \varepsilon_{\gamma 2} I_\gamma \varepsilon_{kx1} I_{ec} + 2\varepsilon_{kx1} I_{ec} \varepsilon_{kx2} I_{ic}) \end{cases} \qquad (2)$$

The contribution of γ-radiation to KX-detector $N_2^\gamma = N_0 \cdot \varepsilon_{\gamma 2} I_\gamma$ is defined using aluminium filters (1mm for ^{54}Mn, ^{57}Co and ^{65}Zn and 5mm for ^{88}Y) and copper filter (1 mm for ^{139}Ce).

Modifying the equations (2) and computing I_γ, I_{ec} and I_{ic} from the data (1), we obtain measurements equation for each radionuclide. The numerical value of corrections standard uncertainty is indicated in brackets.

For ^{54}Mn

$$\frac{N_1 \cdot (N_2 - N_2^\gamma)}{N_c} = N_0 \qquad (3)$$

For ^{65}Zn 1115 keV γ-transition only is taken into account.

$$\frac{N_1 \cdot (N_2 - N_2^\gamma)}{N_c} = N_0 \cdot \frac{(a \cdot I_{ec}^a + b \cdot I_{ec}^b)}{I_{ec}^a} = N_0 \cdot 0.989(9) \qquad (4)$$

Where: $a; b$ - probability of electron capture to the 2 and 0 level for ^{65}Zn,

$I_{ec}^a; I_{ec}^b$ - emission probability of KX-radiation due to of electron capture to the 2 and 0 level.

For ^{139}Ce

$$\frac{N_1 \cdot (N_2 - N_2^\gamma)}{N_c} = N_0 \cdot \frac{(I_{ec} + I_{ic})}{I_{ec}} = N_0 \cdot 1.239(5) \qquad (5)$$

For ^{88}Y 898 keV and 1836 keV γ-transitions are taken into account.

$$\frac{N_1 \cdot (N_2 - N_2^{\gamma})}{N_c} = N_0 \cdot \frac{(a \cdot I_{\gamma}^{898} + X \cdot I_{\gamma}^{1836}) \cdot (a \cdot I_{ec}^{a} + b \cdot I_{ec}^{b})}{(a \cdot I_{ec}^{a} \cdot (I_{\gamma}^{898} + X \cdot I_{\gamma}^{1836}) + b \cdot I_{ec}^{b} \cdot X \cdot I_{\gamma}^{1836})} = N_0 \cdot 0{,}989(10) \quad (6)$$

Where: $a;b$ - electron capture probability to the 2 and 1 level for ^{88}Y, $I_{ec}^{a};I_{ec}^{b}$ - emission probability of KX-radiation due to electron capture to the 2 and 1 level, $I_{\gamma}^{898};I_{\gamma}^{1836}$ - γ-radiation emission probability with energies 898 keV and 1836 keV, $X = \varepsilon_{\gamma 1}^{898} / \varepsilon_{\gamma 1}^{1836}$ - ratio of γ-radiation registration efficiency with energy 898 keV to the γ-radiation registration efficiency with energy 1836 keV in the selected «window» (≥400 keV).

The value of X=1,00(1) was calculated by Monte-Carlo method (6) for selected distances source-detector. The maximum contribution of X in correction standard uncertainty in the right part of the equation (6) was equal 0,1%.

For ^{125}I

$$\frac{N_1 \cdot N_2}{N_c} = N_0 \cdot \frac{(K_1 \cdot I_{\gamma} + I_{ec} + I_{ic}) \cdot (K_2 \cdot I_{\gamma} + I_{ec} + I_{ic})}{(I_{\gamma} \cdot I_{ec} \cdot (K_1 + K_2) + 2 \cdot I_{ec} \cdot I_{ic})} = N_0 \cdot 2.0064(42) \qquad (7)$$

Where: $K_1 = \varepsilon_{\gamma 1} / \varepsilon_{kx1}; K_2 = \varepsilon_{\gamma 2} / \varepsilon_{kx2}$ - ratio of γ-radiation registration efficiency to the KX-radiation registration efficiency in each KX-detector in the selected energy «window» (≥15 keV).

The value of K_1=K_2 = 1,215(45) were calculated by Monte-Carlo method (6) for selected distances source-detector. The maximum contribution of K_1 and K_2 in correction standard uncertainty in the right part of the equation (7) was equal 0,25%.

For ^{57}Co 14,4, 122 и 136 keV γ-transitions are taken into account.

$$\frac{N_1 \cdot (N_2 - N_2^{\gamma})}{N_c} = N_0 \cdot \frac{(K \cdot a \cdot I_{\gamma}^{136} + b \cdot I_{\gamma}^{122}) \cdot (I_{ec} + a \cdot I_{ic}^{136} + b \cdot I_{ic}^{122} + b \cdot I_{ic}^{14})}{(K \cdot a \cdot I_{ec} \cdot I_{\gamma}^{136} + b \cdot I_{ec} \cdot I_{\gamma}^{122} + b \cdot I_{\gamma}^{122} \cdot I_{ic}^{14})} = N_0 \cdot 1.016(9)$$

(7)

Where: $a;b$ - transition probability from 2 to 0 and from 2 to 1 level for ^{57}Co, $I_{\gamma}^{122};I_{\gamma}^{136}$ - γ-radiation emission probability with energies 122 keV and 136 keV, $I_{ic}^{14};I_{ic}^{122};I_{ic}^{136}$ - KX-radiation emission probability due to γ-radiation internal conversion with energies 14,4 keV, 122 keV and 136 keV, $K = \varepsilon_{\gamma 1}^{136} / \varepsilon_{\gamma 1}^{122}$ - ratio of γ-radiation registration efficiency with energy 136 keV to the γ-radiation registration efficiency with energy 122 keV in the selected energy «window» (≥80 keV).

The value of K=1,060(4) was calculated by Monte-Carlo method (6) for selected distances source-detector. The maximum contribution of K in correction standard uncertainty in the right part of the equation (9) was equal 0,2%

Results

The ^{54}Mn, ^{57}Co, ^{65}Zn, ^{88}Y and ^{139}Ce radionuclide activity in film covered sources OSGI type was measured using KX-γ coincidences method. The results obtained are presented in table 1. In the last column of table 1 the deflection of these results from the same obtained by national activity standard of Russia Federation. The ^{54}Mn №5123 and ^{57}Co №5171 sources are the witnesses of international comparisons (7,8). Other radionuclides activity measurements results was traced to the results of key comparisons (9,10,11).

Table 1. The results.

Nuclide	Source number	Date	KX-γ coincidences activity, Bq	Uc, k=2 %	Activity, measured on the standard, Bq	Uc, k=2 %	Deflection, %
^{54}Mn	5123	01.01.09	12 956	1.0	12 860	1.0	0.8
	41-06	01.01.09	36 363	1.0	36 462	2.0	-0.3
	384-08	01.01.09	72 186	1.1	72 451	2.0	-0.4

	16-08	01.01.09	41 130	2.1	41 221	2.0	-0.2
	387-08	01.01.09	90 294	2.1	90 236	2.0	0.1
	350-07	01.01.09	171 258	2.2	171 755	2.0	-0.3
^{88}Y	15-08	01.01.09	14 004	2.3	14 172	2.0	-1.2
	24-06	01.01.09	38 236	2.3	38 549	2.0	-0.8
	469-08	01.01.10	97 031	2.3	98 369	2.0	-1.4
^{139}Ce	14-08	01.01.09	18 446	1.8	18 340	2.0	0.6
	47-06	01.01.09	67 000	1.8	66 007	2.0	1.5
	471-06	01.01.10	150 746	1.9	149 330	2.0	1.0
^{57}Co	5171	01.01.09	8 229	2.0	8 108	1.0	1.5
	01	01.01.09	205 224	2.1	206 731	2.0	-0.7

^{125}I activity was measured in 5 film covered sources, prepared from one solution with well known masses. A detailed description of sources preparation procedure is given in (3). The specific activity is calculated as the average value of 5 results. The result obtained is given in comparison with specific activity (table 2), measured on the national activity standard of Russia Federation with KX-γ coincidences method.

Table 2. ^{125}I Specific activity.

Nuclide	Date	KX-γ coincidences specific activity, Bq/mg	Uc, k=2 %	Specific activity, measured on the standard, Bq/mg	Uc, k=2 %	Deflection, %
I-152	21.05.09	3084	2.0	3135	2.0	1.6

Discussion

Table 1 and 2 data analysis shows, results obtained using described prototype are in good agreement with national standard results. It means spectrometer-radiometer MKGB-01 can be used for activity measurements without preliminary calibration.
Moreover setup described makes it possible to measure radionuclides activity directly in mass-produced film covered sources (12).

On the basis of this investigations an original KX-γ coincidences setup construction is proposed (MKGB-01 units based primary converter, background shielding system, positioning device, secondary electronics).

Conclusions

A concept of creation of the setup, implements the KX-γ coincidences method, based on commercially available spectrometer-radiometer MKGB-01 is developed. The main requirements to the future KX-γ coincidences setup are formulated.

Comparison of two techniques for low-level tritium measurement – gas proportional and liquid scintillation counting

Barešić, Jadranka; Horvatinčić, Nada; Krajcar Bronić, Ines; Obelić, Bogomil
Rudjer Bošković Institute, Zagreb, CROATIA

Abstract

Measurement of low-level tritium activities in natural/non-polluted waters, e.g. in precipitation and groundwater, requires special techniques for water pretreatment and detection of low-level radioactivity. Two methods for low-level tritium measurement have been developed in Zagreb Radiocarbon and Tritium Laboratory: gas proportional counting (GPC) and liquid scintillation counting (LSC). Method of electrolytic enrichment of water samples with tritium followed by measurement by LSC *Quantulus 1220* has been developed in 2008. Here we present the comparison of the two measurement techniques.

Our Laboratory participated in the intercomparison study organized by the IAEA, TRIC2008. The data evaluation of six samples revealed that all results measured by LSC are accepted, as well as four GPC results, while two GPC results of samples with low tritium activity (<2 TU) are in the warning level.

Introduction

Atmospheric thermonuclear tests during 1950es and 1960es introduced large amount of anthropogenic tritium into the atmosphere. The peak of tritium activity with up to 10 000 TU has been reached in 1963 in a monthly rain in North America. The anthropogenic tritium has been used as a global tracer in hydrogeology and meteorology studies (Rożanski at al. 1991). Tritium activity in surface, groundwater and precipitation was measured by a gas proportional counting (GPC) technique, and later on by liquid scintillation counting (LSC). However, the present tritium activity almost approached natural levels (5 – 10 TU), and measurement of samples without tritium enrichment is not precise enough any more.

In Zagreb Radiocarbon and Tritium Laboratory two measurement techniques of low-level tritium activities in natural/non-polluted waters, e.g. in precipitation and groundwater, have been used: gas proportional counting (GPC) and liquid scintillation counting (LSC). GPC technique for measurement of non-enriched samples has been used since 1978. A method of tritium measurement by LSC *Quantulus 1220* using electrolytic enrichment of water samples has been developed in 2008.

Material and methods

CH_4 is used as a counting gas in a multi-wire GPC. It is obtained by reaction of water (50 ml) with aluminium carbide at 150°C (Horvatinčić, 1980). The counting energy window is set to energies between 1 keV and 10 keV to obtain the best figure of merit. Gas quality control has been performed by simultaneous monitoring of the count rate above the tritium channel, i.e., above 20 keV (Krajcar Bronić et al. 1986). The limit of detection is 2.5 TU.

System of electrolytic enrichment consists of 20 cells of 500 ml volume (anodes: stainless steel, cathodes: mild steel) and equipments for primary and secondary distillations. The first step of sample pretreatment is primary distillation. If conductivity of distilled samples is <50 µS/cm, samples are ready for the enrichment procedure. Otherwise, samples have to be distilled again. For each enrichment run 3 spike and 2 dead-water (DW) samples are used for system control. Enrichment procedure lasts for 8 days (1420 Ah). Final volume of water sample after electrolysis is 19±1 ml. The enrichment factor (E) and the enrichment parameter (P) for each electrolysis run have been calculated using initial and final mass of water in cells and individual count rates of spike water before and after enrichment. The average enrichment factor (E) of several electrolysis runs is 21.4 ± 0.9, and the P parameter reached a value of 0.95.

Mixture of 8 ml of water and 12 ml of scintillation cocktail *Ultima Gold LLT* in plastic vials is used for counting in LSC. The measurement run contains 15 samples, 3 enriched spikes, 2 enriched DW samples, 1 non-enriched spike, 2 non-enriched DWs and a standard sample (activity 11 552 TU on 7.7.2008). The limit of detection is 0.3 to 0.5 TU, depending on the measurement duration.

Results

The results of GPC and LSC measurements of IAEA TRIC2008 intercomparison samples are presented in Table 1. The results were evaluated with the z-score and Final score evaluations. The z-score values were calculated using measured laboratory values (A_{lab}) and their sigma values (σ_{lab}) and IAEA true values (A_{IAEA}):

$$z = \frac{A_{lab} - A_{IAEA}}{\sigma_{lab}}$$

The Final score evaluations were determined by the evaluation criteria for both trueness and precision of the measurements (Gröning et al, 2009). In the final evaluation, both scores are combined and a result must obtain ‘Acceptable’ score in both criteria to be assigned final score ‘Acceptable’.

According to the Final score evaluations all our LSC results are acceptable while two GPC results of samples T14 and T15 with low tritium activity are in warning level. The z-score evaluations showed that most of GPC results are lower than the IAEA true values (mean z-score is -0.44) and in the case of LSC results the deviations from the IAEA true values is smaller (mean z-score is -0.29). The comparison of both GPC and LSC results with the IAEA true values is presented in Fig.1.

Table 1. Comparison of GPC and LSC values measured in our Laboratory with IAEA TRIC2008 intercomparison results. The z-score and Final score evaluations are presented for both methods (A – acceptable, W – warning)

IAEA code	IAEA true value (TU)	GPC				LSC			
		Lab. code	Lab value (TU)	z-score	Final score	Lab. code	Lab value (TU)	z-score	Final score
T14	1.54 ± 0.05	T-3867	0.21 ± 0.81	-1.64	W	T-3906	1.25 ± 0.3	-0.97	A
T15	4.07 ± 0.05	T-3868	3.50 ± 0.96	-0.59	A	T-3907	4.11 ± 0.3	0.13	A
T16	7.74 ± 0.06	T-3869	6.60 ± 0.99	-1.15	A	T-3908	7.42 ± 0.3	-1.06	A
T17	14.46 ± 0.08	T-3870	14.23 ± 0.67	-0.34	A	T-3909	14.44 ± 0.4	-0.05	A
T18	0.67 ± 0.05	T-3871	0.03 ± 0.82	-0.78	W	T-3910	0.57 ± 0.3	-0.33	A
T19	568.7 ± 2.3	T-3872	579.24 ±5.70	1.85	A	T-3911	576.0 ± 13	0.56	A

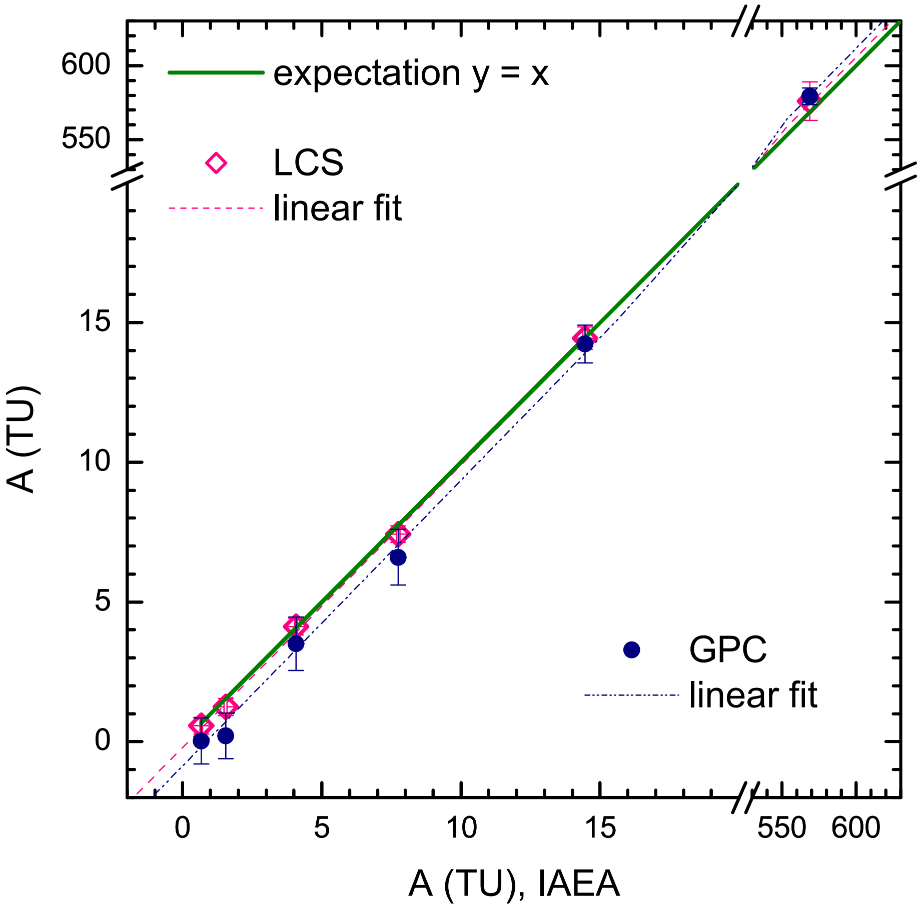

Fig. 1. The comparison of tritium activities of TRIC2008 intercomparison samples measured by GPC and LSC techniques with the IAEA true values.

For additional testing of both systems we measured tritium activity in several precipitation and groundwater samples by both GPC and LSC techniques. The results are presented in Fig. 2. Here we can see that all LSC results have smaller errors then GPC results. For the samples with low tritium activity (<10 TU, mostly groundwater) the GPC results are mainly lower then the LSC results while for the higher tritium activities (precipitation samples) the GPC results are lower than the LSC results. If we take into account also the IAEA intercomparison results obtained by both methods, we can conclude that for the low tritium activity the GPC system is not acceptable because of higher/worse detection limit (2.5 TU). LSC system with detection limit of 0.3 – 0.5 TU and with better precision (Table 1) is more suitable for most natural water samples including precipitation and groundwater samples.

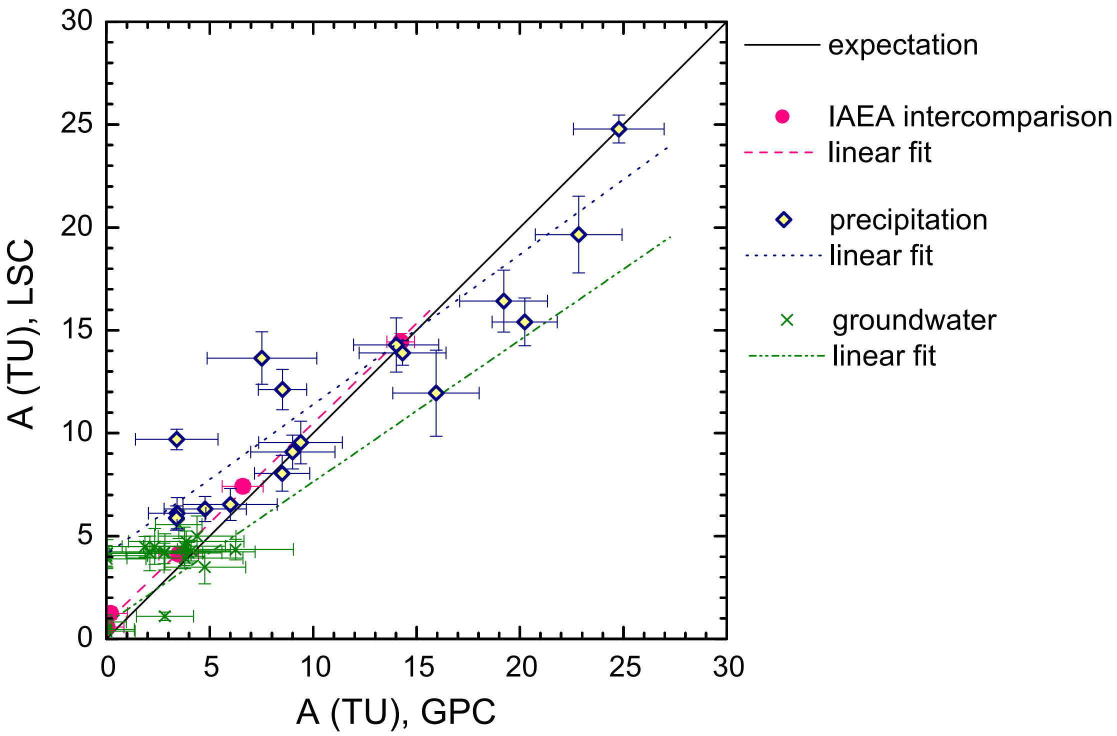

Fig. 2. Comparison of GPC and LSC results of groundwater and precipitation samples, as well as TRIC2008 intercomparison samples.

Conclusion

The data evaluation of six TRIC2008 samples (IAEA intercomparison) revealed that all results measured by LSC are accepted, and for GPC results four results are accepted and two results of low tritium activity (<2 TU) are in the warning level. Measurements of groundwater and precipitation samples show that GPC values are still valid for higher tritium activities (>10 TU), while lower activities can not be measured properly without enrichment and followed by LSC measurement.

Multi-screen diffusion battery for radon progeny dispersion analysis

Zhukovsky, Michael; Bastrikov, Vladislav; Rogozina, Marina; Yarmoshenko, Ilya
Institute of Industrial Ecology, Ural Branch of Russian Academy of Science,
RUSSIAN FEDERATION

Abstract

The screen-type diffusion battery method was enhanced for size distribution measurements of radon progeny air particles. The measurement technique implies multisection arrangement of several dozens of screen stages and a backup filter during sampling with subsequent activity measurement of each component. Variations on quantity of screens, flow rate and screen meshness allows to obtain required cut-off diameters of the stages and essential operating size range in general. Serial mounting of screen blocks with continually narrowing penetration curve is also used. Optimal parameters were adjusted for radon progeny size distribution researches.

Size distribution measurements of radon progeny in the range of 1-400 nm were performed in the laboratory radon box with high radon equilibrium-equivalent concentration (5-20 kBq/m^3). Generally accepted modes of unattached and aerosol fractions were confirmed. The smallest mode is represented by the primary free particles (geometric mean diameter 1.75 nm, geometrical standard deviation $\sigma_g = 2.0$). It appeared that the nucleation mode consists of three modes (8.5, 20 and 40 nm with σ_g 1.5, 1.2 and 1.7, respectively). Two modes of the accumulation mode were also observed (120 and 300 nm with σ_g 1.5 and 1.2, respectively).

Knowledge of dispersion behaviour of natural radioactive aerosols and gases is critical for understanding human exposure and for appropriate measurement technique development, especially in the case of unattached fraction. Results obtained in the work have particular value from this point.

Introduction

Natural radioactive gas radon and its progeny form the most significant radiological hazard on the general population round the world. Inhalation dose due to radon progeny is highly dependent on the size of inhaled particles. Newly generated short-lived radon decay products usually exist as positively charged ions that rapidly attach on atmospheric aerosol particles and form radioactive aerosol. So the size distribution of radon progeny is directly related to the natural particle sizes that primarily assist at the atmosphere.

In order to have an appropriate estimate of radon dose one should determine aerosol size distribution along with the radon concentration. Traditional measurement instruments for dispersion analysis include diffusion battery and cascade impactor. The first is used for measurements in nanometer region, while the second – for micrometer region. In this work a screen-type diffusion battery was designed for the size distribution measurements in the wide range from fractions of nm to several hundreds of nm.

Investigations were conducted in the laboratory radon box in Radon laboratory of Ural State Technical University (Ekaterinburg, Russian Federation). High radon concentration values in the box allowed performing aerosol particle size distribution measurements with high accuracy.

Material and methods

Most commonly used methods for size distribution measurements of atmospheric ultrafine particles are based on their diffusion properties. The smaller particles have higher diffusivities than large ones and diffuse more rapidly to surfaces. In this work we use screen-type diffusion battery method optimized for wide range of particle sizes.

The measurement system consists of a number of wire screens with different penetration characteristics and several backup filters arranged sequentially in a series configuration. Activity collected on each wire screen and filter is measured after sampling with semiconductor alpha counter.

Three different wire screen types that appeared to be optimal for experiments were chosen. In Table 1 the main screen characteristics are summarized. Analytic aerosol filters with standard characteristics were used as backup filters.

Table 1. Wire screen characteristics.

Type	Mesh	Wire diameter, mm	Screen opening, mm	Screen thickness, mm	Screen mass, g	Density, g/cm^3
1	35	0.25	0.5	0.51	2.13	7.8
2	150	0.65	0.1	0.14	0.69	8.5
3	350	0.03	0.04	0.07	0.31	7.8

Particle penetration through a wire screen was described by semi-empirical equations of filtration theory (Cheng et al. 1980). Penetration through the screen depends on its characteristics, geometry, air flow velocity and particle size. From theoretical calculations and experimental testing of diffusion batteries with different screen combinations two main configurations were adjusted for wide range aerosol dispersion analysis (see Table 2).

It should be noticed that for Type II battery ultrafine particles with sizes less than 10 nanometers get stuck already on the first wire-screens. It allows to neglect a control of tube losses, which is significant only for slow motion of ultrafine particles.

Table 2. Multi-screen diffusion battery configurations.

Type	Screen mesh	Quantity of screens	Operating flow rate, l/min	Operating AMTD range, nm
I	35 150 350	5 5 14	25	0.78-27
II	150 350	6 28	0.8	11-400

Sampling procedures were performed in the laboratory radon box with a volume of 4 m^3. Radon was generated inside the box by placing a standard source of Ra with activity of 518 kBq and emanation coefficient 0.26. Equilibrium conditions between radon and its progeny were established before the sampling. The radon equilibrium-equivalent concentration in the box atmosphere was in the range from 4500 to 18000 Bq/m^3. The volumetric flow rate during sampling was kept constant.

Diffusion battery was placed inside the box via locking system in order to neglect particle concentration losses. By use of flexible tubes the device was connected to the air pump with adjustable volumetric flow rate. Sampling procedure was implemented during 10-40 minutes. Individual activity measurements of collecting elements were performed after 40 minutes delay in order to neglect the influence of equilibrium shift between short-lived radon daughters. The primary measurement results were presented as a set of equilibrium-equivalent concentrations, calculated from individual activities of each diffusion battery collecting element according to the Kusnetz method (Kusnetz 1956).

It is well known that aerosol particle distribution in the air is well described by the polymodal lognormal distribution. In the case of unimodal lognormal distribution integral probability function plotted on the log-probability graph is used for definition of the activity median thermodynamic diameter (Hinds 1999). The probability scale of log-probability graph compresses the percent scale near the median (50% point) and expands the scale near the ends such that a cumulative plot of a lognormal distribution will yield a straight line. A log-probability plot can be constructed by plotting the logarithm of diameter versus the probability function, expressed in cumulative percentages. This probability function is defined as:

$$f(D_i) = f(D_{i-1}) - \frac{C_{\text{eq},i}}{\sum\limits_{k=1} C_{\text{eq},k}} \cdot 100\%,$$

where D_i is a 50% cut-off diameter of i wire-screen, $C_{\text{eq},i}$ is an equilibrium-equivalent concentration, corresponding to i wire-screen. The value of the probability function $f(D_1)$ for the first wire-screen is fixed to 100%.

It is supposed that every screen of diffusion battery catches particles related to several modes of aerosol particle distribution. Probability function curve plotted for the full set of collecting elements have some inflections. By the analytical method each diffusion battery type was divided to several sections with specific number of wire screens. Thus, integral probability function curve of every section was linear and corresponded to lognormal distribution of one mode. An example of the probability function curves for one diffusion battery is presented in figure 1.

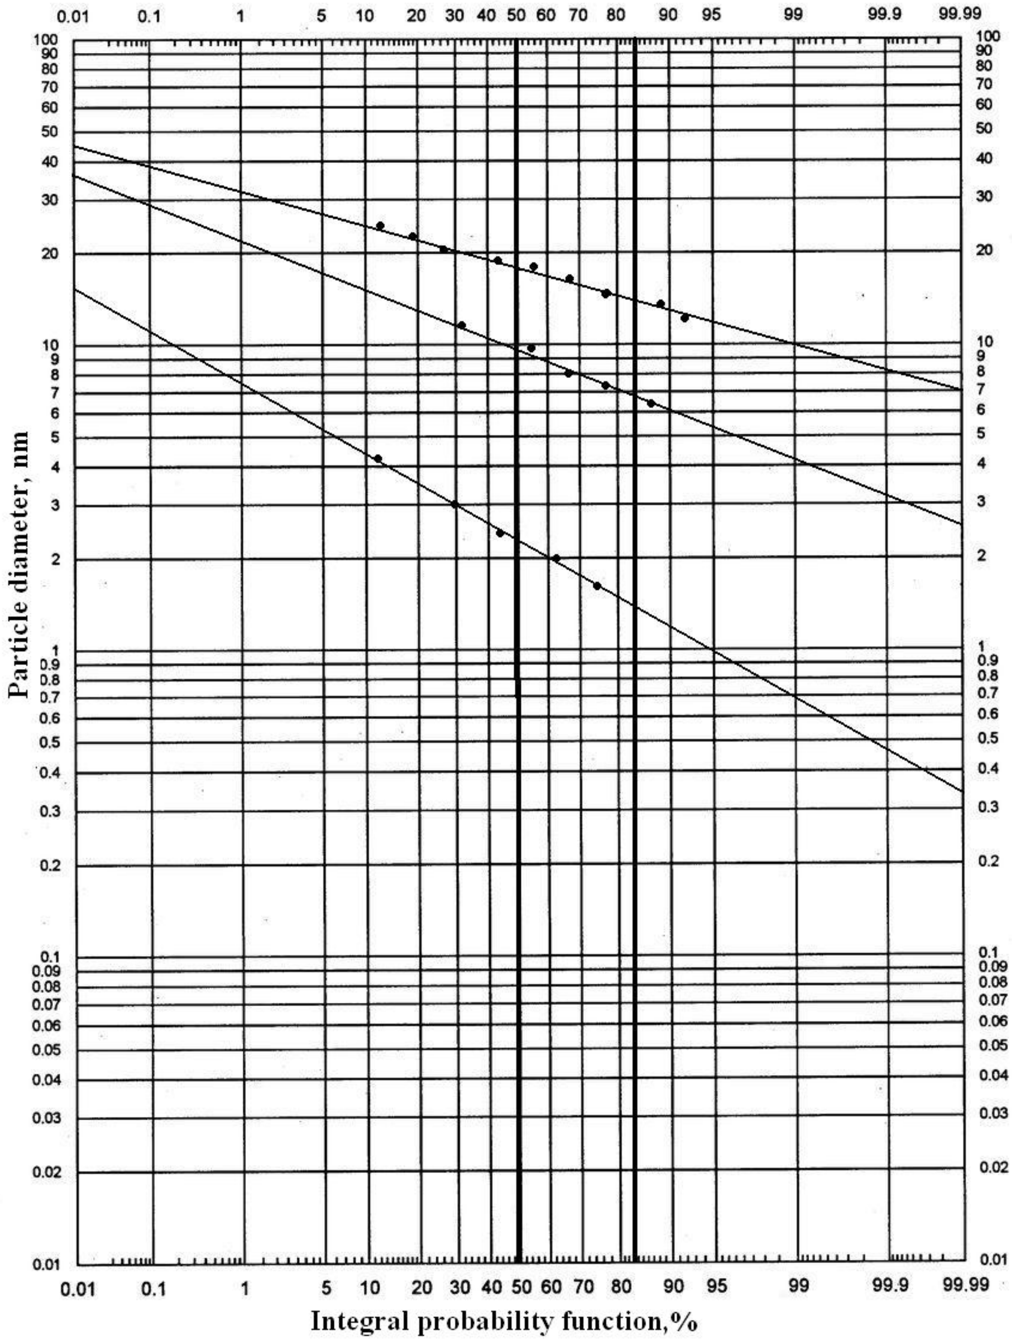

Fig. 1. Typical view of integral probability function for diffusion battery type I.

For a lognormal distribution the geometric standard deviation is defined as:

$$\sigma_{\mathrm{g}} = \frac{d_{50\%}}{d_{84\%}},$$

where $d_{50\%}$ and $d_{84\%}$ are diameters, associated with values of probability function 50% and 84%, respectively.

Results and discussion

In the previous research with primary version of diffusion battery and aerosol cascade impactor four modes of radon progeny particle activity size distribution were observed (Salomatova 2009). In the present research variations of screen quantity, flow rate and screen meshness essentially expanded the overall diffusion battery operating size range. It allows to exclude impactor application which led to large uncertainty. New diffusion battery method produces more detailed data on aerosol dispersion.

For each experiment performed in the radon box total equilibrium-equivalent concentration, activity median thermodynamic diameter and geometric standard deviation were calculated. Six modes of radon progeny particles activity size distribution were defined. Characteristics of the defined modes are presented in the Table 3. Obtained radon progeny particles activity size distribution is shown on the Figure 2.

Table 3. Distribution modes characteristics.

Mode number	AMTD, nm	Geometric standard deviation	Fraction
1	1.75	2.0	0.4
2	8.5	1.5	0.03
3	20	1.2	0.07
4	40	1.7	0.1
5	120	1.5	0.26
6	300	1.2	0.14

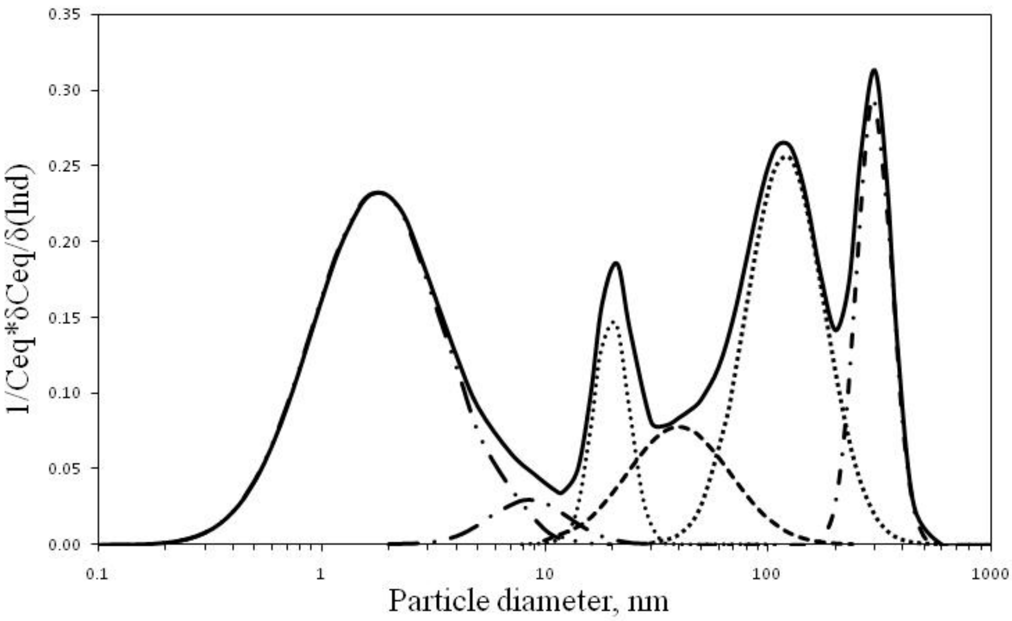

Fig. 2. Radon progeny activity size distribution.

A comparison with independent measurements of activity size distribution in earlier research (Porstendorfer 1996) is shown on the Figure 3.

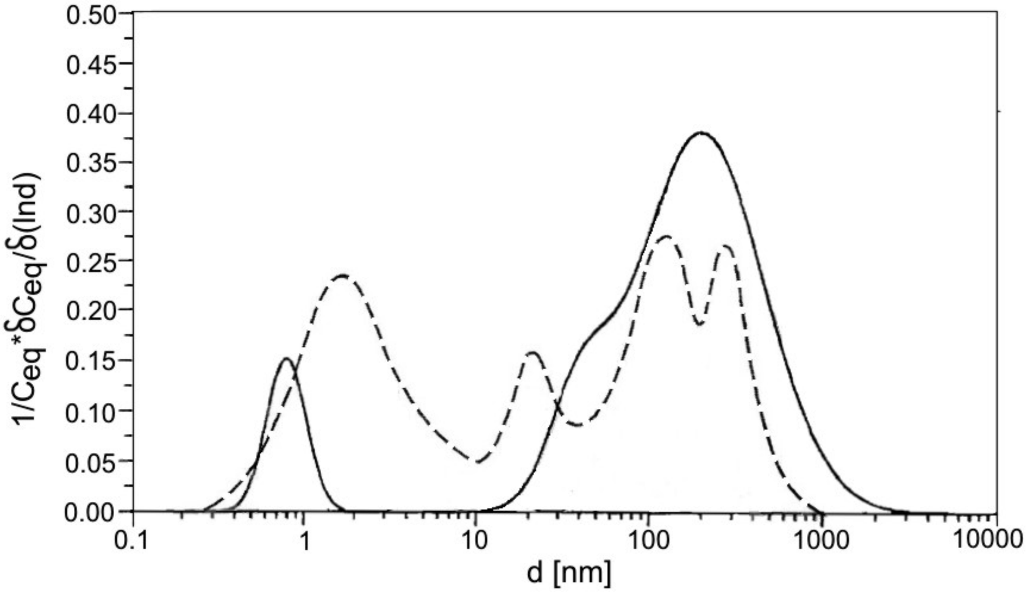

Fig. 3. Measured activity size distribution (dotted line) in comparison with typical distribution (solid line) for indoor air in dwellings (Porstendorfer 1996).

Air particles modes according to established classification could be identified as follows: 2 nm mode represents an unattached fraction of free radon progeny atoms; next five modes are formed by coagulation of unattached fraction atoms with atmospheric particles of different sizes. Thus, 8 nm corresponds to the group of natural particles, formed by the homogeneous nucleation; 20 nm and 40 nm modes are based on the particles, formed not only by homogeneous nucleation, but also condensation (heterogeneous nucleation). The largest modes 120 nm and 300 nm correspond to condensation particles.

On this basis it is possible to make an assumption that radon progeny particles activity size distribution can be an indicator of natural aerosol particles size distribution.

Conclusions

Several conclusions can be made as a result of the work performed.

The screen-type diffusion battery method was enhanced for radon progeny particle activity size distribution in the range from 1 to 400 nanometers with reduced geometric standard deviation in comparison with previous experiments with diffusion battery and cascade impactor.

Modes of the radon progeny particle activity size distribution corresponds to modes of the natural soluble particle size distribution. It is possible to measure concentration and size distribution of the fine soluble particles in the atmosphere through registration of radon progeny particles, coagulated with natural aerosols, by means of standard radiometric techniques.

The influence of atmospheric conditions parameters, such as humidity, temperature, aerosol particle concentration etc, is supposed to be investigated in the following work.

Evaluating on-site monitoring cart conceptually developed for radiation workplace

Kawano, Takao; Nishimura, Kiyohiko
National Institute for Fusion Science, JAPAN

Abstract

In our previous study, an on-site radiation monitoring cart was developed by inspecting apparatuses necessary for radiation monitoring. These apparatuses were selected from those commercially available. It was found that all the equipment could be installed on an appropriately sized monitoring cart. Since the cart was too heavy, key methods for reducing the mass of the cart were suggested. The present study follows the previous study, and literature search was carried out to evaluate the performance of the cart from the viewpoint of radiation detection limits and radioisotope concentration. As a result, radiation detection limits were sufficiently lower than the legal limits stipulated by law in radiation workplaces radioisotope surface contamination, and radioisotope concentration in air, which are stipulated in the Japanese radiation law: The Law Concerning Prevention from Radiation Hazard due to Radioisotope etc.

1. Introduction

For developing an on-site radiation monitoring cart, radiation measurement apparatuses used for monitoring radiation at a radiation facility have been investigated recently. In our previous study (Kawano and Nishimura 2009), these apparatuses were properly selected from those commercially available, and they were investigated to see if they could be compactly installed on an appropriately-sized to be manhandled on-site monitoring cart. Furthermore, the feasibility of the cart and problems to be resolved were examined. It was found that all the equipment necessary for radiation monitoring could be installed on a monitoring cart of 164 cm (W) × 150 cm (H) × 80 cm (D), but the cart was too heavy. Thus, a more lightweight solution was required. Four key methods for reducing the mass of the cart were suggested.

Following the above-mentioned previous study, the cart was evaluated from the viewpoints of radiation detection limit and radioisotope concentration, assuming the selected apparatuses were installed onto the cart. The radiation detection limit was investigated through literature research, and compared with those stipulated in The Law Concerning Prevention from Radiation Hazard due to Radioisotope etc. of Japan (the Japanese radiation law is used as a abbreviated expression below) to evaluate the performance of the cart. It was concluded that the cart conceptually designed using only commercially available radiation measurement systems had a sufficient detection capability for radiation monitoring in radiation facilities including radiation workplaces and radiation-controlled areas.

2. Conceptually designed monitoring cart

2.1. Radiation monitoring in work places

In radiation workplaces that mean radiation workplaces and radiation-controlled areas, and controlled areas means boundary of controlled areas in the present study, radiation monitoring has to be performed at regular intervals. According to the Japanese radiation law, three measurement obligations, the radiation dose in radiation workplaces, radioisotope surface contamination, and radioisotope concentration in air, are stipulated for radiation monitoring at a radiation workplace. In Table 1, radiation and radionuclides to be monitored and legal limits stipulated in the Japanese radiation law as typical cases are summarized.

Table 1. Regulation limits for work place and controlled areas.

Measurement item	Radiation or Nuclides	Legal limits	
		Work place	Controlled area
Radiation dose	Gamma ray Neutron	1000 µSv/40 h (25 µSv/h)	1300 µSv/520 h (2.5 µSv/h)
Radioisotope surface contamination	Alpha Others	4.0 Bq/cm^2 40 Bq/cm^2	0.4 Bq/cm^2 4.0 Bq/cm^2
Radioisotope concentration in air	^{3}H ^{14}C ^{32}P ^{35}S ^{125}I	5.0E-1 Bq/cm^3 4.0E-2 Bq/ cm^3 7.0E-3 Bq/cm^3 2.0E-2 Bq/cm^3 1.0E-3 Bq/cm^3	5.0E-2 Bq/ cm^3 4.0E-3 Bq/ cm^3 7.0E-4 Bq/ cm^3 2.0E-3 Bq/ cm^3 1.0E-4 Bq/ cm^3

Radiation dose limits are 1000 µSv/a week for a radiation workplace and 1300 µSv/3 months for a controlled area, assuming one week and three months are 40 and 520 hr (5 days/week, 8 hour/day and 13 weeks/3 months), the radiation dose limits correspond to 25 and 2.5 µSv/h, respectively. These dose limits are normally unrelated to radiation quality, gamma rays, neutrons, and beta rays. In the case of radioisotope surface contamination, the limits are stipulated under two categories, alpha-ray-emitting nuclides and other radiation-emitting nuclides. For alpha-ray-emitting nuclides, 4.0 and 0.4 Bq/cm^2 are the surface contamination limits for a workplace and a controlled area, respectively. For the other radiation-emitting nuclides, the limits are ten times larger, 40 and 4.0 Bq/cm^2. In the case of radioisotope concentration in air, limits are stipulated for respective radioisotopes. In Table 1, the limits of radioisotope concentration in air are listed for the five typical nuclides of ^{3}H, ^{14}C, ^{32}P, ^{125}I, and ^{35}S. These nuclides are used often in radiation facilities in Japan. Radioisotope concentration in water is not stipulated by the Japanese radiation law because eating and drinking are not permitted in radiation facilities, including controlled areas.

2.2. Construction of on-site radiation monitoring cart

The conceptually designed on-site radiation monitoring cart discussed in the previous study is shown in Fig. 1, containing plan and side views. All the apparatuses used for monitoring radiation dose, surface contamination, and radioisotope concentration are mounted on a battery-powered rover rack, which one person can operate like an electric car. The dimensions of the rover rack are estimated to be 164 cm (W) × 150 cm (H) × 80 cm (D) . The rover rack has a running speed of 3.5 km/h and a running distance of 3.5 km when the battery is fully charged.

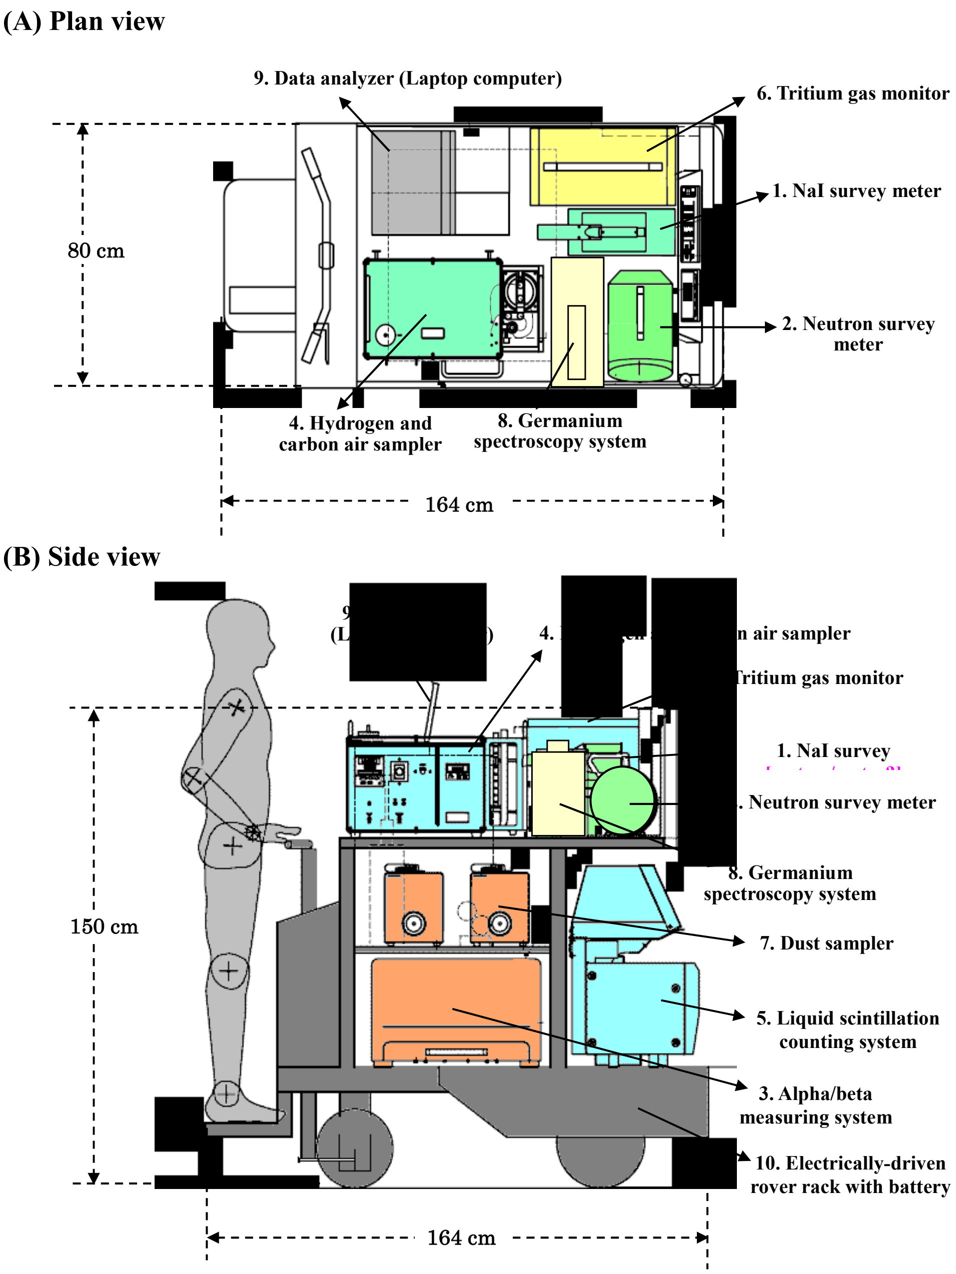

Fig. 1. Illustration of radiation monitoring cart.

(1) Monitoring radiation dose for gamma (X) rays and neutrons

A NaI(Tl) scintillation survey meter and a neutron survey meter are used to measure the radiation dose in radiation workplaces. The neutron survey meter is installed in a ^{3}He proportional counter for detecting neutron radiation. These survey meters are portable and can be replaced with other types of conventional survey meters, such as a Geiger Mueller (GM) survey meter and a tritium survey meter, as the need arises. For this radiation monitoring, alpha rays are ignored because their range in air is short and their penetrating power is weak.

(2) Monitoring radioisotope surface contamination

There are two methods for monitoring radioisotope surface contamination. One is a survey method and the other is a smear method. In the survey method, the above-mentioned survey meters, NaI(Tl) scintillation, neutron, GM, and tritium, can be used to directly detect radioisotope surface contamination. In the smear method, a smear paper is used to wipe up radioactive contamination from floors and the surfaces of devices, tools, etc. The radioactivity of contamination collected on the smear paper can be measured using the liquid scintillation counting system, alpha/beta radiation measurement system, or germanium spectrometer. The liquid scintillation counting system is used to measure tritium and carbon-14 contamination with high sensitivity. The alpha/beta radiation measurement system has a ZnS(Ag) scintillation detector and a plastic scintillation detector for measuring alpha and beta radiation, respectively. The germanium spectrometer is used to analyze gamma-ray-emitting nuclides contained in radioactive contamination. The smear method is highly sensitive but requires time a somewhat longer than the survey methods since it is an indirect measurement.

(3) Radioisotope concentration in air

There are also two methods for monitoring radioisotope contamination in air. One method is continuously measuring radioisotope concentration in air using a vent-type detector. An example of this type of monitor is a tritium gas monitor, which is installed in a vented ionization chamber and can provide live data. In the other method, a tritium and carbon air sampler and a dust sampler are used to collect radioisotope contained in air. With the hydrogen and carbon air sampler, tritium and carbon-14 contained in air are collected in the chemical forms of water and carbon dioxide by a cooled collection tube with dry ice-ethanol and a monoethanolamine tube, respectively. The radioactivity of the tritium collected in water and that of carbon-14 collected with monoethanolamine are measured using the liquid scintillation counting system mentioned above. The dust sampler is used to collect other radioisotopes that are bound to dust suspended in air on a filter paper or an activated charcoal filter. Radioactivity trapped on the filter can be measured using the liquid scintillation counting system, the alpha/beta radiation measurement system, or the germanium spectrometer, which is similar to the smear method.

A conventional laptop computer is installed on the on-site radiation monitoring cart as an on-site data analyzer. The computer can perform data acquisition, data storage, and data display. Consequently, the on-site radiation monitoring cart has the same functions as a conventional radiation measurement room. Furthermore, the cart is movable, allowing it to be brought into the radiation laboratory to carry out on-site radiation monitoring and removed from the radiation laboratory on an as-needed basis. The cart is essentially a portable radiation measurement room.

3. Evaluation of detection limit

To certify that the cart is effective in detecting these radiation limits, a literature search was carried out. Table 2 lists the detection limits and their ratios to the legal limits set by the Japanese radiation law for the respective apparatuses conceptually installed for monitoring radiation dose in radiation workplaces, radioisotope surface contamination, and radioisotope concentration in air. For radioisotope concentration in air, detection limits are shown for five typical nuclides, ^{3}H and ^{14}C, ^{32}P, ^{125}I, and ^{35}S.

Table 2. Comparison of detection and regulation limits.

Measurement item	Radiation or Nuclides	Apparatuses installed	Detection limit	Detection limit/Legal limit	
				Work place	Controlled area
Radiation dose	Gamma ray	NaI(Tl) scintillation survey meters	0.1 μSv/h	4.003-03	4.00E-02
	Neutron	Neutron survey meters	0.01 μSv/h	4.00E-04	4.00E-03
Radioisotope surface contamination	Alpha Others	Alpha/beta measuring system	0.04 Bq/cm^2 0.03 Bq/cm^2	0.01 7.50E-04	0.1 7.50E-03
Radioisotope concentration in air	^{3}H	Tritium and carbon air sampler and	2.9E-5 Bq/ cm^3	5.80E-05	5.80E-04
	^{14}C	Liquid scintillation counting system	8.0E-6 Bq/cm^3	2.00E-04	2.00E-03
	^{3}H	Tritium gas monitor	1.1E-2 Bq/ cm^3	0.022	0.22
	^{32}P ^{35}S ^{125}I	Dust sampler and alpha/beta measuring system	3.8E-6 Bq/ cm^3 2.0E-6 Bq/ cm^3 2.5E-6Bq/ cm^3	5.43E-04 1.00E-04 2.50E-03	5.43E-03 1.00E-03 2.50E-02

3.1. Radiation dose

For radiation monitoring in radiation workplaces, a NaI(Tl) scintillation survey meter and a neutron survey meter are used. Detection limits of the meters are 0.1 µSv/h and 0.01 µSv/h, respectively, as shown in Table 2. These detection limits can be compared to the legal limits shown in Table 1, the ratios are derived as 4.00E-03(1/250) and 4.00E-02(1/25) for gamma ray radiation and 4.00E-04(1/2500) and 4.00E-03(1/250) for neutron radiation in radiation workplace s and controlled areas. These results suggest that the radiation detection limits of these survey meters are sufficiently lower than those stipulated by law.

3.2. Surface contamination

Assuming the alpha/beta measuring system is regularly used to measure radioactive surface contamination with the smear method, the detection limits are 0.04 Bq/cm^2 for alpha-particle-emitting nuclides and 0.03 Bq/cm^2 for other nuclides. Comparing these detection limits to the legal limits for alpha-particle-emitting nuclides, the ratios are derived as 0.01(1/100) and 0.1(1/10) for radiation workplaces and controlled areas. For other nuclides, the ratios are 7.50E-04(1/1000) and 7.50E-03(1/100) for radiation workplaces and controlled areas. The radiation limits of the smear method are sufficiently lower than the legal limits.

3.3. Radioisotope concentration in air

To measure the ^{3}H and ^{14}C concentrations in air, a tritium and a carbon air sampler and a liquid scintillation counting system are used. The detection limits of both nuclides are 2.9E-5 Bq/cm^3 and 8.0E-6 Bq/cm^3, respectively. The detection limits are smaller than the regulation limits, and the ratios are less than 5.80E-05(1/1000) and 5.80E-04(1/100) for radiation workplace s and controlled areas. If only tritium is measured, a tritium gas monitor can be used. The detection limit of the monitor is 1.1E-2 Bq/ cm^3. The ratios of the detection limits to the regulation limits are less than 0.022(1/45) and 0.22(1/4.5) for radiation workplace s and controlled areas.

For monitoring other nuclide concentrations in air, the dust sampler is used to collect dust in a filter. The filtrated dust containing radioisotopes can be measured using the alpha/beta measuring system. The detection limits of these measurements are 3.8E-6, 2.0E-6, and 2.5E-6 Bq/ cm^3 for the more commonly used nuclides ^{32}P, ^{125}I, and ^{35}S. The ratios of the detection limits to the regulation limits are less than 2.5E-03(1/400) and 2.5E-02 (1/40) for radiation workplace s and controlled areas.

The above results show that the on-site radiation monitoring cart conceptually designed using only commercially available radiation measurement systems performs well from the view point of radiation detection limits when used for monitoring radiation workplace s, including controlled areas.

4. Summary

An on-site radiation monitoring cart was developed by conceptually installing necessary apparatuses including a NaI(Tl) scintillation survey meter, neutron survey meter, alpha/beta measuring system, tritium and carbon air sampler, liquid scintillation counting system, dust sampler, and a tritium gas monitor. These apparatuses were all selected from those commercially available. The size of the cart was 635 mm × 800 mm × 1500 mm.

The performance of the cart was evaluated by inspecting its radiation detection limit. The ratios of the detection limits to the legal limits set by the Japanese radiation law were examined. As a result, the detection limit of the cart is, at worst, 1/100 and 1/10 smaller than the legal limits for radiation monitoring of radioisotope surface contamination, radioisotope concentration in air, and in radiation workplace s and controlled areas. The cart has sufficiently detected radiation in a radiation facility.

Abstract

Anthropogenic long-lived alfa-emitting radionuclides have been (and still are) released in the environment by nuclear testing, nuclear accidents, and operations of fuel reprocessing and plant decommissioning. Among these ^{239,240}Pu and ^{236}U are the most significant. The Accelerator Mass Spectrometry (AMS) technique surmounts the limitations of other techniques used.

In Italy no Nuclear Power Plant (NPP) is in operation, but the four dismissed NPPs are now being decommissioned; moreover, new generation of NPPs are reconsidered for future installations. Both the operations demand accurate investigations about the possible contamination by radioactive releases of nuclear sites and neighboring territory and of structural materials of the reactors. The monitoring activity requests ultrasensitive methodologies for the detection and quantification of ultralow activity radionuclides. Among radionuclides the alpha-emitting isotopes of actinide elements are the most critical also because of their toxicity. The radiation counting methods, due to the long half lives, do not provide the necessary sensitivity and, in some cases, resolution (e.g. ^{239}Pu-^{240}Pu).

The present contribution reports on the state of the art of a project, carried out at the AMS facility in the Center for Isotopic Research on Cultural and Environmental Heritage (CIRCE, Caserta, Italy), aiming to establish an ultrasensitive system for the measurement of concentrations and isotopic abundances of U and Pu, and to exploit this technique for the characterization, from the point of view of the contamination by U and Pu, of both environmental samples from the Garigliano NPP site and samples representative of the structural materials of the building and of the reactor of the same plant. At the same time the system provides a tool able to fulfill the analytical needs of IAEA for the campaigns for nuclear safeguards against illegal nuclear activities and the military use of weaponry with depleted uranium.

Introduction

Anthropogenic uranium and plutonium, and fission and activation products were widespread around the world due to human nuclear activities. Different sources of radionuclide contamination affect the environment on various scales of magnitude: plutonium from the atmospheric weapons test fallout is detectable globally in soils and sediments (Roca et al, 1989). In particular, the operation and decommissioning activities of a NPP could lead to airborne and liquid releases of radionuclides that would be mixed with contributions from larger and world scale sources. Useful tools to solve among different contributions are the isotopic ratios: $^{236}U/^{238}U$, $^{238}Pu/^{239+240}Pu$, $^{240}Pu/^{239}Pu$, $^{241}Pu/^{239}Pu$, $^{242}Pu/^{239}Pu$, given that the relative concentrations of plutonium and uranium isotopes depend on the nature of the source material and on its subsequent irradiation history. ^{239}Pu is produced from ^{238}U via neutron capture and subsequent beta decay of the resulting short-lived ^{239}U ($t_{1/2}$ = 23.47 min). In weapon-grade plutonium, ^{239}Pu is the most abundant isotope ($^{240}Pu/^{239}Pu < 0.07$). In weapon test fallout, $^{240}Pu/^{239}Pu$ varies, depending on the test parameters, in the range (0.10-0.35), the integrated ratio for the Northern hemisphere being about 0.18 (Koide et al., 1985); significantly different values (0.035-0.05) are found in Mururoa and Fangataufa atoll sediment, because of the peculiar nature of French testing (Chiappini et al., 1989).

In nuclear reactors, due to the different composition of fuels, uranium enrichment and burn-up degree, characteristic relative abundances of plutonium isotopes will be obtained: $^{240}Pu/^{239}Pu$ increases with irradiation time, which, in turn affects $^{238}Pu/^{239+240}Pu$. This ratio is useful to resolve between different sources in case they show similar $^{240}Pu/^{239}Pu$: e.g., irradiated nuclear fuel in a PWR with 7-20% ^{235}U and burn-up 1.4-3.9 GW·d reaches $^{240}Pu/^{239}Pu$ isotopic ratios of 0.13, a value, that could be ascribed also to global fall out; on the other side, these two sources show quite different $^{238}Pu/^{239+240}Pu$ activity ratio (0.025-0.04 for the global fallout and 0.45 for that nuclear fuel), (Buessler et al., 1995). Another valuable tool to identify a nuclear reactor origin of a radionuclide contamination is $^{236}U/^{238}U$ isotopic ratio. The dominant ^{236}U mode of formation is the capture of a thermal neutron by ^{235}U, a secondary contribution being the alpha decay of 240Pu; its concentration in nature has been heavily increased as a consequence of irradiation of enriched uranium in nuclear reactors. Several orders of magnitude of difference between the $^{236}U/^{238}U$ isotopic ratios in naturally-occurring uranium (10^{-9} to 10^{-14}) and in spent nuclear fuel (10^{-2} to 10^{-4}) imply that also a small contamination from irradiated nuclear fuel in natural sample is able to increase the $^{236}U/^{238}U$ measured in the whole sample. The measurement of U and Pu isotopic ratios requires the sensitivity of mass spectrometric techniques because ^{236}U and plutonium are present in environmental samples at ultra trace levels (^{236}U concentration is quoted to be in the order of pg/kg or fg/kg and ^{239}Pu around 100 pg/kg (Perelygin et al.,1997) and are long-lived radionuclides. To measure $^{236}U/^{238}U$ at natural level the unique able technique is the AMS, because of its capability to suppress background of isobaric molecules as it doesn't suffer of isobaric interferences from $^{235}UH^+$. The hydrides formation in ICPMS devices defines the detection limits of this technique for $^{236}U/^{238}U$ to 10^{-7}. Also, because of the interference from $^{238}UH^+$, the measurement of $^{239}Pu/^{240}Pu$ by ICPMS requires a higher decontamination of the plutonium fraction from uranium than AMS needs. However, no chemical procedure is efficient enough to separate uranium and plutonium fractions to allow the mass spectrometric measure of ^{238}Pu, being the concentration of ^{238}U seven orders of magnitude higher than that of ^{238}Pu. Alpha-spectroscopy remains the only suitable technique for the measurement of ^{238}Pu concentration.

Material and methods

Sample preparation

The extraction of uranium and plutonium was performed following the procedures described in Kritil et al. (1979), applied to soil and sediment samples and adapted to our needs (Quinto et al., 2009). The samples were dried in a muffle furnace at 110°C, homogenized and combusted at 450 °C overnight. ^{236}Pu (30 mBq = 3.8×10^6 atoms) and ^{232}U (86 mBq = 2.7×10^8 atoms) were added as reference isotopes and also as radiotracers to determine the radiochemical yield of the extraction. The samples (2-12 g) were leached in 7.2 M HNO_3 and 0.5 g $NaNO_2$ for at least 3 h. The residue was centrifuged off and the supernatant was stored; fresh acid was added to complete the washing of the matrix. The combined leachates were brought to dryness and the residue was dissolved in 7.2 M HNO3. After adding of 0.2 g $NaNO_2$ the solution was heated until gas formation ceased and, after cooling, was loaded on an anion exchange column (6 ml Dowex 1x2, 100-200 µm particle size, previously conditioned with 7.2 M HNO_3). Plutonium present as Pu (IV) is retained on the resin. Uranium, mostly present as U (VI) is washed from the column with 45 ml of 7.2 M HNO_3. The original solution (now free of Pu) and the washing solutions were combined and kept for uranium determination. The column was washed with 30 ml of 32% HCl to remove thorium. Finally, plutonium was eluted with 50 ml of a mixture of 0.36 M HCl and 0.014 M HF into a teflon beaker containing already 5 ml 65% HNO_3. This solution was brought to dryness, then evaporated three times in 5 ml 65% HNO_3 with some drops of 30% H_2O_2 and another three times in 5 ml 37% HCl. The residue was dissolved in 6 ml fuming HCl, and subdivided in two halves for AMS measurement and alpha-spectrometry, respectively. The uranium fraction contained large amounts of iron. Therefore, the solution was evaporated to dryness and the residue dissolved in 20 ml 8 M HCl, from which iron was eliminated by diisipropylether liquid-liquid extraction. The iron free uranium fraction was evaporated to dryness, dissolved and evaporated twice in 50 ml 37% HCl, and finally dissolved in 80 ml 8M HCl. This solution was brought to a second anion exchange column (Dowex 1x2, 100-200 µm particle size, in 8 M HCl). Calcium and thorium were washed out with 50 ml 8 M HCl, then uranium was eluted with 90 ml 0.1 M HCl. The uranium solution was treated the same way as the plutonium solution; two subsamples for AMS and alpha-spectrometry were prepared. The chemical form of the AMS sample is $U+Fe_2O_3$ and $Pu+Fe_2O_3$, obtained by iron hydroxide co-precipitation and subsequent conversion to iron oxide by combustion at 700 °C. Uranium and plutonium fractions in iron oxide matrix were mixed with a similar volume of silver powder and pressed in aluminium sample holders suitable for the ion source of accelerator system. For alpha-spectrometry, plutonium and uranium fractions where co-precipitated with NdF_3 (Hindman, 1983) and deposited on membrane filters suitable for alpha-spectroscopy (Quinto et al., 2009).

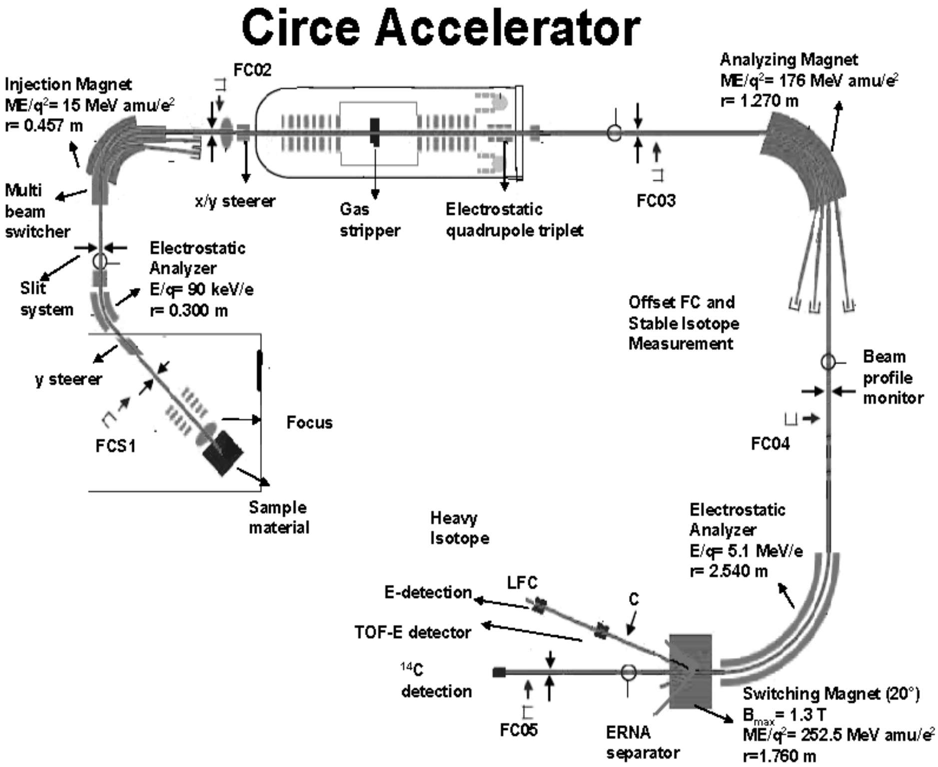

Fig. 1. The scheme of the +3 MV tandem accelerator of Pelletron type installed at the CIRCE.

The AMS measurement

The +3 MV CIRCE tandem accelerator of Pelletron type (Terrasi et al. 2008), similar to others installed in the past years in Europe and USA, is shown in Fig.1. Since the installation of CIRCE in 2005, we have extended the measuring capabilities of the original system with the installation of a switching magnet and a heavy isotope beamline (De Cesare et al., 2009; De Cesare et al., 2010).

The caesium sputter ion source is a 40-sample MC-SNICS. A typical output from 1 mm diameter samples pressed in Al cathodes for $^{12}C^-$ ions is 30 μA at 6 kV cathode voltage and a total injection energy of 67 keV and 0.3 μA for $^{238}U^{16}O^-$ molecules with a total injection energy of 50 keV. These ions are energy selected by a ±45° spherical electrostatic analyzer (r = 30 cm, plate gap = 5 cm) that is operated up to ±15 kV. Maximum electric field strength is 6 kV/cm, resulting in an energy/charge state ratio of 90 keV. The 90° double focusing Low Energy (LE) injection magnet (r = 0.457 m, vacuum gap= 48 mm, ME/q^2 = 15 MeV· amu) allows high resolution mass analysis for all stable isotopes in the periodic table. The insulated stainless steel chamber can be biased up to 15 kV for beam sequencing (e.g. between ^{12}C, ^{13}C, ^{14}C or between $^{238}U^{16}O$, $^{236}U^{16}O^-$).

The accelerator is contained inside a vessel filled with sulphur hexafluoride (SF6) at a pressure of about 86 psig. The terminal voltage (TV) is achieved and stabilized by GVM feedback on the charging system high voltage supply. The TV can be kept constant at 3.000 MV with a ripple of 1 kV. In the stripper, Argon (Ar) is recirculated by two turbo-pumps; the working pressure is about ~13 mTorr for $^{14}C^{3+}$ at 2.550 MV and ~7.3 mTorr for $^{238}U^{5+}$ at 2.875 MV, with an offset of ~6 mTorr

The double focusing 90° High Energy (HE) bending magnet has r= 1.27 m, ME/q^2 = 176 MeV.amu and M/ΔM = 725, with slit opening of ±1 mm both at object and image points, so that, e.g. $^{236}U^{5+}$ at 3 MV can be analyzed. The two 45° electrostatic spherical analyzers (r= 2.54 m and gap = 3 cm) are operated up to ±60 kV; energy resolution is E/ΔE = 700 for typical beam size.

Finally the selected ions are counted in a surface barrier detector.

In order to assess laboratory background for ^{236}U measurements, diluted samples of Joachimsthal uranium (0, 4, 40, 400 and ~104 μg) were prepared for each run. We used the U^{5+} current as an estimate of the uranium content. The effect of a mass-dependent background correction is almost negligible. The ^{236}U count rate, calibrated by the dilution series, was used to estimate the ^{236}U concentration. Results of such measurement are reported in Quinto et al. 2009.

In order to assess the accuracy of the $^{240}Pu/^{239}Pu$ isotopic ratio measurement, a Reference Material, IAEA 368 (sediment sample collected in the Pacific Ocean at Mururoa Atoll, a former French nuclear weapons testing site), was measured in three runs. Each measure of $^{240}Pu/^{239}Pu$ isotopic ratio was in agreement with the certified interval of values (0.035 to 0.05).

Results and discussion

Measurements have been performed with a position sensitive silicon detector with an active area of 58×58 mm², positioned 1.9 m downstream the 4 mm diameter collimator, positioned in turn 80 cm from the switching magnet. To measure the $^{236}U/^{238}U$ ratio a tuning of the transport elements up to the final detector is performed in order to maximize the ion optical transmission. The ^{236}U events are counted in the final detector and ^{238}U current is measured in FC04.

The tuning is made by setting the parameters of the beam line of the ^{238}U current to the Last Faraday Cup (LFC) positioned in front of the detector, using as target material uranium oxide (U_3O_8) obtained from Uranyl Nitrate ($UO_2(NO_3)_2{}^{\cdot 6}$ H_2O) baked at 800°. This material originated from the uranium mines "K. k. Uranfabric Joachimisthal", and is the VERA (Vienna Environmental Research Accelerator) in-house U standard. In our case, the sample preparation provides uranium in form of UxOy+Fe_2O_3 from which xUyO- is sputtered. To select different injected masses the injection magnet bouncing system is used. The stripping yield for $^{238}U^{5+}$achieved by the Ar gas stripper of CIRCE is around 3.1%. At 3 MV terminal voltage, ME/q^2 is ~ 170 MeV·amu/e^2 for $^{238}U^{5+}$ and ME/q^2 is ~ 221 MeV·amu/e^2 for $^{238}U^{4+}$; since the double focusing HE magnet reaches a maximal ME/q^2= 176 MeV·amu, the 5+ represents the lowest charge state which can be bent by the HE magnet. For heavy ion measurements, the object and image slits of the injection magnet are closed to ±1 mm, the slits of the HE magnet are closed to ±2 mm and a collimator of 4 mm diameter is positioned just at the waist of the ESA. The current transmission between FCO4 and LFC is ~ 80 %. Once the setup for the pilot beam $^{238}U^{5+}$ is found, the voltage at the chamber of the injection magnet, the terminal voltage and the voltage of the analyzer ESA are scaled to the other wanted mass ($^{236}U^{5+}$).

The preliminary measurements for the isotopic ratio $^{236}U/^{238}U$ were performed by cycling between ^{238}U, which is measured by means of the current in the Faraday cup just after the HE magnet FC04, and ^{236}U, that is measured in the final 16-strips surface barrier detector. We measured 2 samples: one with a nominal ratio $^{236}U/^{238}U \sim 10^{-8}$, obtained by adding a spike of ^{236}U to the KkU VERA in-house U standard, and the KkU itself with $^{236}U/^{238}U = (6.98 \pm 0.32) \times 10^{-11}$ (Steier et al. 2008). Also, samples with a "chemistry blank" have been prepared by the same treatment as the others. The contribution of the latter is of the order of 1 % of the KkU sample signal. Moreover, comparison with the spatial distribution obtained when the collimator was removed shows that interference from ions of higher magnetic rigidity with respect to $^{236}U^{5+}$ are largely suppressed by the 4 mm collimator; one can estimate that the residual interference background below the $^{236}U^{5+}$ peak, obtained as relative difference between the sum of the 4 central strips of the KkU (4mm C. out) and KkU (4mm C. in), is less than 80 % of the total, which is in turn the interference measured without the collimator. That indicates that "interference + chemistry" background in our $^{236}U/^{238}U$ measurements is $< 5\times10^{-11}$. This value has to be compared with previous result (3×10^{-9}, De Cesare et al 2009) obtained at 0°, before the installation of the switching magnet. De Cesare et al., (2009) have obtained a lower limit of $(9\pm1)\times10^{-9}$ for the spike sample isotopic ratio, in agreement with the expected value. These results imply that with a background $< 5\times10^{-11}$, we are able to measure samples with an isotopic ratio value $\geq 10^{-10}$, without the use of an Energy Time Of Fligth system (TOF-E). In order to obtain the best $^{236}U/^{238}U$ isotopic ratio sensitivity of 10^{-12} (Steier et al., 2004), in samples including about 1 mg of U, a TOF-E system will be included. An upgraded of the CIRCE facility has been planned including the TOF-E system, with a flight path of 1.5 m, aiming to reach the necessary $^{236}U/^{238}U$ isotopic ratio sensitivity.

Further investigations are needed to identify the amount of ^{238}U that is under the peak of $^{236}U^{5+}$ and the amount of ^{235}U, that is also present. A Time of Flight–Energy (TOF-E) detection system (De Cesare et al. 2007; De Cesare et al. 2009) will be used, to discriminate between ^{236}U, ^{238}U and ^{235}U, with the start signal for the TOF measurement given by a MCP (MicroChannel Plate), in electrostatic mirror configuration, positioned about 70 cm from the 4 mm collimator. The energy information is given by the 16-strips silicon detector, which also provides the timing for the stop signal.

As an example of application to investigate the possible contamination of Garigliano Nuclear Power Plant (Caserta, Italy) activities, some soil samples were collected for the measurement of actinides in the neighbour of the plant. The values of activity and isotope ratios in environmental samples measured with AMS allow to identify the origin of the activity, due to the sensitivity of the technique used. The isotope ratio of $^{236}U/^{238}U$ and the specific activity of ^{236}U and ^{239}Pu in soils is shown in Figure 2, where are also reported the results of ^{137}Cs specific activity obtained from gamma spectrometry measurements.

It is evident a correlation between the specific activities of the three radionuclides, indicating a possible common origin. The isotope ratio values ranging between 4.5 10^{-10} and 1.3 10^{-8}. These values are compatible with the value measured in a control sample

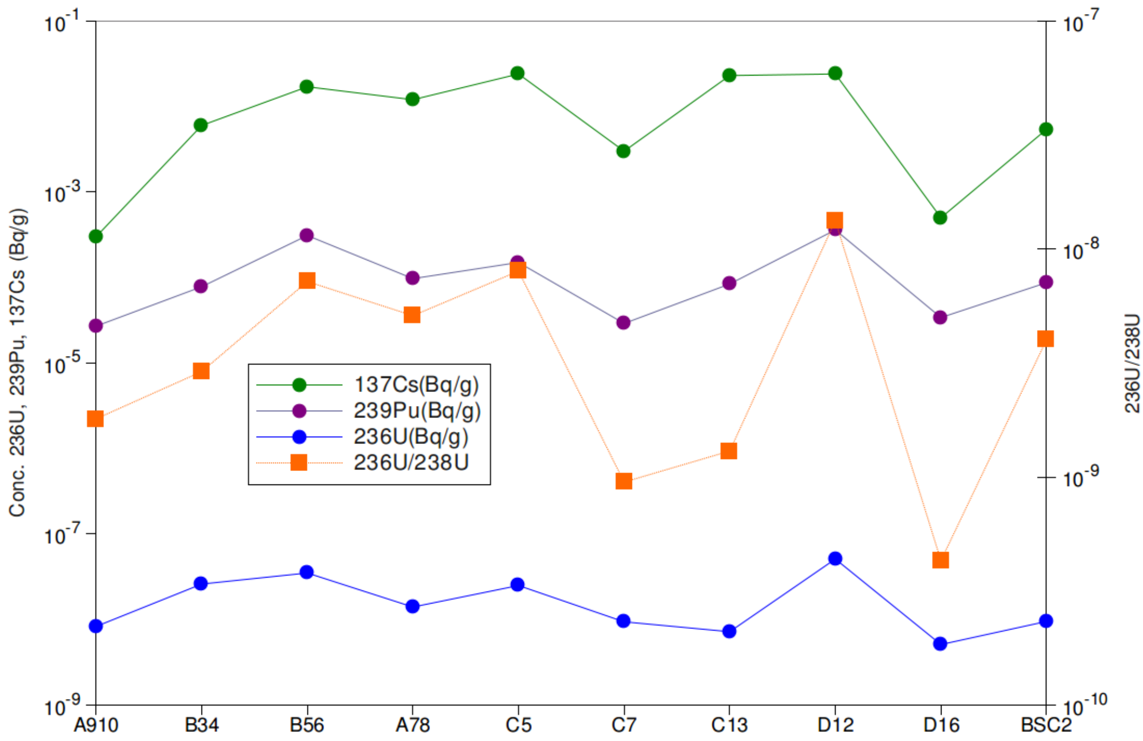

Figure 2. Results of ^{236}U, ^{239}Pu and ^{137}Cs specific activities and of ^{236}U/^{238}U ratio obtained on soil samples collected around the Garigliano Nuclear Power Plant (Caserta, Italy).

collected in the Sele plain (BSC2 sample), about 100 km far from the Garigliano NPP. Moreover, these values are consistent with values of global fallout [Sakaguchi et al., 2009] and are significantly lower than those measured in contaminated sites [Boulyga & Heumann, 2006]. Measurements of samples representative of the structural materials of the building and of the reactor of the same plant are also measured, but data not still available.

Conclusions

In this work an overview of the upgraded CIRCE facility for actinides measurements has been described in order to reach the necessary ^{236}U/^{238}U isotopic ratio sensitivity. The results of CIRCE laboratory are not far from those of ANU e VERA laboratories, but improvements are planning. Applications of method are carried out on soil sample to investigate possible contamination due to a NPP activities.

This system provides a tool able to fulfill the analytical needs of IAEA for the campaigns for nuclear safeguards against illegal nuclear activities and the military use of weaponry with depleted uranium.

Neural network method for activity measuring in environmental samples. Theses.

The spectrometric method is one of the most popular methods for activity measuring in environmental samples. It provides application of semi-conductor and scintillation spectrometers. Despite high measurement accuracy, high price and some difficulties in operation make semi-conductor detectors difficult to apply. Scintillation spectrometers, which are cheaper, are applied to determine activity of natural radionuclides. But continuous spectrum image on the monitor permits the spectrometers to measure not so many radionuclides and, thus, it restricts application of the scintillation spectrometers.

One of the ways to solve the problem is to use sophisticated mathematical analysis of decomposition of scintillation spectra. Examination of different spectrum analyses and devices, produced by means of these methods, reveals that sometimes the above solution is quite improper and has weak solution stability. Besides, some problems appear while applying these methods in field devices, which are to carry out scale analysis without a computer. As a result, simplified methods are applied, which reduce accuracy of activity determination.

The current article describes the method of decomposition of scintillation spectra into spectrum components by means of artificial neural networks. The aim of the above method is to determine activity of radionuclides in the source under measurement according to its radiation spectrum. The spectrum is acquired by means of scintillation spectrometer. If applying a laboratory spectrometer, which, as a rule, is equipped with a computer, the spectrum is transferred from the ADC to the PC, which operates with the above method. If applying field spectrometers, spectrum is to be processed by either a smart sensor or operating control unit. Activity calculation algorithm is equal in both cases.

Introduction

Nowadays industry often has bad unwholesome influence on the environment and a human being. That is why environmental friendliness is one of the quality factors of production. It causes constant development of special equipment and methods for environmental monitoring. Radioactivity stands out from other quality factors to be controlled. High radiation contamination risks, on the one hand, and strict safety regulations, on the other hand, draw special attention to metrological parameters of modern equipment of radiation monitoring.

The spectrometric method is one of the most popular methods for activity measuring in environmental samples. It provides application of semi-conductor and scintillation spectrometers. Despite high measurement accuracy, high price and some difficulties in operation make semi-conductor detectors difficult to apply. Scintillation spectrometers, which are cheaper, are applied to determine activity of natural radionuclides. But continuous spectrum image on the monitor permits the spectrometers to measure not so many radionuclides and, thus, it restricts application of the scintillation spectrometers.

One of the ways to solve the problem is to use sophisticated mathematical analysis of decomposition of scintillation spectra. Examination of different spectrum analyses and devices, produced by means of these methods, reveals that sometimes the above solution is quite improper and has weak solution stability. Besides, some problems appear while applying these methods in field devices, which are to carry out scale analysis without a computer. As a result, simplified methods are applied, which reduce accuracy of activity determination.

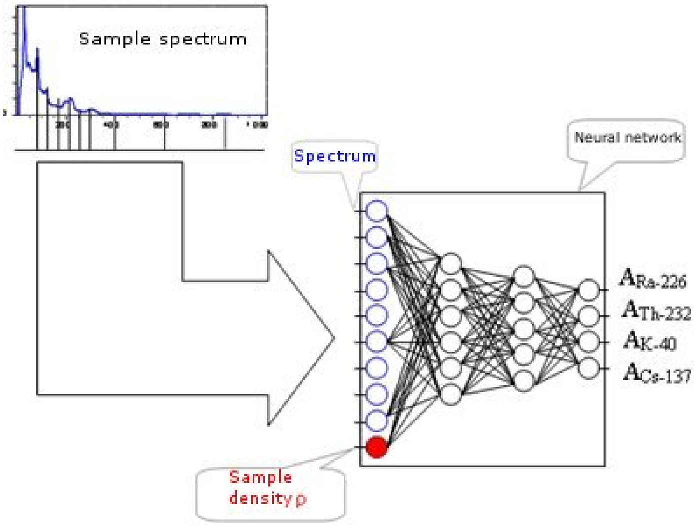
The current article describes the method of decomposition of scintillation spectra into spectrum components by means of artificial neural networks. The aim of the above method is to determine activity of radionuclides in the source under measurement according to its radiation spectrum. The spectrum is acquired by means of scintillation spectrometer. If applying a laboratory spectrometer, which, as a rule, is equipped with a computer, the spectrum is transferred from the ADC to the PC, which operates with the above method. If applying field spectrometers, spectrum is to be processed by either a smart sensor or operating control unit. Activity calculation algorithm is equal in both cases.

Activity calculation of radionuclides

Since the spectrometric method under discussion is relative, calibration of the equipment is required. According to the neural network theory such calibration is called learning.

The step-by-step algorithm of activity calculation follows. Learning (calibration) is described in part 3 of the current article.

First of all, we describe input data. We have a spectrum of a working source N collected by means of a spectrometer. The source (sample) is measured in the preset geometry with the certain density $\rho_{и}$ and life time. We have also a background spectrum $N_{ф}$ measured under the same conditions. Background is usually measured by means of a spectrometer either with an empty shielding chamber or with an empty sample dish in the chamber.



Pic.1. Diagram of activity measurement in samples by means the neural network method.

To reduce the spectrum to the energy scale, we should know energy calibration. Modern spectrometers provide the relation between a spectrum channel No. and energy, which are linearly dependent as follows:

$$E_i = E_0 + k \cdot i \quad (1)$$

where E_i – energy corresponding to the *i*-channel, keV; E_0, k – coefficients of energy calibration fixed during the device setting.

Data gained in the course of learning (calibration) is weights of neural network W, scales of each network input M_{in} and output M_{out} and energy windows where summing up R_E is carried out.

During calibration network parameters should be set up, including the number of layers and neurons in each layer and a type of activation function with parameters. The number of network inputs depends on the number of selected windows, plus one input for density. The number of network outputs corresponds to the number of radionuclides under detection.

First of all, we prepare input data for network calculation.

In the spectrum channels we define corresponding windows for each specified energy window. According to Eq.1:

$$R_{Lj} = \frac{R_{ELj} - E_0}{k} \quad , \text{ j=1..n} \quad (2)$$

where R_{Lj} – channel No. in the spectrum of the left edge of the *j*-window; R_{ELj} – energy of the left edge of the *j*-window, keV; n – number of windows.

The similar equation is used for the right edge:

$$R_{Rj} = \frac{R_{ERj} - E_0}{k} \quad , \text{ j=1..n} \quad (3)$$

where R_{Rj} – channel No. in the spectrum of the right edge of a *j*-window; R_{ERj} – energy of the right edge of a *j*-window, keV.

We define total counting rate in the specified windows for the source working spectrum and background spectrum:

$$S_j = \frac{1}{t} \cdot \sum_{i=R_{Lj}}^{R_{Rj}} N_i \quad , \text{ j=1..n} \tag{4}$$

$$S_{\phi j} = \frac{1}{t_{\phi}} \cdot \sum_{i=R_{Lj}}^{R_{Rj}} N_{\phi i} \quad , \text{ j=1..n} \tag{5}$$

where S_j and $S_{фj}$ – counting rates in the j-window of working and background spectra correspondingly, imp/sec; t и $t_ф$ – real measurement time of working and background spectra correspondingly, sec. [1, 4].

Now we define input values of the neural network as follows:

$$X_j = \frac{S_j - S_{\phi j}}{M_{in\, j}} \quad , \text{ j=1..n} \tag{6}$$

where X_j – value of the j-output of the neural network; $M_{in\,j}$ – scale value for the j-output. Eq. 6 reveals that the value X_j can vary from 0 to 1, which is caused by principles and architecture of neural network.

The number of network inputs m=n+1, with another special input for density, is defined as follows:

$$X_m = \frac{\rho_u}{M_{in\, m}} \tag{7}$$

where $\rho_и$ – density of the sample under measurement, g/cm^3; $M_{in\ m}$ - scale for density input, g/cm^3.

Input data is gathered now and should be put in calculation of the neural network. Network calculation means definition of states and outputs of neurons within inner layers and the last output layer [2]. These are outputs of the last layer, which are desired unscaled activities of radionuclides. One should remember that the number of outputs is not fixed and defined according to research tasks. It means that if activity of a certain radionuclide is to be determined in the sample with a radionuclide mixture, the network can have one output corresponding to a specified radionuclide. In this case network learning is carried out by means of spectra of unmeasured radionuclides.

Network calculation is made in a layer-by-layer manner. Calculation of neuron states for the first layer is not necessary, since their outputs, or network inputs, are known. Thus, neuron states for the second layer are calculated as follows:

$$C_j^{II} = \sum_{i=1}^{P_1} X_i \cdot W_{1,i,j} \quad , \text{ j=1..}P_2 \tag{8}$$

where P_1 - number of neurons in the first layer, similar to the number of network outputs; P_2 – number of neurons in the second layer; $W_{1,i,j}$ – weight between the i-neuron of the first layer and j-neuron of the second layer, the index *l* depicts a layer, which has a link output (the first layer for Eq. 8).

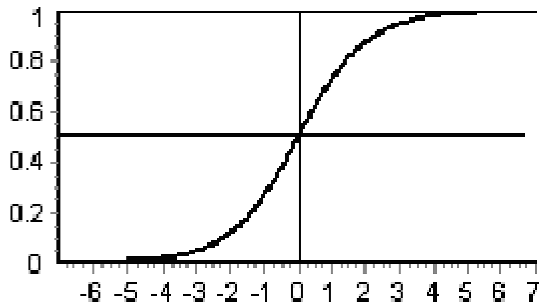
Neuron output is regarded as the function of its state:

$$y_j^{II} = f(C_j^{II}) \text{ , j=1..P}_2 \tag{9}$$

where y_j^{II} - output of the j-neuron in the second layer; f – activation function, defined as:

$$f(c) = \frac{1}{1+\exp(-\alpha \cdot c)} \tag{10}$$

where c – argument of the function or, in this case, neuron state; α – coefficient, which determines the slope of the function graph (Pic.2). The coefficient α is determined in the course of calibration and can vary from 0.5 to 3.



Pic. 2. Sigmoid activation function [3].

Despite vast variety of activation functions, the research revealed that the above type of the activation function provides particularly successful and accurate calculation.

Neuron states for the third layer are calculated as follows:

$$C_j^{III} = \sum_{i=1}^{P_2} y_i^{II} \cdot W_{2,i,j} \text{ , j=1..P}_3 \tag{11}$$

As shown by Eq. 11, the network inputs are replaced by the outputs of the second layer. Thus, we have got the following equation, similar to Eq. 9:

$$y_j^{III} = f(C_j^{III}) \text{ , j=1..P}_3 \tag{12}$$

where y_j^{III} - output of the j-neuron in the third layer.

The network for the rest of layers, including the output layer [2, 3], is calculated on the same principle as illustrated above. In this case, the output layer is described as follows:

$$C_j^{Z} = \sum_{i=1}^{P_{Z-1}} y_i^{Z-1} \cdot W_{Z-1,i,j} \tag{13}$$

$$y_j^{Z} = f(C_j^{Z}) \text{ , j=1..P}_Z \tag{14}$$

where y_j^Z - output of the j-neuron in the last layer; Z – number of layers in the network.

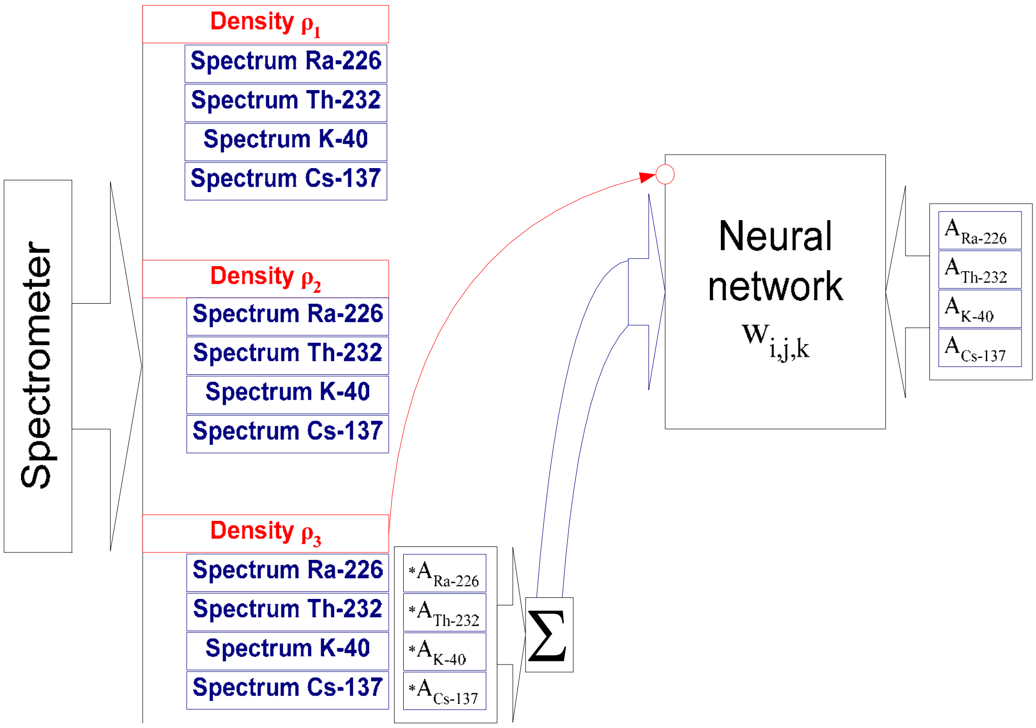
To turn directly to calculation of radionuclides activities, output scales determined during the calibration should be used.

$$A_j = (y_j^Z - k_{\kappa p}) \cdot (\frac{M_{out\ j}}{k_{yM}}) \quad , \ j=1..P_Z \tag{15}$$

where A_j – activity of the j-neuron in order, Bq; $M_{out\ j}$ - scale for j-output of the network; $k_{\kappa p}$ –boundary coefficient, which enables not to use the non-linear range of a sigmoid function and is defined as 0.1; k_{yM} – coefficient introduced to correct a scale disturbed by the boundary coefficient. More detailed description of the above coefficients follows.

Calibration (learning)

To train the neural network, calibration spectra are required, which should be spectra of separate radionuclides measured in calibration samples with different densities (Pic.3).



Pic. 3. Example of choosing calibration spectra for learning.

These available calibration spectra should be included into the learning sample, where each component is a spectrum with different radionuclide content and density. To get such spectra, the additivity concept of simple spectra of radionuclides is to be applied. Thus, the equation for a sample spectrum with activities A_j, where j=1..n (n – number of nuclides in a source) will be the following:

$$Q_i = Q_{\phi_i} + \sum_{j=1}^{n} q_{ij} \cdot A_j \;, \quad \text{i=1..v} \tag{16}$$

where Q_i – counting rate in the i-channel of the mixed spectrum of the sample, imp/sec; $Q_{\phi i}$ – counting rate in the i-channel of the background spectrum, imp/sec; q_{ij} – counting rate in the i-channel for the simple spectrum of the corresponding j-radionuclide, imp; v- number of channels in a spectrum. Eq. 16 can be applied provided that energy calibration of both simple spectra and the background spectrum is similar. If the above condition is not met, the value of energy calibration is to be made equal for all the spectra by means of Eq. 1. Besides, one should take into account that simple spectra *q* are collected for samples with one and the same density.

Simple spectra *q* are calculated as follows:

$$q_{ij} = \frac{\dfrac{N_i}{t} - \dfrac{N_{\phi_i}}{t_\phi}}{A_j} \;, \quad \text{i=1..v, j=1..n} \tag{17}$$

where N_i– counting in the i-channel in the real j-radionuclide spectrum, imp; $N_{\phi i}$– counting in the i-channel in the background spectrum, imp; A_j – sample activity of the j-radionuclide, Bq; t and t_ϕ – life time for measuring source spectra and background spectra correspondingly, sec [4].

As shown by Eq. 15, while changing the value A_j we can acquire the required spectrum Q for a non-existent sample with the density similar to that one, for which simple spectra q were collected. Thus, Eq. 15 can be put down as follows:

$$Q_i^k = Q_{\phi_i} + \sum_{j=1}^{n} q_{ij}^k \cdot A_j^k \;, \quad \text{i=1..v , k=1..r} \tag{18}$$

where r – number of densities; k – density No. in order.

Thus, Eq. 17 is the main one for making both learning and testing samples. The variable k, i.e. density, and variables A_j are subject to variation, or the so-called randomization. And this is the acquired spectrum Q, which is the learning element. There can be as many similar elements as possible. It means that the more information the neural network learns, the more accurate and precise results are achieved.

Now we describe the learning algorithm in details. We have simulated spectra of radionuclide mixtures Q and the activity vector A_B corresponding to each of the spectra. Thus, according to the algorithm described in part 2 of the current article, initialization of the matrix weights W should be carried out by means random variables from 1 to 0.3 [2]. Then, we put different spectra from the learning sample Q in random order to the network input, calculate forward the network by means of Eqs. 1 – 15 and, as a result, get the simulated vector of radionuclide activity A_M. In this case we have already got activity vector A_B from the learning sample for the spectrum Q.

The matrix weights are corrected in the opposite way to the network distribution. Thus, an auxiliary j-variable can be illustrated as follows:

$$g_j^Z = y_j^Z \cdot (1 - y_j^Z) \cdot (y_j^Z - y_{Bj}) \;, \quad \text{j=1..}P_Z \tag{19}$$

where y_j^Z - j-neuron output of the last layer; Z – number of network layers; $y_{B\,j}$ - target value of the j-output, calculated according to the following:

$$y_{B\,j} = \frac{A_{B\,j}}{M_{out\,j}} \quad , \; j=1..P_Z \tag{20}$$

where $M_{out\,j}$ - scale for j-output of the network.

Now we calculate the coefficient of weight correction:

$$\Delta W^T_{Z-1,i,j} = -\eta \cdot g_j^Z \cdot y_i^{Z-1} + \mu \cdot \Delta W^{T-1}_{Z-1,i,j}\,, \quad i=1..P_{Z-1}\,, j=1..P_Z \tag{21}$$

where T- number of learning iteration, if T=1 (i.e. at the beginning of learning) variables $\Delta W^{T-1}_{Z-1,i,j}$ are equal to 0; η – parameter, which determines learning rate, can vary from 0 to 1; μ – learning coefficient (Part 2) can vary from 0 to 1. The minus sign "-" in front of the first component of Eq.21 is caused by the fact that the weight changes in the opposite way to that one indicated by the derivative of error surface.

Weight correction is carried out according to the following equation:

$$W^T_{Z-1,i,j} = W^{T-1}_{Z-1,i,j} + \Delta W^T_{Z-1,i,j} \quad , \quad i=1..P_{Z-1}\; j=1..P_Z \tag{22}$$

The above weight correction (Eqs. 19 – 22) is carried out in the opposite way to the network distribution for each pair of layers. This approach is called "backward error distribution".

For the next pair of inner (hidden) layers (***not for the last and next to last ones***) weights change in the following way:

$$g_j^{Z-1} = y_j^{Z-1} \cdot (1 - y_j^{Z-1}) \cdot \delta_j \quad , \; j=1..P_{Z-1} \tag{23}$$

where

$$\delta_j = \sum_{k=1}^{P_Z} g_k^Z \cdot W^T_{Z-1,j,k} \tag{24}$$

Eq. 23 differs from Eq. 19 on the error of a hidden layer δ_j , which does not correspond directly to target output values. That is why weight correction of the hidden layer is proportional to its "contribution" to the error of the next layer.

Then, weight correction is carried out in a similar way to Eqs. 21 and 22:

$$\Delta W^T_{Z-2,i,j} = -\eta \cdot g_j^{Z-1} \cdot y_i^{Z-2} + \mu \cdot \Delta W^{T-1}_{Z-2,i,j}\,, \; i=1..P_{Z-2}\,, j=1..P_{Z-1} \tag{25}$$

$$W^T_{Z-2,i,j} = W^{T-1}_{Z-2,i,j} + \Delta W^T_{Z-2,i,j} \quad , \quad i=1..P_{Z-2}\; j=1..P_{Z-1} \tag{26}$$

As far as next layers are concerned, weights are transformed according to Eqs. 23 – 26 if correction is carried out from the end of the network to its beginning [2, 3].

After correction completion, another spectrum Q with a density parameter is put into the input the network to start learning. The network is calculated forward and the results are compared with target values of the vector y_{Bj} specified by the spectrum Q. Then, learning is carried out in the opposite way. There can be as many learning iterates as possible (about $5 \cdot 10^6$). It stands to reason that only a computer can calculate the above. The higher capacity computers have, the greater interest to artificial neural networks is aroused in different spheres of physics.

Whole body counting with large plastic scintillators as a tool in emergency preparedness – determination of total efficiency and energy resolution

Nilsson, Jenny; Isaksson, Mats
Department of Radiation Physics, Institute of Clinical Sciences, The Sahlgrenska Academy, University of Gothenburg, SU/Sahlgrenska, 413 45 Gothenburg, SWEDEN

Abstract
The measured total efficiencies for large plastic scintillators (NE 102 A), 91.5 × 76.0 × 24.5 cm^3, has been compared with Monte Carlo calculated total efficiencies. For ^{54}Mn the results show a good agreement except close to detector edges. To investigate light losses the Monte Carlo calculated deposited energy spectrum was converted into emitted light spectrum. The amount of emitted light was then changed depending on where the energy was deposited in the scintillation material. The emitted light per unit energy was calculated with Birks formula, with kB set to 9.65 mg cm^{-2} MeV^{-1}. Even for small light losses the emitted light spectrum resolution was affected.

Introduction and Theory
Increased demands on emergency preparedness have lead to a renewed interest in whole body counting. It is hard to know beforehand the energy and source distributions that will be of interest in a situation and a fast and accurate calibration method is therefore sought after. One possible solution is to do a Monte Carlo calibration of the whole body counter, WBC, system.

The University of Gothenburg has a low-activity laboratory equipped with two WBCs, one with four large plastic scintillators (NE 102A) and one with two large NaI(Tl)-detectors. The ambition is to do a Monte Carlo calibration for both systems, and presented in this work are the preliminary results for the plastic scintillator system.

To verify the WBC model, calculated total efficiencies for several nuclides were compared with measured. This was a relatively straight forward work; a much more demanding task is to obtain a calculated energy deposition spectrum whose energy resolution is comparable to a measured spectrum.

In scintillator spectrometry systems a spectrum is broadened due to multiple processes between the initial energy deposition and the final signal from the photomultiplier tube, PMT. The processes can be divided into five major parts (Valentine 1998): 1) production of scintillation photons; 2) the scintillation photons are collected at the PMT photocathode; 3) production of photoelectrons; 4) the photoelectrons are collected at the first dynode in the PMT; and 5) multiplication in the

PMT. Breitenberger (1955) has given a statistical description of the spectrum broadening in scintillator spectrometers, equation 1, using a theoretical model where the steps 2-4 are combined into a single transfer function. The relative variance V of the number of electrons Q to arrive at the PMT anode is given by

$$V_Q = V_T + \frac{1+V_M}{\overline{X}\overline{T}} \tag{1}$$

Each index indicates the quantity that contributes to the variance: X is the number of photons, M the multiplication including after-effects in the PMT and T the probability for one photocathode electron to reach the first dynode in the PMT per scintillation photon. The number of scintillation photons/MeV is known for NE 102A and V_M should, according to Breitenberger, be considered an instrumental parameter that is adjusted for each individual case. To determine T for the plastic scintillators is still a work in progress and investigated in this work are the effects on spectrum broadening due to nonlinear light yield and loss of scintillation photons, for example by light absorption in the scintillation material.

To convert the calculated deposited energy into emitted light the following relation first proposed by Birks (1964) was used

$$dL/dr = S(dE/dr)(1+kB(dE/dr))^{-1} \Leftrightarrow dL/dE = S(1+kB(dE/dr))^{-1} \tag{2}$$

where r is the range in the scintillator expressed in g cm^{-2}, dL/dr the specific fluorescence, S the absolute scintillation efficiency, dE/dr the specific energy loss, kB a constant expressed in mg cm^{-2} MeV^{-1}, and dL/dE the emitted fluorescent light per unit deposited energy. Birk's equation accounts for nonlinear light yield.

The code used was MCNPX 2.60, Monte Carlo N-Particle eXtended. The calculated energy depositions spectra are scored with MCNPX's f8 tally; it is possible to use a Gaussian energy broadening, GEB, function together with the f8 tally. However, since the broadening process consists of several steps, each with its own probability and variance, which are not necessarily Gaussian, the ambition is to use Breitenberger's equation instead of the GEB function.

Material and methods

The WBC consists of four large plastic scintillators made of NE 102A (NE 102A is equivalent to BC-400) each measuring 91.5 × 76.0 × 24.5 cm^3. Each detector is equipped with two PMTs (EMI 9545A) mounted on a perspex light guide and the stainless steel detector housing has a 0.397 mm copper window. The signal from the photomultiplier tubes are amplified (Canberra Amplifier 816A) and the output fed to an Ortec pulse-height analyser (Ortec ASPEC-927). Fig. 1 shows the detector configuration.

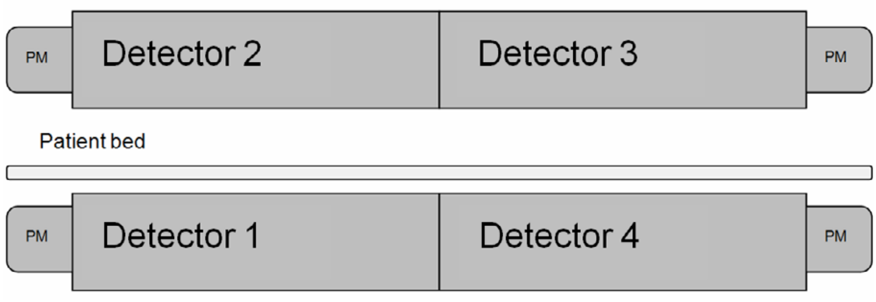

Fig. 1. Two detectors above and two below the patient bed gives, roughly, a 3π geometry. PM stands for photomultiplier tube. Medial direction: along the patient bed, -100 to 100 cm; lateral direction: across patient bed, -40 to 40 cm.

The Monte Carlo model of the WBC included the scintillation material, detector housing with Cu window, light guides, patient bed and a 3 mm lead wall coating of the surrounding steel chamber. Adding more wall or floor material gave a very little difference in total efficiency and it was therefore excluded in the model.

Four button sources were used: ^{137}Cs, ^{54}Mn, ^{65}Zn and ^{60}Co; only the result for ^{54}Mn is presented here.

Total efficiency

The total efficiency was measured and simulated for the source placed along the axis of symmetry in medial and lateral direction with 10 cm intervals. Medial direction: along the patient bed; lateral direction: across patient bed. The total number of counts was compared to the calculated number of counts scored with the f8 tally.

Spectrum broadening

The calculated deposited energy in MeV was converted into MeVee (MeV electron equivalent, a deposited energy of 1 MeV generates 1 MeVee in light output at linear light yield). This was done using the MCNPX's pulse height light tally, PHL. When using PHL, *dL/dE* for all energies has to be stated in the MCNPX input file. *dL/dE* was calculated with equation 2, where *S* was set to 3.0 (Mukhopadhyaya 2004); *dE/dr* was calculated with ESTAR (NIST 2005). For high electron energies the response is linear for NE 102A (Saint-Gobain Crystals 2005) and *kB* was changed until the ^{54}Mn photo absorption energy peak at 0.835 MeV lead to a photo absorption emitted light peak at 0.835 MeVee.

To investigate how light losses, depending on energy deposition site, affected the emitted light spectrum, each detector material cell in the MCNPX model was divided in medial direction into 9 smaller cells, all with the same material properties but with a different *dL/dE* depending on the distance from the light guide. The emitted light per particle track was scored with the f8 tally, and when used together with PHL, f8 sums the emitted light per particle track in MeVee from all 9 cells. Light absorption or light leaving the detector material was represented by multiplying *dL/dE* with a factor A_i (i=1:9; $A_i \leq 1$). A was calculated with the equation $A_i=-Cx_i+1$ where C is a constant and x_i the distance from the light guide to the middle of each of the 9 detector cells. However, this it is not necessarily considered an accurate description of the detector material. The value for C was changed in steps of 0.0005 from 0.0005 to 0.0025, for the box furthest away from the light guide A_9 varied from 0.956 to 0.778.

Results

Total efficiency

In fig. 2 and 3 the medial and lateral total efficiencies for ^{54}Mn are showed for detector 1. The results show a good agreement between measured and calculated efficiencies except close to the detector edges.

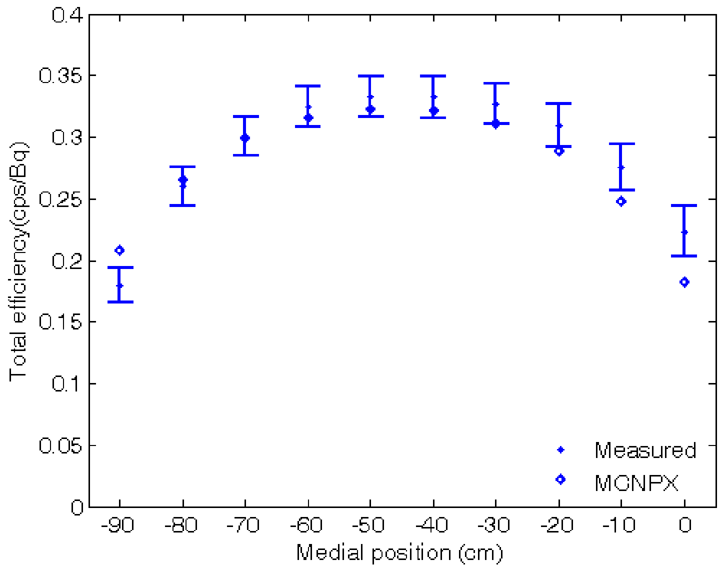

Fig. 2. The total efficiencies for ^{54}Mn placed at different positions along the medial direction. Lateral position was 0 cm in all measurements.

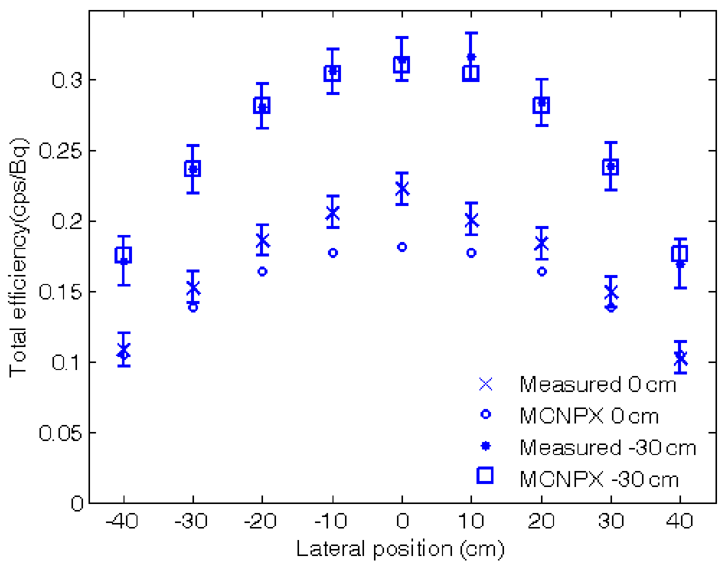

Fig. 3. The total efficiencies for ^{54}Mn placed at different positions along the lateral direction. Medial position was 0 and -30 cm, respectively.

Spectrum broadening

For kB=9.65 mg cm^{-2} MeV^{-1} the photo absorption energy peak at 0.835 MeV lead to a photo absorption emitted light peak at 0.835 MeVee, for lower energies small differences were noticed between linear and nonlinear light yield.

For detector 1, the deposited energy spectrum, and thereby also the emitted light spectra for all A_i=1, were nearly identical when the source was placed at -30 and -60 cm in medial direction, lateral position 0 cm. Fig. 4 and 5 show the emitted light spectrum for both positions for all Ai<1. In fig. 4 C=0.0005 and in fig. 5 C=0.0025. It is obvious that even for a small assumed absorption the emitted light spectra differs for the two source positions and the photon absorption emitted light peaks are shifted.

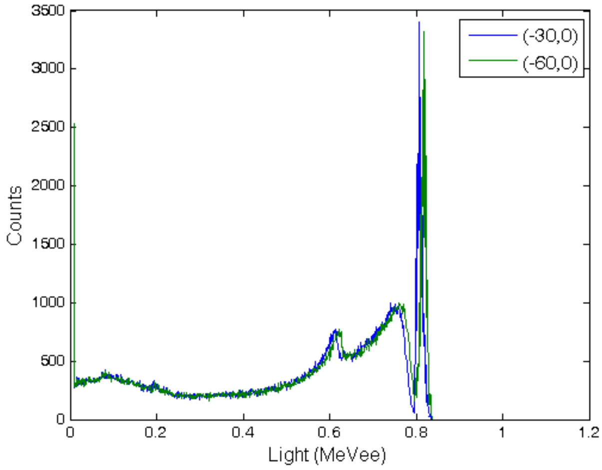

Fig. 4. The blue and green spectra show the emitted light in MeVee for ^{54}Mn placed at -30 respectively -60 cm in medial direction, lateral 0 cm for both. *C*=0.0005 and *A*=0.956 for the detector cell furthest away from the light guide, i.e. a small light loss.

The multiple peaks for C=0.0025 is due to the relative large differences in A between the 9 detector cells. If there was a continuing decrease of A the spectrum would most likely be more smeared without narrow peaks.

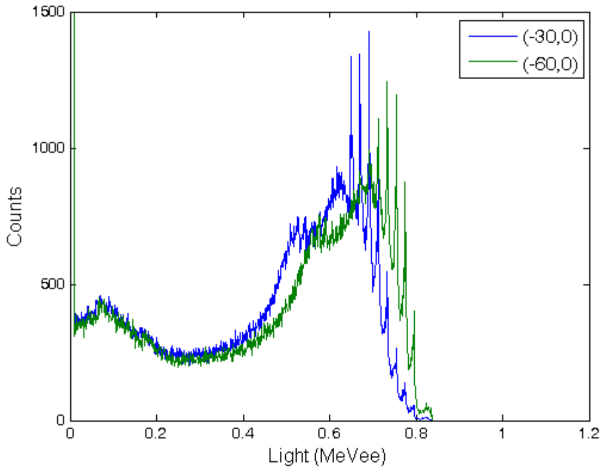

Fig. 5. The blue and green spectra show the emitted light in MeVee for ^{54}Mn placed at -30 respectively -60 cm in medial direction, lateral 0 cm for both. *C*=0.0025 and *A*=0.778 for the cell furthest away from the light guide, i.e. a rather high light loss.

Discussion

The comparison between calculated and total efficiency showed a good agreement for most source positions. Close to the detector edges the accuracy of the source position is quite important, and some deviations between measured and calculated efficiencies could be caused by a difference in stated and actual distance between detector housing and scintillation material. Also, when the source was placed at medial positions, it was assumed that the displacement was only in the medial direction when calculating the uncertainties, and vice versa for the lateral positions. Further analyses of the data results will give larger uncertainties and the calculated results might then be within the measured uncertainties limits.

Birk's constant *kB* was determined to be 9.65 mg cm^{-2} MeV^{-1}, for which there is a nonlinear response for energies below the photo absorption emitted light peak. But, there are other formulas describing the nonlinear light yield and it is also possible to use a linear response for all energies, the question is: what is most accurate? Birk's formula might not be the most accurate description, but it was easy to use together with the PHL tally, and for a detector described in this work the eventual nonlinear effects on spectrum broadening will most likely disappear in other more dominating broadening effects such as multiplication in the PMTs. Even if it is barely noticeable, the results does not imply that any formula would do, but it ought to be acceptable to use Birk's formula as long as one is aware of the assumptions that lie behind equation 2, which is carefully described by Birks (1964).

The results for different *A*, trying to mimic light absorption and light leaving the detector material, show that even for a small light loss the spectrum will be affected. For such large detectors as in this case it seems unlikely that light losses cannot be ignored and must be determined more exactly if an accurate spectrum broadening function is to be made. If so, a better representation of light losses must be done, the method described here gave crude results and how *A* is to be calculated must relate to the physical properties of the material. The attenuation length for NE 102A is 250 cm (Saint-Gobain 2005). The attenuation is described with Beer's law, but the conditions in the plastic scintillators, where light can be reflected, differs from the conditions described in Beer's law where incoming light is assumed to be parallel and attenuation is defined as light absorbed or scattered out of a narrow beam. This suggests that the absorption length would be longer than 250 cm, but how long and if the absorption increases linearly with length is not known. One possibility would be to do a Monte Carlo calculation of the light's path inside the detector material, but then one must know the reflecting index for the material surrounding the plastic scintillators and how long a particle track should be followed. The results show that the light losses are important, but at this moment it is yet to be determined how it should be modelled. The PHL tally has the advantage of being relatively easy and straight forward to use, and once the relationship between light losses and absorption site is more known, it ought to be possible to use the PHL tally to account for it.

Conclusion

Monte Carlo calculated total efficiencies correspond well with measured for several source positions relative to the detector. The effects of light losses are noticed in emitted light spectrum resolution, and for large detectors this ought to be properly accounted for when doing a spectrum broadening.

Examination of patients using the whole body gamma ray counter that is calibrated according to the individual anatomy properties

Yatsenko, V. N.; Borisov, N. M.; Korzinkin, M. B.
Burnasyan Federal Medical Biophysical Center, Moscow, RUSSIA

Abstract
Recently G.H. Kramer, K. Capello and E. Cardenas-Mendez [1] concluded that "whole body counters can now be calibrated more accurately using voxel phantoms, but the improvement is not as great as one might expect".

However, we have a slightly different view on the usefulness of voxel phantoms during the whole body counter-assisted examination of patients. Although the merits of voxel phantoms during calibration of whole body counters using the standard voxel phantoms are really not very significant, during the examination of patients the properties of individual anatomy can introduce considerable corrections into the whole body counting efficiencies (for low-energy gamma emitters, it may lead to the 2-fold increase/decrease of the assessed activity).

As an example, we performed whole body counter calibration and examination of patients, using both standard plastic phantom (developed by the Livermore laboratory, USA) and voxel phantom method (using the OEDIPE software developed at IRSN, France, and the well-known Monte Carlo code MCNP [2]). During our studies, we obtained the correction factors that are needed for the transition from the Livermore plastic phantom to the individual voxel phantom.

Introduction
Monitoring of internal radiation exposure for involved workers is one of the most actual problems in radiation hygiene of nuclear industry. Usually, the routine monitoring is performed using the so-called whole body and organ counters (WBC), i.e. generally semiconductor, more rarely scintillation gamma spectrometers that register the gamma rays, which are emitted by the incorporated radionuclides. In vivo monitoring data are especially important to make solutions on the medical measures that are to be taken in case of accidental radionuclide contamination of the nuclear workers. Modern in vivo counters possess high counting efficiencies for gamma rays through wide energy range, and provide high resolution in terms of absorbed energy values. However, they require the calibration procedure, i.e. determination of spectrometer counting efficiency (in other words, a relational factor between activities of incorporated radionuclides and counting intensities in the pulse-height-spectra of the gamma spectrometers).

The most biologically significant incorporated radionuclides (like ^{239}Pu and ^{241}Am) emit low-energy (13-60 keV) gamma rays. As a result, determination of WBC counting efficiencies is hampered due to intensive absorption and scattering of radiation in the patient's body. To circumvent these obstacles, one could use mathematical simulation (particularly Monte Carlo method as almost the only valid calculation method for such a purpose) rather than measurement of reference phantoms. However, such calculations require an adequate model of the patient's anatomy. This anatomy model could be described in terms of small rectangular boxes (voxels) with certain density and chemical composition.

Material and methods

The OEDIPE software

To provide the adequacy of mathematical simulation regarding to the physical measurements, the voxel representation of the patient's anatomy is retrieved from the x-ray computed tomography (CT) or magnetic resonance imaging (MRI) data. The software OEDIPE has been developed for creation of voxel phantoms of individual patients to conduct MCNP calculations. MCNP is a general-purpose Monte Carlo code, which performs transport calculations for gamma rays, neutrons and electrons in wide energy range. MCNP describes the transport geometry in terms of first- and second-order surfaces, as well as toroidal surfaces, thus enabling voxel representation of the patient's anatomy.

The MCNP input data file is automatically written by the OEDIPE interface. It contains the information on the patient's body in voxel representation, source characteristics, detector materials and geometry (described in terms of standard surfaces rather than voxels), the tally of interest (pulse-height-spectrum of the detector or dose distribution inside the body). To accelerate the calculations, the neighbor voxels with the same density and chemical composition are coupled into larger rectangular boxes using the maximal rectangular area technique. To visualize the transport geometry written in the MCNP input data file, the Sabrina software is used.

Whole body counting lab at FMBC

At the Burnasyan Federal Medical Biophysical Center (FMBC, Moscow, Russia), four Canberra germanium WBCs are placed into a shielded canyon, which shielding is made of exceptionally old steel. This steel was produced in 1930s, i.e. before the nuclear weapon tests had begun. Thus, this special shielding, which does not contain the artificial radionuclides, provides low radiation background inside the canyon. Moreover, the air inside the canyon is being ventilated during the in vivo examination, thus decreasing the radon activity, and creating the exceptionally low background intensity.

The preliminary test of the experimental equipment, measurement technique and voxel phantom-assisted calibration of whole body counters was done by whole body counting of plastic torso phantom developed by Livermore National Lab. ^{241}Am was to be measured using the Canberra whole body counters. This radionuclide is usually incorporated together with other actinides in the lungs of nuclear workers; it has the relatively high (59.54 keV) energy of major portion of emitted gamma rays. During the measurements, perforated lungs of the Livermore phantom contained 27 capsules with ^{241}Am of 3165 Bq total activity. Measurements were conducted by two spectrometers placed at the "chest" of the phantom in from of right and left lung.

Using these WBC devices, we examined exam three patients of the FMBC clinic (see Fig.1). Case histories of all patients (retired employees of Seversk Chemical Plant (Seversk town, Tomsk region) indicate to both inhalation (under routine operations) and wound intake (puncture wounds of hands during industrial operations) of non-soluble actinides, including ^{241}Am compounds in 1960-ties. Within long period of time, patients were regularly examined (natural excreta analysis, whole body counting) and treated (intravenous administration of Ca-DTPA (Pentacin), soft tissue dissection in the wound site) in medical facilities of FMBA of Russia (former 3rd Major Department of the USSR Ministry of Health).

To obtain the voxel phantoms of the patients as well as the Livermore plastic mannequin, we scanned the ex-workers and the Livermore phantom using the Toshiba Aquillion CT machine.

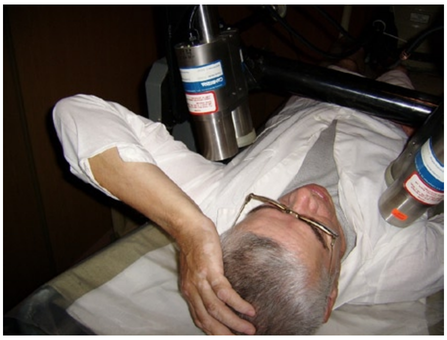

Fig. 1. Lung examination in patients at FMBC clinic.

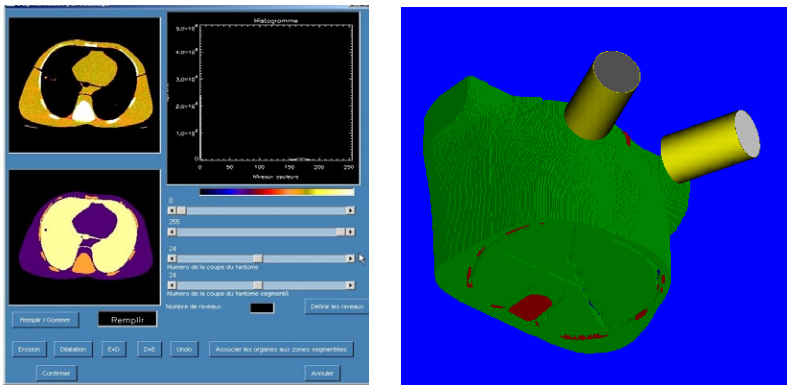
Results and Discussion

Experiments with the Livermore plastic phantoms

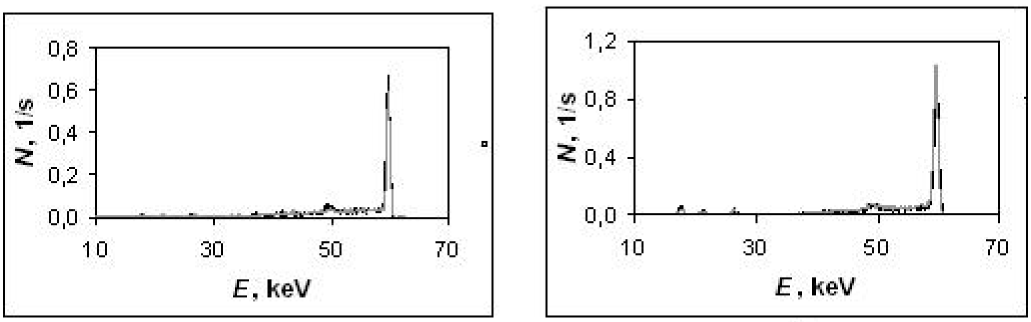
The Livermore phantom counting conditions were simulated using the MCNP software in voxel geometry (256x256x51 voxel resolution) that was retrieved using the OEDIPE software from the CT images obtained at the Burnaysan FMBC clinic. Fig. 2 provides results of OEDIPE software calculations: separation of major organs in the phantom image (panel a) and radiation transfer geometry record in the input data file of MCNP code (panel b). MCNP calculations for plastic phantom have used the source term as multiple points; the point positions were determined by the capsule places in the CT images of the phantom.



a b

Fig. 2. The Livermore phantom CT images processing for WBC calibration. Panel a: separation of organs and tissues applying OEDIPE software. Left upper window: initial CT image and segmented image below (colors are related to the tissue types); right upper window: spectrum of initial image according to the pixel brightness. Panel b: radiation transfer visualization with Sabrina software, which was recorded by OEDIPE software as the input data file for MCNP calculations. The color corresponds to the type of the tissue or substance. Number of voxels: 256×256×51.

The experimental and calculated spectra of whole body counter detectors placed in front of left (panel a) and right (panel b) lung of the phantom are shown by Fig. 3. Table 1 contains data on recalculation factor between the intensity of the photo peak (59.54 keV) and the total activity of ^{241}Am for right and left detector twins. Calculations did not use either counting efficiency correction versus the absorbed energy or spectrum standardization, so the calculated values of Fig. 2 and Table 1 are absolute ones rather than relative ones. The average quadratic deviation in the maximum pulse counting channel for calculated spectrum is about 6% for 1 million histories of random tests, which requires about 20 minutes of calculation time at personal computer (3 GHz, 512 Mb RAM).



a b

Fig. 3. Experimental (light colored) and calculated (dark colored) spectra of the left (panel a) and right (panel b) counting of ^{241}Am gamma radiation for lungs of Livermore National Lab plastic phantom.

Table 1. Experimental and calculated factors for recalculation of the photo peak (59,54 keV) intensity and the total activity of ^{241}Am for Livermore phantom and detectors placed in front of left and right lung.

Detector	Calculation (*C*), $s^{-1}\cdot kBq^{-1}$	Experiment (*E*), $s^{-1}\cdot kBq^{-1}$	Difference *D* = (*C*-*E*)/*C**100%
Left	0.85	0.78	+9
Right	1.41	1.55	-6

The comparison of calculation/measurement demonstrates that calculations have 10% and better accuracy to reproduce absorbed energy spectrum of Canberra Industries detectors both in the photo peak and in the Compton scattering range.

Examination of retired nuclear workers

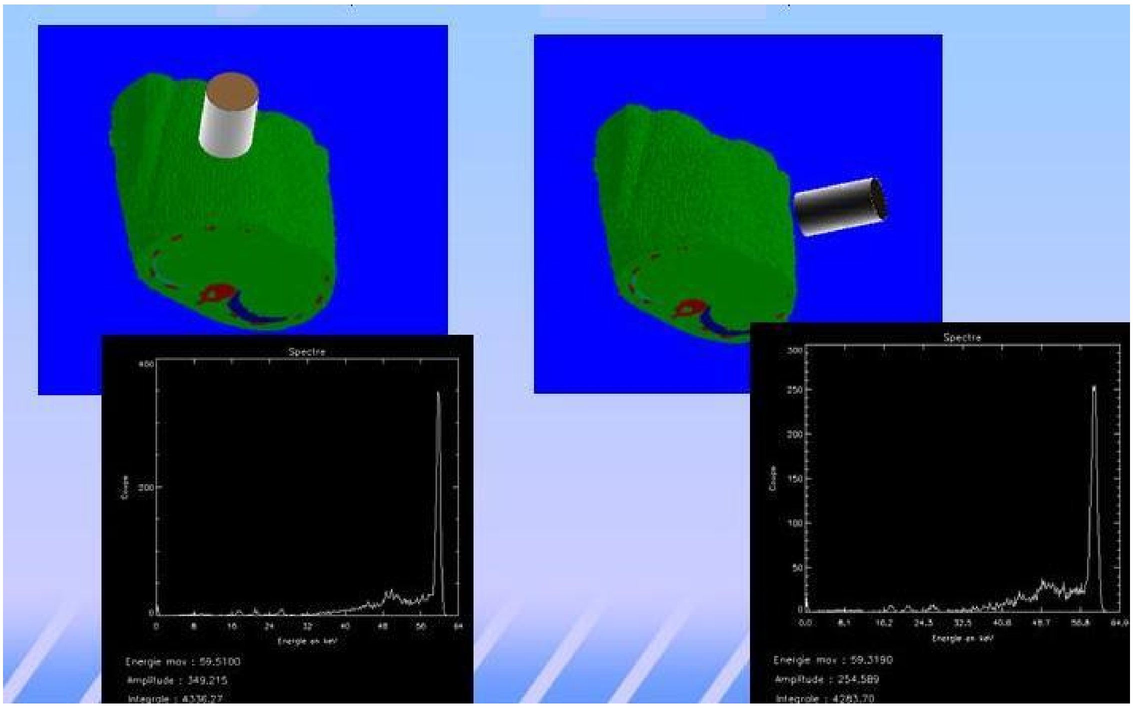


Fig. 4. ŒDIPE computer code application to assess re-calculation factors for counts in the spectrometry channels into ^{241}Am incorporated activity for one of retired employee of atomic industry. In the top: MCNP phantoms (Sabrina software applied for visualization). In the bottom: absorbed energy spectra calculated according to MCNP computer code for homogeneous lung distribution of ^{241}Am of one unit of activity (ŒDIPE software applied for visualization).

To determine ^{241}Am calibration factors in different spectrometry channels, ŒDIPE software was used basing upon CT chest images of patients (256x256pixel resolution for each slice) to create their MCNP voxel phantoms (Fig. 4, on the top). When preparing MCNP phantoms, the incorporated radionuclide distribution was adopted to be homogeneous in each lung.

Applying MCNP4c2 computer code, absorbed energy spectra were calculated for each of detectors placed in front of left and right lung of each patient; the homogeneously distributed ^{241}Am source of one unit of the activity was adopted. The photopeak intensity corresponding to the energy of major portion of photons emitted by ^{241}Am (59.54 keV) has provided the assessment of re-calculation factors.

Experimental calibration factors were determined by Livermore phantom measurement and set of ^{241}Am point sources placed in the "lungs" of phantom. ^{241}Am and ^{239}Pu measurement results are given by Table 2 for patients.

Table 2. ^{241}Am and ^{239}Pu measurement results for patients

Patient	Patient B.		Patient S.		Patient O.	
Lung	left	right	left	right	left	right
Full absorption peak intensity at 59,56 кэВ (N), c^{-1}	10,3	1,8	< 0, 1	0,80	0,43	1,25
Individual (OEDIPE+MCNP) assessment of ^{241}Am lung burden, ($A_C = N/K_C$), кБк	5,1	0,90	< 0, 04	0,31	0,39	0,95
Assessment of ^{241}Am lung burden using the Livermore calibration phantom, ($A_L = N/K_L$), кБк	6,9	0,6	< 0, 07	0,26	0,28	0,40
Relative error in lung burden assessment of ^{241}Am activity, $\eta = (AC - AL)/AC \cdot 100\%$	-35%	+33%	-75%	+16%	+28%	+57%
Correction factor $K_u=A_L/A_C$	1,35	0,67	1,75	0,84	0,72	0,42

The current value of radionuclide burden is proportional to the current value of the internal exposure dose rate. Concerning the internal exposure dose accumulated within long period of time since the examination and, moreover, concerning the retrospective internal exposure dose assessment, such values depend on biokinetics parameters of incorporated actinides, which are subjected to the significant individual variability as well as depend on medical measures accelerating radionuclide body excretion.

Besides, neither the exact portions of different intake pathways, nor the initial isotope composition of the intake are not known well. Large number of unknown factors affecting the internal exposure accumulated dose makes its assessment very approximate. To increase the accuracy and reliability of accumulated dose assessment, it is convenient to elaborate the periodical monitoring of radionuclide burdens in different organs and tissues of the patient.

Conclusions

1. The developed computational and experimental method for internal exposure monitoring was implemented for whole body counting of incorporated actinide patients.
2. The original technique for incorporated radionuclide in vivo measurement is elaborated, which not only increases the measurement accuracy significantly (with excluding the error component related to the incompliance of plastic phantom structure to the individual patient's anatomy) but also provides the uncertainty assessment of routine measurement technique based on plastic phantom calibration for WBC measurement result interpretation.
3. ŒDIPE computer code also provides the internal exposure dose distribution, which finding was tested, when solving industrial hygiene task (radioactive contaminated wound assessment).
4. The application of radiometric monitoring combined with Monte Carlo computational method as the long term program for persons involved in the internal exposure accident victims would significantly increase the reliability of in vivo monitoring of incorporated radionuclides and assessments of cumulated doses of internal exposure.

An extrapolation ionization chamber for α-ray detection and measurement

Bercea, Sorin; Cenusa, Constantin; Celarel, Aurelia;
Sahagia, Maria; Stochioiu, Ana; Ivan, Constantin
"Horia Hulubei" National Institute of R&D for Physics and Nuclear Engineering,
Bucharest, ROMANIA

Abstract

The extrapolation ionization chamber is a special type of the cavity ionization chamber, developed by Böhm (Böhm, 1983) for the absolute measurement of the absorbed dose rate in β-ray beams. The cavity theory was first created for the absorbed dose measurement in photon radiation, but it was also created for charged particles. In the radiation metrology laboratory from IFIN-HH we built such an extrapolation chamber for β-ray, but we tried to find how it would work when irradiated with α-ray.

Firstly, we obtained the experimental curves of the ionization current versus the polarizing voltage, *U*, the former have quite a net saturation region. Then, we measured the saturation current of the chamber for different values of the distance between the electrodes (i.e. different values of the sensitive volume of the chamber). When we represented the graph of the ionization (saturation) current against the distance between the chamber's electrodes, we noticed that this curve is quite analogous to the same curve obtained for β-ray irradiation.

So, by analogy, we concluded that for this chamber, the main requirements of the cavity theory are also fulfilled when the chamber is irradiated with α-ray.

This paper presents the results of the measurements concerning the $I=I(U)$ and $I=I(x)$ characteristic curves of the extrapolation chamber when it is irradiated with α-ray from a Pu-239 radioactive source. Some concluding remarks are also included, concerning the possibility of developing an absolute method for the measuring the absorbed dose for α-ray, based on the cavity theory.

Introduction

The detection and measurement of α-rays are procedures that repeat the general requirements that are imposed to ionizing radiations. In the same time, they must take notice of the characteristics of this type of radiations.α-rays are He nuclei (and therefore have a big rest mass- He^4_2 and (2+) electrical charge) that undergo Coulombian interactions which make them release energy quickly into the medium they pass through. It is for this reason that the path of the α-rays in various mediums is considerably smaller (for example 3.75 cm through air). In solid mediums, α-rays have much smaller paths and are completely absorbed in depths of tens or hundreds of microns.

The properties mentioned above impose that specific methods are elaborated and adequate detectors are designed. One of the methods for the detection and measurement of ionizing radiation is the ionometric method, which is based on the collecting and measuring of the electrical charges produced by ionization inside the gas from the sensitive volume of the detector.

As far as α-rays are concerned, it is necessary that the detector (for example an ionization chamber) have a sufficiently thin window that permits the passing of particles without significant loss of energy; hence, the particles that reach the sensitive volume can produce a sufficient number of ionizations. The ionizations lead to the outcome of an electrical signal that can be measured with adequate precision at the output of the detector.

Initially, the cavity theory, which correlates the generation of ionization electrical charges inside the gas from a cavity, with the energy released in the material surrounding the cavity, was elaborated for photon radiation. Further on the theory was adapted also for radiations made of particles with rest mass and electrical charge Trott (Trott, 1966).

The most complex elaboration of the cavity theory for β-particles was presented by Böhm (Böhm, 1983) he also designed an ionization cavity-chamber with variable volume (the extrapolation chamber). The latter is destined to measure the absolute value of the released energy (meaning the absorbed dose) in a particular medium for the β-radiation.

Material and methods

This type of ionization chamber (extrapolation chamber) was also put into practice by the Radiation Metrology, Testing and Dosimetry Team (CMRID) of the Horia Hulubei National Institute for R&D in Physics and Nuclear Engineering, IFIN-HH.

Description of the ionization (extrapolation) chamber built by IFIN-HH

The ionization chamber has a cylinder shape with plane-parallel electrodes Fig. 1. The voltage electrode (polarization electrode) is made up of an electroconductory layer (an aluminium layer with a thickness of a few microns), which is placed on one of the sides of a very thin sheet of Mylar (70 mg/cm^2); this electrode is also the input window of the detector. The collector electrode is made up of a graphite layer placed on a polystyrene block. This graphite layer is electrically isolated from the guard electrode (guard ring). The latter consists of a circular layer of graphite. The guard ring is connected to the detector's ground and is designed to define the sensitive volume of the detector from an electrical point of view.

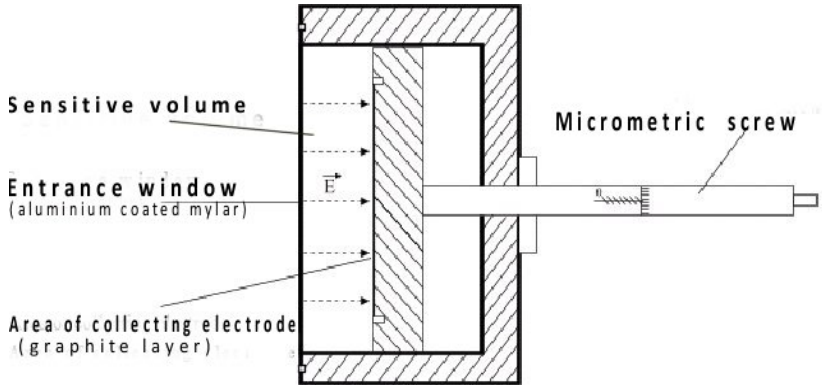

Fig. 1. Schematic view of the extrapolation chamber.

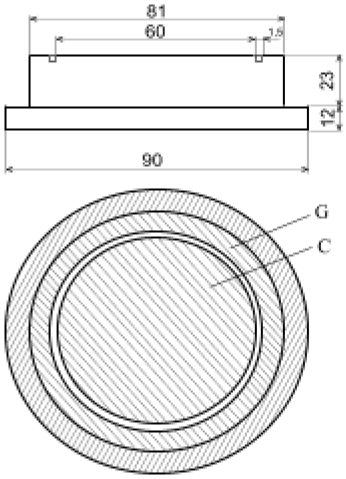
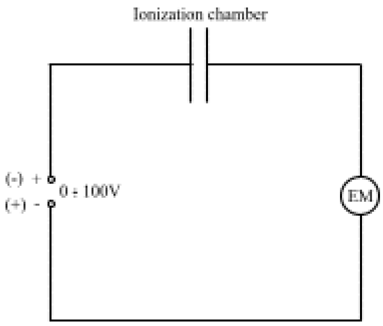
The sensitive volume of the detector can be modified mechanically by varying the distance between the polarization electrode and the collector electrode with a micrometric screw, in the range of 5-16 mm. In Fig. 2 we present the shape and size of the electrodes.



C – collecting aria, G – guard ring electrode

Fig. 2. The shape and size of the electrodes of the extrapolation chamber.

In figure 3 we present the electrical circuit used for measuring the ionization charge (or current) of the ionization chamber, Bercea et al (Bercea et al. 2008a, Bercea et al. 2008b).



EM - electrometer

Fig. 3. The electrical circuit for measuring the ionization charge / current.

The experiment

As we have shown in our introduction, in order to calculate the rate of the absorbed dose, $\dot{D}_\alpha$, we use the relationship (1). This includes the slope of the curve ionization current versus distance *I=I(x),* $\left(\frac{\partial I}{\partial x}\right)$, in the range where it is linear. This is extrapolated for $x \rightarrow 0$, meaning where the perturbator effect on the radiation that interacts with the solid medium that surrounds the cavity filled with gas (air) disappears.

$$\dot{D}_\alpha = K\frac{W}{eS\rho}\left(\frac{\partial I}{\partial x}\right)_{x\rightarrow 0} \qquad (1)$$

K - constant which takes in to account the units of measure
W - the average energy required to produce the air ionization
e - the elementary electric charge
S - the aria of the collecting electrode
ρ - the air density in the sensitive volume of the ionization chamber

In order to see to what extent the ionization chamber made by IFIN-HH acts according to the cavity theory, which refers to α-radiation, the following experiments were made.

The experimental drawing of the curves ionization current versus polarization voltage, *I=I(U),* for a given source of α-radiations in a well-defined geometry. The geometry corresponded to the various distances between the polarization electrode and the collector electrode, *x*, and also the detecting of the range of values of the polarization voltage, values within which the detector is functional.

Choosing a value for the polarization voltage that lies within the saturation range for all the values of the distance between the electrodes, *x*, the graphical representation of the curve that gives the ionization current *I* versus the distance between the electrodes of the chamber, is determined experimentally.

Results

The measurement of the ionization current

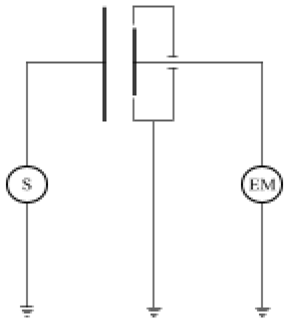
The ionization current generated by the detector was measured in the presence of a source of α-rays, in a fixed irradiation geometry. The α-ray source used in this case was a Pu^{239} source having the following characteristics:

– -extended, circular source with a diameter of 120 mm;
– -emission rate: ε= 13 601 α/s in 2πsr.

The source was positioned with the aid of a special support ring placed at a distance of 2 mm from the surface of the window of the ionization chamber.

The ionization current was measured with a Keithley 617 electrometer.

The arrangement used for measuring the ionization chamber is given in Fig. 4.



S – voltage source; EM - electrometer

Fig. 4. The experimental arrangement for measuring the ionization current.

Considering the order of magnitude of the ionization current (about 1 pA) during the measurements, certain precautions had to be made, in order to reduce the influence of the working conditions on the results of the measurement. Thus, in the working chamber, the temperature was held constant (20 ± 2º C); any actions that may cause powerful noises or vibrations were avoided, as well as the movement of people in the proximity of the measurement stand (less than 1.5 meters from the stand).

Before installing the radioactive source on the stand, we measured the current of the ionization chamber for the value “0” of the polarization voltage. The value we obtained in this case was ±5.6 x 10^{-15}A. After installing the Pu^{239} source on the stand, we waited 2 hours before starting the measurements.

The first important observation was that for U = 0 in the presence of the radioactive source, the ionization chamber presented a positive current , whose values depended on the value of the distance between the electrodes of the chamber (Table 1). A first assumption is that it could be due to the alpha particles reaching the collecting electrode, in absence of any polarization.

Table 1. The values of the ionization current (I) for 3 values of the air gap, for *U* = 0.

x (mm)	I (A)
5	$1.0074 \cdot 10^{-12}$
7	$1.960 \cdot 10^{-12}$
9	$0.2388 \cdot 10^{-12}$

For the three values chosen for the distance between the electrodes, x, we experimentally obtained the characteristic curves I=I(U). The results we obtained are presented in Fig. 5.

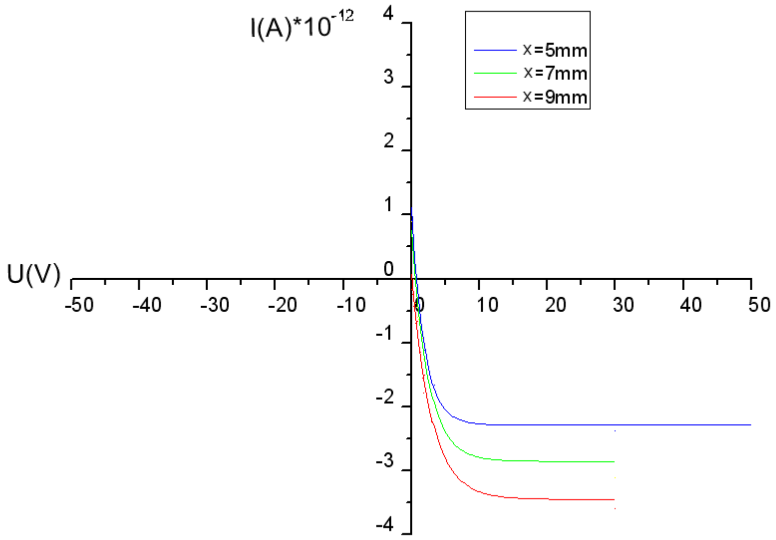


Fig. 5. The I=I(U) curves for three values of x.

For the value of the polarization tension U=15 V situated in the saturation region of the I = $I(U)$ curve we made measurements of the ionization current and we also obtained the curve that expresses the ionizing current versus the distance between the electrodes (the gap depths), x, respectively the volume of the chamber (V), considering the fact that $V = S*x$, and the surface of the collector electrode S = constant.

The results obtained are presented in table 2 and the curve that resulted is presented in Fig. 6.

Table 2. The ionization current corresponding value of the gap depth (*x*).

x (mm)	$I*10^{-12}$ (A)	x (mm)	$I*10^{-12}$ (A)	x (mm)	$I*10^{-12}$ (A)
1	0.48	6	2.8	11	4.4
1.5	0.7	6.5	3	11.5	4.5

5.5	2.5	10.5	4.3		

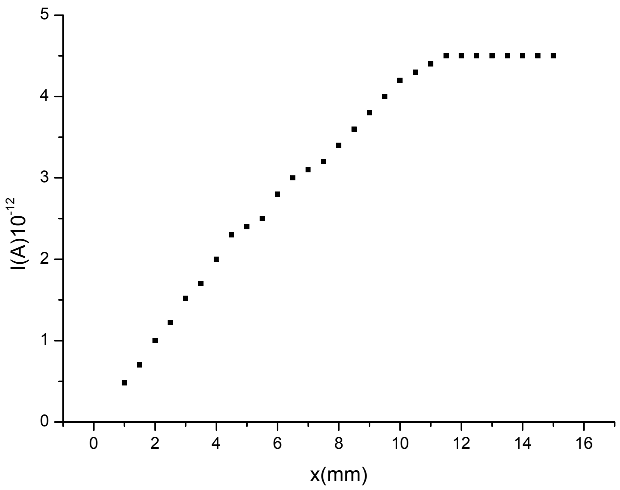

Fig. 6. The *I* = *I(x)* characteristic curve.

Discussion

The analysis of the results obtained regarding the $I=I(U)$ characteristic of the ionization chamber, in the presence of a α-radiation field, as above presented Fig. 5, leads to the conclusion that in the presence of these radiations, the detector has a typical behaviour. The ionization current reaches the saturation value fairly quickly for all the possible values of the distance between the electrodes.

In saturation conditions, we have concluded that the $I = I(x)$ curve also has a typical behaviour for this type of detector, respectively, for $x \rightarrow 0$, the ionization current is proportional to the distance between the electrodes, x, in the range 0 to 4.5 mm, such as the Figure 6 shows, and thus, with the sensitive volume of the chamber. This behaviour indicates the fact that, in the presence of a α-radiation field, the ionization chamber with a variable volume produced by IFIN-HH has the same behaviour as when irradiated with β-radiations.

Conclusions

The experimental results we obtained, especially the shape of the $I=I(x)$ curve, which is linear within the range 0 to 4 .5 mm, and consequently when $x \rightarrow 0$, are an experimental confirmation for the fact that the cavity theory, as presented for the β-radiations /1/, may also be used, in the same experimental configuration, for measuring the absorbed doze in α-radiation fields and beams. All that is left is that further research leads to the identification of all the quantities necessary for obtaining the absorbed doze of α-rays. This relation would connect the absorbed dose rate $\dot{D}_{\alpha}$, to the variation of the ionization current, $\left(\frac{\partial I}{\partial x}\right)$, which would be analogous to the relation for the β ray.

Abstract

Local radiation syndrome is marked by necrosis that may extend to the deep subcutaneous structures. Today, treatment is surgery, excision, graft and flap with sometimes bad results. It has been suggested that Mesenchymal Stem Cells (MSC) therapy could be used in order to treat numerous tissue lesions. We have performed a novel therapeutic approach of local radiation syndrome by using local autologous MSC therapy combined to surgery. For this purpose, autologous bone marrow cells were collected from the unexposed iliac crest. For GMP production, MSC were expanded in a closed system (MacoPharma partnership) containing an innovative serum free medium supplemented with human platelet lysate as previously described (Doucet et al., J. Cell Physiol., 2005). Quality control assays evidenced that expanded cell population retained typical MSC characteristics and did not exhibit chromosomal abnormalities. As previously demonstrated, MSC produced many cytokines and growth factors which could have a critical role in improving the healing process by counteracting the local inflammatory waves and by promoting the autologous skin engraftment.

We believe that MSC act as drug cells delivering in situ in the lesion growth factors which contribute to the healing of the lesion. We have also demonstrated that after in vitro cell activation, the conditioned medium of MSC exhibited a similar effect on wound healing than that obtained with freshly expanded MSC. In case of caryotypic abnormalities occurring after in vitro MSC expansion, the use of MSC conditioned medium could be considered as a relevant alternative of MSC therapy. Other sources of MSC such as adipose tissue, gingival mucosa are also taken in consideration in view of setting up an allogeneic stem cell bank.

A new therapeutic approach for radiation burns combining surgery and mesenchymal stem cell administrations: About four cases

Abstract

The physiopathological mechanisms of severe radiation burns are well described and their treatments are well codified but very difficult to perform with an important functional and vital risk. We present four patients with accidental local radiation burns and propose a new therapeutic approach combining surgery and local stem cell therapy.

The first patient had local radiation burns of left fingers and left buttock (Chile, 2005). We performed early excision of the irradiated part of the buttock after dosimetric reconstruction. We covered the buttock and the fingers with full thickness skin graft. Autologous Mesenchymal Stem Cells were locally administrated in the lesion in combination with surgery. The second patient had a very important radiation-induced skin necrosis located to the left arm from the shoulder to the elbow (Senegal, 2007). The surgical procedure used a pedicle latissimus dorsi muscle flap and a proximal forearm ante bracchial flap after a very large excision of skin and triceps muscle. Several Stem Cell administrations were combined to the surgery after many bone marrow collections. The third patient had a local radiation burn of the hands (Tunisia, 2008). Full thickness skin grafts were combined with local stem cells administrations. The fourth current case presented a local radiation-induced burn of the limb and was also treated by surgery and local stem cell therapy (Equator, 2009). We obtained a complete and stable healing in all cases. Stem cell therapy using autologous expanded MSC has to be considered as an adjuvant treatment of the surgery corresponding to excision of necrosis tissues and flap reconstructions.

Our results demonstrate that this new therapeutic procedure using surgery and local stem cell therapy is very promising. We believe that this innovative approach could improve the treatment of local radiation burns in term of functional and vital results.

Experience of mesenchyme cell's therapy in case of severe local radiation (x-ray) injure of back tissues

Bushmanov, Andrey; Kotenko, Konstantin; Nadezhina, Natalya;
Galstyan, Irina; Kretov, Andrey; Eremin, Ilya
Burnazian Federal Medical Biophysical Center of Federal Medical Biological Agency,
Moscow, RUSSIAN FEDERATION

Abstract

On the 13-th of January of 2008 patient, 61 years old, addressed to admission department of Burnazian Federal Medical Biophysical Center of Federal Medical Biological Agency.

Patient asked for medical help to different hospitals and at 350-th day after exposure diagnose of local radiation injure (LRI) was defined. Unsuccessful try of iterative autografting was made. At 592-nd day after exposure patient was hospitalized to Burnazian Federal Medical Biophysical Center of Federal Medical Biological Agency.

The result of conservative therapy was decreasing volume of fibrin and non-active growth of granulations. In connection with depth and area of wound conservative therapy was not successful, patient was need surgical treatment. But his cardiac pathology did not allow surgical treatment.

This situation was the reason to looking for new strategies of treatment of LRI.

Scientific dates and little clinical experience allowed to use autologous mesenchyme cell therapy to cover wounds in cases of LRI in combination with conservative therapy.

Result of using of new technology was active growth of granulation, active peripheral epithelization and total epithelization of ulcer.

In conclusion, this clinical case shows opportunity to use modern hi-tech medical methods in combination with conservative therapy to treat consequences of severe local radiation injures. At present this strategy of medical management is preferable method for patients with severe LRI and with contraindication to surgery.

Introduction

On the 13-th of January of 2008 patient, 61 years old, addressed to admission department of Burnazian Federal Medical Biophysical Center of Federal Medical Biological Agency. Anamnesis that he told: during long time (about 30 years) he severe from coronary heart disease, in 1996 survived coronary artery bypass grafting, in 2000 - cardiac infarction. In July of 2006 because of frank coronary atherosclerosis and severe angina pectoris try of stents installation was made under fluoroscopic control. Because of technical and anatomical troubles length of operation was about 3½-4 hours.

During early postoperative period patient noticed appearing of itch and little vesicles on interscapular region. In 2 months this symptoms regressed and changed to infiltration and pain syndrome.

Patient asked for medical help to polyclinic near his home, situation was defined like dermatitis with unclear etiology and non-specific treatment was applied.

At 280-th day after exposure black crust appeared in the center of infiltration. Patient used applications with different tinctures, as a result black crust was removed and ulcer was fined under it.

Patient asked for medical help to different hospitals and at 350-th day after exposure diagnose of local radiation injure (LRI) was defined. Unsuccessful try of iterative autografting was made. At 592-nd day after exposure patient was hospitalized to Burnazian Federal Medical Biophysical Center of Federal Medical Biological Agency.

St. Localis: there was ulcer on interscapular region, measurement 5x5x4 cm, bottom of ulcer covered by fibrin, skin around ulcer with fibrous and atrophic changes, palpation aroung ulcer was without pain syndrome.

On the base of anamnesis and objective status diagnose was defined: consequence of severe LRI of back tissues after x-ray exposure.

To define severity and area of local radiation injury following procedures were carried out:

- Radioisotopic study of thorax
- Electron spin resonance of thorax
- Cytogenetic analysis of lymphocytes
- Ultrasonic scanning of back tissues
- Bacteriological analysis of wound microflora

On the base of calculation and results of cytogenetic analysis local dose was about 20-25 Gy without total exposure. The patient was treated according to common pathogenetic mechanisms of LRI:

- Local therapy (specific non-adhesive bandage with antiseptics and antibiotics)
- Disaggregating therapy
- Stimulation of regeneration
- Disintoxication therapy
- Antibiotic therapy

Wound was contaminated with pseudomonas aeruginosa, which was eliminated by systemic antibiotic therapy.

The result of conservative therapy was decreasing volume of fibrin and non-active growth of granulations. In connection with depth and area of wound conservative therapy was not successful, patient was need surgical treatment. But his cardiac pathology did not allow surgical treatment.

This situation was the reason to looking for new strategies of treatment of LRI.

Scientific dates and little clinical experience allowed to use mesenchyme cell's therapy to cover wounds in cases of LRI in combination with conservative therapy. For this aim scientific protocol was worked out, which was passed by ethical committee of

Burnazian Federal Medical Biophysical Center of Federal Medical Biological Agency. Patient subscribed assent to use new medical technology for treating his disease. After that 20 ml of fat was taken. In sterile conditions according standard method, stem mesenchyme cells was separated and cultivated in autologous serum to quantity 1-1,5*10^6. After that 3-5*105 of them was cleaned and injected around ulcer in 10 points.

Results

Result of using of new technology was active growth of granulation, active peripheral epithelization and decreasing of wound measurement on 90% during 1 month.

For stimulation of epithelization of wound with lot of granulation was made successful iterative autografting. We got total epithelization of ulcer during following 3 weeks.

Conclusion

This clinical case shows opportunity to use modern hi-tech medical methods in combination with conservative therapy to treat consequences of severe local radiation injures. At present this strategy of medical management is preferable method for patients with severe LRI and with contraindication to surgery.

New haematological criteria of acute radiation sickness severity

Belyi, David; Bebeshko, Vladimir
State Institution "Research Centre for Radiation Medicine of Ukrainian Academy of Medical Sciences", UKRAINE

Abstract
Diagnostic criteria of acute radiation sickness (ARS), which based on peripheral blood cells, were described in numerous publications. However, not all suggested indices meet the requirements of accurate and early determination of ARS severity and only some of them could be used for integral estimation of hematopoiesis damage caused by radiation. Retrospective analysis of hemograms was carried out in 136 patients who suffered from Chernobyl accident. From this amount 32 patients survived ARS grade 1 (mild), 31 grade 2 (moderate), 8 grade 3 (severe), and 65 persons was irradiated in doses lower 1 Gy. As the new criteria we suggest following indices: a day of granulocytes primary decrease to 2×10^9, 1×10^9 and 0.5×10^9 L^{-1}, and a day of thrombocytes primary decrease to 100×10^9, 50×10^9 and 30×10^9 L^{-1}. The ANOVA statistical analysis showed that the patients, who were discriminated by ARS grade, demonstrated highly significant difference of time period from irradiation (day 0) till granulocytes and thrombocytes came down to above-mentioned levels. For integral estimation of hematopoiesis damage it is suggested the index of summary deficit of peripheral blood granulocytes and thrombocytes count between 10th and 55th day after the irradiation. It was calculated as the square of a figure (or several figures) on a graph, which basis is a straight line meaning the low normal level of granulocytes (2×10^9 L^{-1}) or thrombocytes (150×10^9 L^{-1}) count. Slanting lines granulocytes and thrombocytes decrease or increase on the graph serve as the figure sides. Any calculation follows the graphic presentation of these mature cells dynamics. The summary cells deficit significantly correlated with doses of irradiation. The criteria that were suggested enabled to estimate the severity of radiation damage and start the adequate treatment already on the early stage of ARS.

Introduction
The Chernobyl accident showed that in a case of unforeseen radiation exposure, resulting in ARS development in man, methods of biological dosimetry become the only available for estimation of radiation dose and a rate of sickness severity. Peripheral blood indices are used for this purpose more frequent. Thus G. Andrews (Andrews et al. 1965; Andrews 1980) was one of the firsts who suggested using peripheral blood

lymphocytes count on 1st and 2nd days after radiation exposure for evaluation of whole-body radiation dose and radiation injury rate. Research workers of Moscow Institute of biophysics (Gus'kova et al. 1987; Baranov et al. 1995) used nomographic charts for absorbed radiation dose estimation. These nomograms are based on lymphocytes content in peripheral blood during the first 9 days after irradiation. These researchers determined ARS grade by leukocytes count on the 8-9th days after exposure. D. Densow et al. (1996) consider that it is possible to predict a depth of hemopoiesis injury by granulocytes content in peripheral blood between the 4th and 12th days following irradiation. In accordance with gradation, which they suggested, the injury of hemopoietic tissue changes from transient slight granulocytopenia to entire depression of hemopoiesis.

However all above-mentioned methods of biological dosimetry are not absolutely reliable because they demonstrate essential discrepancy in dose value and ARS grade if applies in the same patient. This fact makes the search of new criteria for estimation of radiation exposure rate and ARS grade is sufficiently topical.

Material and methods

The retrospective analysis of patient's histories was done for the purpose of peripheral blood cells count during first two month after the irradiation. There was 71 patients in the study program who suffered ARS in a result of the Chernobyl accident, including 32 persons survived ARS grade 1 (mild), 31 ARS grade 2 (moderate) and 8 ARS grade 3 (severe). ARS grade determined according to classification had been worked out by A. Gus'kova et al. (Mettler et al. 2007). Additionally 65 patients without clinical and haematological signs of ARS were included in the study (ARS 0). Their whole-body radiation doses were evaluated cytogenetically by count of dicentric in peripheral blood lymphocytes (Gus'kova et al. 1987). Age-specific and dosimetric characteristic of the examined patients are submitted in table 1.

Table 1. Age-specific and dosimetric characteristic of the examined patients.

Indices	ARS 0	ARS grade 1	ARS grade 2	ARS grade 3
Number of patients	65	32	31	8
Gender: M / F	61 / 4	29 / 3	30 / 1	8 / 0
Age at exposure, years mean ± SD min – max 95% confidence interval	 34.9±10.1 20.8-59.4 32.4-37.4	 33.6±8.8 17.6-56.3 30.4-36.7	 38.7±13.9 20.7-79.3 33.6-43.7	 35.8±12.5 20.4-55.1 25.3-46.3
Whole-body radiation dose, Gy n[a] mean ± SD min – max 95% confidence interval	 0.3±0.2 0.1-0.6 0.2-0.4	 1.0±0.6 0.1-3.3 0.7-1.2	 2.4±0.9 0.5-4.2 2.0-2.7	 5.4±1.0 3.9-7.1 4.4-6.3

Note: a – number of patients with the dose evaluated in 1986

Results

As the new haematological criteria for ARS grade evaluation there were studied the following indices: a day of granulocytes decrease to 2×10^9 (lower norm limit), 1×10^9

(the agranulocytosis point), and 0.5×10^9 L^{-1} ("the day of 500 neutrophils" according to Gus'kova et al. 1987), as well as granulocytes the most minimal level and the day, when it came, and a day of thrombocytes decrease to 100×10^9, 50×10^9 and 30×10^9 L^{-1} (the last two points mean the critical level of thrombocytes when risk of spontaneous internal bleeding and haemorrhages becomes high), and thrombocytes the most minimal level and the day when it came.

Statistical analysis ANOVA (analysis of variances) revealed the high significance of intergroup difference between days after exposure when granulocytes decreased to afore-mentioned levels (table 2).

Table 2. The duration of time period from irradiation till the day when peripheral blood granulocytes decreased to certain levels (mean ± SD).

ARS grade	Day after irradiation when granulocytes decreased to:				Granulocytes minimal level, $\times10^9$ L^{-1}
	2×10^9 L^{-1}	1×10^9 L^{-1}	0.5×10^9 L^{-1}	the most minimum	
1	27±8 (n=32)	31±7 (n=23)	32±3 (n=10)	36±4 (n=32)	0.7±0.5 (n=32)
2	13±6 (n=30)	19±7 (n=30)	24±5 (n=30)	29±4 (n=30)	0.1±0.1 (n=31)
3	9±5 (n=8)	14±5 (n=8)	16±5 (n=8)	22±3 (n=8)	0 (n=8)
ANOVA, F (p)	40.0 (0)	29.9 (0)	26.3 (0)	47.8 (0)	47.8 (0)

The time periods when peripheral blood thrombocytes decreased to 100×10^9, 50×10^9, 30×10^9 L^{-1} and the most minimal levels differed significantly as well as thrombocytes the most minimal values in patients with various ARS grades (table 3).

Table 3. The duration of time period from irradiation till the day when peripheral blood thrombocytes decreased to certain levels (mean ± SD).

ARS grade	Day after irradiation when thrombocytes decreased to:				Thrombocytes minimal level, $\times10^9$ L^{-1}
	100×10^9 L^{-1}	50×10^9 L^{-1}	30×10^9 L^{-1}	the most minimum	
1	23±5 (n=31)	26±5 (n=24)	28±4 (n=10)	29±5 (n=32)	36±24 (n=32)
2	15±3 (n=28)	18±3 (n=28)	21±4 (n=30)	26±4 (n=31)	10±6 (n=30)
3	10±2 (n=7)	13±1 (n=7)	14±2 (n=7)	22±5 (n=8)	3±3 (n=8)
ANOVA, F (p)	43.3 (0)	41.5 (0)	37.9 (0)	23.0 (0)	10.1 (0)

The high statistical significance in difference of above-mentioned time periods in patients had survived ARS of various severity made possible to use these indices as diagnostic criteria for ARS. Based on results of statistical analysis it was found by empirical way the fluctuation ranges for granulocytes and thrombocytes time indices (table 4).

The figure 1 demonstrates an example how to determine ARS grade by the way of finding on granulocytes dynamics chart the points that correspond the days when these peripheral blood cells decreased to certain levels. Thus granulocytes decreased to 2×10^9 L^{-1} on 7th day, to 1×10^9 L^{-1} on 15th day, to 0.5×10^9 L^{-1} on 21st day, to the minimal level on 25th day. According to suggested criteria this hemogram corresponds to ARS grade 3.

Table 4. Haematological criteria of ARS grades.

Indices	ARS grade 1	ARS grade 2	ARS grade 3
Day of granulocytes decrease to:			
2×10^9 L^{-1}	19-33	8-18	6-7
1×10^9 L^{-1}	29-41	18-28	9-17
0.5×10^9 L^{-1}	32-42	23-31	12-22
minimal value	34-44	26-33	17-25
Day of thrombocytes decrease to:			
100×10^9 L^{-1}	20-34	13-19	6-12
50×10^9 L^{-1}	22-36	15-21	12-14
30×10^9 L^{-1}	26-35	18-25	13-17
minimal value	32-44	25-31	16-24
Minimal values:			
granulocytes ($\times10^9$ L^{-1})	300-1500	0-300	0
thrombocytes ($\times10^9$ L^{-1})	20-80	10-20	0-8

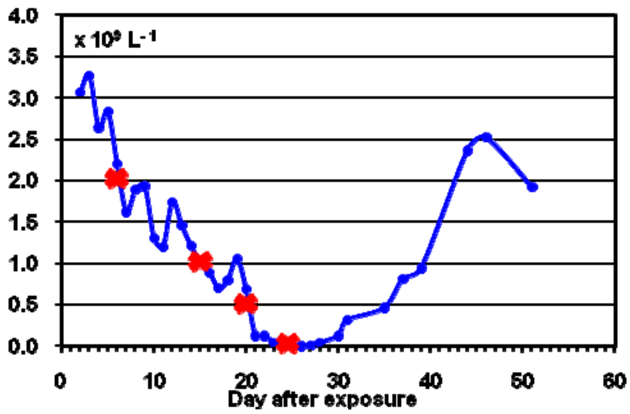

Fig. 1. Granulocytes dynamics in ARS grade 3 survivors (red crosses indicate the days when cells levels decrease to 2×10^9, 1×10^9, 0.5×10^9 L^{-1} and to minimal value)

ARS grade largely reflects a patient's overall clinical status than the depth of hemopoiesis injury. The value of granulo- and thrombocytopenia in ARS survivors of the same grade could vary both during cytopenia rising and the recovery of these cells count in peripheral blood. The deeper and continuously granulo- and thrombocytopenia was the stronger radiation injury of hemopoiesis, and vice versa. Therefore the quantitative characteristics of cytopenia, which is per se a deficit of peripheral blood cells caused by radiosensitive cell loss, may be used for estimation of hematopoiesis radiation injury.

For this purpose hemograms of 65 ARS survivors was analyzed to determine overall granulocytes and thrombocytes deficit in peripheral blood from the 10th till 55th days after exposure. The choice of such time interval are explained by several reasons: first, not all victims visit hospitals or out-patient departments after radiation exposure right away and are examined by physician (as it was during the Chernobyl accident); second, before the 10th day the great possibility of granulocytes abortive elevation exists in patients suffered from ARS grade 1 or 2; third, in the case of successful clinical outcome and hemopoiesis recovery the majority of patients leave a hospital not later the 60th day after exposure.

An index value, which characterizes granulocytes and thrombocytes deficit, was calculated on a graph that showed the dynamics of corresponding peripheral blood cells. This index is equal to square of figure (or several figures) that are restricted by the graph curve from sides and the bottom, and by straight line from the top (fig. 2). This line signifies the lower normal level of blood cells content, which is 2×10^9 L^{-1} for granulocytes and 150×10^9 L^{-1} for thrombocytes. The way of square calculation on graphs is described in statistical manuals (Bland 1995).

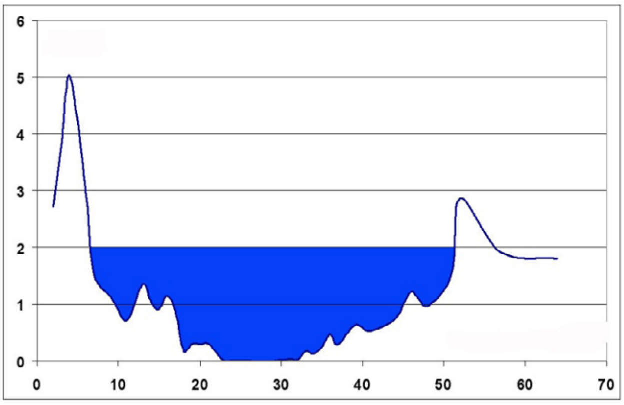

Fig. 2. Granulocytes dynamics in patient K., who survived ARS grade 2 (Y-axis – ×10^9 L^{-1}; X-axis – days after exposure; the blue coloured area indicates granulocytes deficit from the 10th till 55th day after exposure).

A day granulocytes deficit is equal to difference between 2×10^9 and actual cell count in a litre of peripheral blood. The sum of deficit value per every day signifies the overall cells deficit, which is easily measured in conventional units. On the fig. 2 the blue coloured square means granulocytes deficit in ARS grade 2 survivor. This deficit is 60.1 units. Thrombocytes deficit in the same patients is equal to 3987 units (fig. 3). To do the values of granulocytes and thrombocytes deficit more comparable this index was divided on 100. Therefore the summary deficit of both blood cells is the following: 60.1 + 39.87 = 99.97 units.

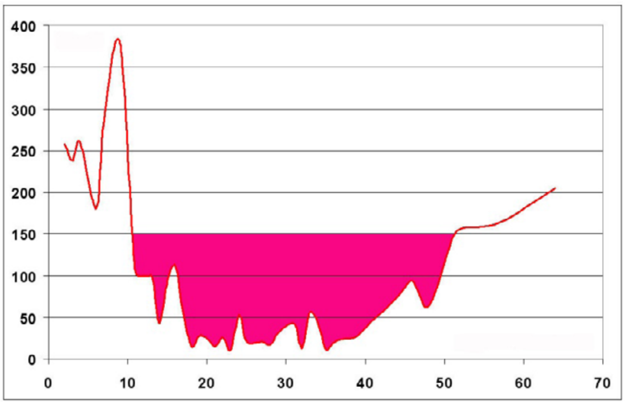

Fig. 3. Thrombocytes dynamics in patient K., who survived ARS grade 2 (Y-axis – ×10^9 L^{-1}; X-axis – days after exposure; the red coloured area indicates thrombocytes deficit from the 10th till 55th day after exposure).

Interrelation between summary deficit of granulocytes and thrombocytes, and whole-body radiation dose was analyzed and showed significant correlation measured by Spearman's, Pearson's and Kendall's methods (table 5).

Table 5. Correlation between summary deficit of granulocytes and thrombocytes and whole-body radiation dose (n=66).

Method	Correlation coefficient	p
Pearson	0.695	0
Kendall	0.608	0
Spearman	0.795	0

From 65 patients with radiation doses less than 1 Gy 41 persons had repeated short-term episodes of granulo- and thrombocytopenia from the 10^{th} till 55^{th} day after exposure. The summary deficit of peripheral blood granulocytes and thrombocytes was estimated in these patients. The values of the summary deficit for ARS survivors and patients with doses lower 1 Gy are showed in table 6. As far as they have a high significance of intergroup difference it was worked out the criteria for evaluation of hemopoiesis radiation injury that based on the mean values of deficit indices and confidence intervals. Thus the summary deficit of granulocytes and thrombocytes 0-20 units means that the hemopoiesis radiation damage could not cause ARS. The deficit value 21-40 units is attributed to ARS grade 1, 41-70 to ARS grade 2, 71-100 to ARS grade 3 and greater than 100 to ARS grade 4.

Table 6. Granulocytes and thrombocytes deficit in ARS survivors and patients with radiation doses lower 1 Gy.

Indices	ARS 0	ARS grade1	ARS grade 2	ARS grade3	ANOVA, F (p)
Number of patients	41	31	27	7

Discussion

In the case of accidental irradiation of man it is not always possible to estimate radiation dose by the methods of physical dosimetry as well as calculate it by the way of experimental imitation of accidental situation. Therefore in this situation the preference belongs to biological dosimetry methods of dose estimation that based on quantitative and qualitative homeostasis changes. Some methods as electron paramagnetic resonance spectrometry of teeth enamel and evaluation of stable chromosomal aberration in peripheral blood lymphocytes are expensive enough, require special equipment and take much time for analysis. In view of such circumstances haematological indices are used wide in clinical practice for dose determination and estimation of radiation injury rate. Peripheral blood analysis requires no trouble and biological material, as capillary or venous blood, is gotten easy. The terms of analysis procedure are short enough so prompt result is expectable that is very important under condition when ARS threatens a patient's life.

All known hematologic indices, which are used for ARS grade estimation, can be divided on two groups: (1) criteria that have a diagnostic importance during the primary reaction or in latent period, and (2) indices that are used in the period of ARS manifestation.

The first group of criteria consists of indices that based on peripheral blood lymphocytes and leukocyte count during the first 10 days after irradiation. However the methods accuracy is under doubt. Thus according to L. Suvorova et al. (1991), ARS grade, which was determined by blood lymphocytes count between the 3rd and 6th day after the irradiation, had true prognosis in 50% of cases. Our results proved this data. The percentage of patients with false ARS grade, which had been diagnosed by leukocytes count, was 58%. When both lymphocytes and leukocytes count was used, not more severe ARS grade but slighter grade was mistakably diagnosed. This means that some patients, who will demonstrate the haematological signs of ARS (based on granulocytes and thrombocytes count) 20-30 days after irradiation, during first decade remains without the true diagnosis.

During the period of ARS clinical manifestation peripheral blood leukocytes and thrombocytes count is the main diagnostic criteria of this disease and the basis of it classification (Yarmonenko et al. 2004). According to this grading leukocytes fall to 3-1.5×10^9, 1.5-0.5×10^9, 0.5-0.1×10^9 L^{-1} and 0, and thrombocytes fall to 40-100×10^9, 20-40×10^9, 10-30×10^9 L^{-1} and 0 corresponds to 1, 2, 3 и 4 ARS grades. However these criteria are not early ones due to they are applicable only on a peak of ARS clinical symptoms.

Other authors (Anno et al. 1989) suggested to be guided by following levels of granulocytes and thrombocytes count: the doses 1-2 Gy cause granulocytes fall up to 2-4.5×10^9 and thrombocytes one to 80-180×10^9 L^{-1}, 2-3.5 Gy to 0.5×10^9 and 80×10^9 L^{-1}, respectively; the doses 3.5-5.5 Gy and higher result in the cells drop till zero.

Other method of dose estimation starting from 1 Gy are based on nomographic chart consisting of several curves of neutrophils and thrombocytes dynamics from the beginning of irradiation till the 60th day (Gus'kova et al. 1987, 1989). The advantage of this method is a dose evaluation on ARS early stage. However the dose that is determined by neutrophils count on the first days after irradiation not always coincides with ones estimated by thrombocytes count, and differs from the dose that is calculated by these cells minimal level in peripheral blood i.e. on late stage of the disease.

So today there are no accurate and sure methods for ARS grade and dose estimation due to all represented haematological criteria have two essential shortcomings: first, they are not designated for estimation of the dose that lower 1 Gy i.e. less than ARS threshold of development; second, they do not allow to accurately determine ARS grade on the early stage of the disease, only on the peak of clinical manifestation.

The diagnostic criteria of ARS that we suggested are based on time of granulocytes and thrombocytes decrease till the certain levels. These criteria have not a claim on high accuracy but are the still one method for ARS grade determination on the early stage of it development. Thus the day when granulocytes drop to 2×10^9 and thrombocytes to 100×10^9 L^{-1} lets to estimate ARS grade in the latent period of the disease. The day of granulocytes decrease to 1×10^9 or 0.5×10^9 and thrombocytes to 50×10^9 or 30×10^9 L^{-1} falls on manifestation period.

Estimating the state of hematopoiesis in patients, who did not suffered from ARS, we came to the conclusion that they had the radiation injury of hematopoietic tissue too. Although the threshold for ARS development is the dose 1 Gy of X-ray or gamma-irradiation, Y. Moskalev (1991) considered that the dose 0.65-0.7 Gy is the minimal portion of energy that is capable of damage blood stem cells. Other authors (Neumann et al. 1981; Uckun et al. 1989) thought that D_0 for a pluripotent stem cell (CFU-GEMM) varies from 0.54 till 0.94 Gy. Radiosensitivity of progenitors of different lineages (granulo-, mono-, and erythrocytopoiesis) is slightly less than the blood stem cell but nevertheless their threshold does not exceed 1 Gy.

G. Gruzdev (1988) showed that starting from the whole-body exposure of 0.5 Gy signs of bone marrow injury in man appear but haematological indices slightly deviate from normal values. This injury is not enough for clinical manifestation of radiation bone marrow syndrome. Our data confirms this statement. Thus from 65 patients with radiation doses lower 1 Gy 41 persons had granulocytes and thrombocytes dynamics that was not corresponded to typical ARS haematological picture but these patients demonstrated transient (single or repeatable) episodes of granulo- and thrombocytopenia. No one known haematological criterion is enabled to estimate neither the radiation dose nor severity of bone marrow injury for these people.

The methods of hematopoiesis radiation injury based on estimation of granulocytes and thrombocytes deficit was applied to a patient who had been irradiated in dose 0.3 Gy (fig. 4). Granulocytes deficit was 6.8 units and thrombocytes one 8.5 units. So the summary deficit was 15.3 units what is less than lower level of ARS grade 1. Therefore this method is applicable not only for ARS survivors but for persons who are undergone to irradiation in dose range lower 1 Gy. It is only the obligatory condition that blood analysis should be done regularly for not to miss cytopenia episodes.

Conclusions

It was worked out the two new types of haematological criteria for estimation of radiation injury rate in man. They are based on changes of peripheral blood granulocytes and thrombocytes count after the exposure. The first method enables to determine ARS grade (the rate of severity) in latent period and during manifestation of disease. Its main advantage is the enhancement of possibility to diagnose ARS grade on the early stage of the disease not excluding the other similar methods but together with them.

The second criterion is not applicable for early ARS diagnosis but gives the possibility to estimate the rate of hemopoiesis radiation injury both in ARS survivors and persons who were irradiated in doses lower 1 Gy and had transient granulo- and thrombocytopenia.

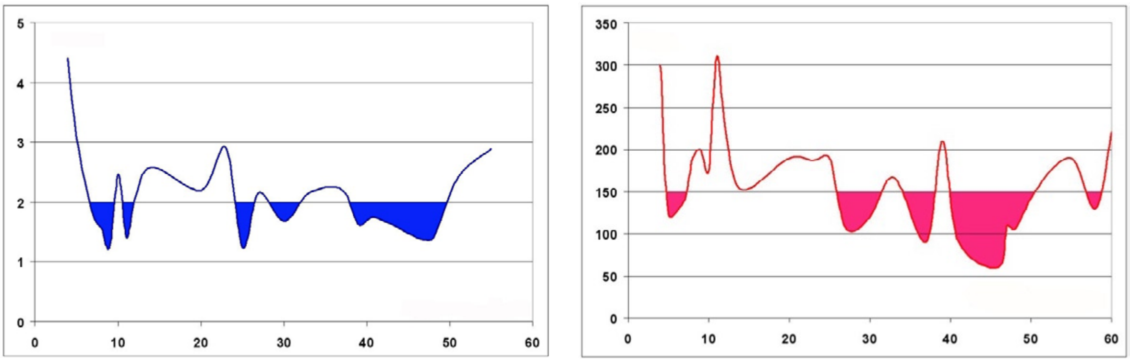

Fig. 4. Dynamics of granulocytes (left) and thrombocytes (right) in patient B. with whole-body radiation dose 0.3 Gy (conventional signs the same as on fig. 2 and 3)

Abstract

Despite protection means implemented in the nuclear industry, some internal contamination cases of workers by actinides such as uranium may occur either by inhalation, ingestion or penetration through wounds or intact skin. In case of cutaneous contamination, no specific emergency treatment exists although it may induce a high internal exposure of contaminated individuals. In this context, we have developed a new topical pharmaceutical form dedicated to emergency treatment of uranium skin contamination. In this order, we have decided to take advantage of the particular chelation properties of calixarene molecules developed in our laboratory for bioassay analyses purpose. The objective of the present work is to integrate calixarene molecules in a topical form for uranium skin decontamination. We have thus developed an oil in water (O/W) nanoemulsion containing these calixarene molecules. The physico-chemical properties of this nanoemulsion have been characterized and its efficiency for uranium extraction has been evaluated by *in vitro* and *ex vivo* experiments.

The characterization of the calixarene nanoemulsion has been performed by oily droplets size, zeta potential and pH measurements, as a function of calixarene concentration. The results suggest that calixarene molecules are present at the surface of the oily droplets. Thus, calixarene molecules are potentially available to trap uranyl ions present in an aqueous contaminated solution. This was confirmed by the *in vitro* evaluation of the calixarene nanoemulsion efficiency by ultrafiltration techniques. Indeed, more than 80% of uranium can be extracted by the calixarene nanoemulsion from an aqueous contaminated solution in optimized experimental conditions (pH, volumes and calixarene:uranium stoechiometry). Then, uranium percutaneous diffusion kinetics over 24 hours experiments, on intact or excoriated pig ear skin samples using Franz cells system, have shown that the application of the calixarene nanoemulsion immediately after the contamination quantitatively (98%) inhibits the uranium cutaneous transfer. Concurrent analysis of uranium distribution in skin samples by SIMS technique showed no significant accumulation of uranium or calixarene-uranium complex through the different layers of the skin, except within the *stratum corneum* in case of intact and non treated skin. A delayed application of the calixarène nanoemulsion (5 min, 15 min or 30 min) after the contamination on excoriated skin

samples is still efficient since uranium transfer is reduced by up to 75%. Thus, for optimal efficiency, the treatments should be applied the fastest after the contamination.

In conclusion, this study has successfully demonstrated the efficiency of the calixarene nanoemulsion constituting a promising system to treat uranium contaminated skin.

Introduction

Internal contamination of power plants workers by actinides may occur by inhalation, ingestion or penetration through wounds or intact skin. Although the most current contamination pathway is inhalation (Gerber and Thomas 1992), the contamination through intact or wounded skins is still a big concern, since it may induce a high internal exposure of contaminated individuals after translocation of the radionuclides from the contamination site into the body (De Rey et al. 1983, Lopez et al. 2000, Petitot et al. 2004, Petitot, Frelon et al. 2007, Petitot, Gautier et al. 2007). The current medical care in case of skin contamination only occurs after transfer of the victim to the medical unit of the nuclear site and it only consists in local decontamination of the wound by rinsing with soaped water or a 25% calcic salt of diethylene triamine pentaacetic acid (Ca-DTPA) solution. This procedure is often followed by a decorporation treatment with intravenous injection of 1 g of Ca-DTPA in 4 mL (ASN 2008) to reduce the risks of tissue damage and induction of cancer. A surgical excision of the contaminated tissues can be needed in order to remove residual radionuclides and prevent their penetration into the body (Gerber and Thomas 1992, Bailey et al. 2003). Nevertheless, Ca-DTPA exhibiting a lack of selectivity and affinity for uranium in biological medium, these procedures are ineffective in case of uranium contamination that may induce strong kidney toxicity (Lopez et al. 2000, Métivier 2001). Some chelating agents more specific to uranium have been developed in order to decorporate uranium from the body (Durbin 2008). Except the biphosphonate molecule series (Houpert et al. 2004, Yang, et al. 2005, Xu et al. 2008), none of those chelating agents have been used in pharmaceutical forms dedicated to skin decontamination. In addition, the specific uranium chelation by the biphosphonate molecules within the proposed formulations has not been demonstrated.

In this context, we have developed a new topical pharmaceutical form dedicated to emergency treatment of uranium skin contamination. We have taken advantage of the particular chelation properties of a calixarene molecule (Fig. 1) developed in our laboratory for radiotoxicological analyses purpose. The selectivity, affinity and extraction efficiency of uranium present in trace in biological media by this calixarene have been successfully shown in previous works (Boulet et al. 2006). The objective of the present study is to integrate these calixarene molecules in a topical form for skin decontamination. We have thus developed an oil in water (O/W) nanoemulsion displaying calixarene molecules at the interface between the oily and external aqueous phase. The physicochemical properties of this nanoemulsion have been characterized and its efficiency for uranium extraction has been evaluated *in vitro* by using an adapted ultrafiltration method and *ex vivo* with first experiments on intact and excoriated pig ear skin explants in Franz diffusion cells.

Material and methods

Materials

Calixarene molecule (Fig. 1) was synthesized as described in the patent (Duval et al. 2006). Other compounds used for preparing calixarene nanoemulsions were paraffin oil (d = 0.86), (VWR, Fontenay-sous-Bois, France), non ionic surfactants sorbitan monooleate (Span® 80) and polyoxyethylene glycol sorbitan monooleate (Tween® 80), purchased from Sigma-Aldrich (Saint-Quentin-Fallavier, France) and water obtained from a Milli-Q® Synergy 185 water purification system (Millipore, Saint-Quentin-en-Yvelines, France).

Uranium-contaminated solutions were prepared by diluting a standard depleted uranium solution (1,000 $mg.L^{-1}$ in 2% HNO_3, SPEX Certiprep, Horiba Jobin Yvon, Longjumeaux, France). The pH of the contaminated solutions was adjusted to 5 with 0.01 M acetate buffer. A bismuth (^{209}Bi) stock standard solution at 100 $\mu g.L^{-1}$ (from a 10 $mg.L^{-1}$ single element standard, SPEX Certiprep, Horiba Jobin Yvon, Longjumeaux, France) and a multielemental standard solution containing depleted uranium at 1 $\mu g.L^{-1}$ (from a 10 $mg.L^{-1}$ tuning solution SPEX Certiprep, Horiba Jobin Yvon, Longjumeaux, France) were prepared in 2% HNO_3 (from a 67% HNO_3 stock solution, Normatom, VWR, Fontenay-sous-Bois, France) for Inductively Coupled Mass Spectrometry (ICP-MS) measurements. All reagents were used as received without any further purification. Pig ears used in Franz cell diffusion experiments were purchased from Guy Harang abattoir (France) with the authorization of the French Departmental Directorate of Veterinary Services of Hauts-de-Seine. Pig ears were stored at -20°C until use.

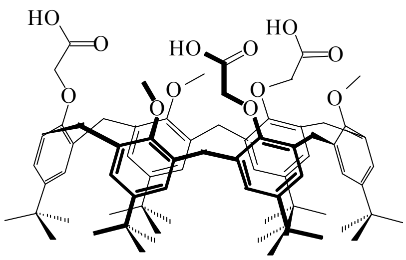

Fig.1. Structure of 1,3,5-OCH_3-2,4,6-OCH_2COOH-*p-tert*butylcalix[6]arene.

Methods

Preparation and characterization of calixarene nanoémulsions

Oil in water calixarene nanoemulsions were prepared by the emulsion inversion point method as previously described (Spagnul et al. 2010). The amounts of surfactants, oil and water were respectively 5%, 20% and 75% (w/w). The dispersed oil droplet size and zeta potential were both measured with a Nanosizer/Zetasizer® ZS apparatus (Malvern Instruments, Worcestershire, U.K.), and pH measurements were carried out with a MeterLab/pH M240 pH-meter (Radiometer Copenhagen, Denmark). These parameters were determined as a function of the calixarene concentration in the nanoemulsion.

In vitro calixarene nanoemulsion efficiency study

Equal volumes of uranium-contaminated solution (40 µg.L^{-1}, pH 5) and calixarene loaded nanoemulsion (2 mg.g^{-1}) were mixed and the mixture was kept under static condition during definite times. Aliquots of the mixture were put into Microcon® centrifugal filter devices (3,000 Da, Millipore, Saint-Quentin-en-Yvelines, France) and centrifuged at 6,000 rpm for 30 minutes at 20°C. The uranium extraction by the calixarene nanoemulsion was determined by quantifying free uranium present in the aqueous filtrate phase recovered by ultrafiltration-ultracentrifugation of the mixture using Inductively Coupled Mass Spectrometry (ICP-MS) technique (Spagnul et al. 2010).

Ex vivo calixarene nanoemulsion efficiency study on pig ear skin explants

The diffusion kinetics of uranium through intact and wounded skins was studied after application or no application of the calixarene nanoemulsion treatment in Franz diffusion cell assays using MicroettePlusTM apparatus (Hanson Research Corp., Chatsworth, California, USA). Full thickness skin pieces were removed from pig ears and wound was generated by removing the *stratum corneum* of the skin by tape stripping using 60 standard D-Squame® discs (Monaderme®, Monaco) pressed onto the skin using a D-Squame® applicator that provides a constant 150 g cm^{-2} pressure (Monaderme®, Monaco). Each skin sample was put on receptor compartment of the diffusion cell, its dermal face in contact with a 0.025 M carbonate buffer receptor medium (Sigma-Aldrich Saint-Quentin-Fallavier, France), covered with the donor compartment and the whole device was fixed with a clamp. The contamination was made by depositing 600 µL of a 10 mg.L^{-1} uranyl nitrate solution at pH 5 on the skin sample in the donor compartment of the Franz diffusion cell. Skin decontamination was evaluated by depositing 600 µL of 4 mg.g^{-1} calixarene nanoemulsion in the donor compartment immediately after the skin contamination. The dosage form was also applied 5, 15 and 30 minutes after the skin contamination step on excoriated contaminated skin samples. 24 hours later, uranium diffusion was then evaluated by uranium quantification in the receptor fluid. The Receptor medium was kept under stirring and at the constant temperature of (33.5 ± 0.1)°C during the experiment. All experiments were conducted under occlusive conditions.

ICP-MS uranium analysis

Quantification of ^{238}U content in the aqueous samples was made by ICP-MS measurements using optimized protocols originally designed for human urine samples: aliquots were properly diluted in 2% HNO_3 and ^{209}Bi was added as internal standard at 1 µg.L^{-1} (Baglan et al. 1999, Bouvier-Capely et al. 2003, Bouvier-Capely et al. 2004). As diluted solutions were prepared by weighing, the related uncertainties can be neglected compared to the statistical ones. The combination of the statistical errors was made using the conventional law of uncertainty propagation. The ICP-MS signal was optimized at mass 238 before each measurement series.

Localisation of uranium in skin biopsies by SIMS microscopy

At the end of the 24 hours Franz cell diffusion experiments, skin biopsies were thoroughly rinsed with water and fixed in a solution containing 6% glutaraldehyde in a sodium cacodylate buffer at 4°C during one day. Skin samples were then dehydrated in various propylene oxide and ethanol baths, permeated with a propylene oxide/Epon mixture and then embedded in pure EPON-type resin. Skin sections (0.9 µm) of embedded samples were cut and laid on silicium or gold holders for SIMS (Secondary Ion Mass Spectrometry) analysis. The SIMS microscopy, which allows the elemental and isotopic analysis of a solid surface, is based on the sputtering of a few atomic layers from the surface of a sample by O^{2+} primary ions beam bombardment. The ejected secondary ions are collected and analysed by mass spectrometry. Then, compositional images of the surface are formed from the secondary ions spectra. A more detailed description of the physical phenomenon is provided in the literature (Castaing and Slodzian, 1962; Tessier et al., 2009). For each skin area analysed, $^{40}Ca^+$ or $^{23}Na^+$ images gave the histological structure of the skin and $^{238}U^+$ images showed uranium localisation within the cutaneous structures. The SIMS analyses were performed with a CAMECA IMS 4F-E7 instrument (Gennevilliers, France).

Results and discussion

Characterization of the calixarene nanoemulsion

A previous study on the physicochemical characterization of the calixarene nanoemulsion showed that the oil droplet size is nearly 175 nm and decreases significantly ($p < 0.05$) to 150 nm from a calixarene concentration in the nanoemulsion of 2 mg g^{-1} (Spagnul et al. 2010). Tension measurements at the oil/water interface showed that calixarene molecules have surfactant properties which can explain the droplet size diminution after the calixarene molecules addition in the nanoemulsion.

The zeta potential measurement of the dispersed oily droplets showed that increasing calixarene concentration in the nanoemulsion leads to a zeta potential decrease from -13 mV to -50 mV until a 4 mg g^{-1} calixarene concentration at which the zeta potential value did not change significantly from its -50 mV minimal value (Spagnul et al. 2010). This zeta potential decrease due to the emergence of negative charges at the surface of the oily droplets can be explained by the presence of calixarene molecules at the oil droplets surface. Indeed, the carboxylic functions of calixarene molecules may be partially deprotonated at the nanoemulsion aqueous phase pH which is about of 4.5 (Boulet 2006).

These results tend to demonstrate that calixarene molecules are at the surface of the oil droplets under ionised form. Calixarene molecules are thus potentially available to extract uranyl ions from an aqueous uranium contaminated solution.

In vitro evaluation of uranium extraction by the calixarene nanoemulsion

The decontamination potential of the calixarene nanoemulsion was first evaluated by keeping under static contact a mixture of equal volumes of 2 mg.g^{-1} calixarene loaded nanoemulsion with a 40 µg.L^{-1} nitrate uranyl solution at pH 5, ensuring a 10,000-fold calixarene molar excess. The extraction ability of the calixarene nanoemulsion was compared to that of a solution of calixarene in paraffin oil in the same conditions of calixarene excess (molar ratio calixarene/uranium = 10,000). The results presented in Table 1 indicate that the calixarene nanoemulsion is able to extract $(83.4 \pm 0.6)\%$ of uranium of the contamination solution after only 5 minutes of contact (total contact time of 35 minutes after ultrafiltration) and the optimum of uranium extraction is quickly achieved. The presence of calixarene in the nanoemulsion is itself largely responsible for the extraction ability as the nanoemulsion without calixarene extracts only about 20% of uranium at equilibrium. The use of a more simple galenic form consisting in a solution of calixarene in paraffin oil only allows the extraction of ~7% of uranium from the contaminated solution. This last result shows that the emulsified system ensures a high uranium extraction yield due to the larger oil/water interfacial contact. The calixarene nanoemulsion form seems thus to be well suited for the decontamination of an aqueous solution contaminated by uranium.

Table 1. Uranium extraction (%) by paraffin oil and nanoemulsion in presence or not of calixarene, as a function of contact time between uranium solution and nanoemulsion or paraffin oil, in static conditions.

	U extraction (%)		
Contact time	Calixarene loaded Nanoemulsion	Nanoemulsion without calixarene	Calixarene in paraffin oil
5 min	83.4 ± 0.6	23.2 ± 0.8	-
1 hour	87.4 ± 0.7	16.7 ± 4.9	7.0 ± 0.9
4 hours	80.0 ± 3.9	25.3 ± 8.8	8.3 ± 0.3

Ex vivo evaluation of uranium extraction by the calixarene nanoemulsion

From the good uranium extraction yields obtained by the calixarene nanoemulsion in the previous *in vitro* tests, the calixarene nanoemulsion extraction efficiency for skin decontamination was evaluated. A 4 $mg.g^{-1}$ calixarene loaded nanoemulsion was deposited in the donor compartment of the Franz diffusion cells on pig ear skin explants immediately after a contamination with a 10 $mg.L^{-1}$ uranyl nitrate solution. A concentration of 4 $mg.g^{-1}$ of calixarene in the nanoemulsion was chosen in order to allow an excess of calixarene molecules compared to uranium ions (molar ratio calixarene/uranium = 80) and ensure a good uranium extraction. The uranium diffusion through the skin was followed during 24 hours under occlusive conditions and as a function of the application or no application of the calixarene nanoemulsion immediately after the contamination. The results obtained on intact skin 24 hours after the contamination are presented in Fig. 2-A. Intact skin seems to be a good barrier against uranium penetration as only 0.026 ± 0.006 % of the deposited uranium diffused through the skin 24 hours after the contamination. The application of the calixarene nanoemulsion immediately after the contamination allowed an uranium diffusion decrease of (98.4 ± 5.3)%. A reduction of uranium diffusion is also observed after application of nanoemulsion without calixarene, which can be partly explained by the dilution effect of the contaminated solution with the nanoemulsion aqueous phase and by the electrostatic interactions between uranium ions and the surfactants.

At the issue of the 24 hours Franz cell diffusion experiments, intact skin biopsies were analysed by SIMS microscopy (Fig. 2-B). The images and mass spectra showed that after the application of the calixarene nanoemulsion on uranium contaminated skin explants, uranium was no more significantly detected in skin structures whereas the radionuclide is significantly retained in the *stratum corneum* layer of the epidermis without treatment (Fig. 2-B) or after application of the nanoemulsion without calixarene (not shown) .

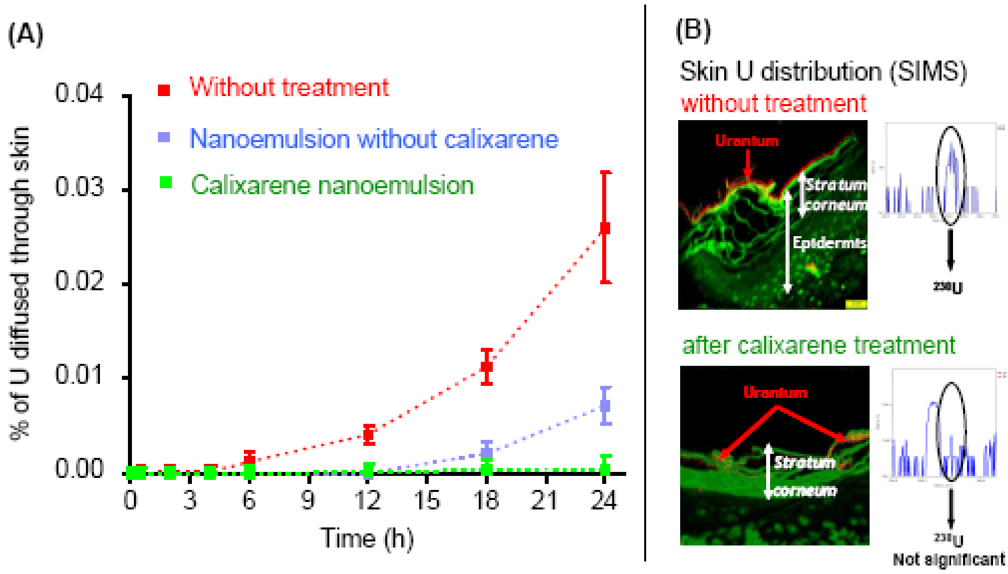

Fig.2. (A) Uranium percutaneous diffusion kinetics through intact skin in absence of treatment (■) or after application of nanoemulsion without (■) or with 4mg.g^{-1} calixarene (■). The treatment was applied immediately after the contamination step and the percentage of initially deposited uranium that diffused through intact skin biopsies was recorded during 24 hours. Each point corresponds to the mean of 10 assays ± standard deviation.
(B) Ionic images and corresponding mass spectra of intact skin biopsies without treatment (up) and immediately treated after the contamination step by calixarene nanoemulsion (down). Biopsy was analysed by SIMS 24 hours after the beginning of Franz cell experiments. In the ionic image, $^{238}U^+$ image (red) was superposed to $^{23}Na^+$ (green) image (200 µm x 200 µm image field).

In the case of excoriated contaminated skin (Fig. 3-A), (44.3 ± 6.4)% of the deposited uranium diffused through the skin, which is significantly higher than what was observed for intact skin. The prompt application of the calixarene nanoemulsion treatment conducted to an uranium diffusion decrease of (97.7 ± 0.8)% after 24 hours. The calixarene nanoemulsion is thus still efficient in case of contaminated wounds.

After 24 hours of Franz cell diffusion experiments, SIMS images and mass spectra showed that no significant uranium accumulation was detected in the excoriated skin structures after the application of nanoemulsion with calixarene on contaminated excoriated skins (Fig. 3-B). Uranium traces were found to be retained in the areas where a few residual *stratum corneum* layers remained after the tape stripping step.

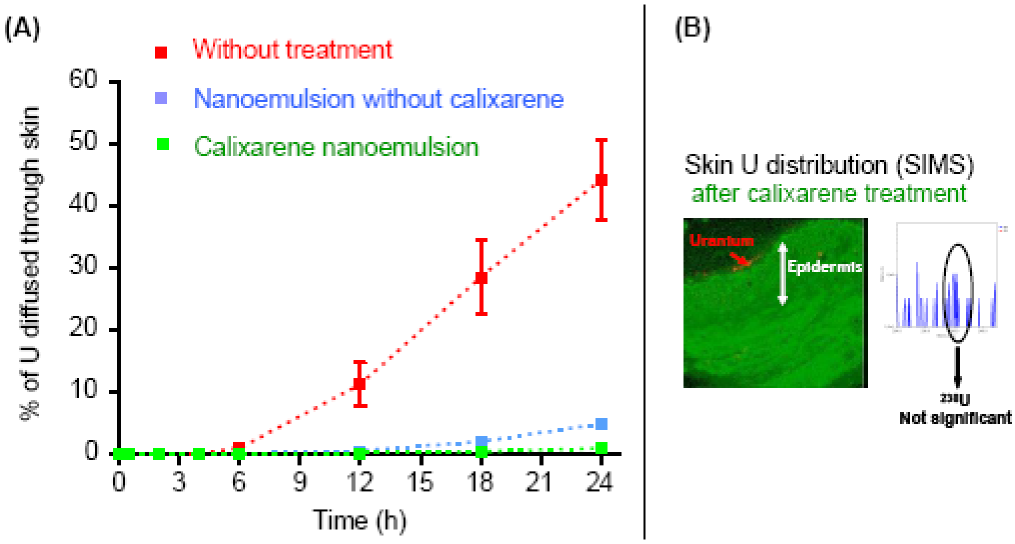

Fig.3. (A) Uranium percutaneous diffusion kinetics through excoriated skin in absence of treatment (■) or after application of nanoemulsion without (■) or with 4mg.g^{-1} calixarene (■). The treatment was applied immediately after the contamination step and the percentage of initially deposited uranium that diffused through intact skin biopsies was recorded during 24 hours. Each point corresponds to the mean of 10 assays ± standard deviation.
(B) SIMS mass spectrum and ionic image of excoriated contaminated skin biopsy treated immediately after the contamination step by calixarène nanoemulsion. Biopsy was analysed by SIMS 24 hours after the beginning of Franz cell experiments. In the ionic image, $^{238}U^{+}$ image (red) was superposed to $^{23}Na^{+}$ (green) image (200 µm x 200 µm image field).

The effect of time elapsed between the skin contamination by uranium and the application of the treatment on the uranium diffusion kinetics was studied on excoriated contaminated skin by delaying the application of the calixarene nanoemulsion by 5, 15 and 30 minutes. As illustrated in figure 4, uranium diffusion kinetics was roughly the same when the calixarene nanoemulsion was applied 5, 15 or 30 minutes after the contamination step. In these three cases, the calixarene nanoemulsion allowed a 3.5-fold uranium diffusion percentage decrease after 24 hours as compared to the absence of treatment: indeed, 11.55±2.79% in average of deposited uranium diffused after 24h (Fig. 4). Thus calixarene nanoemulsion is less efficient in case of delayed application but still allows a very significant uranium diffusion decrease as compared to the absence of treatment application. This reduction of efficiency being approximately the same whatever the delay of application (5 to 30 minutes), we assume that a part of the deposited uranium fastly penetrates in the upper excoriated skin structures, saturates them and then diffused passively through the skin to later reach the receptor medium. Experiments are in progress to better understand this phenomenon. From these results, it appears that it is preferable to treat the cutaneous contamination as soon as possible to ensure an optimal decontamination efficiency of the calixarene nanoemulsion.

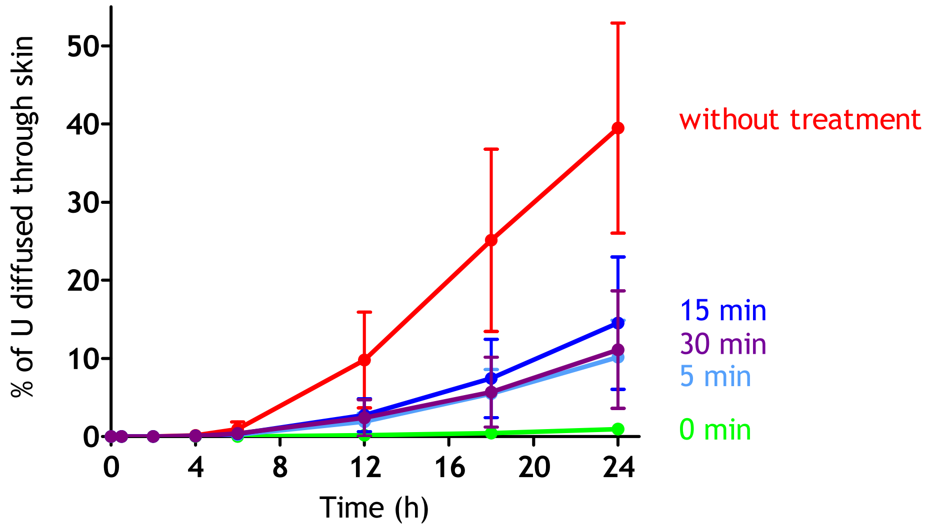

Fig. 4. Uranium percutaneous diffusion kinetics through excoriated skin in absence of treatment (■) and after immediate (■) application or 5 minutes (■), 15 minutes (■) and 30 minutes (■) delayed application of calixarene nanoemulsion. The percentage of initially deposited uranium that diffused through excoriated skin biopsies was recorded during 24 hours. Each point corresponds to the mean of 10 assays ± standard deviation.

Conclusions

In summary, our study demonstrates that the calixarene nanoemulsion allows decreasing almost quantitatively uranium percutaneous diffusion by trapping and retaining uranyl ions at the surface of the skin. This patented formulation (Bouvier-Capely et al., 2008) thus constitutes a promising therapeutic approach for the local treatment of intact and wounded skin contaminated by transferable uranium compounds. For optimal efficiency, the treatment should be applied as fast as possible after the contamination. As the calixarene molecules used in this study also efficiently chelate other actinides, we planned to evaluate the calixarene nanoemulsion efficiency on skin contaminated by other actinides such as plutonium and americium and to perform *in vivo* studies.

Abstract

A dose calibration curve for a practical PCC-ring assay was established and applied in a simulated, mass casualty accident. The PCC assay was validated against the conventional dicentric assay. A linear relationship was established for PCC rings after Co-60 irradiation with doses up to 20 Gy. In the simulated accident experiment, 62 blood samples were analysed with both the PCC ring and the conventional dicentric assay, applying a triage approach allowing crude dose estimate through analysis of a relatively small number of cells. Samples received various uniform and non-uniform (10-40% partial body) irradiations up to doses of 13 Gy. The results indicated that both assays yielded good dose estimates for the whole body exposure scenario, although in the lower dose range (0-5 Gy) dicentric scoring resulted in more accurate whole-body estimates, whereas PCC rings were better in the high-dose range (above 8 Gy). Both assays succeeded poorly in identifying partial body exposures, most likely due to the low numbers of cells scored in the triage mode. In conclusion, the study confirmed that the PCC ring assay is suitable for use as a biodosimeter following whole-body exposure to high doses of radiation. However, there are limitations for its use in the triage of people exposed to high, partial body doses.

Introduction

Several markers of exposure are available for biological dosimetry purposes. The dicentric assay is generally considered to be the gold standard of biodosimetric methods (Blakeley et al. 2005). The assay can be applied for dose estimation after whole- and partial-body exposure. The disadvantages of the dicentric assay are the time consuming and technically demanding analyses and limitations in assessing doses in excess of about 5–8 Gy due to impaired cell proliferation (Sasaki and Norman, 1966).

Impaired cell proliferation after high-dose exposures can be circumvented by the method of premature chromosome condensation (PCC). The original PCC technique is based on fusion of interphase lymphocytes with mitotic cells (Waldren and Johnson, 1974; Hittelman and Rao, 1974; Pantelias and Maillie 1983). Later it was discovered that PCC could be induced in G2-phase lymphocytes with the help of Calyculin A or okadaic acid— both phosphatase inhibitors. Kanda et al. (1999) suggested scoring PCC rings for the purpose of biological dosimetry after high doses of radiation. They obtained a good dose–response curve for PCC rings in the dose range up to 20 Gy of X rays. Similar results were reported by Lamadrid et al. (2007).

In large radiological accidents, fast and reliable dose assessment may be crucial for early decision of medical care and methods providing reliable triage method for assessing exposed and nonexposed people are needed. To increase the throughput of the dicentric assay, Lloyd et al. (2000) suggested a triage approach in which a reduced number of cells would be scored. For a whole-body exposure up to a dose of 8 Gy, they obtained a satisfactory result from scoring 20 metaphases per subject. After partial-body exposure with irradiated fractions in the range of 50–97%, a satisfactory result was obtained when 50 cells per subject were analyzed. In a mass casualty accident, people may be exposed to doses in excess of 5–8 Gy. One possible scenario is that of a very strong γ-ray source (for example, a source used for industrial radiography) hidden below a seat of a public transport vehicle. For highly exposed individuals, the dicentric assay may fail due to impaired division of lymphocytes. Thus there is a need to validate the PPC method for such exposure scenarios to cover the range of potential exposures.

In the present study, we have established a PCC ring calibration curve for γ-radiation validated it for use in a mass casualty accident. The validation was conducted by comparison to the dicentric method in a triage exercise that simulated an accident scenario involving a large number of casualties. Each case obtained an individual uniform or non-uniform irradiation.

Material and methods

PCC and dicentric dose response curves

Whole blood was irradiated with the following doses: 0, 1, 2.5, 5, 10, 15, and 20 Gy. All irradiations were performed with a ^{60}Co gamma source at 0.3 Gy/ min in a water bath with a fixed temperature of 37 ºC. The blood samples were further incubated for 2 hours at 37°C to allow for repair of DNA damage before lymphocytes were isolated. The dicentric dose response curves used in this study were developed previously in STUK (Lindholm et al. 1998) and FOI + NRPA (Stricklin et al. 2005).

Simulation of mass casualty accident scenario

A scenario of malevolent use of radiation was simulated by in vitro irradiation of blood samples. The simulation of doses was planned by a third party. The scenario was based on the assumption that a very strong gamma source had been hidden in a public transport vehicle, giving rise to a dose rate of 20 Gy/h close to the source and 2 Gy/h at 5 m distance. In this scenario, 62 persons with clinical symptoms and potential exposure were evaluated. Specifically, 62 blood samples were exposed to different doses at STUK, using the same irradiation conditions as described above. For the purpose of the simulated scenario, blood samples were collected from 14 volunteer donors in compliance with institutional guidelines for research on human samples.

Forty four samples were exposed in a homogeneous manner (simulation of whole body exposure) to the following doses (numbers of exposed cases are given in parentheses): 0.0 (7), 0.4 (3), 0.8 (2), 1.2 (3), 1.6 (2), 2.1 (3), 2.7 (2), 3.2 (3), 3.6 (2), 4.4 (2), 4.9 (3), 5.7 (3), 6.2 (2), 7.0 (2), 8.0 (1), 9.0 (1), 10.0 (2), 13.0 (1). 18 samples were irradiated in a non homogeneous manner (simulation of partial body exposure). The latter involved mixing of irradiated and non-irradiated blood in the following proportions (given doses in brackets): 10% (8, 9 and 13 Gy); 15% (7, 8, 8 and 10 Gy); 20% (9, 9, 9, 10, 13 and 13 Gy); 25% (7 and 7 Gy); 30% (10 and 13 Gy) and 40% (7 Gy) of irradiated blood.

Lymphocyte culture and analysis

Lymphocytes were separated and cultured at a density of $0.5x10^6$/ ml for successful cell growth. In the PCC protocol okadaic acid (final concentration 500 nM) was added for the last 1 hour in a 48 hour cell culture. In the dicentric assay colcemid (final concentration 0.2 µg/ml) was added for the last 2.5 h of the 48 h cultures. Cells were harvested according to standard cytogenetic procedures and stained with Giemsa. Analysis was performed in a blind manner on coded slides.

For all PCC analyses, fast scoring approach, ie. inclusion of intact cells without counting centromeres, was applied. PCC cells in any cell cycle phase were scored and rings were analysed irrespective of the presence of a centromere, in accordance with Kanda et al. (1999). Large PCC rings with either a clear open space or large spherical rings with a diameter greater than the width of chromosomes were scored.

For the simulated accident scenario, the analysis of dicentric samples was performed according to the routine in the respective laboratory. Scoring criteria for dicentrics were according to IAEA (2001), ie. metaphases with 46 centromeres were approved, and thirty dicentrics or 50 metaphases were scored according to Lloyd et al. (2000). From PCC preparations, 50 rings or 300 PCC cells per sample were analysed.

Statistical analyses, dose assessment and dose categories

The PCC ring data was fitted by the maximum likelihood method (Papworth 1975). The distribution of PCC rings scored for each dose was analysed with the help of the software NETA, which identifies distributions as Poisson, Neyman-type A or none of the two (Morand et al. 2008). Appropriate confidence limits (Neymanian or Poissonian) for the PCC yields were also calculated using NETA.

The calibration curve established in the current work was used to estimate the doses based on PCC rings. For dicentrics, each laboratory used its own calibration curve (Lindholm et al. 1998; Stricklin et al. 2005) that covered dose range 0-5 Gy. The fit of the estimated doses to the given dose was evaluated by the chi-square goodness of fit test. For samples irradiated in a partial body exposure scenario the dose to the exposed fraction of cells was calculated by the Dolphin method (IAEA 2001). No account was taken of the fact that, following homogeneous exposure of blood, PCC rings tend to show overdispersed distributions.

Results

PCC ring frequencies were evaluated at both STUK and FOI for seven dose points. Full data of this study have been published earlier (Lindholm et al. 2010). Data from the two laboratories were not statistically different and were therefore pooled. The distributions of PCC rings were generally overdispersed, and were best fitted to Neyman type A distribution after doses of 5, 10 and 15 Gy. Poisson distributions were observed after 2.5 and 20 Gy, while the distribution after 1 Gy was neither Poisson nor Neyman. The PCC data were fitted to a linear equation. The fit coefficients are shown in table 1, along with the linear-quadratic fit coefficients for dicentrics. Figure 1 demonstrates the linear fit of PCC rings to dose. The 1 Gy dose point, which was distinctly lower (marked with a square symbol in the figure) was excluded from the fit. The dose response of PCC rings showed a slight downward curvature at 20 Gy. The linear fit was chosen for practical reasons to represent the PCC ring dose relationship to be used for dose assessment of large scale accidents. However, it does lead to underestimation of dose in the dose range above 15 Gy.

Table 1. Dose coefficients used for dose estimations.

	Control (± S.E.)	Linear coefficient (± S.E.)	Quadratic coefficient (± S.E.)
PCC rings	0.0018 ± 0.0001	0.049 ± 0.001	
Dicentrics, STUK	0.0005 ± 0.0002	0.013 ± 0.0043	0.054 ± 0.003
Dicentrics, FOI and NRPA	0.0016 ± 0.001	0.014 ± 0.006	0.065 ± 0.003

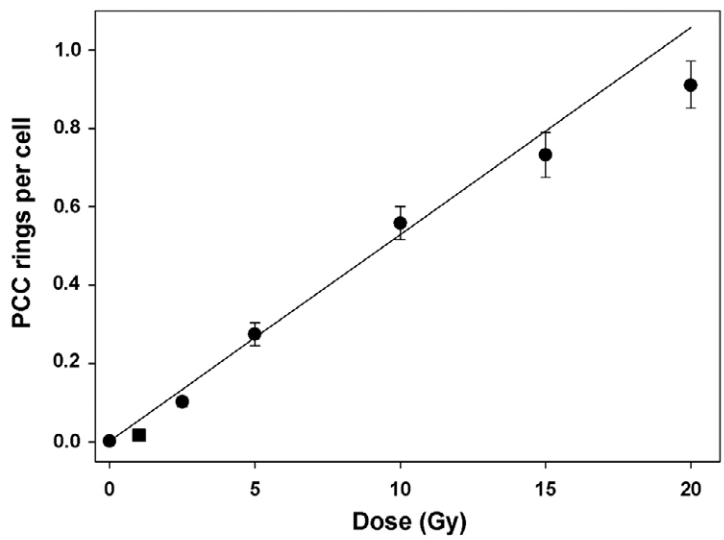

Fig. 1. PCC ring data fitted to a linear model. Square symbol displays the data point at 1 Gy which was omitted in the fitting procedure. Error bars represent 95% confidence limits.

For the accident simulation exercise, estimated doses for samples of uniform exposures and calculated from dicentric and PCC ring frequencies are plotted against the given dose in Figure 2. The chi square values of the goodness of fit are 13.86 for dicentrics and 20.00 for PCC rings (with 41 degrees of freedom), indicating a better fit of the dicentric data. Triage analysis of dicentrics resulted in a better dose estimate in the dose range below 6 Gy which is explained by the dose range of dicentric curves that reaches up to only 5 Gy and dose estimates above this are extrapolations. The PCC ring assay resulted in a slight underestimation of doses in the range 2-6 Gy.

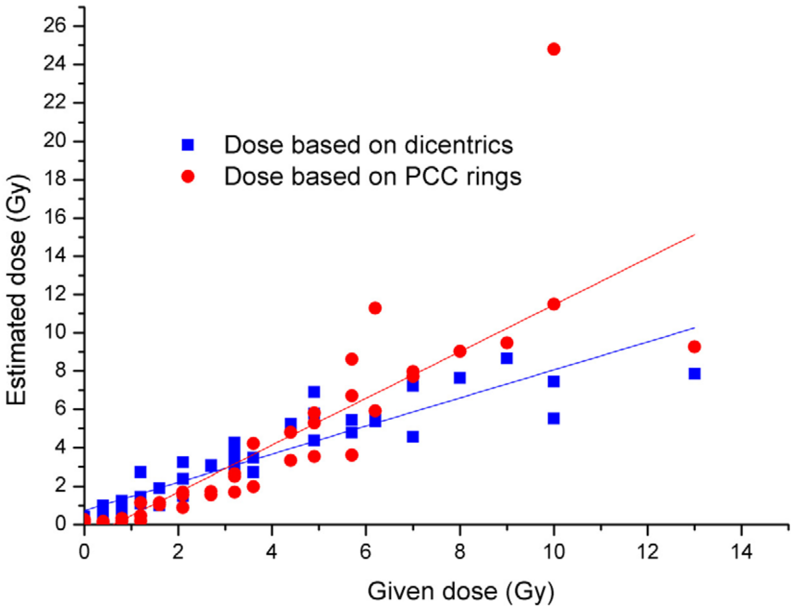

Figure 2. Dose estimates based on dicentric and PCC ring frequencies plotted against the given dose for 46 samples exposed in a homogeneous manner. Solid lines represent linear fits (Rdicentrics = 0.73 ; RPCC rings = 1.26) to the data points. Due to overlapping, all individual plots can not be differentiated.

Figure 3 demonstrates how well the triage scoring of dicentrics and PCC rings allowed to identify exposed and non-exposed cases. Of non-exposed samples, one case was missed with the dicentric assay and two cases were not correctly recognized by PCC rings. In the lower dose categories, the dicentric assay was more efficient in placing the cases into the correct category than the PCC assay. Above the dose of 6 Gy, PCC ring scoring was superior to dicentrics in identifying the correct category. Taking all dose categories into account, data from the dicentric assay were slightly albeit not significantly better than from the PCC assay in placing doses into the right category (75% vs. 59%). The same was true with respect to the 95% confidence limits: 75% for dicentrics vs. 64% for PCC rings.

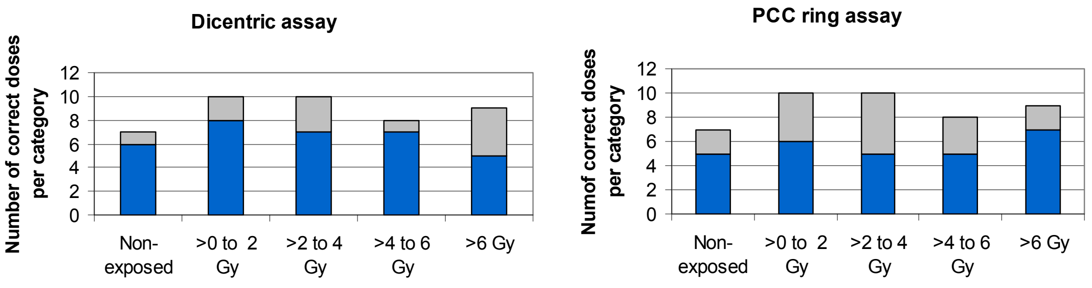

Figure 3. Homogeneously exposed cases correctly estimated by dicentrics and PCC rings. Numbers of cases (in dark blue) where the 95% confidence limits of the dose estimate encompassed the given dose.

Partial body exposure was identified by a significant overdispersion of dicentrics and PCC rings. Analysis of dicentrics allowed identification of 61% of cases, while analysis of PCC rings accommodated 56% (data not shown). There was no trend of an improved identification with increasing size of exposed blood fraction. Both assays were inefficient in estimating the given partial body doses. Also, no correlation between the doses estimated by the two assays was observed.

Discussion

The evaluation of the PCC ring assay in parallel with the dicentric method for feasibility in triage dose assessment demonstrated that for whole body exposure, the dicentric scoring resulted in somewhat more accurate estimates in the lower dose range (below 6 Gy), whereas PCC rings performed better in the high-dose range (above 6 Gy). The difference is best explained by inherent characteristics of the calibration curves. Underestimations observed at low doses using PCC rings are most likely due to the sub-linear dose-response as indicated with the data obtained at 1 Gy. A more accurate analysis with several dose points in the low dose range would be required to obtain adequate calibration. The published studies of PCC ring dose-response for low LET radiation have not included doses below 5 Gy (Kanda et al. 1999, Lamadrid et al. 2007), since the aim of the PCC studies is mainly to investigate high doses. The obvious explanation of the underestimation of high doses applying the dicentric assay lies in the saturation of dicentric aberrations at 8-10 Gy, caused by the inhibition of cell proliferation (Sasaki and Norman 1966). We observed a saturation of PCC rings at doses of 15 Gy and higher. A similar effect was reported by Kanda et al. (1999) but, interestingly, not by Lamadrid et al. (2007) who reported 2.5 times lower PCC ring yields than the linear coefficient obtained in our study using the same radiation quality. This implies that there are clear differences in scoring of PCC rings between the two studies, a fact that may influence the observed yield of rings at high dose range.

An attempt was made to assess the correct placement of homogeneously irradiated samples in dose categories by checking if the 95% confidence limits of the dose estimate encompassed the given dose. Dicentric assay was superior in the categories spanning dose range below 6 Gy whereas PCC rings performed better in categories above 6 Gy.

Lloyd et al. (2000) also tested the efficacy of the triage dicentric assay to identify inhomogeneous exposure. They simulated exposure scenarios where 50 – 97 % of blood was irradiated. According to our accident scenario, the fraction of irradiated blood could be below that, and we simulated exposures where 10-40% of blood was irradiated. The results from this study showed that both assays, applied in triage mode, were not effective in identifying the exposure as partial body: only 61% of the cases were correctly identified by the dicentric assay and 55 % by the PCC ring assay. As a result, the attempt to identify the doses given to the exposed fractions of blood was not successful. In general, the dose was either missed completely or underestimated by the dicentric assay and overestimated by the PCC ring assay. Although the number of inhomogeneously exposed samples was very low for extensive conclusions, the results seem to indicate the limitation of both triage assays to detect partial body exposures where the fraction of irradiated blood is below 40%.

Comparing the efficiency of two biodosimetry assays for triage purposes also includes the aspect of time. In the current study, scoring times were not systematically followed but time recording of occasional sample analyses indicated no radical differences in performing fast scoring to 300 PCC cells in comparison to analysis of 50 metaphases with centromere counting.

PCC rings demonstrated non-Poisson distribution after most of the doses in establishing the dose calibration curve and this observation induces problems with respect to identification of partial-body exposures. We think that the overdispersion of is due to scoring of rings in both metaphases and G2 cells. Because differentiating between G2 phase and early metaphase cells is often impossible, we scored PCC rings in cells from both phases of the cell cycle. Consequently, the yield of PCC rings obtained is representative for two phases of the cell cycle: the "normally damaged" mitotic cells and the "highly damaged" G2 cells.

In a mass casualty accident it is essential that a fast and reliable triage method for crude assessment of radiation dose covering a large dose range is available. Our study confirmed that the PCC ring assay is suitable for use as a biodosimeter following whole-body exposure to high doses of radiation. However, the technique appears to possess limitations in the triage of people exposed to high, partial body doses.

Abstract

The French Defense radiation protection service (SPRA) is located on the site of the Percy military hospital which is well known for the treatment of radio-contaminated and irradiated wounded.

The SPRA is involved in many military and civilian training courses, especially to teach the principles of medical response in radiation accidents (triage of absolute and relative emergencies, specific technics and drugs, psychological aspects). Intervention in case of a radiological or nuclear event is also one of the major missions.

First of all, the SPRA has to control all the Centers for the treatment of radio-contaminated wounded in France (CTBRC). During the exercises performed by the French Navy or the Air Force (transportation of a nuclear weapon, accident on a ballistic missile submarine), the SPRA provides hygiene and safety support to Ministry of Defense and advises the headquarters.

If necessary, the SPRA is permanently able to send, by road or by aircraft, an expert team and an analysis team with mobile laboratories (spectrometric and radiochemical analysis) in France or overseas if requested by military or civilian authorities.

The SPRA has initiated for the French armed forces health service conventions with institutions like the French Atomic Energy Commission (CEA), EDF Group (Electricité De France) or the French Radiation Protection and Nuclear Safety Institute (IRSN) in order to supply the best medical care for an ionizing radiation victim in the nearest CTBRC or in the Percy military hospital.

Radioprotective efficiency from consecutive application of indralin and interleukin-1β at the acute irradiation

Abstract

Experiments in 316 male mice (CBA x C57Bl) F1 have shown, that consecutive application of indralin in a dose of 200 mg/kg 15 minutes before irradiation and interleukin-1β in a dose of 50 mkg / kg in 15 minutes after irradiation increases the survival rate of the mice irradiated in $LD_{50\text{-}90/30}$ for 40-60 %, reduces the depth of postradiation infringements of hemopoiesis, increases proliferative activity of hemopoietic cells. It allows to reduce expressiveness of leuko-, lympho- and neutrophilopenia in early terms after irradiation and to speed up restoration of the contents of cells in peripheral blood. The stimulating effect of consecutive application of indralin and interleukin-1β is shown also in prevention of decrease in activity of myeloperoxydase and alkaline phosphatase, maintenance of higher level of glycogen in neutrophils of peripheral blood of the irradiated animals.

Introduction

The existing system of medical radiation protection is based on the complex of therapeutic and preventive arrangements aimed at the preservation of life and health of people exposed to ionizing radiation. Decrease in the intensity of adverse effects of irradiation in dangerous for human being doses is achieved by application of special pharmacological drugs of preventive or therapeutic action (Bump E., Malaker K. 1997; Kuna P. et al. 2004; Grebenyuk A. et al. 2007; Baranov A., Rozhdestvensky L. 2008).

Indralin is one of the most effective modern radioprotectors which was successfully applied for protection of participants in the rectification of the consequences of the accident at the Chernobyl Atomic Power Station (Vasin M. 2006). One of the most prospective radioprotective substances from the group of means and methods of early therapy of radiation injuries is interleukin-1 (IL-1) (Neta R. 1997; Grebenyuk A. et al. 2005; Rozhdestvensky L. et al. 2008).

The efficiency of consecutive application of radioprotectors and modern means of early therapy of acute radiation syndrome has not been investigated by now. The most prospective of these schemes is the application of radioprotector indralin and recombinant interleukin-1β (IL-1β), which is applied in Russia as a means of emergency therapy of radiation injures.

The purpose of the research was the experimental estimation of efficiency of consecutive application of indralin and interleukin-1β at acute irradiation.

Material and methods

Experiments were carried out in 316 male mice (CBA x C57Bl) F1. The animals were housed in standard conditions of vivarium. The rules of humane treatment of experimental animals were observed during experiments.

Indralin was entered *per os* (with the help of a probe into a stomach) in a dose of 200 mg/kg 15 minutes before irradiation. Interleukin-1β was injected intraperitoneally in a dose of 50 mkg/kg 15 mines after irradiation.

The estimation of radioprotective and therapy effects of preparations was carried out by studying 30-days survival rate and average life expectancy of the dead animals and by estimating the number of hemopoietic cells in endogenous and exogenous colony formation techniques (Till J, McCulloch E. 1991). The total number of leukocytes and differential white blood cells count were estimated with the help of standard methods. Cytochemical determination of myeloperoxidase, alkaline phosphatase and glycogen was carried out in peripheral blood neutrophils.

The animals were exposed to X-ray irradiation on the RUM-17 unit with the following conditions: voltage 180 kV, current 15 mA, filter 0.5 mm Cu + 1.0 mm Al, source to skin distance 50 cm, dose rate 0.292 mA/kg (52.2 R/min), one-way irradiation, the direction of exposure: back-to-chest. Dosimetric support of experiments was carried out with the help of a dosimeter ID-11 and calculation method.

The data obtained in experiments were put to the standard statistical analysis with average value and error of mean calculations with the help of the computer program Statistica 6. Fisher's exact test and Mann-Whitney U-test were taken for the estimation of the reliability of the differences of mean values. Probability $p<0.05$ and more was considered to be reasonable for a conclusion about statistical confidence of the differences of the obtained data.

Results

The data from Table 1 show that consecutive application of indralin and IL-1β led to the significant increase in the number of mice survived after exposure to radiation in comparison with the control group and groups of animals which received these preparations separately.

Table 1. Effect of indralin and interleukin-1β on the survival rate of mice (CBA x C57Bl) F1, exposed to X-ray irradiation in doses of 6.3, 6.8 and 7.3 Gy.

Dose, Gy	Experimental group	Number of mice in group	Survival rate, %
6.3	Irradiation (control)	10	50
	Indralin + irradiation	10	60
	Irradiation + IL-1β	10	60
	Indralin + irradiation + IL-1β	10	90 *
6.8	Irradiation (control)	12	25
	Indralin + irradiation	12	40
	Irradiation + IL-1β	12	25
	Indralin + irradiation + IL-1β	12	83.3 *
7.3	Irradiation (control)	15	0
	Indralin + irradiation	15	33.3 *
	Irradiation + IL-1β	15	20
	Indralin + irradiation + IL-1β	15	46.7 *
* p < 0.05 in comparison with irradiation (Fisher's exact test).			

At the same time none of the studied schemes of preventive treatment and therapy of radiation injures hasn't had a significant effect on average life expectancy of animals died after irradiation. The major part of the mice died on the 10-14th day after irradiation which is typical for small laboratory animals with bone marrow form of acute radiation syndrome.

The estimation of radioprotective and therapy efficacy of separate and combined use of indralin and IL-1β on the number of hematopoietic early precursors was carried out in endogenous and exogenous colony formation techniques.

It has been found out that indralin, IL-1β and their combination prevented postradiation hemopoiesis depression. The number of colonies on the spleens of mice-hybrids, estimated in endogenous colony formation technique, was higher in the group of mice which were injected with the combination of preparations than in the groups of animals which received indralin or IL-1β only (Tab. 2).

Table 2. Effect of indralin and interleukin-1β on the number of the 9-th day colony-forming units grown on the spleens of X-ray irradiated mice (CBA x C57Bl) F1 in the endogenous colony formation technique.

Experimental group	Dose, Gy		
	6.5	7.0	7.5
Irradiation (control)	3.9 ± 0.8	2.8 ± 0.9	1.9 ± 0.8
Indralin + irradiation	12.0 ± 0.0 *	9.7± 1.2 *	6.8 ± 1.8 *
Irradiation + IL-1β	9.5 ± 2.0 *	9.2 ± 1.8 *	6.7 ± 1.2 *
Indralin + irradiation + IL-1β	16.0 ± 0.0 * # "	12.1 ± 1.0 * # "	10.5 ± 0.5 * # "
* p < 0.05 in comparison with irradiation (Mann-Whitney U-test); # p < 0.05 in comparison with irradiation + indralin; " p < 0.05 in comparison with irradiation + IL-1β.			

The data in Table 2 demonstrate that radiation exposure caused dose-dependent decrease in the number of endogenous colonies on the spleens of irradiated mice-hybrids**.** The largest number of colonies grown on the spleens of irradiated mice (i.e. the largest number of hemopoietic stem cells which retain viable) was registered in animals which received both preparations. For example, consecutive preventive application of indralin and early therapeutic application of IL-1β led to fourfold increase in the number of colonies on the spleens in mice-hybrids exposed to radiation in a dose of 6.5 Gy. When exposed to radiation in a dose of 7.5 Gy, consecutive application of indralin and IL-1β led to more than fivefold increase in the number of endogenous colonies in comparison with the animals of the control group (mice exposed to radiation without pharmacological protection) and to 1.5 time increase in comparison with the separate use of indralin or IL-1β .

Moreover, it has been found out that the separate use of indralin or IL-1β didn't have a significant effect on the number of the 9-th day colony-forming units (CFU-S_9) on the spleens of irradiated male mice (CBA x C57Bl) F1 detected in the exogenous colony formation technique. At the same time the number of CFU-S_9 of irradiated mice-hybrids injected with indralin and IL-1β was 2 times more than the number of CFU-S_9 in the control group (irradiation), 1.4 times more than in animals injected with indralin only and 1.7 times more than in animals injected with IL-1β only (Tab. 3).

Table 3. Effect of indralin and interleukin-1β on the number of myelocaryocytes and number of the 9-th day colony-forming units grown on the spleens (CFU-S_9) of X-ray irradiated mice (CBA x C57Bl) F1 in the exogenous colony formation technique.

Experimental group	Number of myelocaryocytes, x 10^6/femor	Number of CFU-S_9	
		in one femor	on 10^6 myelocaryocytes
Irradiation (control)	18.3	64 ± 16	3.5 ± 0.9
Indralin + irradiation	20.0	88 ± 24	4.4 ± 1.2
Irradiation + IL-1β	20.8	72 ± 16	3.5 ± 0.8
Indralin + irradiation + IL-1β	22.3	136 ± 8 *	6.1 ± 0.4 *
Endogenous level	23.8	320 ± 100	13.4 ± 4.2
Indralin	20.8	520 ± 60	25.0 ± 2.9
IL-1β	22.8	340 ± 40	14.9 ± 1.8
Indralin + IL-1β	25.3	400 ± 140	15.8 ± 5.5
* $p < 0.05$ in comparison with irradiation (Mann-Whitney U-test)			

Moreover, it has been found out that combined introduction of the indralin and IL-1β had a positive effect on hemopoiesis of irradiated mice estimated by the dynamics of the number of leukocytes in peripheral blood during all follow-up period (Fig. 1).

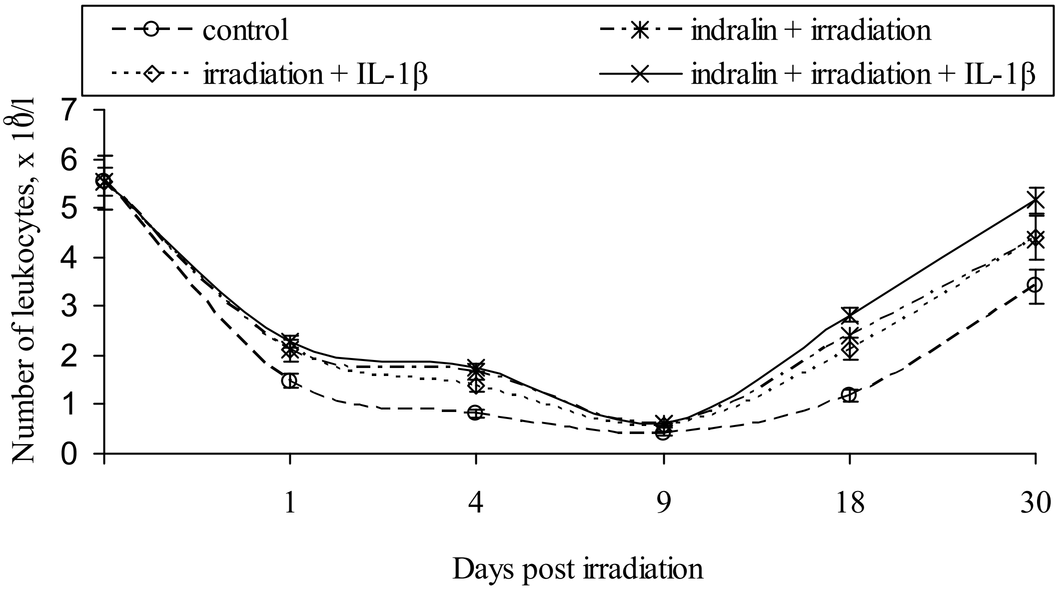

Fig. 1. Effect of indralin and interleukin-1β on the dynamics of the total number of leukocytes of peripheral blood of mice (CBA x C57Bl) F1 exposed to radiation in a dose of 8 Gy.

For example, even on the first day after irradiation the number of leukocytes in the blood of animals which received both preparations was higher than in the control group (50%) and in groups with separate injection of indralin or IL-1β.

Consecutive preventive application of indralin and early therapeutic application of IL-1β significantly prevented the decrease in the total number of neutrophils of peripheral blood of mice irradiated in a dose of 8.0 Gy during all follow-up period and didn’t differ from the background count on the 20-th day.

In addition, both separate and consecutive application of indralin and IL-1β stimulated the functional capacity of peripheral blood neutrophils of irradiated animals which was manifested in significant increase in the content of myeloperoxidase, alkaline phosphatase and glycogen in these cells in comparison with control groups.

The data in Fig. 2 demonstrate that glycogen content in neutrophils of mice which were consecutively injected with the radioprotector and hemopoiesis stimulator was higher than in irradiated mice during all follow-up period, but did not differ from those in groups of mice injected with indralin or IL-1β only.

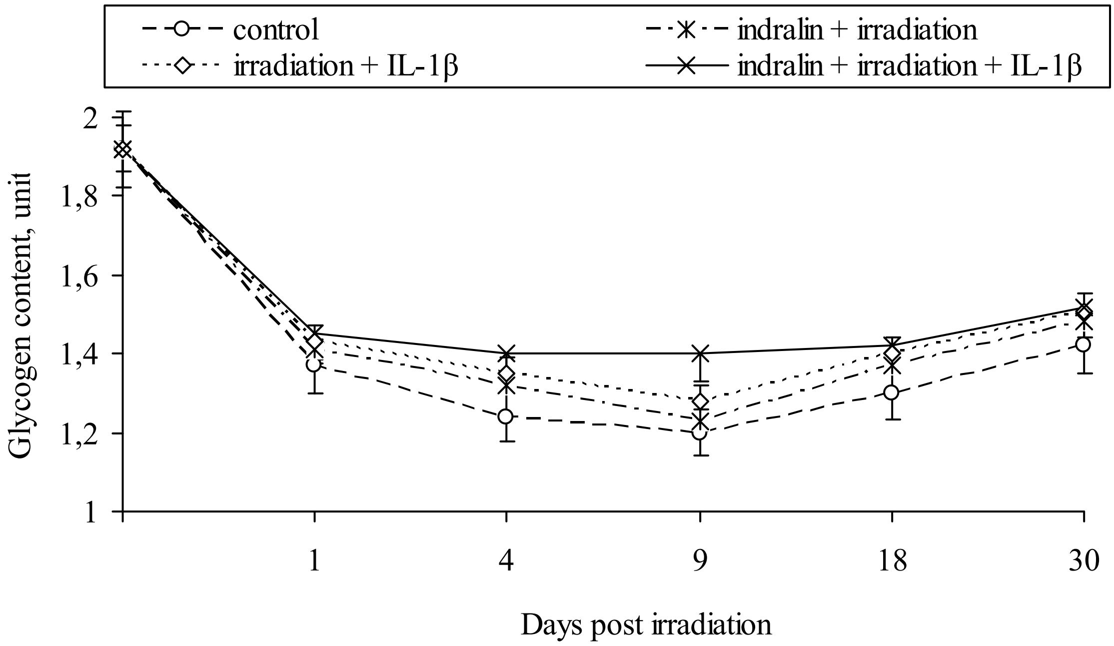

Fig. 2. Effect of indralin and interleukin-1β on the content of glycogen in peripheral blood neutrophils of mice (CBA x C57Bl) F1, exposed to radiation in a dose of 8 Gy.

Discussion

Our findings on radioprotective efficiency of indralin and early therapeutic activity of IL-1β agree with those of the other authors (Neta R. 1997; Legeza V., Chigareva N. 1999; Rozhdestvensky L. et al. 2008; Vasin M. et al. 2008), supplement them and increase the sum of knowledge of the mechanism of therapeutic action of these preparations.

It was found out that application of indralin 15 minutes before exposure to radiation effectively protects mice irradiated in $LD_{50\text{-}100/30}$ against death increasing their survival rate by 10-30%, has a positive effect on bone marrow hemopoiesis of irradiated animals, reduces the intensity of leuko-, lympho- and neutrophilophenia in early terms after irradiation, accelerates restoration of the contents of cells in peripheral blood. High radioprotection level on application of indralin has been established earlier in experimental studies in many species of laboratory animals: mice, rats, Syrian hamsters, guinea pigs, rabbits, dogs and monkeys (Vasin M. et al. 2008). Radioprotective effect of this preparation is based on its ability to reduce oxygen content in the cell, thereby reducing the intensity of “oxygen effect” and manifestation of oxidative stress. For hemopoiesis stimulator IL-1β this mechanism is not essential (Neta R. 1997). However, its introduction to mice after exposure to radiation can increase radioprotective efficacy of indralin, which is estimated both by the survival criterion and the condition of bone marrow hemopoiesis. For example, consecutive preventive application of indralin and early therapeutic application of IL-1β can increase the survival rate in mice irradiated in $LD_{50\text{-}100/30}$ by 40-60%, although do not have a significant influence on average life expectancy of dead animals.

In our opinion, one of the most important mechanisms, which form the basis of radioprotective effect of combined use of these preparations, is that IL-1β activates proliferation and differentiation of hemopoietic stem cells in a great number preserved in the bone marrow of irradiated mice due to the protective action of indralin. This statement can be confirmed by the fact that both separate application of IL-1β and combined application of IL-1β and indralin reduce intensity of postradiation disorders in bone marrow hemopoiesis, increase proliferation activity of hematopoietic stem cells, which finally leads to faster recovery of absolute content of cells in peripheral blood.

The fact that IL-1β mainly has an effect on the hemopoietic stem pool retaining some of the cells from death and/or intensifying its proliferation has been shown earlier (Neta R. 1997; Grebenyuk A. et al. 2005; Rozhdestvensky L. et al. 2008). However, in the course of our investigations it was found out that the largest number of CFU-C_9 in irradiated mice can be observed in condition of combined application of indralin before exposure to radiation and IL-1β after irradiation.

Conclusions

The results of the research have shown the effectiveness of consecutive preventive administration of indralin and early therapeutic application of IL-1β for protection against acute irradiation. In this case, hemopoiesis stimulator IL-1β increases the radioprotective efficacy of indralin estimated by the survival criterion of irradiated mice, the condition of bone marrow hemopoiesis and functional activity of peripheral blood leukocytes.

Hospital response plan for radiation emergencies: the project of Careggi University Hospital in Firenze

Busoni, Simone; Gori, Cesare; Gatto, Gaetano; Niccolini, Fabrizio; Piccinno, Giusi
Azienda Ospedaliero-Universitaria Careggi, Firenze, ITALY

Abstract

The plan described in this paper outlines the procedures used by Careggi University Hospital in Firenze in response to incidents where individuals are exposed to radioactive material either in case of radiological accidents (for instance during transportation, industrial or medical activities) or in case of malevolent use of radioactive sources.

The main challenge in planning a radiological emergency response is the proper definition of departments and people involved, their own duties and responsibilities, the effective coordination among them, also taking into account the pre-existing hospital structures and concurrent routine activities. Moreover in a mass casualty incident, many people may come to an healthcare facility injured, contaminated, or not. Most of them are likely to be minimally injured or simply concerned about potential contamination, therefore needing just an ambulatory care or measurement. In any case the correct answer to everyone has to be given without interfering with the other activities of the Emergency Department.

In this plan the functions, duties and responsibilities of staff people of every involved departments are reported in detail. The plan covers all the operating procedures starting from the radiation emergency alert till the closure of emergency operation, including the waste disposal.

The main topics of the plan are the preliminary hospital activation, the contamination assessment procedure, the possible decontamination of patients, the radiation protection of the staff. Special sections are devoted to define a list of radiation measurement instruments, emergency supplies and pharmaceuticals to be stored in the Emergency Department in order to properly handle the response.

This plan is part of a more general CBR hospital response plan, and a first step towards a regional response plan to radiological emergencies through the Italian National Health Service structures.

Introduction

The plan has the goal to analyse and describe the hospital response to a radiological emergency, defining departments involved, duties and responsibilities, facilities, materials and instrumentation required.

The plan takes into account the already planned response to conventional emergency and it is intended as a component of a more comprehensive CBR plan.

Main goals of the hospital response to the emergency are:

- the rapid identification of the type of emergency
- the subsequent activation of the response
- the interaction with other external structures
- the coordination with other regional highly specialized hospitals.

Material and methods

Florence University Hospital (Azienda Ospedaliero-Universitaria Careggi, AOUC) is located in Tuscany Region, Italy, and it is one of the main hospitals of the Italian National Health Service (NHS). It is tightly integrated within the Florence University, thus maximizing the synergies between health care, research and teaching. The hospital is organized as a campus with different buildings, that together house over 5,800 employees, 1650 beds, 54000 in-patients, 22000 day hospital admissions and nearly 10 million medical examinations per year.

The hospital hosts nuclear medicine, radiodiagnostic and radiotherapy and Health Physics departments, where health care workers are highly trained in radiation protection. RPE responsibilities are included in the Health Physics Dept. activities.

Available facilities and instruments are a gamma spectroscopy system for isotope identification and activity measurement, a portable gamma spectrometer, TLD and electronic dosimeters, contamination and exposure measurement instruments, decontamination kits, gamma probes.

The Emergency Department is located centrally with respect to other buildings, and has enough outdoor spaces to host a radiation assessment mobile tent and a decontamination mobile tent as well.

A Tuscany region reference centre for toxicology and an internal occupational health department charged to deal with all the medical aspects related to exposure to ionising radiation are also present. Bioassay labs can provide immediate assessment of blood contamination as well as the other clinical blood parameters.

Considered scenarios

At present no nuclear power plant is operating in Italy, so the considered scenarios are:

- incident in industrial facilities
- incident in medical facilities
- incidents during transport of radioactive material
- orphan sources incidents
- malevolent use of radioactive material

Involved departments

The departments/services involved in the emergency response are:

- Emergency Department (ED): resources are necessary for the treatment of patients suffering from injuries in combination with possible radiation contamination or exposure (combined injuries).
- Health Physics Department: for radiation protection, radiation screening, isotope identification and any dosimetric assessment
- Toxicology and occupational health services to provide physician competent in radiation health effects
- Technical services department for security, mobility and logistics operation
- Press Office
- Psychology team

Results

Allocation of roles

An Hospital Operation Command Team (HOCT) has to supervise the emergency operations and has to be alerted by the ED manager.

The components of the HOCT are the hospital medical director, the ED director, the Radiation Protection Expert, the technology services director and the nurse staff director.

The proper management of people arriving to the hospital is provided by the security staff.

The contamination screening of people arriving to the hospital is performed by Health Physics staff, that assures at least one Medical Physics Expert (MPE) and one Radiology Technician on call at any time.

Patient medical treatment is provided by the ED personnel. In order to reduce the spread of contamination and to allow the routine operation, a section of the ED is isolated and dedicated completely to the radiation emergency.

Information workflow

The radiation emergency plan is activated at once as a notification is transmitted by First Responders (Fire Department).

From this moment on the medical operations are lead by the ED, while the HOCT coordinates the global hospital response. The information workflow is shown in Fig.1

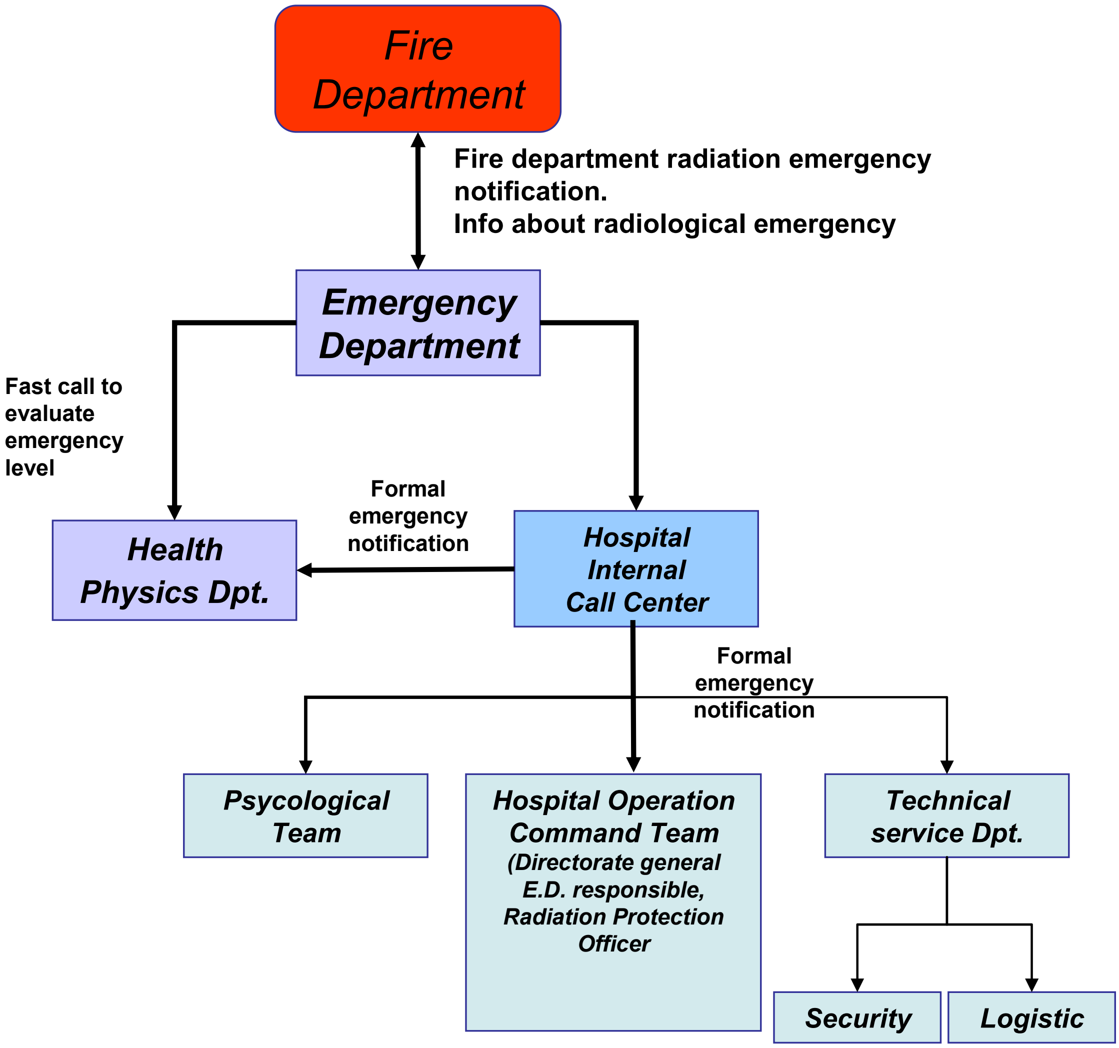

Fig. 1. Information workflow in case of radiological emergency.

Patient admission

In case of radiation emergency, every access to the hospital is closed but one in order to properly filter the accessing people. At the entrance of the ED people involved in the radiological emergency are redirected to the pertinent special ED section. All other kind of access is limited until the first response to the emergency is declared over by the HOCT.

The radiation screening and decontamination are performed outside the buildings, in dedicated mobile tents (Fig.2).

Personnel Training

People involved in the emergency plan (health care professionals, security and logistics staff, psychology team, HOCT) are required to attend training courses.

The training course includes a general section about the radiation protection and the plan structure, and a more specific session devoted to health care staff only.

The goal of the training is to provide a basic overview of the most important issues in an effort to raise the level of confidence and lower the level of anxiety of the staff who may be called to deal with this kind of event.

The training covers the following topics:

- Characteristics of ionizing radiation and radioactive materials
- Differentiation between radiation exposure and radioactive material contamination
- Causes of radiation exposure and contamination
- Staff radiation protection procedures and practices
- Facility preparation
- Patient assessment and management of radioactive material contamination and radiation injuries
- Health effects of radiation exposure
- Facility recovery and waste disposal

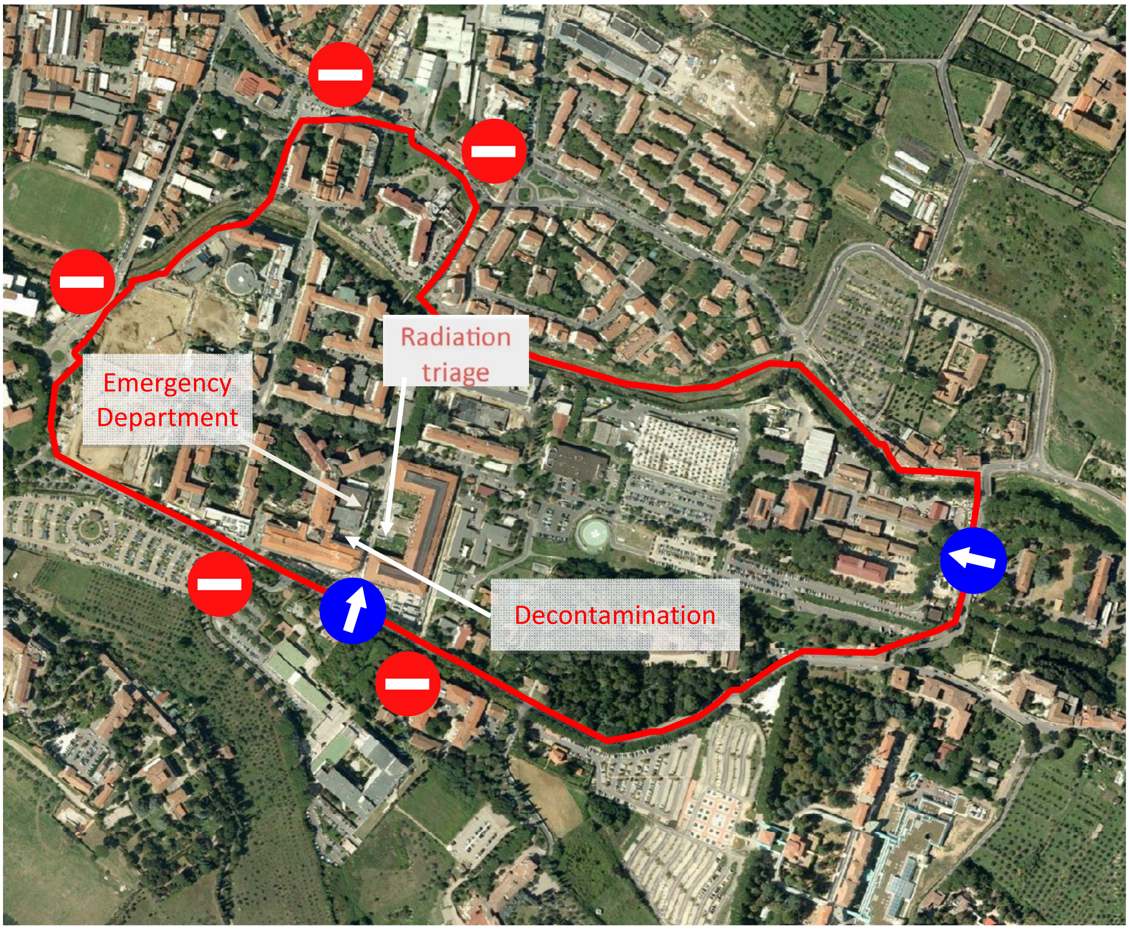

Fig. 2. Plan of the hospital, with closed access in case of radiological emergency. The access close to the ED is devoted to people involved in the radiological emergency, the other access to patients.

Conclusions

The proposed plan covers the organisational aspects, defines the professional roles, charges the departments and structures to provide effective response in case of radiological emergency.

This plan is part of a more general CBR hospital response plan, and a first step towards a regional response plan to radiological emergencies through the Italian National Health Service structures.

Occupational medicine professionals and radiation accidents

Djurovic, Branka[1]; Spasic-Jokic Vesna[2]
[1] Military Medical Academy, Belgrade, SERBIA
[2] Faculty of Technical Sciences, University of Novi Sad, SERBIA

Abstract

Protection of the public exposed to nuclear/radiological (NR) agents in medical or industrial installations is required in many countries by Regulatory and Health Authorities. National Authorities require training in all aspects of occupational and public exposures to ionizing radiation, as well. Specific aspect of public exposure is in the case of accidents or terrorist/malevolent acts. Many countries increase their efforts to prepare medical workers for the intentional release of NR agents within the civilian population by terrorists or accidents on nuclear/radiological installations. Presumed targets for terrorist attack are urban or suburban heavily populated locations. They are usually industrial parts of the cities, and bring additional risk correlated with industrial installations. For many people, the first point of contact with harmful agents could be their workplace, and therefore occupational medicine professionals (OMP) are considered as potential first responders to a terrorist attack. They are educated in health surveillance of personnel occupationally exposed to low-doses of harmful agents, including radiation. Still, the lack of training for medical response in radiation emergency has been recognized. Therefore, OMP must be additionally trained on the specific challenges of terrorism and emerging situations, including how to recognize and isolate, treat and track individuals who will need prompt and appropriate care, especially in the case of mass casualties. OMP from MMA, as members of NRCB team, are involved in different radiation emergencies: from decommission, depleted uranium, to terrorism, and therefore additional educational courses for students, general practitioners, and OMP have been organized. In this paper, our experiences and the main topics of this program are presented.

Introduction

Ionizing radiation has been used for the benefit of humankind for a long time. Still, it`s harmful effects, overexposure and accidents are the first associations of radiation for more the 60% of adults from EU. This attitude is probably caused by horrible experience from Hiroshima and Nagasaki, as well as some other accidents.

More recently, NR terrorism became an actual problem. Modern society is known by global anti-terrorist activity. It seems like there has never been so much activity on reducing nuclear threat, and at the same time, never bigger possibility of it being used.

That was the main reason for global anti-nuclear activity and efforts for improvement of public protection against malevolent use of NR material.

Many countries in the world created wide and detailed national plans for emergency preparedness in the case of NR accident, as well as for NR attack. One of the most important elements of preparedness is adequate education of the responders. Medical workers are unavoidable members of the team. Even though radiation effects are usually studied in medical schools and numerous specialization courses it seems that physicians are not sufficiently prepared for the emergency in case of NR accident, especially in the case of the mass causalities. Therefore, the global attitude is that the improvement of knowledge and skills of medical workers in this area are needed for providing help and treatment to the public.

Material and methods

In this paper, programs of additional education for OMP, young general practitioners on compulsory military service and doctors on specialization courses in Military Medical Academy are presented. They are based on IAEA recommendations and adapted to previous knowledge of the participants and their possible role and responsibilities in the NR accidents.

Results and Discussion

Potential sources of nuclear/radiological accidents

here are several potential sources of nuclear/radiological accidents. At the first place, the source of the accident could be nuclear installations due to damage or human mistake. These accidents are rare; they involve a lot of people and demand the activity of many services. The second potential source of the accident could be lost sources, so called *orphaned sources*. These accidents are not so rare, and the number of people involved is different depending on scenario.

More recently, important potential sources became NR terrorist devices. In a last decade, numerous blackmails and threats involving these devices were denounced worldwide. Until now, no cases of terrorist actions involving radioactive material have been known. Nevertheless, efforts to prevent them are still needed. There are two groups of devices: improvised nuclear devices (IND) and radiological dispersal device (RDD). It is presumed that attack by IND is less possible, because they are harder to produce, transport and provide with sufficient nuclear material. The most possible scenario is attack by RDD, which is easy to produce, transport and use. Most of all, it is easy to provide a smallest quantity of radioactive material needed for production of RDD. The highest advantage of RDD is the fear and panic they cause, even if they contain the smallest quantity of radioactive material.

Potential targets for terrorist nuclear/radiological attack

Presumed targets for terrorist attack are urban or suburban heavily populated locations. They are usually business or industrial parts of the cities, or specific places like underground, harbors, airports, theatres, even objects like hospitals, kinder-gardens, and schools. Finally, nuclear or industrial installations could be marked as targets and induce mixed-hazards situation.

For many adults, the first point of contact with harmful agents could be their workplace, and therefore occupational medicine professionals (OMP) are considered as potential first responders to a terrorist attack.

Emergency response

Emergency response in these situations is complex and demands activity of numerous services. Medical workers are unavoidable members of the rescue teams on all levels, from the first response to final hospital treatment. The aim of the protection and response is to prevent deterministic effects and minimize the possibility of stochastic effects.

Final treatment for wounded and sick people who are irradiated or contaminated in NR attack should be provided in specialized hospitals. In order to prevent pressure on these hospitals it is crucial to organize qualified medical teams on-site and on pre-hospital level. They will provide first aid and triage. Therefore, it is extremely important to educate first responders and to organize the entire network. It is presumed that city emergency medical teams would react, but in the case of attack they could be slowed down or even stopped due to panic, traffic troubles or any other reason. In the case of NR attack with several explosions, and the unknown number of radiation sources, numerous emergency teams are needed. Therefore, it would be rationale to provide emergency medical response from the nearest medical professionals.

Why OMP

OMP are trained to follow-up harmful effects of many physical, chemical, biological and psychological factors from the workplace. They are also trained to detect and measure doses or levels of these agents and effects, as well as to assess the risk of exposure to them. Most of OMP are situated in the medical centers in the industrial areas or factories. They are responsible for medical treatment of the workers on daily basis. In the accidental situation of any kind, OMP are the nearest medical teams to provide help on-site. Besides the emergency medical treatment, OMP teams could be useful for a few different reasons.

OMP services settled in industrial areas are supplied by materials necessary for emergency situations connected with industrial process. OMP are completely aware of all the physical, chemical pollutions released from the industrial process. They are usually equipped with detection and dosimetric tools and have a date base of previous measurements taken before the accident, so they can notice any significant difference and increase in pollutions. These data could be of a great importance for the activity planning and risk assessment. OMP are familiar with early notification of accidents, as well as the chain of action and responsibility. This service has a data base of workers health. In the accidental situations they can provide previous results and help in treatment planning. Occupational medicine departments have epidemiological data which could be of great importance in the evaluation of the accident.

Still, further education of OMP is needed, because the main goal of their interest is professional exposure and the effects of chronic or prolonged exposure to low doses or low level doses to harmful agents from working environment. Besides that, health surveillance is based on previously planned activities. On the contrary, in the accidental situations they are faced with sudden exposure of many people to high doses/levels of harmful agent/s. That implies necessity for further education of OMP. Good educational programs should be specific and adapted to target groups, to their assignments and responsibilities in the accidental situations. One of the most important assignments is first medical aid on-site of the accident, so the training and education of the first responders are crucial for the good help, as well as the protection of responders.

Courses in Military Medical Academy

Military Medical Academy organizes medical education for different profiles of medical workers. Basic NRCB course is compulsory for all the specializations. The main topics of this course vary for different specializations, from preventive medicine to clinical sciences.

OMPs course

Considering OMP as very important for the mentioned accidental situations, courses on urgent toxicology in National Center for Poison Control are organized, including the basic principles of emergency toxicological procedures and detection of toxic substances. The second part of the course consists of: basic principles of detection, prevention and protection in the case of bioterrorist acts, as well as basic principles of microbiological diagnosis, clinical signs and treatment. The third part of the course is radiation protection. Emergency medical response is the main goal, and also detection of different kinds of ionizing radiation, basic dosimetry (field and personal), decontamination, treatment of acute radiation syndrome and skin injuries. At last, OMPs are well trained to protect themselves and members of their team. This program is sufficient to prepare them for all-hazard situations. Further trainings are needed to refresh their knowledge and skills.

After this program our OMP could be involved in post-accidental follow-up of late consequences of harmful agents, as well. Besides the contamination of the people, contamination of the food, water and the environment is a potential consequence of the radiological accident/attack. Radiation protection department, as a part of the Occupational medicine, is responsible for the monitoring of these goods. The results of radiometric analysis are crucial for further activities of the OMP.

NRCB for doctors on compulsory military service

Young doctors-general practitioners on compulsory military service are obligated to attend additional NRCB course. Main goal of this course is medical management in accidental situations with mass causalities. These groups are trained for field work. Besides the basic topics mentioned above, they are trained to organize decontamination of large groups of people in a tent which is the part of the field military hospital. They are trained for the first aid, triage, transport and basic treatment of victims in NR accident.

These courses are part of our efforts to provide a network of adequately trained first responders. For the real improvement, regularly repeated trainings and preparedness are needed. Increased spectrum of NR devices and possible scenarios of NR attacks, in turbulent political situation, imply further development of emergency preparedness, not only on local, but also, on global level.

Brain tumour risk in relation to mobile telephone use: results of the INTERPHONE international case-control study

Cardis, Elisabeth
CREAL, Barcelona, SPAIN

Abstract

The rapid increase in mobile telephone use has generated concern about possible health risks related to radiofrequency electromagnetic fields from this technology. An interview-based case-control study with 2708 glioma and 2409 meningioma cases and matched controls was conducted in 13 countries using a common protocol.

A significantly decreased risk was seen in relation to ever having been a regular mobile phone user both for glioma (odds ratio (OR) 0.81, 95% confidence interval (CI): 0.70,0.94) and meningioma (OR 0.79; 95% CI: 0.68, 0.91), possibly reflecting participation bias or other methodological limitations. Odds ratios were below 1.0 for all deciles of lifetime number of phone calls and nine deciles of cumulative call time. While there was no evidence of dose-response, a significantly increased risk of glioma was seen among users in the highest decile of cumulative call time (OR 1.40; 95% CI: 1.03, 1.89). That risk was greatest among subjects with tumours in the temporal lobe, where RF absorption is generally highest, and among subjects who reported using their phones on the side of the head where their tumour occurred. Self-reports of phone use are, however, subject to considerable recall error. Sensitivity analyses conducted to evaluate the robustness of the findings generally showed similar results.

Overall, no increase in risk of either glioma or meningioma was observed in association with use of mobile phones. There were suggestions of an increased risk of glioma at the highest exposure levels, but biases and errors prevent a causal interpretation. The possible effects of long-term heavy use of mobile phones require further investigation.

UV-A radiation enhances melanoma metastasis in mice

Pastila, Riikka[1, 2]; Pitsillides, Costas[2]; Zhang, Li[2];

Extended abstract

Ultraviolet (UV) radiation is considered the major factor in skin cancer development (1). Due to the increasing popularity of skin tanning lamps, the potentially deleterious effects of solarium-derived UV radiation have become a public health concern, since the use of solaria has been linked to the development of melanoma, a particularly aggressive subtype of skin cancer (2,3). Melanoma is characterized by high risk of hematogenous metastases in the early stages of disease and it is the major reason for melanoma mortality. An understanding of the physiological consequences of UV exposure is of crucial importance in the prevention of melanoma. The possibility that UV radiation may affect melanoma metastasis has not been addressed widely, although it is known that some of the UV-induced cellular effects, such as the systemic immunosuppression (4,5), increased expression of matrix degrading enzymes (6) and adhesion molecules (7,8), are events that can mediate the autonomous growth of melanoma and possibly enhance the metastatic potential of the melanoma cells.

We have investigated the effect of solarium-derived UV-A (320-400 nm) irradiation on the metastatic capacity of mouse melanoma reporting possible link between UV radiation exposure and melanoma metastasis both *in vitro* (9) and *in vivo* (10). Previously we have shown that *in vitro* UV-A radiation enhances the metastatic properties of mouse melanoma B16 cell lines by increasing the adhesiveness of melanoma cells to endothelium and changing expression of adhesion molecules. We have also shown that *in vivo* UV-A exposure of mice increases the formation of melanoma lung metastases in C57BL/6 mice injected *i.v.* with low-metastatic B16-F1 cells. Obtained results have confirmed that mice, that were *i.v.* injected with B16-F1 cells and exposed to UV-A, developed 14 days after treatment 4-times more of lung metastases as compared with the non-exposed group. However, the *in vitro* exposure of melanoma cells, prior to injection into mice, lead to induction only of 1.5-times more metastases as compared with the animals injected with non-irradiated cells. Therefore, UV-A-induced changes in the adhesive properties of melanoma cells cannot, alone, account for metastasis increase observed after *in vivo* exposure of mice.

The fate of the melanoma cells in mice circulation and the body during the first hours as well as days after melanoma cell injection remains obscure in the used mouse model. Although *in vitro* systems to assess melanoma metastasis exist, these systems do not adequately reflect the complexity of the in vivo microenvironment. Similarly, the rapid changes in cell surface molecule expression that occur in dynamic systems are most effectively observed in real time *in vivo*. Therefore the next step was to investigate the metastatic process in real time and to determine how an *in vivo* UV exposure of the mouse affects the melanoma cell circulation kinetics, cell trafficking to the host-organs, and their long-term ability to form metastases utilizing different *in vivo* molecular imaging technologies.

In vivo flow cytometer (IVFC) is an excellent tool with the capability to count circulating fluorescently labeled cells in living animals (11,12), since the migration of cell population of the interest can be observed in the native environment without the need to draw blood samples. Since the circulation kinetics of the B16 melanoma cells in this experimental metastasis model was totally unknown, the depletion rate of the fluorescent-labeled cells was determined using the IVFC technique. Melanoma cells were cleared very fast from mouse circulation and mainly for this reason no significant changes in the cell clearance were found between the UV-exposed mice as compared to the non-exposed controls.

To assess the localization of the B16 melanoma cells after the UV irradiation, the short term trafficking into the lungs during the first hours after melanoma cell injection was studied by non-invasive *in vivo* biochemiluminiscense system that allows the whole body imaging. Bioluminescence imaging showed increased melanoma cell arrest in the lungs 60 minutes after UV-A exposure compared to controls. As a long-term effect of the UV exposure on melanoma cells, UV-A irradiation was also shown to enhance remarkably the proliferation of B16-F1 cells in the lung parenchyma as compared to the non-exposed group during the next 15 days.

As conclusion we suggest that UV-A-derived increase of metastasis *in vivo* might be a combination of enhanced adhesion to pulmonary vasculature and enhanced proliferation that both contribute to the observed UV-A effect on melanoma metastasis. These results presented in this study suggest that, if occurring also in humans, exposure to UVA radiation during extensive sunbathing or solaria tanning periods might have the potential to cause increase in the hematogenous melanoma metastasis in patients with metastatic disease, but this needs to be confirmed in the future studies.

Investigation of sun habits in Sweden 2005–2009

Gulliksson, Johan
Swedish Radiation Safety Authority, SWEDEN

Abstract

Between the years 2005-2009 a questionnaire has been used by the Swedish Radiation Safety Authority in order to see how much UV-radiation the Swedish population is exposed to. This Questionnaire has also made it possible to learn about how the sun habits for the Swedish population, their attitudes and knowledge about UV-related matter. A description of the method used will be presented together with result and discussion about what can be said about the years the questionnaire has been used. The questionnaire has been distributed to 2000 persons in Sweden and is collected by the Statistics Sweden, which also summarizes the results.

Introduction

Sweden has an environmental goal which states that the annual skin cancer incidence shall not be higher in the year 2020 than it was in 2000. A reason for setting up this goal is the fact that skin cancer is one of the fastest increasing types of cancer in Sweden and the main cause for this is the exposure of UV-radiation.

This goal is followed by two indicators, the annual number of skin cancer incidence and the exposure of UV-radiation of the population. The disadvantage of the annual skin cancer incidence as an indicator is that it does not correlate with the exposure of UV-radiation today. The delay between the damage and the onset of skin cancer makes it hard to draw any conclusions from the exposure today and the skin cancer incidence. In order see the actual exposure of UV-radiation one cannot rely on the incoming radiation alone but the crucial part is the behaviour and attitude when it comes to the sun or solarium.

This paper will present the model and questionnaire being used in order to estimate the actual exposure of the Swedish population as well as get knowledge about sun habits.

The indicator for the environmental work reflects how much UV radiation people are exposed to, depending on their behaviour. There are two interesting aspects of exposure to consider, first, the total exposure for the population (population exposure) and the extent of the exposure (burns). Both of these aspects are linked to the risk of getting skin cancer.

The questionnaire also provides information on attitudes toward sun exposure and various protective behaviours, knowledge about ultraviolet radiation and skin cancer. The work with the questionnaire began in autumn 2004 with the participant Katarina

Yuen, Lars-Erik Paulsson and Ulf Wester from SSI[1] and Richard Bränström from Karolinska Institutet (KI) and Helena Bäckström from Statistics Sweden (SCB).

Material and methods

When the purpose of the questionnaire was established the variables that would be used was determined. This section presents the approach when the exposure model and questionnaire was designed. As a first step a decision was made to construct at model that was rough but more easy to work with instead of a model with high precision which would increase the cost and workload. Because of the roughness in the model it is best to compare the results only from the same questionnaire, even though the exposure can be expressed in physical units. The exposure can be based on the following factors:

The duration of our time outside when the sun is reasonably strong.
What we use to protect ourselves from the radiation.
Exposure from other sources than the sun. (Solarium).

The model

The model takes into account behavioural aspects of the exposure and not weather conditions. It is based on MED, minimal erythemal dose where MED is the dose of UV-radiation that barely gives a redness on the skin and should in principle be decided for every individual and situation. Here MED is set as 210 J_{CIE}/m^2 (weighted erythemal dose). The coefficients used in the model has been chosen in order to give the exposure a physical quantity. The simplifications and assumptions in the model make it difficult to speak about the calculated exposure in terms of MED. Therefore the exposure is simply named the exposure in this paper. The exposure can vary between 0 and 1372,5.

Sunprotection

The protection from the sun can be divided into three components, surface, intensity and frequency. Surface means how large part of the skin that are being protected. For example some clothes only cover parts of the body, and the parts that are unprotected is exposed to the radiation that the current environment. The parts that are covered can still be exposed to the radiation depending on the fabric. Intensity takes into account the intensity of the sun and how much the UV-radiation is filtered by the protection. This concerns sparse, thin fabrics and its sun protective properties, badly applicated sunscreen etc. Frequency is how often a protection is being used.

The questions in the questionnaire is for a general situation with beautiful summer weather, i.e. no division for different situations as working time, free time or time abroad. The model assumes mainly free time. But different weights are used for free time and work time since it is reasonable to assume more clothes and shadow in a working environment. Since the model lacks precision, an estimate for the protective properties for different sun protective means as the size of hats, densities of the clothes etc. is built upon reasoning rather than measurement. For example shorts and t-shirts

[1] In July 2008 the Swedish Nuclear Power Inspectorate (SKI) and the Swedish Radiation Protection Institute (SSI) merged into the Swedish Radiation Safety Authority (SSM)

give a protection up to 50 %, scattered radiation can still reach people in the shadow and a protection of about 50 % can be assumed.

One question is concerning how many hours one usually spends outside a day with beautiful weather. The question is limited between 10 am and 4 pm between May and August. A division is made between a working day and a free day/weekend in Sweden and a free day abroad. Weeks of vacation in Sweden and abroad can also be extracted.

Even though the current weather conditions was not included in the model maps from the SMHI (Swedish Meteorological and Hydrological Institute) were studied for the years 1961 – 1990 in order to get a reasonable estimation for weather reduction. From these maps the weather reduction was set as 0,5.

The Exposure outside

The average UV-index in Sweden for the period of interest was approximately 3. One UV-index represents 90 J/(m^2h) erythemal UV-radiation against a horizontal surface i.e. 0,4 MED/h. Thus UV-index 3 corresponds to 1,3 MED/h. But for a realistic situation a person does not expose the entire body to UV-radiation at the same time. The fact that radiation before 10 am and after 4 pm can be of importance 1 MED/h was chosen for the exposure in Sweden and 2 MED/h for the exposure abroad.

Today, most of the sun bed used are full body tanning devices and most people tan with very little clothes. In this case it is reasonable to consider the entire body exposed to the radiation. In the model 2,5 MED/h was used for one tanning session in a solarium.

Results

The exposure

The exposure has been calculated according to the above mentioned model and is shown in figure1 and 2 for the years 2005-2009. During these years the exposure is relatively constant and no tendencies can be seen. The contribution from trips abroad to the exposure is relatively high. If you compare the different age groups from 2009 it is clear that the group with ages 18-24 has the highest degree of exposure. Generally the exposure is decreasing with increasing age.

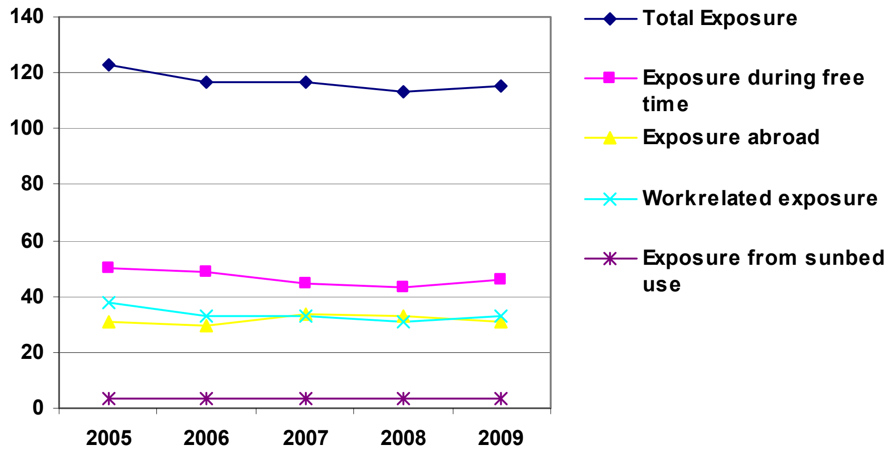

Fig. 1. UV-exposure for the years 2005-2009.

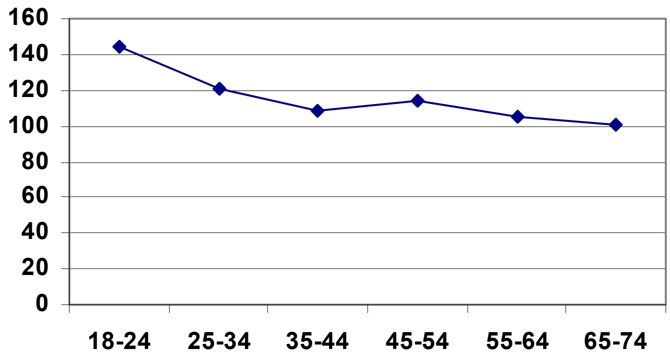

Fig. 2. UV-exposure for the year 2009 divided into different age groups.

Burns

Apart from the total exposure of UV-radiation the burns from UV-exposure is a riskfactor for skincancer. The most common places for getting a sunburn were a garden or balcony and a beach in sweden. Being burned abroad and on a lake was almost just as common.

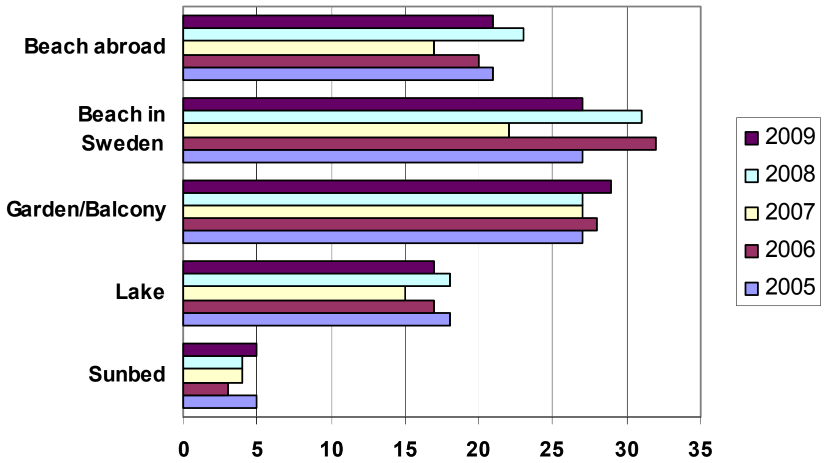

Fig. 3. Percentage of people suffering from sunburn at different locations for the years 2005-2009.

Protection

There are several ways to protect oneself from the sun. For example you could stay in the shade, avoid being outside in the middle of the day, using sunglasses, wearing clothes, cap or a hat or use sunscreen. As is shown below the most common protective behaviour is to wear clothes and the least common behaviour is to avoid being outside in the middle of the day.

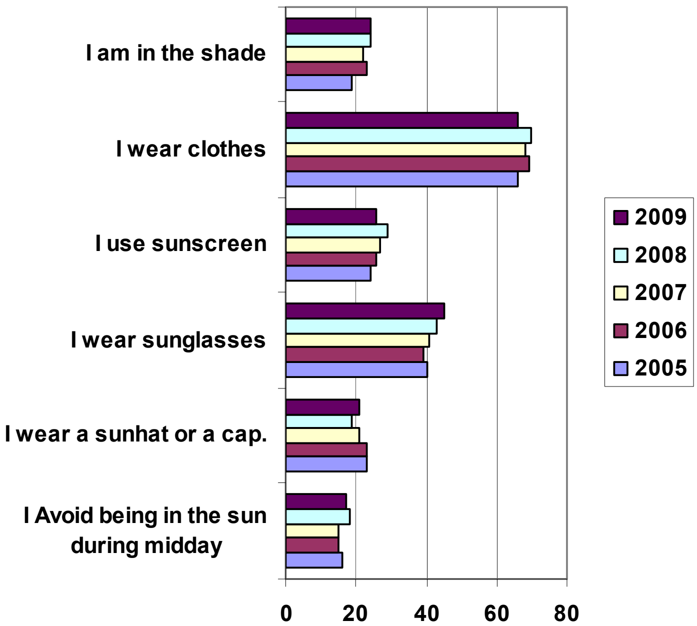

Fig. 4. Percentage of the respondents that always or often protect oneself in different ways.

Attitudes

The most important factor for how much UV-radiation the population is exposed to comes from the behaviour in the sun. There has not been any drastic change between the years 2005 and 2009. Most people enjoy being in the sun and try not to burn themselves. About two thirds think they look better and feel healthier when they have a tan and these statements are truer for women than men. One third worries about getting skin cancer. For the different age groups one can see that the youngest age group compare to the older ones think that using clothes as sun protection is more uncomfortable but the oldest age groups think using a sunscreen is more uncomfortable than the youngest age group.

Knowledge

The knowledge about the sun, skin cancer and other related topics is relatively high. Almost everyone knows that the sun can cause skin cancer and that children are more sensitive to the rays of the sun. There are no drastic differences between the age groups but one might see tendencies that women has a little more knowledge about matters that concerns health.

Discussion

A summary of the questionnaire and its results gives a relatively good overview of the sun habits in Sweden. But so far it is hard to see any obvious trends. Because of this, the questionnaire will not be sent out annually but every second or third year. Not unexpectedly the group with the greatest risk behaviour is the people in the youngest age group. The reasons why people act in a way they know can be harmful most likely depend on several factors. In terms of acute injuries there is only sunburn and possibly some eye damage, but these usually heal reasonable quick and therefore it is probably not a great concern for most people. The long time effect of UV-exposure and burns, skin cancer and cataract, usually lies way ahead in the future and does not affect the behaviour when you go to the beach or work in the garden.

Apart from the indicator for the UV-exposure and knowledge about sun habits and attitudes the data from the questionnaire has been used in press releases every year it has been sent out. For example:

2005: “Every second person burn during sun vacation!”
2006: “Every fourth Swede burn in sun when gardening!”
2007: “Risks well known, but sun sense practice rare (1 of 3)!”
2008: “Small improvement of sun habits! Sunburns down 6%”
2009: “Sun bed burns doubled among young persons!”

Conclusions

The Questionnaire will not be sent out annually but every second or third year. This gives the opportunity to make more specific studies that can focus on the potential risk groups. Since the risk behaviour is the “worst” in the youngest age group generally it would be interesting to see how the behaviour is for even younger ages. In order for the authority to give proper advice and information it is necessary to continue this kind of study.

Role of modulation in the biological effects of radiofrequency radiation

Juutilainen, Jukka; Höytö, Anne; Kumlin, Timo; Naarala, Jonne
University of Kuopio, Department of Environmental Science, FINLAND

Abstract

The biological effects of modulated radiofrequency (RF) radiation have been a subject of debate since early publications more than thirty years ago, suggesting that relatively weak amplitude-modulated (AM) RF electromagnetic fields have specific biological effects different from the well-known thermal effects of strong radiofrequency energy. This discussion has been recently activated by the increasing human exposure to RF radiation from wireless communication systems. Modulation is used in all wireless communication systems to enable the signal to carry information. A previous review in 1998 indicated that experimental evidence for modulation-specific effects of RF energy is weak. This paper reviews recent studies (published after 1998) on the biological effects of modulated RF radiation. The focus is on studies that have compared the effects of modulated and unmodulated (continuous-wave, CW) RF fields; studies that have used only modulated or only CW signals are not included. While the majority of recent studies have reported no modulation-specific effects, there are a few interesting exceptions that warrant follow-up studies.

Location of glioma in relation to mobile phone use

Abstract

The objective of our study was to evaluate whether the gliomas within the brain differ between mobile phone users and never-users. The energy absorbed from the radiofrequency (RF) electromagnetic fields of mobile phones depends strongly on the distance from the source. We would expect gliomas among users to be located nearer to the source of exposure i.e. mobile phones if such exposure increases the risk of gliomas. We used case-case analysis to evaluate whether location of the gliomas in the brain is related to the source of RF exposure. The study methods applied were novel and provide an improved approach to studying focal effects in the etiology of gliomas. By utilizing information on the tumor location instead of only amount of mobile phone use as in earlier studies, the case-case method enables focusing on SAR distribution of RF field. This offers a possibility to study biologically and physically more meaningful and refined hypotheses. The data consisted of 888 gliomas from seven countries with tumor mid-points assigned by neuroradiologists on a three-dimensional (1 x 1 x 1 cm) grid based on radiological images. The typical position of the mobile phone while used was assumed to be in the line from the external acoustic meatus to the corner of the mouth and distance was computed between this line and the mid-point of the tumor. The data analyses were made using unconditional logistic regression with distance as a categorical outcome (5 cm as a cut-point) in the case-case approach. In the case-case analyses never-regular users and those using mobile phone at the opposite side as the tumor had their gliomas nearest to the exposure line, but the differences were statistically non-significant. Our results do not suggest gliomas being located in excess in those parts of the brain with the highest exposure to the RF field of mobile phones.

Background

Mobile phones emit radiofrequency (RF) electromagnetic fields. RF fields have not been shown to be tumorigenic, but their biological and health effects have not been firmly established so far (Ahlbom et al. 2009). The energy absorbed from the RF fields of mobile phones depends strongly on distance from the source decreasing to one tenth in 5 cm of tissue (Cardis et al. 2008).

As the RF field emitted by the mobile phones penetrates the brain in a highly localized fashion, a local effect restricted to the part of the brain closest to the handset would be expected, if there is one. Instead of concentrating on crude indicators of phone use (such as self-reported number and duration of calls) as in most previous studies, utilizing the accurate tumor location enables focusing on the postulated distribution of the RF field within the brain, thus offering a biologically and physically more meaningful and more specific approach. However, only a few studies have assessed the location of glioma in relation to mobile phone use (Takebayashi et al. 2008, Hartikka et al. 2009), and these studies are based on small sample sizes.

The objective of the study was to evaluate whether gliomas among phone users occur preferentially in the areas of the brain having the highest RF exposure from the handset.

Methods

This study is based on data from seven European centers (nationwide studies in Denmark, Finland, Norway, Sweden; Bielefeld, Heidelberg and Mainz regions in Germany; Rome, Italy; and Thames region of Southeast England) within the Interphone study, an international collaborative case-control study, whose main objective was to assess whether mobile phones increase the risk of brain tumors (Cardis et al. 2007).

The study included 888 gliomas (61% of all glioma cases diagnosed during the study-period) diagnosed between September 2000 and January 2004 with tumor mid-point(s) assigned on a three-dimensional grid (1 x 1 x 1 cm). These mid-point(s) were defined by neuroradiologists, blind to the data on mobile phone, based on radiologic images.

The main exposure indicator in the analyses was the shortest estimated distance from the mid-point of the glioma to the putative source of exposure, i.e. typical location of the phone. The exposure line was assigned as a line from the external orifice of the ear canal to the corner of the mouth with the entire phone regarded as the source of exposure (as most phones have an integrated antenna with the whole body of the phone emitting an RF field). To avoid potential recall bias, distance was calculated to the nearest source of exposure on the same side as the glioma was located, irrespective of the patient's reported typical side of use.

Case-case analyses were carried out using unconditional logistic regression with distance between the mid-point of the glioma and the putative source of exposure (location of the phone) as a binary outcome (≤5 cm, >5 cm). Exposure indicators analyzed included regular use of mobile phone (regular use defined as ≥1 call/week for ≥6 months, use in the 6 months prior to glioma diagnosis excluded), cumulative call-time (divided into tertiles: 0.001-46 hours, 46-339 h and >339 h, with median of 133 hours and maximum of 20,000 hours), laterality (preferred side of use) and duration of use (cut-points chosen to correspond to those in previous studies: 6 months to 5 years, 5 to 9 years and 10 or more years of use). Never-regular use of a mobile phone was the unexposed reference category in all analyses. All analyses were adjusted for country, sex, age group and socioeconomic status.

Results

Information on mobile phone use was obtained from 98% of the cases, with 57% regular mobile phone users and 43% reporting no regular use. Laterality of use was known for 490 cases (99% of all regular users).

The mean distance between the tumor mid-point and the phone (for all gliomas, 6.25 cm) did not vary substantially by the indicators of mobile phone use. The mean distance was somewhat shorter among cases who had not used a phone regularly (6.19 cm) and those reporting the preferred side of use as contralateral to the tumor (6.29 cm) in comparison to regular (6.29 cm) and ipsilateral (6.37 cm) use. The mean distance was slightly longer for those with the highest cumulative call-time or those having used mobile phone for more than ten years, but the differences were not significant.

In the case-case analysis, using unconditional logistic regression with categorical distance as the outcome (≤5 cm, >5 cm), non-significantly decreased ORs for gliomas located within 5 cm of the presumed phone location were found in regular users compared with never-regular users (OR 0.87 (95% CI 0.63-1.20)). The odds ratios for higher exposure were below unity for all exposure variables in these analyses, indicating no excess in the highly exposed parts among regular vs. never-regular users.

Conclusion

Our results do not support the hypothesis of gliomas among users of mobile phones being preferentially located in the parts of the brain with the highest RF exposure from mobile phones. In the case-case analyses, gliomas among never-regular users, representing lower RF exposures, had a shorter mean distance between tumor mid-point and the presumed source of exposure than regular users. Consistent findings indicating no increased frequency of gliomas in the areas closest to the typical position of the mobile phone handset were observed with all exposure characteristics, e.g. cumulative call-time and duration of use.

Hyperthermia-induced proliferative response in human cancer cell lines is counteracted by a 2.2 GHz pulsed signal

Abstract
The present study describes the cell growth response of two human cancer cell lines, HepG2 and NB69, to 24-h simultaneous exposure to two physical agents: mild hyperthermia and 2.2-GHz, pulse-modulated, radar-like radiofrequency (RF) signals. The samples were sham-exposed or RF-exposed simultaneously inside two identical waveguides placed in a CO_2 incubator set at 37 ºC (standard temperature) or 38 ºC (mild hyperthermia). A complete discretized model of the setup was created for numerical dosimetry using FDTD software SEMCAD X. The average dose of RF radiation absorbed by the cultures was calculated to be subthermal ($\Delta T<0.1$ ºC). At the end of the 24 h treatment the cell growth was analyzed through Trypan blue exclusion and cytometry. At 37 ºC the NB69 line responded to the RF exposure with a consistent reduction in cell number (13.5% % below controls; $p<0.001$) together with slight but significant changes in the kinetics of the cell cycle. In contrast, the HepG2 cell growth and cell cycle were not changed after the RF treatment. The + 1 ºC thermal stimulus alone induced significant increases in the number of cells in both NB69 and HepG2 lines (17.9% $p< 0.05$ and 18.8%, $p < 0.01$ above controls at 37 ºC, respectively). This cytoproliferative, thermally-induced response was blocked in both cell lines by the simultaneous exposure to RF. Consequently, the results indicate that under standard temperature conditions the HepG2 line is not responsive to the cytostatic effect exerted by the RF exposure in NB69 cells, whereas, under thermal stimulation of cell proliferation, both lines showed a similar, cytostatic response to RF, likely to be mediated by changes in the cell cycle. Studies are in progress investigating the mechanistic and molecular basis of the herein described cellular response.

Introduction
The study of the potential hazards of chronic exposure to weak, radiofrequency (RF) electromagnetic fields in residential or occupational environments has been addressed by a number of epidemiological studies (see Hietanen, 2006; Hardell and Sage, 2008 for recent reviews) and experimental investigations (Garaj-Vrhovac and Orescanin,

2009; Xu et al., 2010). RF fields in the GHz range are of particular interest because of the rapid implantation of recent and emerging telecommunication technologies. International regulatory bodies like ICNIRP or the European Council (ICNIRP, 1998; EU Council Recommendation, 1999) have developed their standards for protection of the public and workers against non ionizing radiation on the basis that only RF doses inducing thermal increases $\Delta T \geq 1$ °C in the exposed tissues can be considered detrimental to humans. There is general agreement that the energy at which most RF telecommunication signals are emitted are too low to induce significant thermal increases in the tissues of potentially exposed individuals (Hietanen, 2006). Consequently, it has been widely assumed that under normal conditions in residential and occupational environments, the exposure to RF radiation at subthermal doses can be considered safe. This assumption is supported by data from a large body of experimental studies that have failed to detect potential harmful effects of weak RF signals on a number of in vitro biological models (Higashicubo et al., 2001; Chauhan et al., 2007; Prisco et al., 2008).

On the other hand, several experimental studies have reported effects on cell cycle control and apoptosis (Marinelli et al., 2004; Joubert et al., 2008), on gene expression (Remondini et al., 2006; Buttiglione et al., 2007), and tumorigenesis (Repacholi et al., 1997) in different biosystems exposed to RF at doses estimated to be subthermal. This data would provide limited support to some epidemiological results indicating that chronic exposure to weak RF fields could represent a risk factor in the etiology of a number of ailments, ranging from perceived electromagnetic hypersensitivity or neurological symptoms to neurodegenerative diseases or different cancer types (Rubin et al., 2006; Sage and Carpenter, 2009). Taken together, both blocks of epidemiological and experimental evidence seem to be indicative that different, presently undetermined factors may be responsible for the controversial data obtained so far. Even if subthermal mechanisms of RF interaction existed, at high power densities the thermal effects would prevail, leading to adverse consequences. At lower exposure levels biological effects have been reported but, due to limitations in modeling and dosimetry, the possibility cannot be ruled out that thermal mechanisms could also intervene in the biological response. Under the present circumstances there is general consensus that experimental studies using sensitive biological models are crucial to the study of the thermal/subthermal mechanisms underlying the bioeffects of weak RF fields. The present study investigates the cell growth response of two human cancer cell lines, HepG2 from hepatocarcinoma and NB69 from neuroblastoma, that have been reported to be sensitive to RF fields (Hernández-Bule et al., 2007; Trillo et al., 2009). The cells were exposed for 24 hours to a 2.2 GHz, pulse-modulated radar-like signal with high instantaneous amplitude and very low average power. Little is known on the biological interactions of this type of signals, and their potential relevance to the human health needs to be more efficiently addressed by the standards for radiation protection. Additionally, in order to determine whether a potential response to the RF exposure could be mediated by thermal phenomena, a set of experiments was conducted in which cell cultures were exposed to the RF treatment and/or incubated under mild hyperthermia (38 °C).

Material and methods

Exposure System

The schematic view of the RF exposure equipment is shown in Figure 1. The system has been described in a previous paper by Varela et al. (2010). Briefly, the system consists of: 1) A signal generator (MCL 15156, MCL Inc, USA) in the 2.0 – 2.5 GHz band, with specification for CW power ≥ 35 W and pulse duration ≥ 5 µs; 2) A modulator that controls the pulse duration and repetition rate; 3) A double rectangular waveguide applicator (95 x 45 mm section, 500 mm in length) connected to a high power matched load; 4) Ancillary equipment composed of a RF counter HP-5347A, a power meter HP-432A and a detector for pulse shape control.

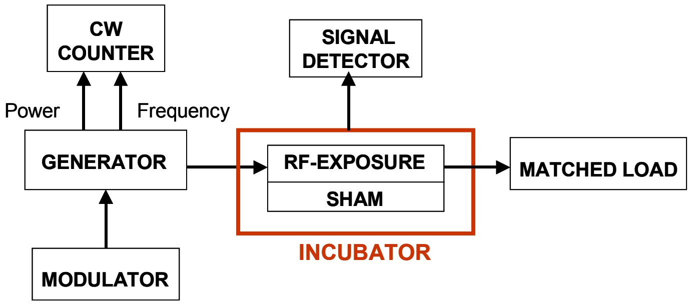

Figure 1.- Diagram describing the configuration of the System: The electromagnetic signal is generated by a signal generator sweep oscillator ranging 1 - 3 GHz. The RF applicator is located inside a CO_2 incubator and is composed of two waveguides, one for RF-exposure and another for sham-exposed control samples.

The RF applicator

During RF- or sham-exposure the samples are placed on a double-shelf Teflon support holding eight Petri dishes, inside each of the two wave guides (Fig. 2). Both guides have a lateral, copper hinged section and are closed by slotted short circuits equipped with fans, for temperature homogeneity and proper atmosphere exchange within the guides. A coaxial probe in the centre of the top wall waveguide is used for monitoring the parameters of the RF signal applied to the cells. Since all in vitro procedures have to be conducted in sterile conditions, the waveguides, sensors, connectors, holders and wiring were designed and built to withstand the 9-hour incubator routine for inner decontamination at 90 °C and RH > 95%.

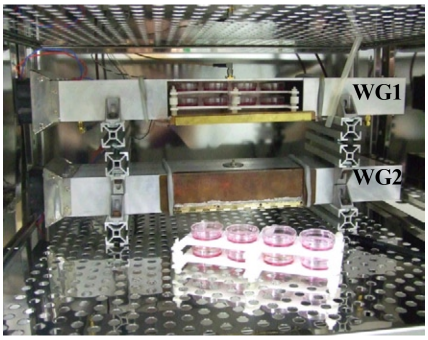

Figure 2. Waveguide pair for simultaneous RF- and sham-exposure within a CO_2 incubator. The trapdoor to the upper waveguide (WG1) has been opened to show the holder with Petri dishes. The 8-dish holder corresponding to WG2 is displayed outside the guide.

RF signal and dosimetry

The dosimetric procedures and results have been described in detail by Varela et al. (2010). Briefly, a 28 W (CW), 2.2-GHz, pulse-modulated (5 µs pulse duration, 100 Hz repetition rate) signal was applied to cell cultures grown in 35-mm Ø plastic Petri dishes, where the cells formed a monolayer on the bottom of the dishes. Dosimetric calculations were performed after a homogeneous model of the exposed materials, considering the dishes filled with 1.5 ml of lossy medium with relative dielectric constant $\varepsilon r = 77.5$ and electric conductivity $\sigma = 2.3$ S/m, and taking into account the presence of a meniscus at the surface of the culture medium. The Finite-Difference Time-Domain (FDTD) method was used to calculate the SAR distribution in the cell cultures through commercial software SEMCAD X (Schmidt & Partner Eng. AG, Zurich, Switzerland). The space-averaged SAR for CW exposure was calculated to be 46 W/kg. Since the samples were exposed to 5-µs pulses at a 100 pps repetition rate, the estimated time-averaged SAR would be 23 mW/kg. Considering that the experiments were conducted under strict temperature control and taking into account the damping thermal effect of the heat diffusion, we can assume that in our experiments the RF stimulus was applied at a dose well below those at which significant thermal effects can be expected.

Cell Culture

The human hepatocarcinoma cell line HepG2 obtained from the European Collection of Cell Cultures (ECACC, Salisbury, UK) was grown in Dulbecco's modified Eagle's medium (D-MEM, BioWhittaker-Lonza, Verviers, Belgium) supplemented with 10% heat-inactivated Foetal Calf Serum (FCS, GIBCO-Invitrogen, Paisley, Scotland, UK), 2 mM L-glutamine, and 100 U/ml penicillin - streptomycin. The human neuroblastoma cell line NB69, obtained from ECACC, was cultured in D-MEM medium supplemented with 15% heat-inactivated FCS, 4 mM L-Glutamine, 100 U/ml penicillin – streptomycin and 0.25 µg/ml amphotericin B. The media were always pre-heated at 37 ºC in order to avoid abrupt temperature changes that could induce cellular stress. In all experimental runs, four days prior to RF exposure, HepG2 or NB69 cells were aliquoted from a single parental flask to individual 35-mm Ø Petri dishes at densities of 9×10^4 or 7×10^4 cells per millilitre of medium, respectively, and grown in a humidified atmosphere with 5% CO_2 at 37 ºC.

Cell Growth and cell Viability Analyses

HepG2 or NB69 cells at a 60% confluence (day 4 after plating), were transferred in sterile conditions to the experimental incubators and grown inside/outside energized/unenergized waveguides. In all experimental runs, two cell culture samples were incubated simultaneously: A group of 8 Petri dishes was grown inside WG1 (Fig. 2) and an identical, 8-dish group was incubated inside WG2. In a set of experiments investigating the cellular response to mild hyperthermia, a third group of 8 control dishes was grown simultaneously inside an identical, separate CO_2 incubator, at a 37 ºC temperature. At the end of the 24-hour incubation the cells were detached from the dishes, resuspended in 1 ml of medium and studied for viability and proliferation. The number of alive and dead cells was determined through haemocytometer analysis of 50-

µl aliquots. Each sample was double-counted using the Trypan blue exclusion method. All experimental procedures and analyses were conducted in the blind.

Flow cytometry (FACS)

Cell samples grown for 24 hours with or without RF stimulation were harvested and fixed in 70% ethyl alcohol at room temperature for 4 hours. Subsequently, the cells were treated with RNAse-DNAse free (100 µg/µl; Roche) and stained with the fluorescent dye propidium iodide (IP, 20 µg/ml; Boehringer-Manheim) for 1 hour at room temperature. The relative fractions of cellular subpopulations in different phases of the cell cycle were determined through quantification of DNA content by flow cytometry, using Becton-Dickinson FACScan (FACScalibur, Becton Dickinson, Franklin Lakes, NJ, USA). Cell cycle parameters were determined by CellQuest 3.2 Software (Becton Dickinson Immunocytometry Systems, San Jose, CA, USA). Twenty thousand cells per sample were analyzed.

Statistical Analysis

Data was expressed as mean ± standard error (SEM) of at least three independent replicates, using GraphPad Prism software (GraphPad Software, Inc., San Diego, CA). The ANOVA test followed by two tailed Student's t-test was applied. Statistical significance was set at $p < 0.05$.

Results

Viability and cell growth response to the RF signal at standard temperature

Fig. 3 summarizes the cell growth response of the HepG2 and NB69 cell lines to the RF treatment at standard conditions of temperature (37 ºC). In the HepG2 line, at the end of the 24-h RF treatment no significant differences were observed with respect to sham-exposed controls. In contrast, NB69 cells responded to the same RF treatment with a consistent, statistically significant reduction (13.5% below sham, $p<0.001$) in the total number of cells (Fig. 3). This effect was accompanied with a modest, thought statistically significant increase in the proportion of necrotic cells in the exposed samples (15.9 ± 2.1%; $p<0.01$) when compared to the respective sham-exposed samples (spontaneous death rate: 13.9 ± 2.0%).

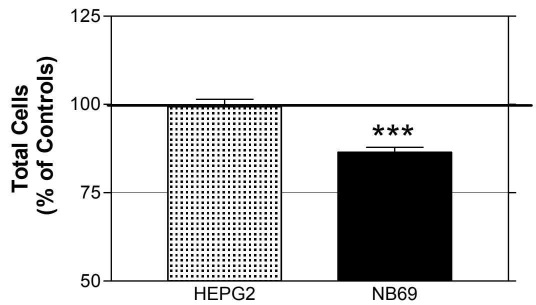

Figure 3. Comparative growth response after 24 h of RF- or sham-exposure. Means ± SEM of a total of 6 (HepG2) and 8 (NB69) independent replicates, with 8 RF and 8 sham dishes per replicate. Normalized data over the total cell number in the corresponding group of samples incubated simultaneously inside the non-stimulated waveguide (sham-exposed). In NB69, the overall effect was statistically significant ($p<0.001$) with respect to sham-exposed samples.

Cell Growth response to treatments with RF and/or mild hyperthermia

Figure 4 summarizes the cell growth response of the HepG2 and NB69 cancer lines when exposed to the RF signal under conditions of mild hyperthermia (38 ºC). At the end of the 24-h incubation at 38 ºC the sham-exposed samples of both cell lines showed significant increases in total cells (18.8% in HepG2, $p< 0.01$, and 17.9% $p< 0.05$ in NB69) when compared to controls incubated at 37 ºC. Such a temperature-induced effect was not observed when the thermal treatment was applied simultaneously with the RF exposure. When compared to their sham-exposed controls incubated at 38 ºC, the RF-exposed samples kept simultaneously in the same incubator showed significant reduction in the total cell number at the end of the 24-h treatment, both in HepG2 (13.7% below sham, $p<0.01$) and in NB69 (10.1% below sham, $p<0.01$).

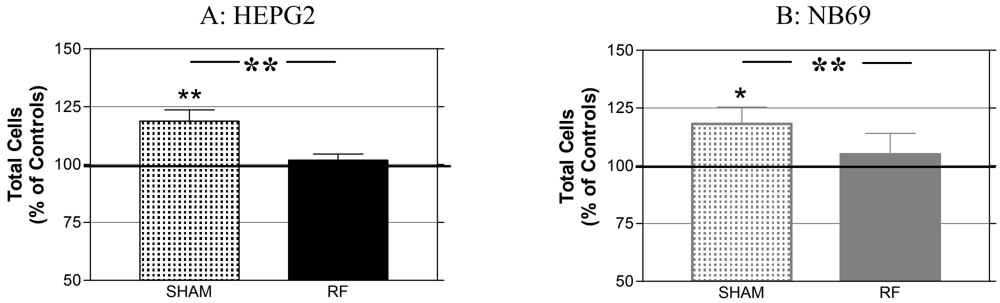

Figure 4. Growth response of HepG2 and NB69 cells after 24 h of simultaneous treatment with mild hyperthermia and RF- or sham-exposure. A total of 5 independent replicates were performed per cell line, with 8 dishes exposed to RF at 38 ºC, 8 sham dishes incubated at 38 ºC and 8 controls growth at 37 ºC, per replicate. Means ± SEM. Data normalized over the total cell number in the corresponding group of controls incubated simultaneously at 37 ºC.

Changes in the kinetics of the cell cycle in response to the RF stimulus

FACS analyses were conducted in order to investigate whether the differential growth responses in HepG2 and NB69 could be due, at least in part, to RF-induced alterations in the cell cycle regulation. No significant changes were observed in the distribution of HepG2 cells in the different phases of the cycle after RF- exposure (data not shown). In contrast, the NB69 line responded to the RF treatment with slight but consistent and statistically significant increases in the percent of cells in G0/G1, both under standard temperature and mild hyperthermia (6% and 3.4 % over controls, respectively, $p < 0.05$; Fig. 5). Also, a significant increase in the percent of cells in G2/M phases (9% over controls, $p < 0.05$) was observed when RF was applied at standard temperature, but not at 38 ºC.

As for the influence of the thermal treatment alone, it induced significant changes in the cell cycle progression of both lines; resulting in shortening of the S-phase in samples incubated at 38 ºC (approximately 30% below controls at 37 ºC, $p < 0.05$). The simultaneous treatment with RF blocks this thermally-induced response, and only small but significant increases in the G0/G1 phases were observed (Fig. 5B).

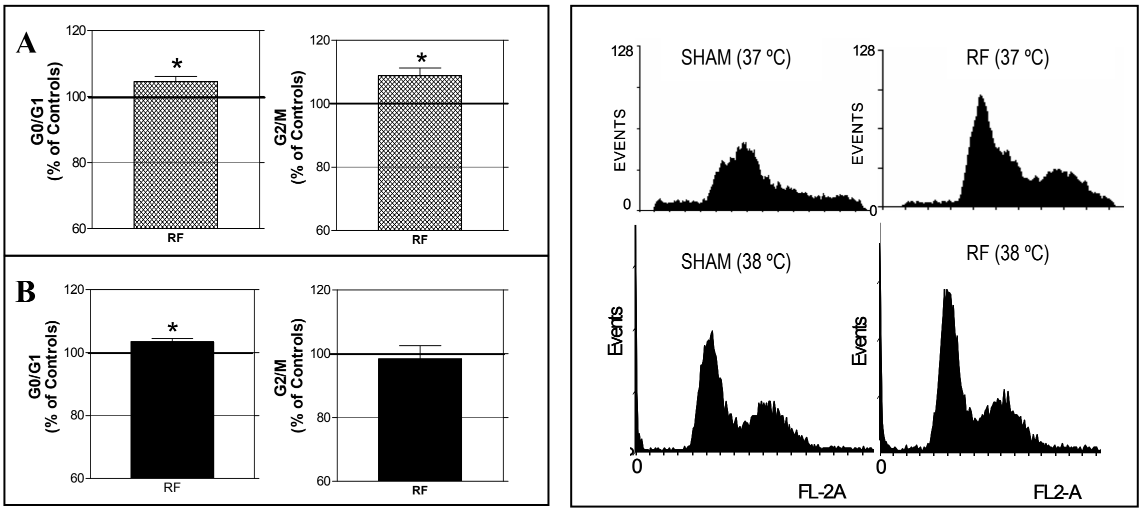

Figure 5. Left: Changes in the percent of NB69 cells in G0/G1 and G2/M phases of the cell cycle in response to RF exposure. A total of 4 independent replicates with 8 RF and 8 Sham dishes per replicate were carried out at (A) standard temperature (37 ºC) and (B) Mild hyperthermia (38 ºC). The data (Means ± SEM) are normalized over the respective sham-exposed samples. Right: Four flow cytometry histograms, representative of RF-exposed and Sham-exposed samples of the line NB69, incubated at 37 ºC or 38 ºC.

Discussion

The biological effects of low power or short-pulse RF signals that do not induce significant hyperthermia in the exposed tissues have not been investigated sufficiently. A more complete knowledge of the non thermal or subthermal effects of the RF radiation on biological systems is of utmost interest from two biomedical points of view. On the one hand, an increasing number of medical applications based on RF treatments have been developed in recent years. A better understanding of the biological responses to RF involving phenomena other than thermal could be useful to the development of new treatments, including co adjuvant therapies in oncology, traumatology or pain relieving, among others. Furthermore, it is widely accepted that hyperthermia can enhance the sensitivity of cells to radiation and drugs, and mild hyperthermia (by 1–2 °C) has been reported to induce heat-shock proteins, increase biophylaxis and immunocompetence, prevent stress and fatigue, and reduce depression or anxiety, which could contribute to diminish adverse reactions to chemotherapy and potentiate its antitumor effects (Skitzki et al., 2009; Yamada et al., 2009).

On the other hand, the level of exposure to environmental RF emissions has progressively increased in developed countries. A positive correlation between RF exposure and tumorigenesis has been suggested by a number of epidemiological studies (Hardell et al., 2008; Sadetzki et al., 2008; Khurana et al., 2009). These results have received limited support from experimental data indicating that RF fields can induce DNA breaks (Garaj-Vrhovac and Orescanin, 2009), chromosome aberration (Mazor et al., 2008), as well as alteration of gene expression (Remondini et al., 2006; Zhang et al., 2008). Despite of the fact that these in vivo and in vitro results could be indicative of possible damaging effects of RF fields, other experimental results do not support such a possibility. Thus, whether or not the reported biological responses may be induced through subthermal phenomena, is presently a controversial issue that needs to be elucidated.

Altered cell proliferation is among the most sensitive phenomena currently used to study the cellular response to environmental carcinogens. However, the available evidence on RF effects on cell proliferation is scarce and the results are conflicting (Higashicubo et al., 2001; Pérez-Castejón et al., 2009). The present study addresses the hypothesis that RF signals at subthermal doses could influence cancer progression by increasing or accelerating cell proliferation in two human cancer cell lines. We examined cell proliferation following exposure to RF radiation at standard incubation temperature (37 ºC) or at mild hyperthermia (38 ºC), and analyzed comparatively the cell responses induced by a 2.2-GHz pulse-modulated, S-band radar-like RF signal with high instantaneous amplitude and very low average power, and by a 1 ºC hyperthermia caused by the corresponding increase of the incubation temperature.

In the NB69 line the RF treatment at standard temperature resulted in significantly decreased cell number (13.5% below sham-exposed samples), accompanied with significantly increased proportions of cells in the phases G0/G1 and G2/M of the cell cycle. Also, a modest but consistent and statistically significant increase in the rate of necrosis (2% over sham) was observed in the NB69 line; however, this subtle cytotoxic effect would have little impact on the overall cell growth rate. The other human cancer line tested, HepG2, did not respond to the 24-h exposure to the same RF treatment when it was applied at standard temperature of 37 ºC. However, under +1 ºC hyperthermia, which induced significantly increased cell growth in sham-exposed NB69 and HepG2 cultures (about 18% over control samples at 37 ºC), both cell lines responded to the RF signal with significant ($p < 0.01$) reductions in cell growth, (10.1 % below sham-exposed in NB69 and 13.7 % in HepG2). In NB69 this RF-induced reduction in cell growth at 38 ºC was accompanied with a modest, though significant increase in the fraction of cells in phases G0/G1.

A similar RF effect on cell proliferation was observed by Velizarov et al. (1999) in transformed human epithelial amniotic cells exposed to a 960 MHz microwave radiation. These authors reported that at incubation temperature of 39 ºC a significant reduction in cell proliferation occurred in the exposed cells when compared to non-exposed (control) samples. However, in contrast to our results, the treatment with mild hyperthermia alone did not change significantly the proliferation of the amniotic cells with respect to control samples incubated at 37 ºC. Taken together, the results of both studies indicate that, when administered alone, mild hyperthermia induces different responses in different human cell types; whereas exposure to subthermal doses of RF signals in the GHz range could elicit a common, antiproliferative response in different, thermally stimulated cell lines.

Additionally, in both NB69 and HepG2 cell lines the RF treatment neutralized the thermally-induced proliferative response observed after incubation at 38 ºC. This result could explain the apparent lack of response reported by other authors in cells exposed to relative high, thermal doses of RF radiation (see, for instance, Takashima et al., 2006). It is possible that in some of those studies a mild thermal effect had occurred in fact, that would be counterbalanced by an electromagnetically-induced response. In other words, the thermal electromagnetic signal would have induced two opposite, simultaneous responses resulting in a null or non detectable overall effect.

In conclusion, a 24-h treatment with subthermal doses of 2.2 GHz, pulse-modulated RF radiation elicited different responses in two human cancer cell lines. The NB69 line was proven responsive to the RF stimulus, exhibiting significant reduction in the number of cells, both under standard incubation temperature (37 ºC) and under mild hyperthermia (38ºC). Such antiproliferative effect was associated to cell cycle alterations. The HepG2 cell line was not responsive to the RF signal when applied at standard temperature conditions. However, at a temperature of 38 ºC, the RF stimulus induced in HepG2 an antiproliferative response similar to that in NB69, the cultures reaching growth rates equivalent to those of controls incubated at 37 ºC. Additionally, the thermal treatment alone induced significant shortening of the S-phase in both lines, which resulted in significant acceleration in the cell cycle progression and increased cell number when compared to samples incubated at 37 ºC. The simultaneous treatment with RF neutralized this thermally-induced response, indicating that the electromagnetic and the thermal stimuli might exert opposite effects on cell proliferation and cell cycle progression. As a whole, the antiproliferative responses elicited in two different human cancer cell lines are not supportive of the hypothesis that repeated exposure to weak, RF electromagnetic signals in the GHz range can exert carcinogenic effects on transformed or initiated human cells. Further research would be necessary in order to elucidate whether or not the described, RF-induced cytostatic effects might be relevant to the potential development of emerging, electromagnetic-based therapeutic strategies.

Abstract

To study the exposure of the French population to 50 Hz magnetic fields (MF), two samples (children and adults) representative of this population were created. Each person wore an EMDEX II measuring and recording the MF to which he/she was exposed during 24h, and has progressively filled in a timetable and a questionnaire with information about themselves and their homes. When returning the meter, the pollster recorded the GPS coordinates of their homes.

In total, 978 series of MF were validated for children and 1054 for adults. The arithmetic and geometric means observed were respectively 0.09 and 0.02 µT for children and 0.14 and 0.03 µT for adults.

Introduction

The magnetic field (MF) at extremely low frequency (ELF) have been suspected, for around 30 years, to be responsible for several pathologies in humans, more precisely, childhood leukemia (Wertheimer et al., 1979). In 2001, the International Agency for Research on Cancer (IARC) classified ELF MF in the category II-B ("possibly carcinogenic to human").

The last collective assessment by international expert groups (WHO 2007, SCENHIR 2009) concluded that the last major questioning concerning ELF MF is the statistic correlation observed in several meta-analysis between the increase of childhood leukemia risk and a MF exposure higher that 0.4µT in means over 24h (Ahlbom et al., 2000), without any causal relation.

The exposure of the French population to these types of fields is known only very approximately. In 2007 the Health Ministry initiated a study about the exposure to 50 Hz MF of a representative sample of the French population (1000 children from 0 to 14 years and 1000 adults of 15 years and over). We present here the results of this study called "EXPERS" for EXposure of the PERSson.

Material and methods

Recruitment of the volunteers

One of the problematics linked to this study was to create a sample of 1000 children and 1000 adults based on random sampling method. For this a call for tender was launched and MV2 Conseil was chosen to conduct this work and collect the data.

This phase of data collection was conducted in 3 campaigns (February-April 2007, October 2007-April 2008 and October 2008-January 2009).

MV2 created a database made up of a file with 95 362 phone numbers taken in a totally random way from the general file of phone numbers attributed in France, except professional phone numbers. The selection of individuals was based on these numbers, respecting the distribution of the population in the 22 regions[1] of metropolitan France according to the 2006 census (www.insee.fr).

Data collection

Each volunteer recruited wore an EMDEX II (Enertech, USA) measuring and recording every 3 seconds the 40-800 Hz MF during 24h. Figure 1 gives an example of measurements recorded by a volunteer.

Among the equivalent models on the market, we chose this meter because it enables the distinction between the 50 Hz component and the harmonics, which is useful in analysing the different sources of MF. Moreover, we have checked that it was not disturbed by electromagnetic fields emitted by GSM. (Magne et al., 2006).

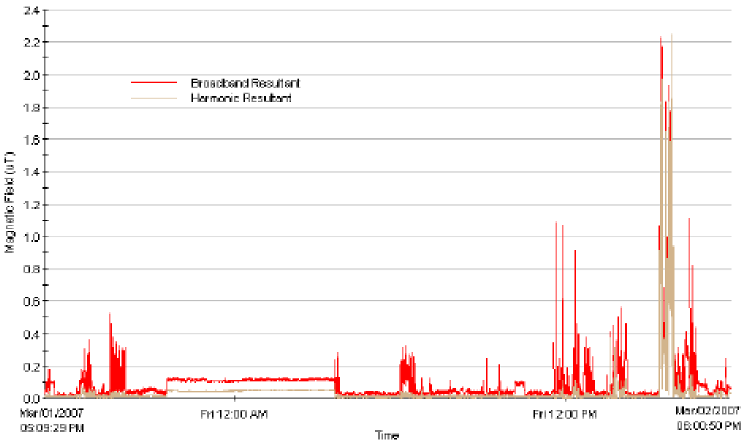

Figure 1. example of MF record for a volunteer.

Each volunteer progressively completed a timetable in which he noted his activities, with starting and ending time, the location and the electric appliances used.

When returning the meter, the pollster filled in with the help of the volunteer a questionnaire containing information relative to the volunteer (age, sex, profession, …), his home (year built, number of years spent in the home, number of people living in the home, energy type, heating method of home and water, …)

[1] France is divided into 22 regions and 96 departments.

He also noted the GPS coordinates at the volunteer's home front door. These coordinates were transmitted to ERDF (the French electricity distribution network operator) and RTE (the French electricity transport network operator) in order to identify all the electric networks close to each home. The criteria of identification of electric networks around homes are given in another communication (Magne et al., 2010). The results given here concern overhead and underground high voltage networks, from 63 to 400 kV, and the electrified train networks (data June 2009).

Description of the database

The number of volunteers having participated in the MF measurements was 2 148 (2.25 % of the phone numbers called). In total, the information relative to 2 048 people (989 children and 1 059 adults) was validated by MV2 Conseil.

When looking at the distribution of the database created, we notice that 11 departments out of 96 are not represented (note that we did not fix any quota per department).

After checking the compatibility of MF series and timetables, 16 series were deleted. The sample analysed was composed of 978 children and 1054 adults.

Results

Descriptive analysis

The arithmetic means (MA) and geometric means (MG) observed are respectively 0.09 and 0.02 µT for children and 0.14 and 0.03 µT for adults. Figure 2 gives the distribution of MA for both populations.

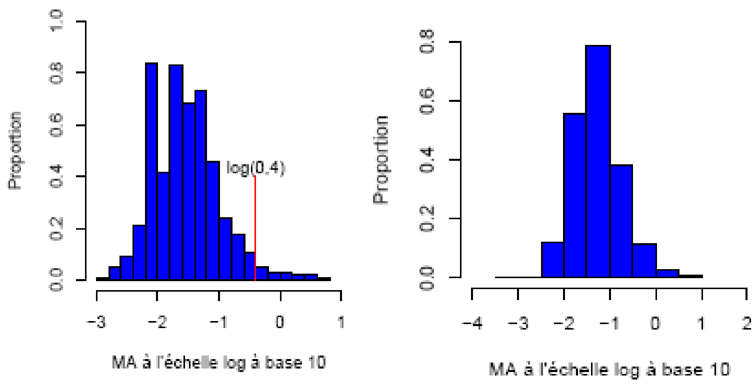

Figure 2. distribution of MA over 24h (children/adults).

On the whole, 3.1% of children observed an arithmetic mean higher than 0.4 µT. Two of them observed a geometric mean higher than this value.

When considering the exposures outside the period of sleep, the mean exposures for children are 0.05µT (MA) and 0.02 µT (MG). Eleven children (1.1%) have recorded a MA higher than 0.4 µT.

The mean exposure for adults are 0.10 µT (MA) and 0.03 µT (MG).

A comparison of mean exposures was performed for both populations with the help of rank tests. Figure 3 gives an example.

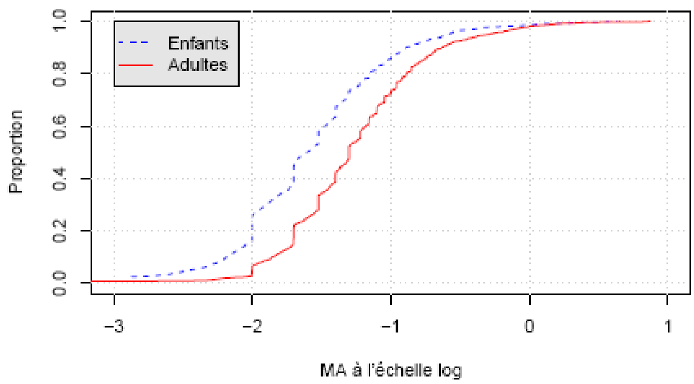

Figure 3. distribution function of 24h MA for children and adults.

The results show that:

- children are less exposed than adults,
- children are more exposed at home than outside, while it is the opposite for adults,
- at home, both populations are more exposed during the day than during the night (it is the opposite for adults in MG),
- regarding electric networks:
  - for both populations, the mean exposure (at home and over 24h) are higher for the volunteers living close to electric networks than for those living far away from these networks,
  - the MA (at home and over 24h) are not different for children living close to high voltage networks and for those living close to train networks,
  - the MG at home (with and without sleep period) are higher for children living close to high voltage networks than for those living close to train networks (it is the opposite for MG over 24h),
  - the MA and the MG (at home and over 24h) are not different for adults living close to high voltage networks and for those living close to train networks,
- people living in Ile-de-France are more exposed than in the other regions.

Characterization of the exposures

We are seeking to characterize the mean exposures in function of the data collected. A study on the data of the first phase has shown that there exists relationships of dependence between the mean exposures and some explicative variables. In order to characterize theses structures, we chose firstly linear models. These models gave very low levels of explained variance. This can be explained by the fact that the studied variables are not the only ones to influence the exposure, or by the fact that the relationship is not linear. For further analysis, we thus decided to use non parametric multidimensional models.

The factors identified as influencing the mean exposure are:

- the age,
- the density of population of the department,
- to have placed the EMDEX II close to a clock radio (for 24h exposure),
- living in a city of more than 2 000 inhabitants,
- living in a building,
- the presence close to the home of overhead power lines or of electric train networks,
- the time spent on a computer,
- the time spent in shopping centres,
- the time spent on train transports,
- the time spend in non-electric transport,
- the time spent at school.

All are not factors influencing both populations, nor both means, nor exposure over 24h and outside period of sleep.

The level of variance explained remains very low (between 10 and 30 %). The models obtained are thus non predictive.

Search of exposure classes

We are seeking to separate the population studied in several classes, by regrouping those who have the most similar exposures. Each series of MF is described by 7 indicators: maximum value, 3rd quartile, MA, MG, median, standard deviation and RCMS (Rate Change of Metric Standardized, indicator measuring the temporal variability of the signal). A hierarchic classification is then applied on these indicators centered and reduced.

Figure 4 gives an example of dendogram of classification. For each population and each scenario (24h or outside period of sleep), we chose 3 classes of exposure.

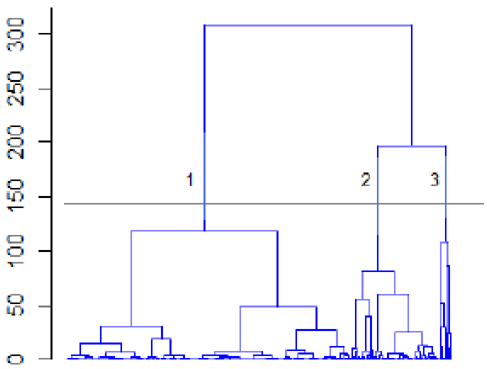

Figure 4. example of classification (exposition aver 24h for adults).

After we used a logistic regression in order to identify the variables leading a subject to belong to the most exposed class. The results depend on the scenario, type of mean and population considered.

The main factors which increase the probability to belong to the most exposed classes are:
- to have placed the EMDEX II close to a clock radio (for 24h exposure),
- the presence close to the home of overhead power lines or of electric train networks,
- living in a city of more than 2 000 inhabitants and the density of population of the department (for adults),
- the time spent on train transports,
- the time spent in shopping centres (for adults).

The main factors which decrease the probability to belong to the most exposed classes are:
- the time spent in non-electric transport,
- the time spent at school.

Discussion

The mean time to recruit one volunteer was 70 minutes. The recruitment of children was even more difficult than those of adults. This led to modifying the recruitment protocol by privileging children from the second campaign.

Tests of homogeneity have been performed in the 11 departments without subjects comparing to the corresponding regions: we looked at if the probability of selecting an individual in these departments is the same as the probability of selecting an individual in the corresponding regions. The statistical tests show that the fact of having no volunteers in these 11 departments is completely by chance.

One the one hand, the analysis of volunteer profiles does not show any difference in the ratio boy/girl in the children compared to the French population. On the other hand, women are more represented than men in our sample. In the same way, the profile of ages show a deficit of children under 6 years of age, and a surplus of 35 to 50 year old adults. This can be explained by the modification of recruitment protocol: we suggested to the adult to record the measurements at the same time as the child, often it was probably the mother who accepted.

On the whole, 3.1% of children observed an arithmetic mean higher than 0.4 µT. Two of them observed a geometric mean higher than this value. These percentages are higher than what is given in the literature, that is why we have tried to explain these high exposures. This phenomena has appeared during the first measurement campaign. We have then noticed that the high exposures corresponded to signals with values which were sometimes high (several µT) and constant during the night, and a ratio of harmonics around 1/3. These signals corresponded to magnetic fields emitted close to clock radios. Additional investigations into clock radios have shown that:
- the MF level vary strongly from one model to another,
- the MF source is the transformer, which is located in the clock radio or deported in the socket,
- the level of MF decrease very rapidly with the distance,
- at 50 cm, the magnetic field emitted by the clock radio is negligible.

So the highest 24h measurements can be explained by the presence of clock radios during the night. But are these measurements representative of the exposure of the person? In order to avoid measuring MF in contact with clock radios, we asked in the following campaigns to respect a distance of 50 cm between the EMDEX II and any electric appliances during the night, and we asked the volunteers whether they had respected this requirement. All did not do it!

When considering the exposures outside the period of sleep, 11 children (1.1%) have recorded a MA higher than 0.4 µT. This result is coherent with the literature.

The 24h measurements may thus include a measurement bias which overestimates the exposure. That is why we studied the exposure over 24h and the exposure outside the period of sleep.

Conclusions

Beyond the difficulties encountered by MV2 Conseil to perform the measurements, we can remember that 3.1% of the children have observed an arithmetic mean higher than 0.4 µT. The main exposure sources for these high exposures are clock radio (the real exposure of the person was overestimated). When looking at the exposures outside the time of sleep, 1.1% of children have observed an arithmetic mean higher than 0.4 µT. This value is consistent with the literature.

Children are less exposed than adults. An explanation could be the fact that they move less during school periods.

With the descriptors calculated on the series, each type of population is divided in 3 classes of exposure. The factors identified in terms of higher means or belonging to most exposed classes are mainly having put the EMDEX II close to a clock radio, having his home close to overhead power lines or to electric train networks, the time spent on train transports, in commercial centres, on a computer or watching television, living in a city of more than 2 000 inhabitants or in a building. These factors depend on the population considered (adult or children), the type of mean (arithmetic or geometric), and the scenario (over 24h or outside period of sleep).

The analysis of mean exposures has shown than the variables retained do not alone allow to characterize these means.

The work presented here will be continued by including the presence or not of distribution lines and substations. This information could improve the characterization of mean exposures in terms of explained variance.

Another possible use of these data is the validation of physical models of assessment of magnetic fields.

Acknowledgment

This study was funded by the Ministry of Health and Solidarities and conducted by Supélec, with the technical collaboration and financial support of EDF and RTE.

Abstract
In order to comply with the requirements on the exposure of workers to electromagnetic fields, numerical simulation is necessary because the currents induced in the body are very difficult to measure. Induced currents are computed by solving Maxwell equations by means of different numerical methods (FEM, BEM, FIT, etc...) operated on a panel of models of human body which are available with variable geometrical sharpness. To be able to compare the numerical accuracy of these models, we need to understand, for each numerical method, the impact of the quality of the meshing on the reliability of the maximal computed value of the induced current.

In this study, we apply four quality criteria on four types of methods working in the ELF domain, applied to one single mesh offering medium sharpness. By analyzing the maximal induced currents in a particular exposure case to vertical induction, we found that the efficiency of our criteria is highly dependent on the method of resolution in parts of the body which are too coarsely meshed.

Introduction
The European Directive 2004/40/CE dealing with electromagnetic fields for workers defines two reference values: the AV (Action Value) which is a warning threshold, and the ELV (Exposure Limit Value) which have not to be exceeded for biological reasons. We can compare both values via simple models such as on Fig. 1.

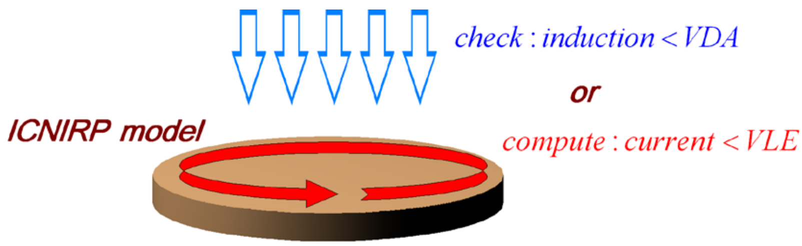

Fig. 1. Simple ICNIRP exposure model illustrating AV and ELV.

The magnetic and electric field can be easily measured *in situ* and then compared with the AV which is $500\mu T$ at $50 Hz$ for the magnetic induction and $10 kV/m$ for the electric field, while the ELV corresponds to the RMS value of the current density averaged over $1 cm^2$ surface normal to the current vector, and is considered only in the CNS (Central Nervous System). To evaluate such a value inside the body, and compare it to the $10 mA/m^2$ threshold, not only a numerical simulation is required, but the computation must ensure reliable results all over the CNS organs, which depends on the association of a robust resolution method and a anatomically realistic modelling of the body (Ducreux et al 2009).

The numerical methods to solve Maxwell equations in ELF domain

In order to so solve the Maxwell equations for the induced currents in the human body at 50 Hz, we considered four different formulations : two of them are general purpose FEM (Finite Element Method) for industrial applications of the QSA domain (Quasi-Static Approximation), the third one is a dedicated method derived from the first one, and the last one is derived from the FIT (Finite Integration Technique).

Formulation 1: general purpose magnetic FEM “A-Phi”

The unknowns are the magnetic vector potential $\mathbf{A}$ in the entire space and the scalar electric potential φ in the body. The computer code we used for that formulation is *Code_Carmel3D* (Henneron et al. 2007), which is well fitted to magnetic hysteretic media in electrical machines accounting rotation and circuit coupling. That method is the most ancient and the most practised in ELF domain of electrotechnics.

Formulation 2: general purpose electric FEM “T-Omega”

The unknowns are the electric vector potential $\mathbf{T}$ in the body and the scalar electric potential Ω in the whole space. The tools we have selected for that formulation are *Code_Carmel3D* and Maxwell3D (Miller et al. 2008). That second method is comparable with the first one, while in this context it seems to be more accurate, as it ensures strongly the normal continuity of the vector current at interfaces (which is much more interesting than the analogous condition on the magnetic flux density imposed by the A-Phi formulation).

Formulation 3: a human body dedicated magnetic FEM “Phi-A”

In case of human body, the magnetic vector potential $\mathbf{A}$ depends much more on the incident field than on the induced currents. So it may be sufficient to compute the electric scalar potential φ in the body in response to an incident magnetic potential vector $\mathbf{A}$ associated with the incident field, considered as a volume source term. The resulting advantage is a very cheap computation. The code we used for that formulation is an academic one, based on the library Getfem++ (Renard et al 2010).

Formulation 4: a « FEM-like » Finite Integration Technique

Generally, the FIT is devoted to the high frequency domain, because it solves the complete Maxwell equations, and moreover it can work directly with short wavelengths on the high resolution voxel-phantoms. Recently, this method was made usable with linear tetrahedrons, within non-structured meshes, by running the CST-EM Studio code

(Weiland et al 2008), and in addition, a low frequency domain solver is now proposed, so that the FIT can easily compete in our human body ELF benchmark.

Benchmarking our formulations on a simple meshing test case

First we compared the formulations on a very simple problem, i.e. an non-magnetic ellipsoïd with an homogeneous conductivity of $0.2\ \mathrm{S/m}$, subjected to an uniform $50\mathrm{Hz}$ incident magnetic induction of $500\mu\mathrm{T}$ directed along the small axis shown on Fig.2.

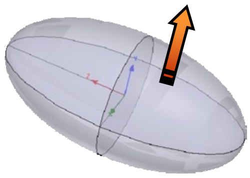

Fig. 2. Configuration of the test.

For such a system, we easily obtain the following analytical expression of the maximal current $J_{\max}$:

$$J_{\max} = \omega B \frac{ab^2}{a^2 + b^2}$$

Where a and b are the major axes, B is induction and ω its angular frequency. Then we can evaluate the impact of the mesh refinement on the local maximal value of the induced current computed with the four formulations. For that purpose, we treated different axis dimensions for the two types of meshes of Fig. 3.

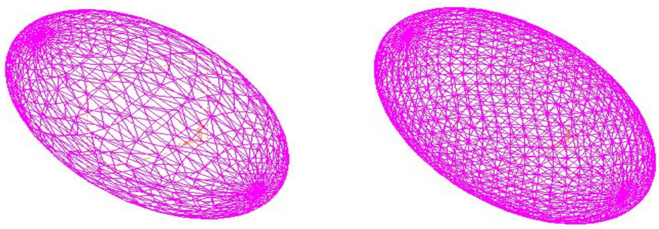

Fig. 3. Coarse mesh (3000 tetras) and fine mesh (15000 tetras).

As we can see on Table 1, the refinement of the mesh fit the formulations when they are of the same family (i.e. 1 with 4 and 2 with 3) but it cannot make all the four formulations converge to the exact result.

Table 1. Maximum induced current density ($\mathrm{mA/m^2}$) : case of the 60x30 cm ellipsoid.

	Formulation	Coarse mesh	Fine mesh
1)	Carmel ($A-\varphi$)	8.29	5.30
2)	Carmel ($T-\Omega$)	5.46	5.18
	Maxwell3D ($T-\Omega$)	4.87	5.18
3)	Getfem++ ($\varphi - A$)	7.50	5.30
4)	CST (FIT)	6.04	5.19
Analytical solution		**5.30**	

Benchmarking our formulations on a particular human body model

The « formulation sensitivity » that we found in the above elementary test is much more significant on a realistic human body mesh such as shown on Fig. 4.

Fig. 4. Studied human body mesh (provided by Ansoft).

This model contains around 100000 tetras (70% for the body) and 21 organs for which we can see on Fig. 5 that their size, shape and conductivity are ill-assorted.

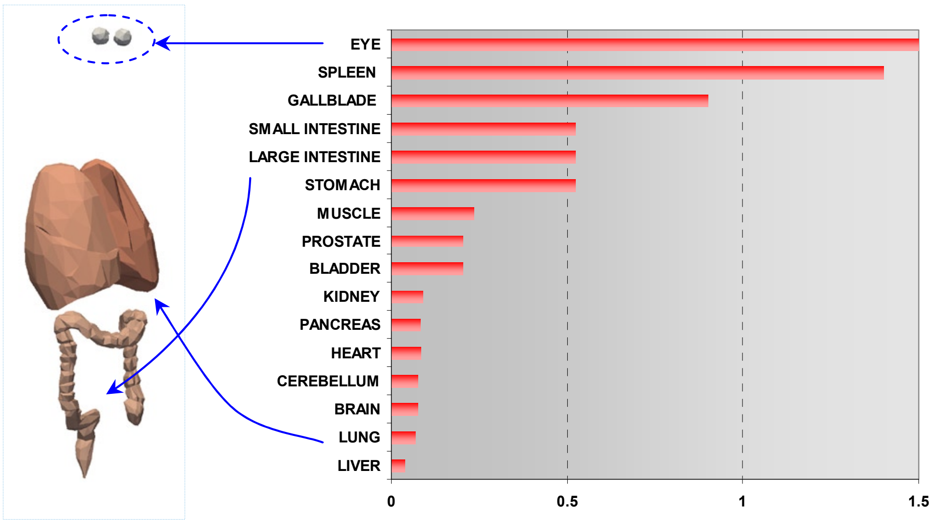

Fig. 5. Some components of the human body model and their conductivity (S/m).

Assuming a uniform vertical incident field of $1\,\mu T$ at $50 Hz$, we computed the maximal induced current in each organ obtained by the four formulations. The results show important discrepancies (see “EYE” on Fig. 6), which are not located into the high conductivity organs only (see “PROSTATE” and “PANCREAS” on Fig. 6). In all the conductive organs, the two general purpose formulations 1 and 2 are relatively close together compared to the derived formulations 3 and 4. Nevertheless, Fig. 6 shows that formulation 1 and 2 differ in the muscle, that suggest some meshing effect (muscle has a complex shape because it is defined as the whole body less all other organs).

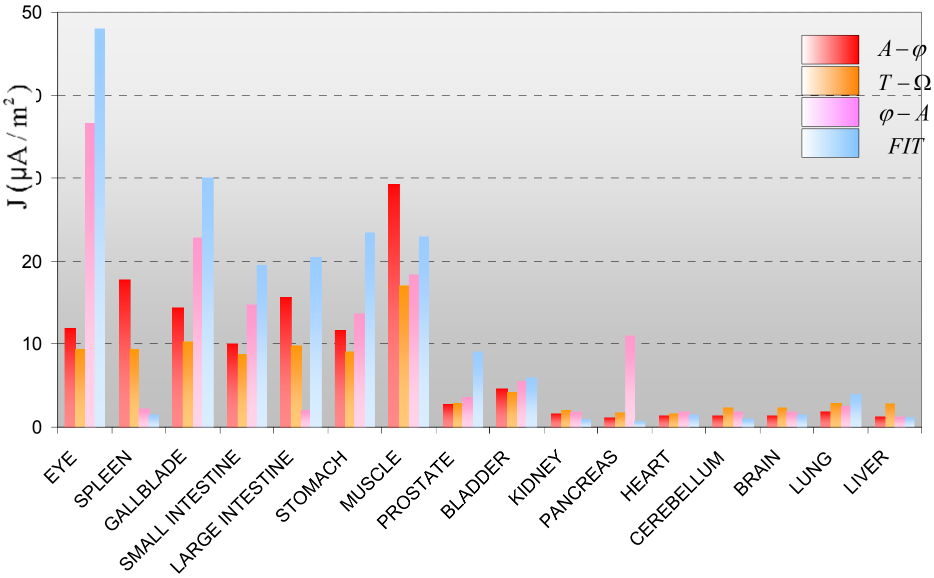

Fig. 6. Maximum induced current density in organs.

Post-processing of the results using mesh quality criteria

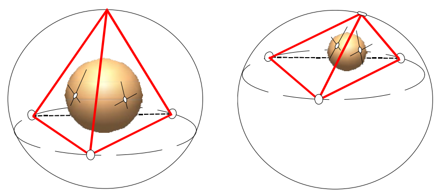
In order to quantify the impact of the mesh quality and of the formulation on the reliability of the maximum computed current, we can use local error estimators. As the computation provides one current value for each tetrahedron, we associate the local error with a so called "quality criterion" assigned to each tetrahedron, which can be estimated "a priori" or "a posteriori" (i.e. before or after the computation) – see table 2.

Table 2. "A priori" and "a posteriori" error estimators.

Error estimator	a priori	a posteriori
mesh dependant	geometrical	statistical
formulation dependant	spectral	energetical

A priori geometrical criterion

This very well known criterion is based on the shape of the tetrahedron. It is build with the ratio of the radius of in-sphere R_{int} to the radius of circumscribed sphere R_{ext} as shown in Fig. 7. So the quality q is unity for an equilateral tetrahedron and is zero for a flat one (*sliver*).



$$q = 3\frac{R_{int}}{R_{ext}}$$

Fig. 7. Example of a "good" and of a "bad" tetrahedral geometry

A priori spectral criterion

This criterion is based on the numerical conditioning of the elementary matrix. In that sense, it includes some physical properties of the problem, such as the static or dynamic nature of the magnetic response. Hereafter the elementary matrix for the $A-\varphi$ formulation is considered (the dynamic term is the one which depends on the skin depth δ). N_A and N_φ are respectively the edge and nodal shape functions for tetrahedra:

$$\mu M(\delta) = \begin{bmatrix} (rotN_A)^2 & 0 \\ 0 & 0 \end{bmatrix} + \frac{i}{\delta^2} \begin{bmatrix} N_A^{\ 2} & \frac{1}{i\omega} N_A^T gradN_\varphi \\ \frac{1}{i\omega} gradN_\varphi^T N_A & \frac{1}{\omega^2}(gradN_\varphi)^2 \end{bmatrix}$$

Once the above matrices are gauged, we easily compute the non-zero eigenvalues (there are 3 non-zero eigenvalues for the first static matrix and 6 for the second dynamic matrix). Then we deduce the condition number ρ and draw the static and dynamic quality criteria q by the following classical form :

$$q = 1 - \left(\frac{\sqrt{\rho} - 1}{\sqrt{\rho} + 1} \right)^2$$

We found that for the $A-\varphi$ formulation, the static and dynamic criteria are very similar except for very large distortions for which the static criterion is slightly more selective. Moreover, after a scaling of 30% accounting that “perfect regular” shape is equilateral for geometrical quality and rectangular isosceles for spectral quality, one observes (Fig. 8) that both “a priori” criteria are quite similar. This fact can be explained by arguing that for flat elements have a nearly singular jacobian matrix, which is used for computing the derivatives of shape functions. Therefore, the more the jacobian matrix is close to be singular, the more the resulting elementary matrix will be ill-conditioned.

Fig. 8. Bad elements selected by “a priori” criteria : geometrical (a), spectral (b) for the A-Phi formulation.

A posteriori statistical criterion

This criterion is based on the distribution of the values computed for the entire mesh. Generally, it can be assumed that the few last percentiles of the distribution are non-significant because these extreme values are due to a poor numerical behaviour of the badly shaped elements. This very simple approach works in most cases.

As expected, the rejected poor elements depend on the formulation. The Fig. 9 compares the last deciles of the current obtained with both general formulations $A-\varphi$ and $T-\Omega$, and exhibits an exploding divergence for the last 2%, what implies that aberrant elements are sensitive to the formulation : on Fig. 10 (a), the tetrahedrons filtered with $A-\varphi$ are mainly located in the interior of the body, so they are supposed to be bad elements, while on Fig. 10 (b) the same filtering with $T-\Omega$ eliminates some tetras on the surface of the trunk, although they seem to be "true" high current elements.

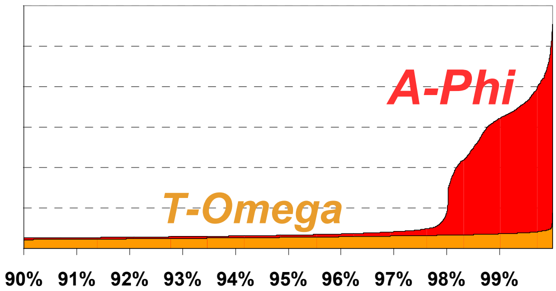


Fig. 9. Diverging last decile of currents distribution.

A posteriori energetical criterion

This criterion is based on the detailed comparison of both general formulations $A-\varphi$ and $T-\Omega$, which are supposed to bound the exact solution (Ren et al, 2002). A measure of the distance between both solutions may be evaluated for each tetrahedron via some energetic normalisation of the residue of constitutive laws, either conductive or magnetic, such as defined in last column of Table 3.

Table 3. Combination of solutions for the constitutive law checking.

formulationr	solution field	derived field	constitutive law
$A-\varphi$	$B_{A-\varphi} = rot\ A$	$E_{A-\varphi} = -i\omega A - grad\varphi$	$J_{T-\Omega} = \sigma E_{A-\varphi}$
$T-\Omega$	$J_{T-\Omega} = rot\ T$	$H_{T-\Omega} = T - grad\Omega$	$B_{A-\varphi} = \mu H_{T-\Omega}$

We can adjust that norm so that the quality criterion on each element returns unity if the residue is null and returns zero if the relative residue is for instance more than 100%. We found the second criterion (magnetic law) is unity in the whole body, what justifies the basic hypothesis of the $\varphi-A$ formulation, i.e. scattered induction is negligible before the incident one. Moreover, we can note on Fig. 10 (c) that the first criterion (conduction law) is much more selective than the statistic criterion, what indicates that both "a posteriori" criteria are far to be equivalent.

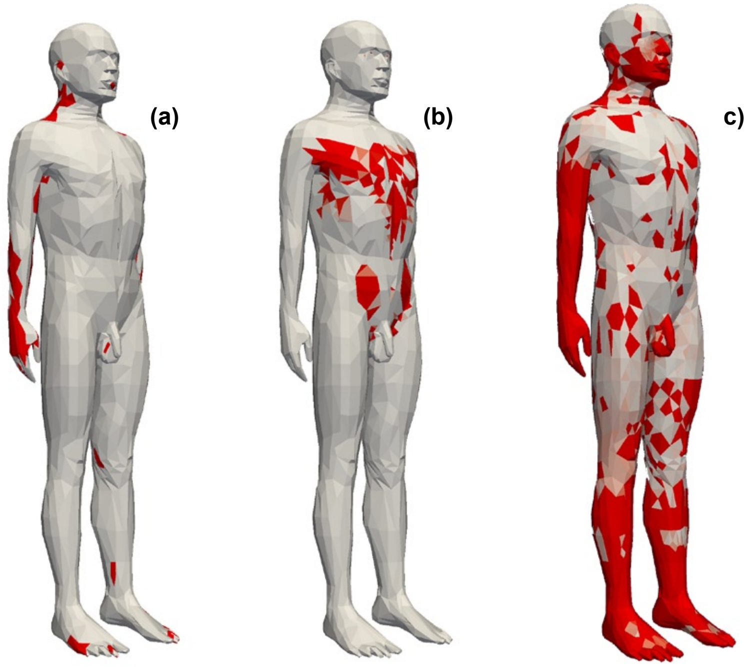

Fig. 10. Bad tetrahedrons selected by our "a posteriori" criteria : statistical A-Phi (a), statistical T-Omega (b), energetical (c).

As pointed before, the case of the muscle is very particular, since in our computational phantom, it is meshed as the complementary volume of other organs, each of them presenting more or less a convex geometry. Therefore, there are a lot of thin interface layers, such those spotted on Fig. 11. There interfaces are not clearly detected as badly meshed by our "a priori" criteria, but reveal nevertheless a poor "a posteriori" quality, as shown on graph of Fig. 11.

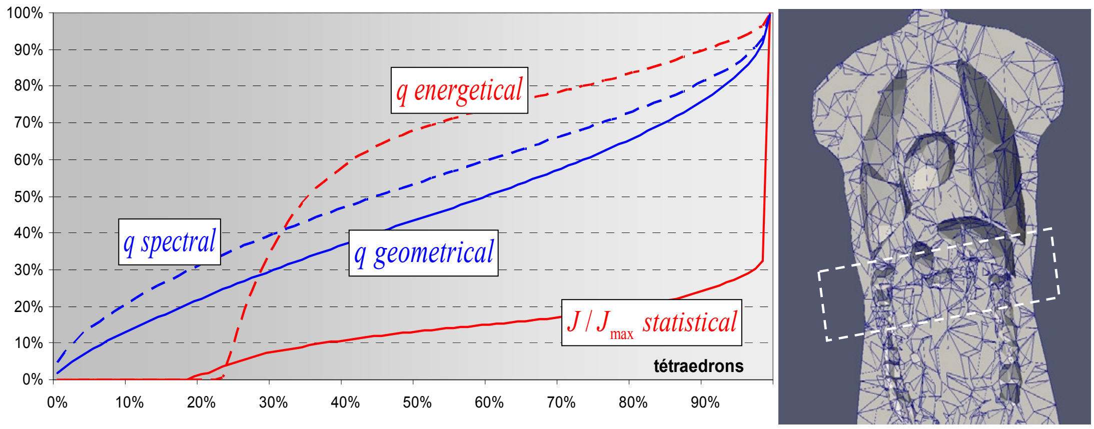

Fig. 11. Case of the "muscle" region. Left : distribution of criteria and right: cut plane in the muscle organ including narrow layers interfacing heart / left lung / intestine / liver / right lung.

Conclusions

Several finite element models of human body and different formulations are available to solve the problem of induced currents by ELF electric and magnetic fields. But till now, there is no general consensus on what combination formulation + mesh is able to provide a reliable maximal current.

We applied four existing formulations on a single human body mesh, two of them working in general purpose codes, the two others being adapted from Maxwell equations to ELF human body configuration. We noticed some discrepancies between results of these formulations, mainly in the high current zones (conductive organs) and in the badly meshed parts of the model.

Then, we defined four quality criteria in order to post-process these results, two of them so-called "a priori" depending on the mesh and the two others called "a posteriori" depending on the results. We found that the "a priori" criteria detect the bad shaped elements but not the high current elements. The "a posteriori" criteria can detect both the contorted elements and the high currents elements at a time, but they are highly sensitive to the formulation in complex organs such as muscle. For that reason, a mesh refinement should be tried in the inter-organ zones before testing energetical criteria.

Abstract
Electromagnetic radiations may interact with biological tissues by the way of biomedical devices for therapeutic or diagnostic purposes (hyperthermia, ablatherapy, NMRI,…). Another situation is related to electromagnetic fields sources in the daily life such as mobile or public or domestic devices. Many studies are currently done to determine their potential effects leading sometime to controversy between the published results. The electric properties of biological tissues are frequency dependence and major parameters that governs these interactions inside the human body.

Techniques for both invasive and non-invasive assessment of tissue characterization were proposed since many decades. Different methods are used to determine them among which the so called bioimpedance.

This paper presents and discuss results of ex vivo measurements on mammalian tissues done less than two hours after excision in a surgery department at the Nancy Cancer Center (France). Dielectric permittivity and electrical conductivity of female breast human tissues in the frequency range from 1 MHz to 1 GHz were measured. They are compared to previously published results and the differences discussed according to the influencing parameters.

Introduction
Interactions between electromagnetic field (EMF) and biological tissue find applications in therapeutic or diagnosis methods. On the other hand, development of devices radiating electromagnetic field, like mobile phone, led to the questions of their possible biological effects. These so called EMF bio-effects have led to controversial models for electromagnetic (EM) dosimetry simulation. One reason is that these models are depending on the knowledge of the electric characteristics of the human body. Electromagnetic properties of biological tissues are thus fundamental parameters necessary for any research in bioelectromagnetics.

Many techniques and methods for measuring the bio impedance exist and are primarily motivated by the frequency band of interest (Burdette & Cain, 1980 ; Foster & Schwan, 1996). Interest in the EM properties of biological tissues began more than one century ago (Schwan & Kay, 1957 ; Foster & Schwan, 1986). Bioimpedance spectroscopy is one of the no-destructive, low-invasive and most promising techniques for biological tissues characterization (Rigaud et al, 1996).

Up to now, the values provided by the literature are not always reliable since these data are sparse and disseminated over the frequency range with great variations even for a same biological organ (Gabriel et al., 1996 ; Surowiec et al., 1985). This is not the only major factor and other parameters had to be taken into account for reliability of the experimental results . Moreover, the measurements taken from a sample are likely to be affected by multiple influencing factors such as the contact with the membrane, the temperature at which the measurement is performed, the pressure on the sample, duration post mortem or the structure of the tissue.

The measures on biological tissue are particular for two reasons : firstly because of variations between the samples under test, on the other hand because of the diversity of influencing factors and the non-availability of references for the sensor calibration (Nadi, 2008). Bio impedance measurements need to compensate for the influencing factors related to biological aspects and those related to metrology and instrumentation. This is a crucial factor at low frequency. The dielectric behaviour of biological tissues is dependent on their nature and on the frequency of interest (Schwan & Kay, 1957). They are deformable, heterogeneous, anisotropic and may be solid or liquid. As example of the parameters influencing the measures, the temperature is one whose effects on the variations of the conductivity and permittivity have been previously investigated and is now well known (Foster & Schwan, 1996 ; Jaspard & Nadi, 2002). Precautions taking account of these influencing parameters are required to ensure metrological reliability of the results by adequate corrections.

Comparative studies remain thus a real challenge. In this paper, ex vivo dielectric data are presented and discussed for female breast tissue.

Material and methods

Measurement cell

The experimental set up is based on a material analyser (HP 4291A). Its measurement cell was modified to allows measurement of small biological samples (Gagny, 1998). Data acquisition is done throught an IEEE connection to a PC. This material analyser works on an original method V/I extended to a large frequency band, up to 1 GHz. The main principle of the cell is similar to the geometry proposed by Von Hippel (Von Hippel, 1954).

The experimental set up and the measurement cell are presented on figure 1 & 2. It is constituted by two circular electrodes of which the upper one could be adjusted throught a precision micrometer. The lower electrode is surrounded by a ring guard and ground planes.

Cell for measuring ex vivo samples

A small support (relative permittivity of 1.1 ; loss tangent δ 0.01) permit to fix the position of the sample on the edge outside the circular lower electrode (Gagny, 1998) in order to cover it completely. According to the cell manufacturer specifications the optimal dimensions of the sample placed in the middle of the measurement cell have a diameter higher than 15 mm and a thickness equal or less than 3 mm. This is one of the technical influencing parameters that could affect the reproducibility but it is not discussed here.

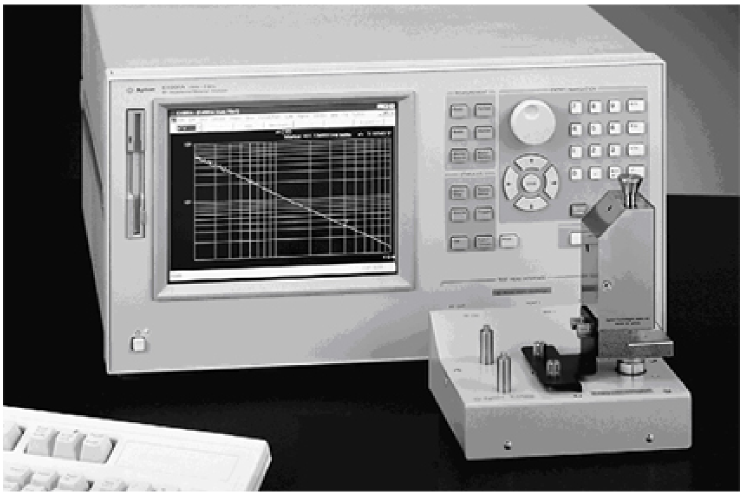

Figure 1.View of the material analyser HP 4291A and the measurement cell.

Eight tissues samples used in this ex vivo study were obtained from surgical ablation procedure on female breast tumor performed in the Cancer Center at the University hospital of Nancy (Gagny, 1998). The samples were excised in tissues surrounding and inside the tumor in the thirty minutes following the surgical procedure by the surgeon. Dimensions of the samples obtained were limited by the clinical constraints since they were given to us on the side to the medical analysis. The necessity to preserve the quality of the tissues excised for biological and medical analysis of the tumor effective excision is one of these constraints. The measurements were performed at ambiant temperature in the maximum of two hours following the surgery, the experimental set up being placed in a room close to the surgery department.

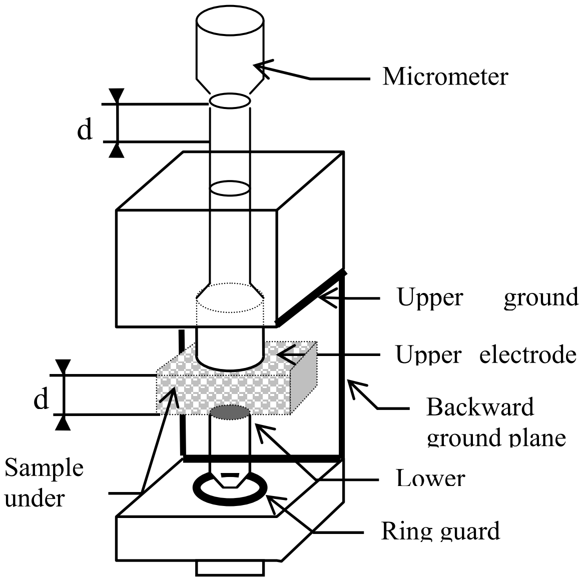

Figure 2. Modified measurement cell for ex vivo electromagnetic characterization.

Method

The instrumentation measures a complex admittance of a 3 points calibrated cell in which the sample is inserted between the two circular electrodes. Theoretical model of the measurement cell allows to solve the inverse problem in order to deduce the permittivity and the conductivity from the measurements. The electric parameters are deduced from the real and imaginary parts of the measure.

$$\varepsilon_r^* = \frac{Y_m^* . d}{j\omega \varepsilon_0 S(1+E_{edges})}$$

where

$E_{edges} = 454 . d^{0.825} . \varepsilon_r^{-0.554}$ is a factor for compensation of edges effect

d : distance between the electrodes [m]

ε_r^* : complex permittivity

Y_m^* : complex admittance

ω : pulsation [rad/s]

ε_0: vaccum or air permittivity

S : surface of the circular electrodes [m^2]

In the low frequency band, one must take account of major influencing parameters such as the well known phenomena of electrodes polarization (Foster & Schwan, 1986). Other metrological parameters like the difficulty to calibrate the measurement cell, the variations of biological parameters such as the anisotropy and heteregoneity of the samples affect the reproducibility of the results.

One advantage of the material analyser HP 4291A is that it operates with the V/I procedure extended in a broad band, typically from 1 MHz up to 1 GHz. The automated data acquisition permit to scan this broad band with a logarithmic step giving 201 frequency between 1MHz et 1GHz. All measurements were made between 21 and 25 °C.

Results and discussion

Ex vivo samples

A systematic spectroscopic measurements were done for different samples and compared to the previous results obtained by other authors.The samples were classified according to their nature (muscle, fat) and dimensions. We present below the mean value deduced from measures done on a single sample (mostly non fat) and the mean value for measures on three similar samples with different dimensions and structure (mostly fat).

Measurement of electric conductivity and dielectric permittivity

Among the datas obtained with our method, only the results that could be compared to others for ex vivo human breast are presented on this paper. Measurements for permittivity and conductivity of breast muscle and breast fat samples are presented on figure 3 & 4 and compared to those from Schwan (Schwan & Kay, 1957 ; Stoyes et al.,

1982 ; Foster & Schwan, 1986), Joines (Joines et al., 1994) and Gabriel (Gabriel et al, 1996). One goal is to check the high differences that can be observed between results from one research team to another in the low frequency range.
Concerning our results, as explained above, a spectroscopic logarithmic measures were done between 1 MHz and 1 GHz. For the clarity, the standard deviation is given only for 15 points.

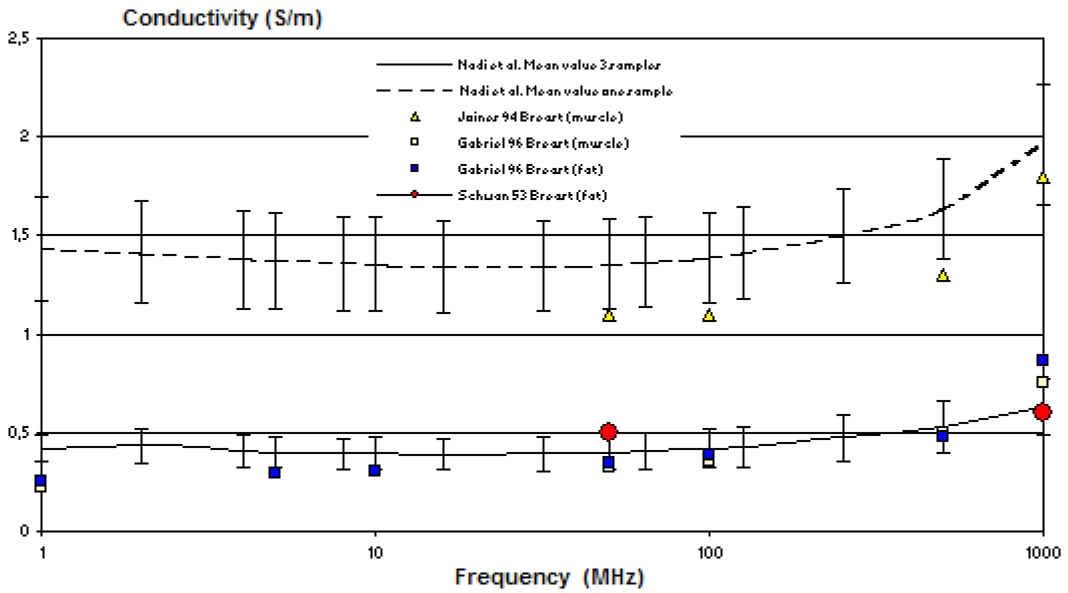

Fig. 3. Electric conductivity of muscle and fat from female breast samples versus frequency compared to previous datas

One can observe that the set of measurements obtained with the mean value from different samples (mostly fatty) is similar to the results given by Schwan (fat) and Gabriel (muscle and fat). However, on can observe that Gabriel's measures on fat and muscle breast are very close. The difference between her datas for fat and muscle are less different than between Joines datas for muscle and her datas for muscle even at high frequency. This is strange and we have no explanation for such high difference.

A mean value was deduced from a set of measures on the same sample (mostly muscle, plain line). The second curve (dashed line) corresponds to the mean value obtained from three different samples and are far from those of Schwan (fat) and Gabriel (muscle and fat). Joines (muscle) datas are also overestimated compared to the other results. However his datas seem similar to our results obtained by mean value on one sample (mostly muscle).

The most important differences for both the conductivity and the permittivity are situated below 10 MHz. It is well known that in this frequency range current conduction through tissue is mainly determined by the tissue structure, i.e. the extra- and intra-cellular compartments and the insulating cell membranes. Thus the nature of the biological tissue is more sensitive at low frequency. On the other hand, the polarizarion effect on the electrodes is also more important below 1 MHz.

Obviously, according to the conditions of both the procedure and the preparation of the sample and its nature, the time after excision, it is normal to find such differences from an author to another.

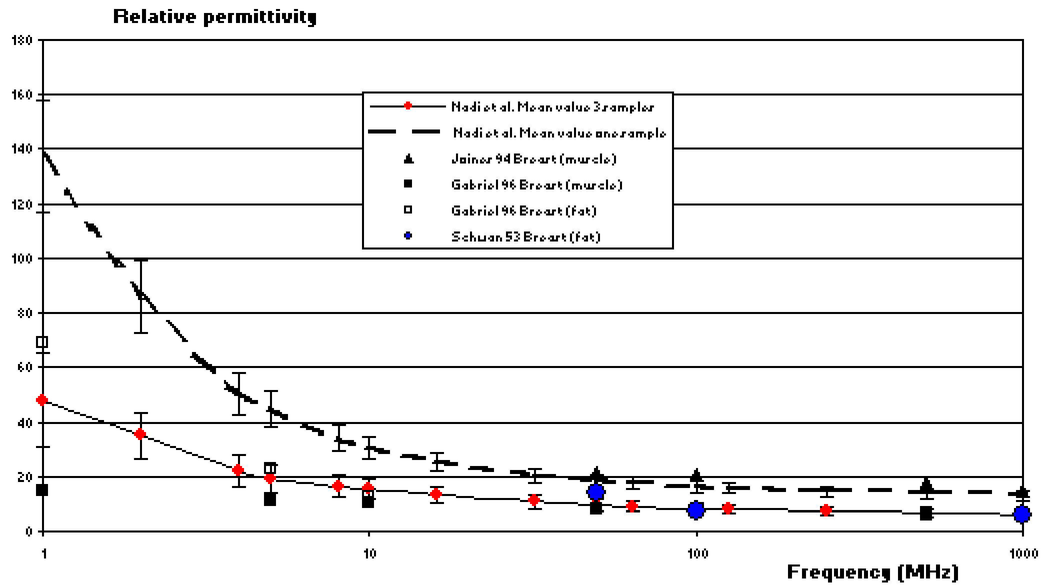

Fig. 4. Dielectric permittivity of muscle and fat from female breast samples versus frequency compared to previous datas

The fact that results are obtained by using different instruments, conditions and procedures (40's up to 80's for Schwan) could explain partly these differences. Schwan used for his early datas manual bridges that did not allow a systematic spectroscopic measurement. This is one reason why some of his first results are sparse and focused on specific frequency. Results from Gabriel were deduced by compilation of datas from the literature and measurements in her laboratory. Joines datas are not overestimated but the differences are certainly due to the nature of the sample used and its preservation after excision. These differences could be by evidence be explained by the importance of fat and muscle heterogeneity of the breast samples and their dimensions that have been used by each author. Over 10 MHz one can accept the hypothesis that all the values are in the same order for the permittivity but this is not true for the conductivity since the difference is greater than 100% between fatty and non fatty breast muscle.

Conclusion

Electric characterization of female breast samples measured ex vivo two hours after the surgery were presented and compared to previous datas. The electrical conductivity and relative permittivity of mammalian human tissues were measured at frequencies from 1 MHz to 1 GHz. The measurements were made using a material analyzer whose measurement cell was adapted to receive small human samples. All measurements were made between 21 and 25 °C.

These results were compared to previous well known datas. Obviously, the differences and variations are due to biological species under test as well as to the metrological difficulties due to the interface between the electrodes and the biological tissue at low frequency.

Metrological parameters affect the reproducibility of the results according to the medium under test and the procedure used by each research team. These differences and variations are due to biological species or organ under test as well as to the metrological difficulties related to the interface between the electrodes and the biological tissue). For mammalian tissues that interest us here, it is necessary to class their heterogeneity as fatty or non fatty since the difference could be over 100% from a sample to another. Other influencing parameters had to be taken into account. Experimental results cannot be rigorously compared as regard to the differences between the natures of the ex vivo sample under test and to the physical and metrological constraints. Comparative studies remain thus a difficult challenge. However, the measurements must stay inside a domain of confidence based on a mean value with standard deviation. At high frequency over 10 MHz, it is possible to admit that the permittivity values are of the same order for fat and muscle breast samples but this is not true for the conductivity.

Occupational exposure to electromagnetic fields in electrotherapy services and possible related health effects

Danulescu, Razvan; Goiceanu, Cristian; Balaceanu, Gheorghe; Danulescu, Eugenia
Institute of Public Health Iasi, Occupational Health Department, ROMANIA

Abstract

Aim: The assessment of possible adverse health effects in occupational exposure to electromagnetic fields (EMF) generated by electrotherapy equipments (ETE).

Methods: Exposure evaluation included ergonomical analysis and EMF measurements (static and low-frequency magnetic flux density, low- and high-frequency electric and magnetic strengths). Health status analysis comprised anamnesis, clinical and neurological examinations, exposure and subjective symptoms questionnaires. Psychological tests aim to put in evidence subtle changes of nervous system activity.

Results: 38 electrotherapists vs. 82 matched controls were studied. Magnetic and electric field measured levels generally didn't exceed ICNIRP Guidelines. However, when personnel get closer to the applicators, higher local exposure occurs. Hands and head seem to be the higher exposed. The number of treated patients and the different electrotherapy procedures induce variations in exposure duration. We met three generations of ETE and stray fields seem to be important in older ones. The newer devices show significant lower levels of non-intentional exposure. Health investigations show mainly nervous system subjective symptoms and signs (asthenia, memory and attention disturbances, irritability, vegetative disorders, headaches, dizziness, etc.). These findings seem to be more frequent in exposed and seems to be correlated with the exposure length.

Conclusions: Significant levels of EMF occupational exposure levels were found. Higher exposures are attributable to practice procedures, to peculiar electrotherapy procedures, to bad positioning of ETE, and to older generations of ETE. The lack of risk knowledge is an important factor for some exposure situations, but it could be corrected. Health findings point out to possible effects at higher levels but further studies should be done. Risk awareness policies are to be performed for both employees and decision factors.

Analysis of electric network data in the EXPERS study

Abstract

The Health Ministry initiated a study on the personal exposure of the French population to 50 Hz magnetic field. One of the points of interest of this study is the contribution of each exposure source to the total exposure. We focus here on electric networks. The different data of the study, which includes a little more than 2000 subjects, allow us to identify for some subjects the presence of one or several networks close to home. The distance for taking such networks into account depends on the type of network: we considered all distribution and transport networks, as well as electric train networks. From magnetic fields measurements, after we checked whether the identified networks are really influencing the exposure of subjects. The results depend on the type of network.

Introduction

The French Ministry of Health initiated a study on the personal exposure to 50 Hz magnetic field of the French population (Souques et al. 2008). The global results of this study, called EXPERS, are presented in another communication (Bedja et al. 2010). A point of interest is the contribution of each source of exposure to the total exposure. We focus here on electric networks.

Material and methods

MV2, poll institute in charge of the collection of data, collected for each subject:

- 24h magnetic field measurement
- timetable
- general questionnaire about home and electric appliances used
- GPS coordinates of the home
- Address of the home

For each type of electric network (low to very high voltage), we determined the maximum distance at which the magnetic field generated by the electric network remains theoretically measurable in a residence. This distance was calculated for overhead power lines of voltage 63kV and higher by simulating magnetic fields generated by the different types of networks, in the middle of the span and with the annual mean current. The distance kept is the one where the mean calculated magnetic field is less than 0.1 µT. The magnetic field depends also on the geometry of the line and the distance kept was the largest of the distances calculated for different geometries.

Note that for train networks, a distance of 200 m was arbitrarily chosen. The transport like metro or tramway were not taken into account.

All subjects within these corridors were arbitrarily classified as "exposed" to magnetic fields generated by electric networks. The address of the home was converted into Lambert II étendu coordinates (French Lambert coordinates) by RTE (the French electricity transport network operator). The results of this calculation was validated by comparison to GPS coordinates measured.

The "exposed" subjects were identified from the addresses of subjects of EXPERS study by the network operators using their geographical data bases (all data not yet available for ERDF (the French electricity distribution network operator), the low and medium grid operator in France).

However, as the width of the corridor is overestimated, it is important to know, for the subjects arbitrary classified "exposed", whether their magnetic field measurements show or not the influence of electric networks. Indeed, the variation over one day of the field generated by electric networks is quite characteristic, and a visual check generally allows to confirm or not the contribution of one (or several) electric lines to the magnetic field record.

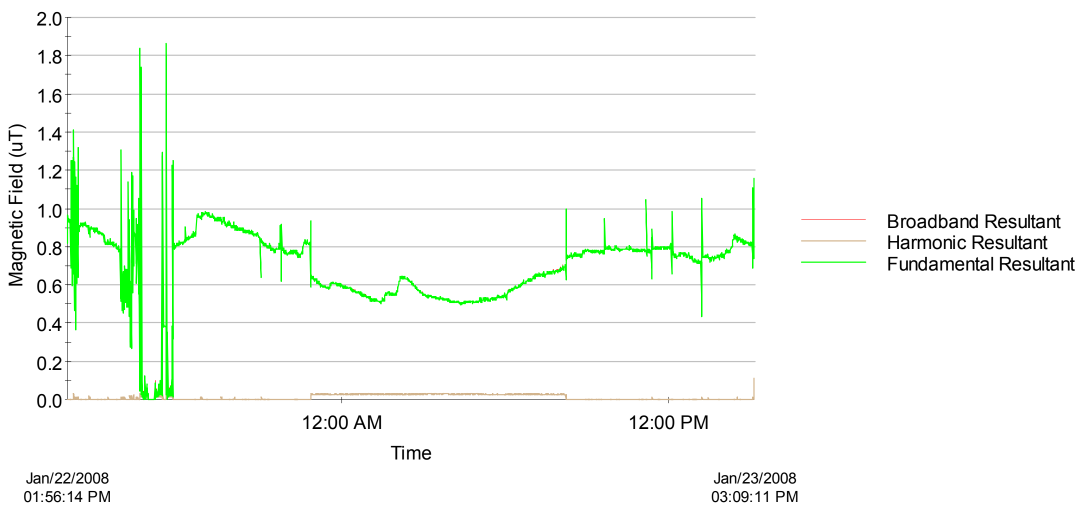

Figure 1. example of a subject really exposed to the magnetic field generated by a high voltage power line.

Figure 1 gives the example of a subject where the source is a high voltage overhead power line. The characteristics are a signal with little noise and proportional to a load curve of a power line, i.e. maximum at the end of the day, decreasing during the night then increasing again in the morning.

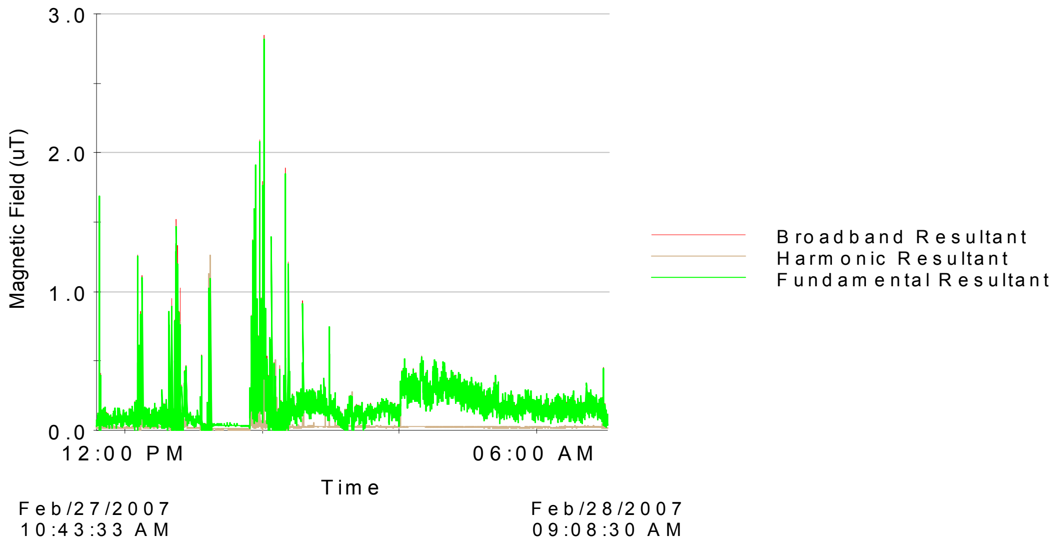

Figure 2. example of a subject really exposed to the magnetic field generated by a middle voltage power line.

Figure 2 gives an example representative of a subject where the source could be a middle voltage underground network. The signal presents the trend of a load curve during the night, but is noisy.

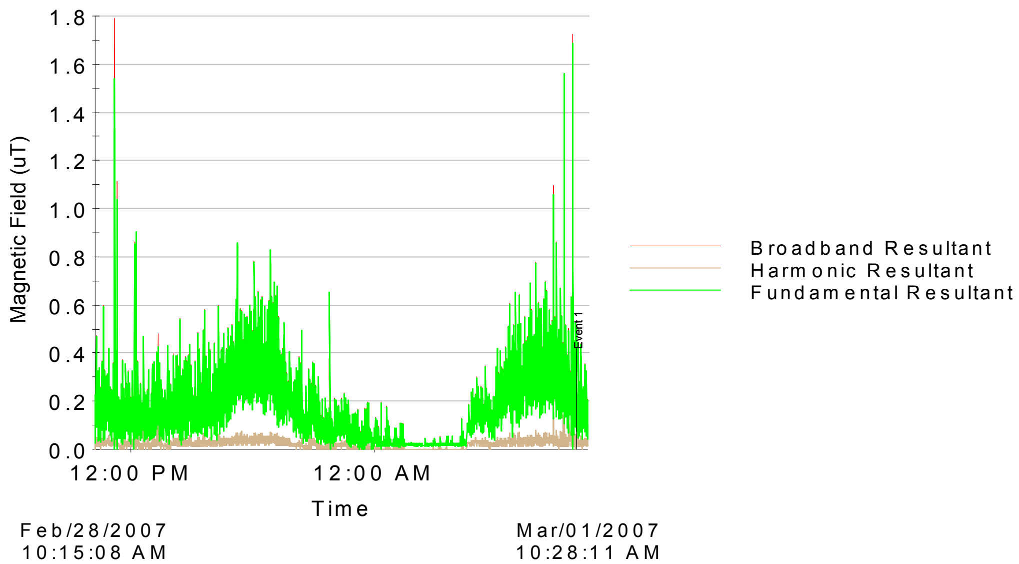

Figure 3. example of a subject really exposed to the magnetic field generated by a train line.

Figure 3 gives the example of a subject where the source is a train line. The characteristics are: a very noisy signal, proportional to traffic (maximum the evening and the morning, zero during the night), and with a ratio of harmonics above zero.

Signals are obviously not all as clear as in the examples given above. A lot are barely detectable and at the limit of ground noise. In order to privilege a conservative approach, we noted as “really exposed” all subjects as soon as we noted a very low tendency at the limit of ground noise.

Results

The EXPERS magnetic field database contains 2048 volunteers and 1581 addresses. There are less addresses than subjects because an adult and a child of the same family could participate in the study.

Table 1 gives the corridor width taken into account around electric networks, in function of the type of networks.

The position of RTE and ERDF networks is known with a precision of 10 m. For electric train networks, a distance of 200 m was chosen because of a lower precision on the position of networks, determined from IGN[1] data, with a precision around 100 m.

Table 1. Definition of corridors around electric networks.

Type of network	Distance (m)
400 kV overhead line	200
225 kV overhead line	120
150 kV overhead line	100
63 and 90 kV overhead line	70
Low voltage to 20 kV overhead line	20
Train line	200
Underground line 225 kV	20
Underground line 63 to 150 kV	20
Underground line low voltage to 20 kV	20
MV/LV substation	20

The number of « exposed » subjects varies between 9 for 400 kV lines (table 2), 162 for train lines (table 3) to more than 1024 for low voltage underground lines (table 4).

Table 2. Distribution of subjects « exposed » to magnetic field generated by RTE networks (data February 2010).

	Number of addresses	Number of individuals	remarks
Overhead line 400 kV	7	9	6 addresses (8 individuals) « exposed » to several lines
Overhead line 225 kV	9	13	
Overhead line 63 to 150 kV	20	26	
Total Overhead line	35	46	
Underground line 225 kV	16	17	5 addresses « exposed » to several lines
Underground line 63 to 150 kV	18	20	
Total Underground line	34	37	

[1] Institut Geographique National

Table 3. Distribution of subjects « exposed » to magnetic field generated by train lines.

	Number of addresses	Number of individuals	remarks
Train line	128	162	70 individuals are in Ile-de-France - 2 individuals with TGV line

Table 4. Distribution of subjects « exposed » to magnetic field generated by ERDF networks (data available today for 1565 individuals over 2032).

	Number of addresses	Number of individuals	remarks
Overhead line 20 kV	25	35	Provisional figures
Overhead low voltage line		620	
Total Overhead line		639	
Underground line 20 kV	455	543	
Underground low voltage line		880	
Total Underground line		1024	
MV/LV substation	60	66	
From which MV/LV substation in building	23	23	

Table 5. Analysis of the magnetic field measurements for subjects « exposed » to magnetic field generated by electric networks.

	Number of individuals	Measurements with influence of an electric network	Remarks
Overhead line 400 kV	9	7	
Overhead line 225 kV	13	11	
Overhead line 63 to 150 kV	26	8	
Underground line 225 kV	17	6	
Underground line 63 to 150 kV	20	8	
Train line	162	37	2/3 in Ile-de-France
Overhead line 20 kV	35	2	Provisional figures (analysis ongoing)
Low voltage overhead line	620	At least 54	
Underground line 20 kV	543	116	
Low voltage underground line	880	At least 115	
MV/LV substation	66	12	
Fro which MV/LV substation in building	23	4	

The visual analysis of measurements for all “exposed” subjects (table 5) shows that the magnetic field generated by the networks was detected in a proportion varying from 85 % of subjects “exposed” to magnetic field generated by very high voltage overhead power lines to 20 % of subjects exposed to magnetic field generated by train lines and less than 10 % of subjects “exposed” to magnetic field generated by 20kV overhead lines.

Discussion

This result must however be balanced by the following remark: the magnetic field measured is the result of the summation of magnetic fields emitted by all magnetic field sources, and not only by electric networks detailed here. As such the results are quite reliable for high voltage overhead lines and train lines whose signals are well characterised on the measurements, but for underground networks, substations and low voltage lines, the signal is at the limit of ground noise and non specific.

For example, for the individuals noted “exposed” to a magnetic field generated by MV/LV substation in buildings, and whose measurements are reflecting an electric network, no one is living at immediate proximity of a substation: the magnetic field “seen” on the measurement is thus not due to the substation.

In the same way, a part of the individuals noted « exposed » to a magnetic field generated by an underground line are living in buildings on a floor too high for underground networks be able to influence their exposure: it could be in this case the electric networks of riser shafts in buildings. A more detailed analysis will be necessary on this point.

Conclusions

This paper shows that:

– the part of the population whose exposure to 50 Hz magnetic field is influenced by high voltage power lines is small,
– the criteria of distance chosen in this study is maximizing and thus overestimates logically the number of people whose exposure to 50 Hz magnetic field is influenced by electric networks,
– it is not conclusive that underground electric networks are really the source of exposure seen in some measurements.

This study will continue with the analysis of all ERDF network data.

To discriminate the real influence of underground networks, it should be necessary to:

– look at the influence of the parameter “floor of the building”,
– look at the measurements of individuals noted as “non exposed” to magnetic field emitted by an electric network, to see whether all are presenting exposures non influenced by electric networks or whether if some are presenting exposures influenced by electric networks, which would accredit the hypothesis of the influence of electric networks from riser shafts in buildings.

Acknowledgment

This study was funded by the Ministry of Health and Solidarities and conducted by Supélec, with the technical collaboration and financial support of EDF and RTE.

On implementation of the new methodologies concerning measurement of occupational electromagnetic field levels

Goiceanu, Cristian; Danulescu, Razvan; Danulescu, Eugenia
Institute of Public Health – Iasi, Occupational Health Department, ROMANIA

Abstract

Measurement of electromagnetic field levels is a very important step in assessing human exposure to electromagnetic fields present in the working environment. After the year 2000, the methodologies on electromagnetic field measurement have been much developed and improved and, at present, there is a big number of technical standards dedicated to various exposure situations.

The implementation of the new methodology on electromagnetic field measurement in the national practice might be difficult, expensive, time consuming and it requires high qualified and special trained personnel. Considering the big change in the methodology to be applied, we analyze the limitations, difficulties and errors that might alter the quality of field measurement and exposure assessment.

To overcome the temporary lack regarding the good knowledge and clear understanding of the new methods, the authors propose a simple strategy consisting in a few steps. A general methodology was elaborated to be assimilated by the personnel involved in this domain, before learning complex methods. Standardized models of measurement report have been proposed. To ensure a solid background, training activities of measurement operators should be carried out by experts.

In agreement with European demands, some specific measures have been proposed to be taken concerning information dissemination, consultancy activities and, if the case, classification of measurement service providers into basic level and high level services. As an example, our activities in Romania in this domain are briefly described.

Microlens formation as protective mechanism against direct laser radiation

Muric, Branka; Pantelic, Dejan
Institute of Physics, Belgrade, Photonics, SERBIA

Abstract

Laser radiation poses a significant threat to human eyes. Depending on power, even scattered radiation can produce damage (mostly to retina), not to speak of direct laser beam. The usual method of protection is through different kinds of filters (absorption, reflection, polarization, holographic) inside goggles or protective windows. Without exception all types of filters protect human eye from scattered or otherwise diffuse reflected laser light. All manufacturers of laser goggles specify that the eye is not protected against direct laser beam. We describe a novel principle of eye protection which is based on expanding laser beam by the filter material itself. In other words, when the laser beam hits the filter material, negative (diverging) microlens is formed almost immediately. The beam is strongly expanded by the microlens, thus reducing the energy density to tolerable level. To test the idea we have developed a suitable material – tothema sensitized gelatin. Tothema is a trade-name of a mixture of gluconates used to treat anemia. Mixture is added to ordinary cooking gelatin, rendering the material sensitive to laser radiation. Sensitivity was further enhanced at 532 nm by additionally doping material with eosin or betanin. Experiments have shown that upon irradiation, strong microlens (focal lengths far below -1 mm) forms quickly and the laser beam diverges, reducing the overall energy density. Results of measurements of dynamics of the process are shown.

Biological hazard of low-intensity radio frequency electromagnetic fields – Model experiments with protozoa

Sarapultseva, E.; Igolkina, J.
Obninsk Institute for Nuclear Power Engineering of the National Research Nuclear University "MEPhI"; RUSSIAN FEDERATION

Abstract
The effects of low-intensity 1 GHz (a mobile connection frequency) and 10 GHz (radar and satellite communications) electromagnetic radiation with energy flux density (EFD) of 5, 10 and 50 μW/cm^2 on a laboratory population of unicellular aquatic organisms – ciliates *Spirostomum ambiguum* were studied. The effects were registered by the criterion of change in spontaneous motor activity (SMA). SMA of ciliater was observed under the microscope. Two lines were deposited in the eyepiece of the microscope, crossing each other at right angles. A quantitative measure of motor activity of each ciliate was a number of intersections of the lines on the eyepiece of the microscope for 1 min. To do this, each ciliate was placed individually in a drop of water in a special cell with holes 5 mm in diameter and 2 mm in depth.

Sp.ambiguum used for a long time to estimate the negative effect of chemical and physical factors on the environment. These ciliates have proved to be a sensitive bioindicator of low-intensity influences. Our research has shown that electromagnetic radiation reduces motor activity of ciliates already at such low levels of exposure as 10, 45 minutes and 8–9 hours respectively with EFD 50, 10 and 5 μW/sm^2. The negative effect did not depend on a frequency of electromagnetic radiation in the diapason from 1 to 10 GHz. The effect had a threshold character. After reaching the threshold, the negative effect did not change with exposure and had a mass character. The level of SMA in the population of ciliates decreased at 40%. The negative effect transmitted to descendants of irradiated ciliates. The results were confirmed by independent experiments involving more than 5000 *Spirostomum*.

Our results are interesting for practical using of protozoa's behavioral reactions for testing of biological hazard of electromagnetic pollution of aquatic environments. It is of interest as the general problem of electromagnetic activity on the biota.

Introduction
It is known that not only sufficiently powerful fluxes of energy (in tenths of W/cm^2) of radio frequency electromagnetic fields (EMF) have had a negative impact on organisms. The negative biological effect occurs when the energy flux density (EFD) is comparable with the level in tens and units of μW/cm^2. Such levels of EFD are

observed in many workplaces and places of human habitation. Interest in the biological effects of low intensity electromagnetic fields has increased significantly with the advent of mobile communications.

Experts did not have general opinion about safety of radio frequency electromagnetic radiation with nonthermal power in spite of the duration studies with help of different biological subjects. There are opposing points of view. This is reflected in huge differences of the maximum allowable levels (MAL) of electromagnetic fields which are recommended in different countries. Until recently, differences in the MAL for the population in different countries were to 1000 times. In Russia the MAL installed as 10 $\mu W/cm^2$ (Sanitary rules and norms 2.1.8/2.2.4.1190-03, Russia), that is less than in Europe and in the USA. These regulations, however, are not sufficiently substantiated. The experimental data are contradictory. The theoretical justification is absent.

The biological risk of electromagnetic radiation has been studied with help of very labor-intensive methods. It hampered the expansion of research. We used an express method which is based on a quantitative assessment of changes in spontaneous motor activity of aquatic ciliates *Spirostomum ambiguum* Ehrbg (Tushmalova et al 1998). The toxicity of pesticides, heavy metals, phenols and other factors, including those at low doses of agents, as well as the differentiation of spirostomum's motor activity by alpha- and beta-irradiation were detected within 1-2 h (Tushmalova et al 1998; Tseplin et al 2005; Sarapultseva 2008). High sensitivity of this method was shown in all cited works. We carried out several studies of the influences of radio frequency electromagnetic fields on the motor activity of *Sp.ambiguum* (Sarapultseva et al 2008; Sarapultseva et al 2009). The results, in our opinion, have the theoretical and practical interest. We found negative effects of low-intensity 1 GHz (a mobile connection frequency) and 10 GHz (a frequency of radars, satellite television, radio, wireless computer networks, satellite navigation, etc) electromagnetic radiation. The negative effects of electromagnetic radiation i) was manifested at low energy flux density, ii) did not change with increasing exposure of EMF in a wide time range, and iii) was inherited during vegetative reproduction.

Let's consider the obtained results.

Material and methods

Ciliates were cultured at 20 ± 2^{0}C in the biological test tubes with tap water, devoid of chlorine. Installations for the electromagnetic irradiation of biological samples consisted of generators, antennas and cables which were giving energy in the mode of continuous generation. The energy flux density had regulated in accordance to the established relationship for each frequency electromagnetic radiation.

Ciliates were irradiated in the mass culture in Petri's plastic dishes with a diameter of 4 cm and 0.3 cm layer of water. The time of exposure in the electromagnetic field was dependent on the energy flux density and ranged from 5 minutes to 16 hours. The control groups of ciliates were in similar conditions, but without the influence of electromagnetic fields.

Quantify changes in motor activity of ciliates was carried out immediately after irradiation. To do this, 20 ciliates were selected randomly from mass culture, which was irradiated with the frequency of 1 or 10 GHz and energy flux density of 5 or 10 or 50 μW/cm^2 and during from 5 min to 16 h. Spontaneous motor activity (SMA) of ciliates from the control groups was tested at the same time. Ciliates from irradiated and control groups were placed individually in a drop of water in special plastic plate with holes of 5 mm in diameter and 1-2 mm in depth. SMA of each ciliate was observed under the microscope. At the eyepiece of the microscope were did two lines crossing each other perpendicularly. A quantitative measure of motor activity of each ciliate was the number of intersections of the lines for 1 min.

The ciliates after irradiation were continued to cultivate at optimal condition in order to clarify the question of inheritance of negative effects of low irradiation. The effect of irradiation was estimated by reduce of motor activity in the experimental groups of ciliates. These changes were measured immediately just after irradiation and at the 4th, 14th, 21st and 30th days.

It was held on 3–5 series of observations at each case. Thus, it was tested more then 5 000 ciliates. Assessing the reliability of experimental data was carried out with help of the nonparametric Fisher test.

Results

Study of biological electromagnetic radiation effects at 1 GHz with a flux density of energy 10 μW/cm^2

First, consider the results of low-intensity electromagnetic radiation at a frequency of mobile communications (1 GHz) with the maximum allowable in Russia energy flux density 10 μW/cm^2. The change in ciliates' motor activity after radiofrequency exposure duration 15–60 minutes you can see in the Table 1.

Table 1. Changing in ciliates' motor activity (in absolute terms and in % relative to control) just after radiofrequency exposure duration 0.25-1 h at 1 GHz (EFD 10 μW/cm^2).

The exposure time, minutes	$M \pm m$	%, $(M_{exp}/M_c)\cdot 100$
0 (Control)	2.15 ± 0.18	100.0 ± 8.4
15	2.20 ± 0.17	102.3 ± 7.7
30	1.80 ± 0.21	83.7 ± 11.6
45	1.20 ± 0.15*	55,8 ± 12.5*
1	1.25 ± 0.17*	58.1 ± 13.6*

* $p \leq 0.05$
$M \pm m$ – average motor activity with a standard error
M_{exp}* – *motor activity in experiment
M_c* – *motor activity in control

Statistically significant ($p \leq 0.05$) decrease in motor activity of ciliates occurs "abruptly" after 45 minutes stay in the EMF at 1 GHz and EFD 10 μW/cm^2. Table 2 presents the results of observations in 3 series of experiments at the threshold exposure time of 45 minutes.

From Table 2 shows that the average SMA of ciliates in the experimental groups is significantly lower than SMA in the controls groups. Change in motor activity is well reproduced in all series of experiments and differs by 40–45% of control.

In subsequent experiments the effect was studied with increasing exposure in EMF. At Figure 1 shows the results of change in motor activity of ciliates immediately after RF exposure in a wide time interval from 15 minutes to 10 hours.

Table 2. Changing in ciliates' motor activity in control and after exposure at 1 GHz during 45 minutes in three series of experiments.

№ Experiments	Control, $M_c \pm m_c$	Experiment, $M_{exp} \pm m_{exp}$	%, $(M_{exp}/M_c) \cdot 100$
1	2.10 ± 0.18	1.20 ± 0.15*	57.1 ± 12.5*
2	2.25 ± 0.18	1.32 ± 0.17*	59.2 ± 13.0*
3	2.20 ± 0.15	1.15 ± 0.19*	52.3 ± 16.5*
Average	2.18 ± 0.16	1.22 ± 0.17	55.9 ± 13.9

*** $p \leq 0.05$**
***$M \pm m$* – average motor activity with a standard error**
***M_{exp}* – motor activity in experiment**
***M_c* – motor activity in control**

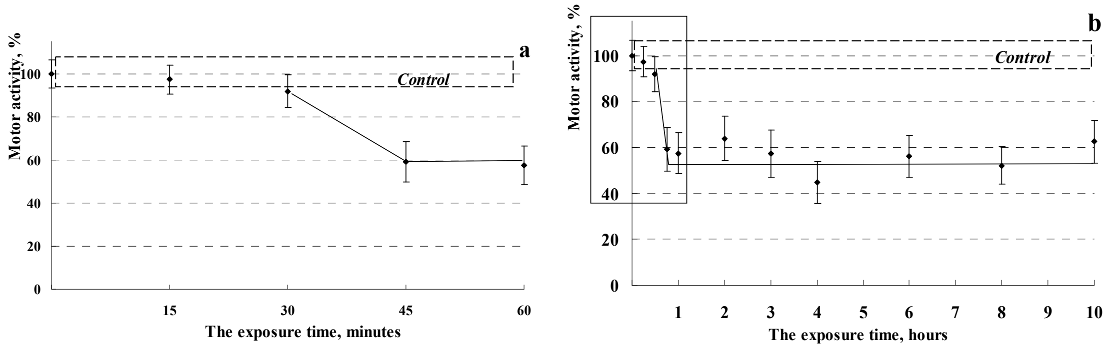

Fig.1. Changing in ciliates' motor activity (in% relative to control) at the electromagnetic irradiation with 1 GHz and 10 μW/cm² duration up to 60 minutes (a) and up to 10 hours (b).

The differences in ciliates' motor activity between the experimental groups and controls are evident, equal and don't change with increasing exposure from 0.75 to 10 h.

Study of biological electromagnetic radiation effects at 10 GHz with a flux density of energy 10 μW/cm²

At Table 3 shows the changes in motor activity of ciliates immediately after exposure of up to 10 hours at a frequency of 10 GHz.

Statistically significant ($p \leq 0.05$) decrease in motor activity occurs "abruptly" after 45 minutes stay in the EMF. That time coincides with the time of the "safe" location in the EMF with the parameters of mobile communication (Table 1 and 2). Table 3 also shows that the negative effect produced by radiofrequency exposure within 45 minutes, didn't change even with increasing exposure time to 10 hours.

Save a negative effect in the generations of ciliates

Let's consider the results of motor activity's changes in the offspring of irradiated ciliates. Figure 2 shows the change in motor activity of ciliates on the 4th (a), 14th (b), 21st (a) and 30th (d) days after exposure.

Table 3. Changes in ciliates' motor activity (in absolute terms and in% relative to control) immediately after radiofrequency exposure duration of 0.25–10 h at 10 GHz (EFD 10 μW/cm^2).

The exposure time, h	*M* ± *m*	%, $(M_{exp}/M_c)\cdot 100$
0 (Control)	2.14 ± 0.06	100.0 ± 2.8
0.25	2.09± 0.10	97.7 ± 4.8
0.50	1.95 ± 0.09	91.1 ± 4.6
0.75	1.33 ± 0.08*	62.2 ± 6.0*
1	1.24 ± 0.06*	57.9 ± 4.8*
2	1.19 ± 0.10*	55.6 ± 8.4*
3	1.13 ± 0.07*	52.8 ± 6.2*
4	1.08 ± 0.06*	50.5 ± 5.6*
6	1.34 ± 0.08*	62.6 ± 5.9*
8	1.42 ± 0.12*	66.4 ± 8.5*
10	1.42 ± 0.09*	66.4 ± 6.3*

*** p ≤ 0.05**

***M* ± *m* – Average motor activity with a standard error**
M_{exp}* – *motor activity in experiment
M_c* – *motor activity in control

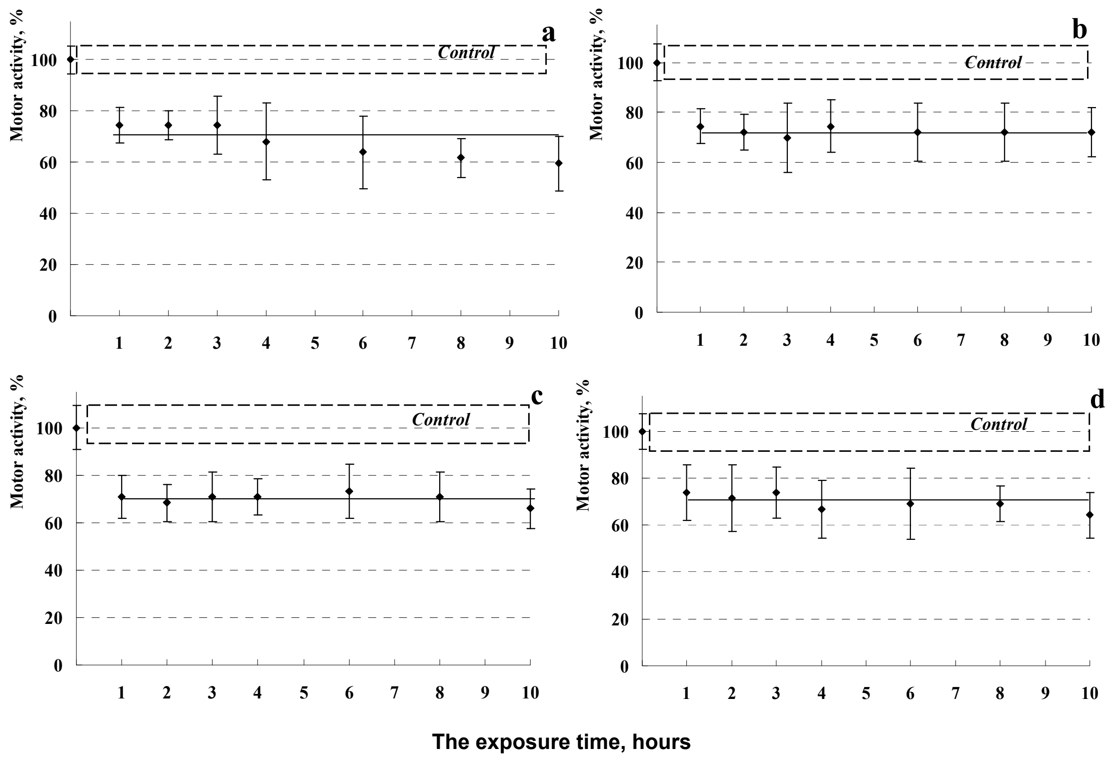

Fig. 2. Changes in ciliates' motor activity (in% relative to control) after radio frequency exposure at 10 GHz and 10 μW/cm^2 on the 4th (a), 14th (b), 21st (c) and 30th (d) days

Figure 1 shows that the significant decrease ($p<0.05$) in SMA was approximately the same at all times (immediately and in distant periods after exposure) and at all period of irradiation. That effect took place at exposure from 1 to 10 h. The effect was recorded on the 30th days after irradiation. During that time the ciliates replaced about 10–12 generations (average length of the cell cycle was about 2 days (Wichterman R., 1953). It follows that the effect can transmitted to descendants of irradiated cells.

Study of biological hazards of electromagnetic radiation at different radio frequency energy flux density

Figure 3 shows the results of changes in motor activity of ciliates at electromagnetic radiation at a frequency of mobile communications (1 GHz) with EFD 5 μW/cm^2.

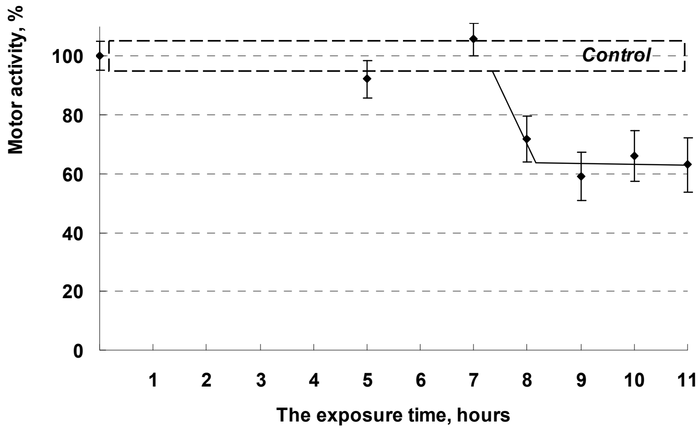

Fig. 3. Changing of ciliates' motor activity in electromagnetic field with EFD 5 μW/cm^2 at 1 GHz up to 11 hours.

Recall that such energy flux density is in 2 times less than the maximum allowable level in Russia. However, Figure 3 shows that the ciliates' motor activity reduces about the same as it is in the electromagnetic field with the energy flux density of 10 μW/cm^2. Decreased of motor activity occurs, however, after much longer exposure, after 8–9 h. The effect in that case when the exposure reached a threshold no longer depends on the duration of exposure. The saltatory nature of the effect in these experiments was clearly registrated. If a 7-hour exposure was not causing reduction of spontaneous motor activity, the 8-hour exposure caused this effect. Increased exposure time up to 9, 10 and 11 h hadn't influence on the degree of change in ciliates' motor activity. The time which ciliates spent in the electromagnetic field with a lower energy flux density of 5 μW/cm^2 (when the changes in ciliates' motor activity did not occur) increased in 16 times (from 45 min to 8-9 h) compared with the exposure time in the EMF with the energy flux density of 10 μW/cm^2.

The overall pattern and degree of changes in SMA were the same after irradiation at a frequency of 1 GHz with an even higher energy flux density – 50 μW/cm^2. The effect was absent in a certain time range, but then the motor activity of the experimental ciliates abruptly decreased by about 35–40%, as happened in previous cases. In the case when the energy flux density was 50 μW/cm^2, irregularities in the motion ciliates occurred with exposure of no more than 10 minutes.

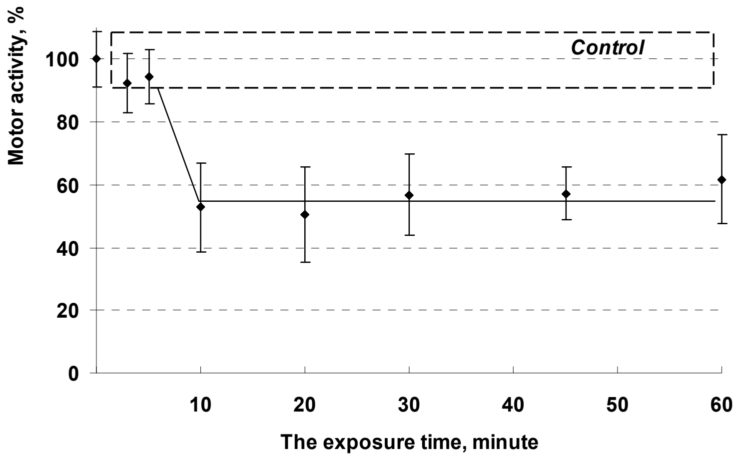

Fig. 4. Changing of ciliates' motor activity in electromagnetic field with EFD 50 μW/cm^2 at 1 GHz with exposure of 1 minutes up to 1 hours.

Next, we evaluated the biological effectiveness of EMF at a frequency of 10 GHz. The degree of inhibition of ciliates' motor activity was significant and approximately equal and didn't changed with increase of energy flux density from 5 up to 50 μW/sm^2. However, the time of occurrence of dysfunction movement depended on the energy flux density. The safe duration of exposure at 10 GHz was about 8–9 h, 45 and 10 minutes respectively with the EFD of 5, 10 and 50 μW/cm^2 as was observed at a frequency of 1 GHz (figure 5).

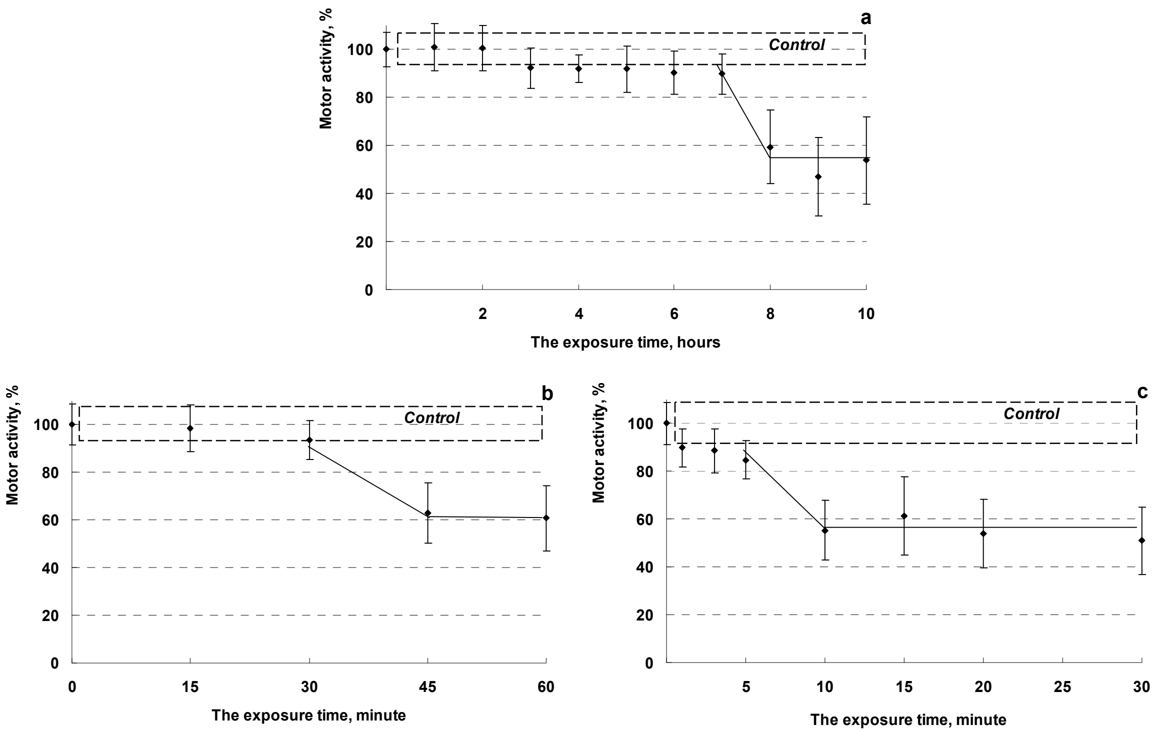

Fig. 5. Changing of ciliates' motor activity in electromagnetic field at 10 GHz with EFD 5 (a), 10 (b) and 50 (c) μW/cm^2.

From Figure 5 shows that the extent and nature of the effect of electromagnetic radiation at a frequency of 10 GHz was not appreciably different from those which were found after irradiation at the frequency of mobile communications 1 GHz (Fig.3 – 4 and Tabl.3). Decrease in ciliates' motor activity was approximately 40%. The degree of change in the ciliates motor activity wasn't depended of the time of exposure after reaching a threshold.

Discussion

The study shows that even very low levels of electromagnetic radiation of radio frequencies, which is widely used by people, could harm the function of motion of the representative biota. A massive inheritable independent from duration of electromagnetic irradiation a decrease of ciliates' motor activity is unusual phenomenon for low-intensity non-ionizing radiation.

However, the results are quite consistent with the data obtained by us after γ-irradiation *Sp.ambiguum* in a wide range of doses, including the low doses (Sarapultseva et al., 2008). A mass effect of decreasing the viability of individuals in populations of other species of ciliates (*Paramecium caudatum, Climacostomum virens*), amoebae and mammalian cells after exposure to low doses of radiation was described also in the book of I.Bychkovskaya et al (Bychkovskaya et al., 2006 http://irbb.ucoz.ru). These violations persisted in remote periods after irradiation – inherited. This proves the reality of the effect and assumes a possible common mechanism of biological action of low-dose of electromagnetic radiation of different nature.

The data about the occurrence of negative effect in motor activity of ciliates after relatively low electromagnetic effects in the early periods after irradiation and irreversible transfer to the progeny rule out the possibility of mutational nature of these changes. We assume that one possible mechanism is a change in the structure of DNA. It is the basis of epigenetic inheritance (Jablonka E. et al., 2008).

Despite numerous studies to date were not significantly determined the basic mechanisms (except thermal) effects of electromagnetic radiation on biological subjects. There are recent theoretical developments and some, though not indisputable facts that the electromagnetic radiation is not only a background against which the unfolding basic biological processes, but it plays a decisive role in all processes of exchange. Several studies show that water plays a decisive role in the effects of electromagnetic radiation on biota. The observed biological effects of low doses of electromagnetic radiation may be due to the formation of reactive oxygen species in the aquatic environment. This is accompanied by stronger oxidative process and the formation of a large number of free radicals that bind to protein components (especially in the tissues which involved in metabolism). It is known that free-radical processes violate the metabolism of DNA, causing mutations. It violates the complementarily of the structure of DNA, breaking hydrogen bonds; induce chromosomal and genomic disorders. Such processes are for non-thermal electromagnetic radiation. The specificity of the non-thermal radiofrequency electromagnetic field is determined of the resonance character of the energy and informational nature. The primary effect is realized at the cellular level and is associated with elements of cytoplasmic membrane, in particular, molecules of proteins and enzymes with a significant electric dipole moment.

Conclusions

We obtained the data that the negative effect of electromagnetic radiation to ciliates' motor activity takes place already at the maximum allowable, and even in two times lower than maximum allowable limit of energy flux density. It is shown that the nature and extent of damage from electromagnetic radiation with frequencies differing by ten times (1 and 10 GHz) are virtually identical. Those are of particular importance in terms of EMF practical application. This is interesting in connection with the problem of standardization of EMF on biota.

Analysis of the new data will be interesting as a fundamental aspect in the discussion of dose-independent reactions, which were obtained in different biological subjects after low radiation (Bychkovskaya et al., 2006 http://irbb.ucoz.ru; Sarapultseva et al., 2008; Sarapultseva, 2008; Sarapultseva et al, 2010). In this case, however, remains an open question how formed the equal response to exposure of low doses of different agents if those agents are very differ among themselves on transferred energy. This question requires further experimental studies.

Abstract

In Iceland, polls have been conducted every year since 2004 among 1800 randomly selected individuals aged 12-23 years inquiring whether they used sunbeds in the previous 12 months. The intention was to determine the level of sunbed use by the young and to monitor the effectiveness of a yearly information campaign on the possible consequences of such usage.

On average; approximately 20% of those between ages 12 and 15 said they used sunbeds as compared to 52% of those aged 16-19 years. For the whole group of 12-23 years old, 41% reported using sunbeds.

A statistically significant 20% reduction in the number of users took place for the whole group aged 12-23. However, the reduction was smaller and statistically insignificant for those aged 12-15.

Introduction

In Europe, young people below age of 18 have long been discouraged from using sunbeds by mandatory user instructions in sunbed saloons. The effectiveness of this discouragement is not well known since data on the usage by the youngest users is scarce. Published information on sunbed use normally only spans age groups 18 year and older.

Concerns over a rising incidence of melanoma in Iceland, especially among young women, led to the formation of a UV-task group in 2004 by the Icelandic Radiation Safety Authority, the Cancer Society, the Association of Dermatologists, the Directorate of Health and the Public Health Institute of Iceland. Advertisements from sunbed saloons aimed at children preparing for their confirmation ceremony at the age of 13 to 14, prompted the group to employ Capacent-Gallup, a professional polling agency to monitor the sunbed usage of young people with annual user-polls.

Advertisements, prepared by an advertising agency (ENNEMM) were published on the 10th of March 2004 in newspapers with an open letter to parents, signed by the directors of the above named health authorities, see Figure 1.

Fig. 1. Advertisement aimed at parents. A confirmation figure with an imprint of sunbed-goggles in its face. The text asks parents to consider the health consequences of cosmetic tanning.

The advertisements were followed up by interviews with health specialists in the news-media. In the following years, similar activities have been repeated. In Figure 2 is an example of an interactive Internet banner prepared in 2008 to grab the attention of the young. This effort had support from newspapers, radio and TV-stations and received much attention.

Fig. 2. An Internet banner aimed at youths with a title in slang-language followed by a simple message: "Young people should not use sunbeds". When the lever is moved the smiley goes through several stages of burning (three are shown).

Material and methods

Data on sunbed usage was collected by Capacent-Gallup in Reykjavik, using 1800 randomly selected individuals aged 12-23, each year in March to May. During the first years, individuals were contacted by telephone, but presently the majority is polled through the Internet.

In the first few years, answers were received from almost 70% of those selected but this number is down to almost 50% in the most recent polls. This is however not believed to skew the results because the reason for declining response is not believed to be linked to sunbed usage. The questions on sunbeds are among many others that are mostly relevant to product marketing and responses to all polls have been decreasing in recent years. For children younger than 18 years, permission from parents must be sought which probably reduces the response rate.

When averages are made over different groups (sex, age, living in or outside Reykjavik), they are corrected for differences in group response.

Results

Usage percentages are presented in Table 1. Those who are 12 to 15 years old have not finished their compulsory schooling and are grouped together. Most of those aged 16-19 are in high school / junior college (Icelandic: menntaskóli, Danish: gymnasium) and many of those aged 20-23 are university students.

Table 1. Percentages of different age groups that said they used sunbed the previous 12 months.

Year	12 -15 year	16-19 year	20-23 year	12-23 year +/- 95% CI
2004	25%	56%	61%	46% +/- 3%
2005	13%	49%	57%	38% +/- 3%
2006	19%	51%	55%	40% +/- 3%
2007	21%	52%	52%	40% +/- 3%
2008	20%	56%	55%	42% +/- 3%
2009	21%	47%	43%	37% +/- 3%
Averages	20%	52%	54%	41%

The young people were also asked how often they used sunbeds. As could be expected, the age group 12-15, reported less use compared to users 16 years and older. Among the former, who used sunbeds at least once, around 15% used them monthly or more often, while some 28% of users in age group 16-19 and 24% of those aged 20-23 did the same (averages for the whole period). A corresponding number for 16-75 years old in 2004-2007 is reported as 19% in another study [1].

Figure 3 shows how the number of sunbed users has decreased for the population of young people aged 12-23. The decrease is 20% from the year 2004 to 2009 and statistically significant.

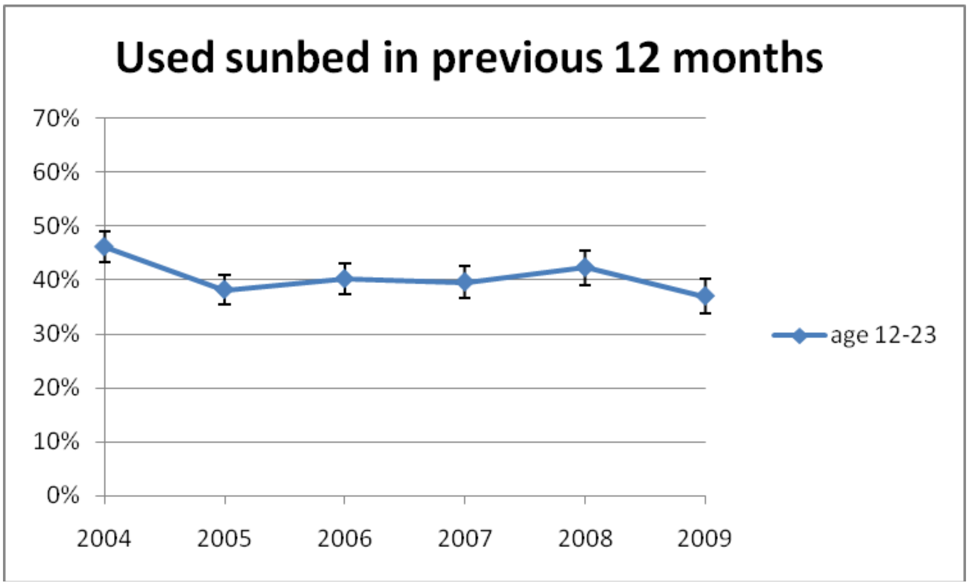

Fig. 3. Percentage of young people (age 12-23) that said they used sunbeds at least once the previous 12 months, both sexes and rural locations included. A 95% confidence interval is shown.

Figure 4 displays the change over time in sunbed usage for the three groups. The number of users 12-15 year old was almost halved the first year of active information dissemination, but it has grown since to similar level as it was earlier (the difference is statistically not significant). The number of sunbed users in age group 20-23 year old was however reduced by 30%.

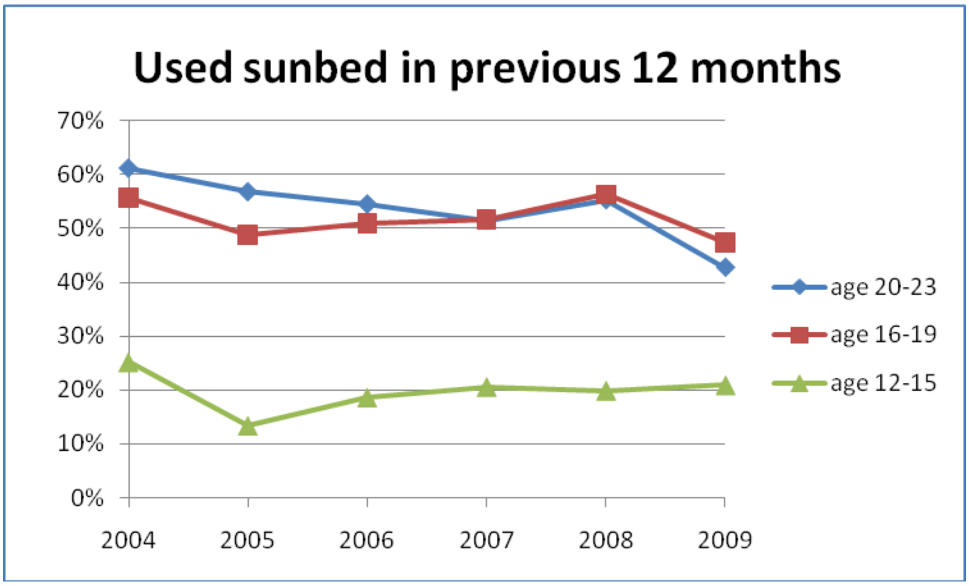

Fig. 4. Sunbed usage of three age groups. Confidence intervals are not shown but can be estimated to be ~√3 wider than in Figure 3.

Discussion

The results presented here are in line with data gathered by different means, see reference [1]. Information on sunbed numbers indicates that sunbed usage has been very common in Iceland but it has been reduced in recent years. It does not come as a surprise that sunbed usage was sharply reduced by children at confirmation age in 2004, it is more surprising how resilient this usage has later proven to be. The drop in sunbed usage reported in 2009 seems mostly to have affected adults and could be due to the sudden economic turmoil in Iceland in the late 2008.

The results seem to be internally consistent but there is no other data on the usage by 12-15 years old in Iceland with which to compare it.

In 2005 Nordic radiation protection authorities issued a common statement [2] strongly advising young people not to use sunbeds. The radiation protection agencies of Iceland, Norway, Finland and Sweden issued another statement 11th of November 2009 recommending regulation of tanning facilities that includes the prohibition of use for people below 18 year of age [3]. This recommendation was unanimously supported by the Icelandic UV-task group.

The government of Iceland decided in March 2010 to introduce a legislation to ban sunbed use by people less than 18 years of age. This legislation is now in preparation.

Conclusions

According to this study, 20% of 12 through 15 years old Icelanders used sunbeds in Iceland in 2004-2009. It has proven difficult to permanently decrease this usage through information campaigns. The campaigns have however been effective in reducing usage by adults who were not their primary target.

Abstract

This paper presents an in-vitro characterization set up of implantable cardiovertor defibrillator (ICD) immunity. A set up has been modeled by using a Helmholtz coil and an electric ad hoc interface. It generates and controls uniform magnetic fields. A comparison was made between the file that contains the parameters of emitted disturbances at a given time and the time of the occurrence of each event recorded by the ICD. This has allowed us to deduce the signal level that caused false detections in one case, or inhibition of the detection in the other case. Evidence is that the higher the level of disturbance, or when the frequency is in the "cardiac" frequency band, the number of false detections increases. One result is an amplitude "window effect" for the detection and dysfunction.

Introduction

Risks of electromagnetic fields (EMF) exposure associated with patients bearing medical implants such as the implantable cardiovertor defibrillator (ICD) are under a concern since this population is increasing. Cardiac devices are the most common medical implants(Nuegell et al 1996, Occhetta et al 1999) and are subject to specific international standards. However, since the European directive 2004-04 CE on the limitation of a worker's exposure to EMFs, supplementing the 1999/519/CE recommendation, many questions remain unanswered. Establishing a risk assessment procedure for workers with medical implants is very complex due to the diversity of potential situations involving EMF interactions in the professional environment. The effect of radio frequencies (RF) on ICD's has been widely investigated (Inrich et al 1996, Guertin et al 2007) and there are many papers in the literature describing the electromagnetic interference between ICDs and RF systems such as medical devices (X-rays), cellular phones and security systems (Inrich et al 1996, Mathew et al 1997, Shellock et al 2007).In addition, the effects of extremely low frequency (ELF) fields (e.g those generated by power lines for transport such as railways or for power supplying) have also been considered. The ICD bearer, until a few years ago, was typically excluded from his job after his implantation. Since ICD may concern also young people now, this situation implicates a real social problem when they come back to their work after surgery. Research has been performed on ICDs in the proximity of high voltage power lines (Souques et al 2002) and the susceptibility of implantable medical devices to the EMFs generated by electric security systems has also been investigated, highlighting transient anomalies (McIvor et al 1995, Mugico et al 2000). Nowadays, the average age of ICD bearers is decreasing, therefore, an ICD bearer could be working in a factory where high power machines generate EMFs. For example, in the proximity of high power welder machines (75 kVA), the magnetic field ranges from 100 µT (at 1.5 m) to 2000 µT (at 0.15 m) (Cooper et al 2002, Fetter et al 1996). In this sense, particular effort is devoted to analyze the electromagnetic interference (EMI) effects of ELF fields on cardiac implants, both from an experimental (Della Chiarra 2006) as well as from a theoretical simulation approach (Dawson et al 2002) .The exposure to uniform electric field and contact currents has also been investigated(Dawson et al 2000). Assessment of human exposure at the workplace for persons bearing active implantable medical devices in electromagnetic fields is thus a current challenge for all the concerned electrical industries. Previous relevant studies have already been conducted on pacemakers in vitro at the Laboratory of Electronic Instrumentation of Nancy (Nancy University) for frequencies of 50/60 Hz, (Scmitt et al 2005). In this paper we describe a method for the in vitro characterization of the immunity of ICD to electromagnetic interferences at low frequencies (50 Hz-60Hz).

Methods and materials

An experimental set up (Katrib et al 2009) using a source for environmentally relevant interferences consists of a programmable low frequency generator connected to a power amplifier then to a transformer to deliver a sinusoidal current connected to Helmholtz coils (uniform magnetic fields) to simulate the EMF. Helmholz coils and the device under test (DUT) are placed in a Faraday cage (fig 1).

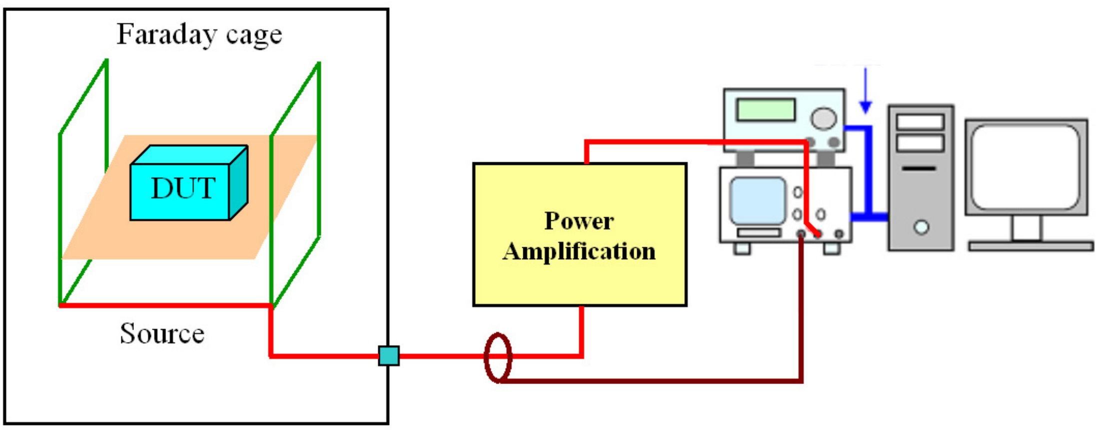

Figure 1 Experimental set up for testing the ICD immunity.

The entire set up is controlled with a PC by an IEEE488 connection and a data acquisition program that can control and communicate with a piece of test equipment to adjust the amplitude levels and frequencies of the EMF. The acquisition of these parameters is synchronized with the clock of the DUT, by a telemetric controller. The oscilloscope allows the monitoring of the signals during routine settings. The exposure system presented here offers the possibility to investigate the immunity of ICD to magnetic fields by placing the device, together with its leads, inside a homogeneous testing field. A Plexiglas support, holding the ICD and the leads in a well-defined position, is placed between the induction coils so that the DUT is positioned in the homogenous field volume for tests. This support may be used in the air as well as in a Plexiglas tank that can be filled with saline solution or gelatin mimicking electrical properties biological tissues (Marchal et al 1989). In latest study Silny (Scholten et al 2001) estimated the closed loop formed by the metallic housing and the tissues to 225 cm ^{2}, in unipolar detection. In this case big phantom was needed (45*30*24.5 cm) to simulate a realistic situation. In the bipolar detection we don't have this problem as the distance between proximal and distal electrodes does not exceed 2 cm. Our proposed tank simulator has a height of 12 cm and a length of 28 cm. Finally, the induction coils are placed on a wooden support to avoid distortion of the magnetic field.

Results

Figure 2 presents the electrocardiogram (ECG) registered when testing the ICD with a lure heart signal simulating a ventricular fibrillation. In this study, we apply an arrhythmic signal (fibrillation or tachycardia) during 15s followed by a normal rythme signal during 45s, so that the ICD is able to recover between each arrhythmic episode.

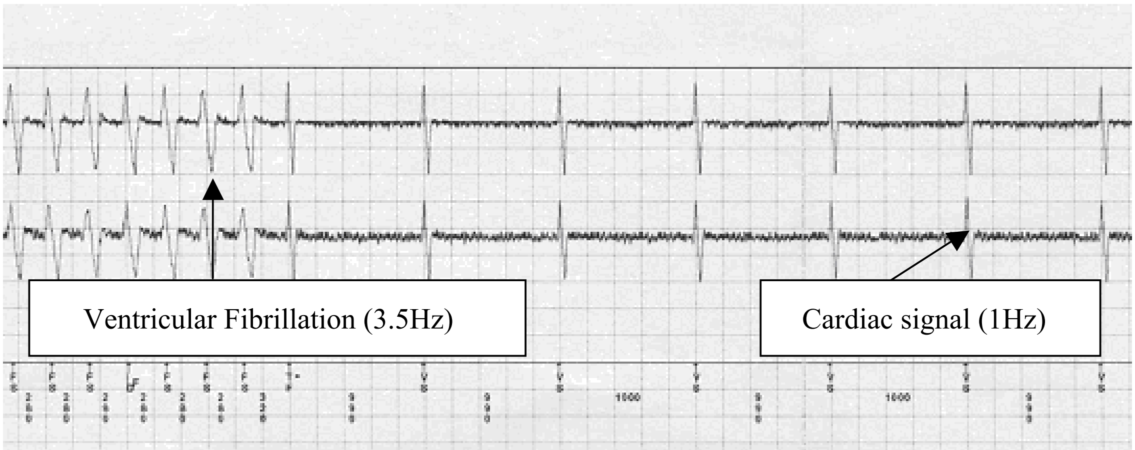

Figure 2 Chart of ECG during a simulated fibrillation episode.

Once the physiological signals are set up, we study the behaviour of ICDs in the VVI mode in order to plot the immunity of ICD versus applied magnetic fields. For magnetic fields up to 1000 µT, which is 2 times higher than the standard threshold for occupational exposure to magnetic fields, no interaction was found. Above 1000 µT, figure 3 and 4 presents the behaviour of ICD exposed to different inclinations angles of the magnetic field with respect to perpendicular exposure. One can remark that when the inclination angle increased, the disruptive level decreased. At an inclination angle of 19°, the inhibition (pathologic signal undetected) occurred at the disturbance level of

2570 μT for 50 Hz and 2640 μT for 60 Hz. On the other hand at 90°, the inhibition began at 1750 μT for 50 Hz and 2020 μT for 60 Hz. We still remark that most of the ICD are non-sensitive to magnetic fields below 1400 μT, where the induced voltage does not exceed the limit of 2 mV according to the standard (EN54505). All the interference threshold curves measured until today have shown that the filter structure or input/output systems used for ICDs have a major influence on their behaviours faced with EMF. The pass band filter structures were found the most sensitive at frequencies between 10 Hz and 100 Hz, and especially at 60 Hz where we can see a lot of interferences. Bipolar electrodes are the most effective remedy for low frequency interferences compared with unipolar electrodes. The present research results substantially improve the currently unsatisfactory situation with regard to the assessment of the safety of persons with active implantable medical devices who are exposed to magnetic fields in the low frequency ranges at their workplace.

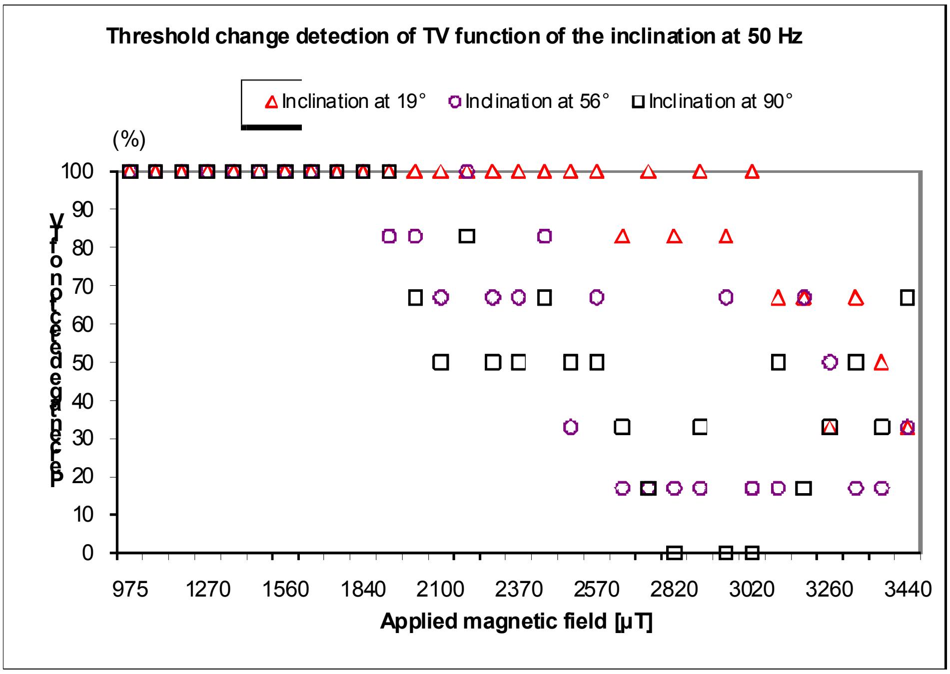

Figure 3. Behaviour of ICD in relation to magnetic field inclination at 50Hz.

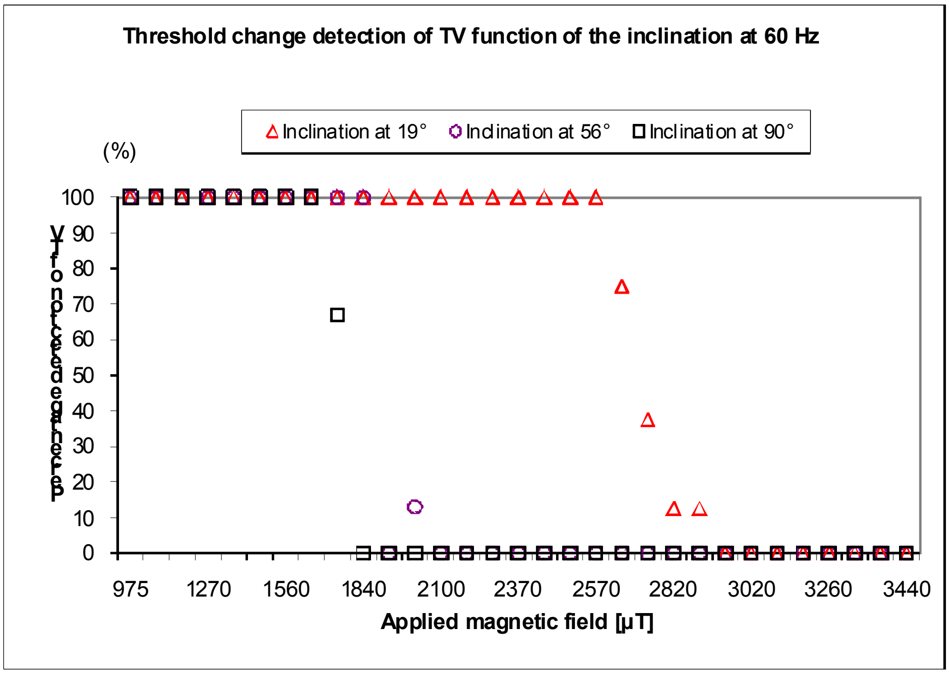

Figure 4. Behaviour of ICD in relation to magnetic field inclination at 60Hz.

Discussion

In this paper we present a protocol and setup dedicated to test the immunity of ICD exposed to low frequency homogenous magnetic fields. We present the methodology used to generate a pathological signal, and we show the influence of the inclination angle on the implant at 50 Hz and 60 Hz. In future work we will test more ICDs at test frequencies up to 100 KHz, and it would be efficient to also test a modulated signal as stated in the standard (EN54505).

[2] Burnasyan Federal Medical Biophysical Centre, RUSSIAN FEDERATION

Abstract
The status of radiation protection and radiation safety at the Russian hazardous enterprises is assessed as satisfactory. According to data of long-term monitoring, annual dose to nuclear workers is not higher than 2.5 mSv. Contribution of the nuclear industry to the public doses is not higher than some parts of the percent. Over many years, any excess radionuclide discharge/effluent has not been registered and chemical contamination of the common air and water environmental media do not exceed the permissible concentrations. Indexes of the public health are similar to those for the whole Russian Federation. Chronic occupational morbidity rates are lower than 2.0 cases per 10 000 workers. The acute occupational pathology occurs very seldom, mainly due to incidents. Over 60 years of the nuclear industry history, 754 persons have been radiation injured, 350 persons of them had diagnosis acute radiation disease; amount of radiation-induced deaths was 71 (taking into account consequences of the Chernobyl accident). Today, Russia must develop the national system for control and keeping radiation protection at the required level. This paper will give some examples of the current radiation protection problems important for public health and scientific results of research on the health effects of long-term, low-dose radiation exposure.

Introduction
The Foundations for the state policy in nuclear and radiation safety assurance in the Russian Federation for the period till 2010 and future perspectives (approved by the RF President 4 December 2003) serve as a basis for development of radiation safety assurance and public health protection in respect to impact of radiation factors in Russia. The Foundations for the state policy are implemented in work of the federal authorities. The Federal Medical Biological Agency (FMBA of Russia) is one of them. Since 1946 up to now, the FMBA of Russia develops practically all issues of radiation safety and health protection in Russia.

The FMBA of Russia is a federal authority, which was assigned the responsibility for medical sanitary support and state sanitary epidemiological supervision both of workers from some industrial institutions with especially hazardous work conditions and residents of some Russian areas. The listing of such organizations includes: the state atomic energy corporation "Rosatom", state shipbuilding corporation, federal agency of marine and river transport. They have nuclear and radiation hazardous facilities and cover 22 settlements situated in the supervision areas of the mentioned facilities. Moreover, the FMBA of Russia regulates safety during nuclear energy using and it is one of the customers and coordinator of the medical part of the Federal target program «Nuclear and radiation safety assurance for 2008 and for the period till 2015».

The structure of the FMBA of Russia includes research institutes specialized in radiation medicine and biology; clinics; institutions under the sanitary epidemiological supervision system, which institutions are located according to the principle of optimum dislocation with respect to organizations with especially hazardous work conditions. Thus, three interconnected components – science, medical support and regulation – predetermine the foundation for radiation safety assurance system. The special feature of this system is its complex functioning: from surveillance, control and supervision of work conditions at radiation hazardous facilities and population living at the areas of their allocation, medical aid rendering and to scientific support of radiation safety and health protection problems.

Current status of radiation safety

Annual analysis of the operator's radiation passports and territorial bodies' reports shows that today, ionizing radiation is not the key health affecting factor both for workers of radiation facilities and population living at the supervision areas. Over many years, excess radionuclide discharges/effluents have not been registered. Contamination of common air and water environmental media with different chemicals do not exceed the maximum permissible concentrations. Radiation safety conditions at the facilities under the State Corporation "Rosatom" are evaluated as satisfactory. Long-term monitoring shows that annual doses to nuclear workers do not exceed 2.5 mSv (Fig. 1).

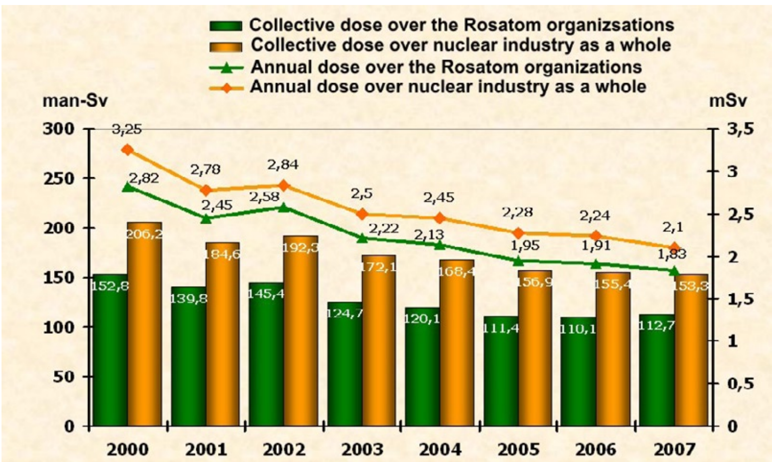

Fig. 1. Dynamics of annual and collective doses to nuclear workers of Russia.

Comparison of some demographic indexes of the public health in Russia as a whole and those for the contingent under the FAMB of Russia service (Table 1), shows that the birth rate here is lower than the similar index over the Russian Federation. This fact can be explained by the age structure of residents in the close territorial formations, where the older residents dominate. The morbidity found is also higher a bit because of improved medical care. At the same time the death and infant death rates are much lower than the similar indexes over Russia due to timely revelation and treatment of different pathology.

Table 1. The public health indexes for the population under the FMBA of Russia service.

Index (over 1000)	Over FMBA of Russia	Over Russia as a whole
Birthrate	8.8	11.3
Public morbidity:		
All residents	1740	1703
Adult residents	1600	1360
Total mortality	11.5	14.7
Infant mortality	6.9	9.4

Over the recent years, indexes of the chronic occupational morbidity at the facilities serviced are lower than those over the Russian Federation. The acute occupational pathology occurs very seldom, mainly due to emergencies.

Table 2 includes data on clinically significant consequences of radiological incidents in territory of the former USSR and Russia, according to information from the FMBC Register. Over the 60-year period of the nuclear industry existence, 754 persons were radiation injured, among them 350 cases of the acute radiation disease has been registered; amount of radiation induced deaths was 71 (taking into account consequences of the accident at the Chernobyl nuclear power plant).

Table 2. Information on clinically significant consequences of the radiological incidents in territory of the former USSR and Russia (as of 01.01.2009).

Classification of incidents	Number of victims with clinically significant consequences		
	Total	Among them: acute radiation disease	Among them: died
Radioisotope installation induced incidents	170	51	16
X-ray installation induced incidents	50	-	-
Reactor incidents (without the accident at the Chernobyl NPP)	82	73	13
Incidents at the PA «Mayak» (1949–1956)	168	-	-
Accidents at nuclear submarines	133	85	12
Other incidents	17	7	2
Accident at the Chernobyl NPP, 1986	134	134	28
Total	754	350	71

The public effective doses originated from operation of facilities in the supervision area were lower than minimum value of 0.01 mSv.

Radiation safety problems significant for health protection

There are some problems in the nuclear industry connected with the ageing primary funds; isolation of some shallow facilities for radioactive waste storage from the environment; large volume of liquid radioactive waste; a lack of reserve in the facilities for the spent nuclear fuel storage at some nuclear power plants; and radioactive waste storage facility under such plants management etc.

Some problems originate from past defense activity of the specific facilities and radiological accidents there. Unfortunately, such accidents resulted in severe consequences for workers, population and environment. First of all, we mean here "the first-born of the nuclear industry" – the production association "Mayak", which got the very difficult research and industrial tasks to produce nuclear weapon at the late 1940s.

The South Urals problems

The most serious consequences for the public health were induced by the radioactive waste discharges into Techa River and the accident at the PA "Mayak" of 1957. Since 1949, some part of the waste water containing radioactive substances, the gross activity of which was about 3 mln. Ci, has been released into Techa River and till July 1951, such releases were practically uncontrolled. This resulted in high radioactive contamination of the river system and radiation exposure to residents of the coastal settlements at doses of 4 - 5 Sv, which induced 940 cases of the chronic radiation disease over the first two years after the releases. In 1957, the explosion of the tank for the liquid radioactive waste storage resulted in radioactive contamination of the large area of the Urals region (the Eastern-Urals radioactive track) and the public exposure at 0.9 Sv.

Table 3 includes the summarized specification of the PA "Mayak" register. Inspection of the health conditions of this contingent revealed such late effects as increasing mortality due to malignant neoplasms and leukemia of workers being employed over 1948-1958. Over those years, learning of the new technology was accompanied with significant over-exposure of workers. After 1958, the cancer death rate was twice lower in comparison with average national data.

Table 3. The register of the PA "Mayak".

Indexes	Time of employment		
	1948-1958	1959-1972	1948-1972
Total number of individuals	12.692	6.154	18.846
Number of persons-Plutonium carriers	9.423	4.997	14.420
Number of persons with known life status	92.1%	96.3%	93.5%
Dose, cGy	112.8	18.9	83.4
Amount of Plutonium accumulated, kBq	2.5	0.4	1.7

The experts from the Urals Research and Practical Centre of Radiation Medicine and South-Urals Institute of Biophysics made the following conclusions:

1. The late radiation-induced effects such as increasing death due to malignant neoplasms and leukemia have been registered both of some residents of the Techa

River coastal villages, in Chelyabinsk region, and injured to the highest doses over the period of the highest releases, and of workers employed over 1948-1958.

2. The long-term observation of descendants of the exposed persons living at the coastal areas of Techa River and in the territory of the Eastern-Urals track did not demonstrate any changes in the public health.
3. The radiation situation around the Techa Reservoir System is now under control and causes radiation exposure neither to workers nor to the population, except for the critical population group of Muslyumovo village.
4. Because of increasing filtration of radioactive substances from the Techa Reservoir System, stabilization of concentrations in the river water is being registered. At that, the ^{90}Sr specific activity within the Muslyumovo village area is permanently higher than the intervention level established by the NRB-99 (5 $Bq \cdot l^{-1}$). The ^{137}Cs concentrations in the river water are lower and generally do not exceed the maximum level of the ^{137}Cs content in water of 11 $Bq \cdot l^{-1}$.
5. The ^{90}Sr specific activity in milk became 10-15 times lower since 1958 up to now. At the same time, since 2003 the steady tendency to the ^{90}Sr increasing in milk is obvious due to increased concentration of this radionuclide in the river water. In samples of the cow milk being pastured in the floodplain and drunk from the river the ^{90}Sr content in milk is higher than the permissible limit.

In this light, life in the settlements at the Techa River, especially near Muslyumovo village is potentially hazardous. In 2006, the FMBA of Russia made the associated conclusions and recommendations and sent them to the Rosatom. Our conclusions were used to justify the decision making, jointly with the Chelyabinsk regional authorities, to re-settle the residents from this village to the safer place.

Peaceful nuclear explosions

Today, evaluation and regulation of radiation safety in the regions affected by the peaceful nuclear explosions is very important radiation hygienic problem. More than 80 underground nuclear explosions have been made in territory of 16 Russian Federation subjects over the period since 1965 to 1988, with the peaceful purposes. At that, 79 explosions were confined (camouflet), after which neither radioactivity release into atmosphere nor environmental contamination assumed to be taken place. At the same time, during two explosions rather significant release of radioactive products into atmosphere and environmental contamination really took place. So, after Craton-3 explosion of 1978 in the Republic of Sakha (Yakutia), the radioactive track has been generated, the length of which was several kilometers. A wide range of problems are to be solved, including:

- Uncertainties in the legal status of the sites where the peaceful nuclear explosions were being performed;
- A lack of principles for distribution of responsibilities for safety at such sites;
- The public concern in the vicinity of such sites, in addition to concern of workers from the facilities functioning at such sites.

Radon in dwellings and on the industrial floor

In some subjects of the Russian Federation, the population is under significant exposure originated from high contents of radon 222, thoron 220 and their short-lived airborne progenies in dwellings. The situation at two areas under the FMBA of Russia service is unsatisfactory. These are: Octyabrsky village of Chita region and Lermontov city of the Stavropol Territory.

Octyabrsky village of Chita region began to be built in 1964, as a temporary residence of members of the geological prospecting expedition and builders. The village appeared to be situated at the area of the mining dump of the uranium mining-milling facility, as the Priargunsky mining chemical association was being built. It was situated just in the health protection zone of the facility surrounded by the units of the mining complex and other industrial units of the Combine. The experts of the Burnasyan Federal Medical Biophysical Centre inspected the radiation hygienic situation in Octyabrsky village. The excess of the radon regulation (200 Bq/m3) has been registered in 39 % dwellings (Figure 2). The average dose induced by radon intake in rooms was 14 mSv/year. The State Corporation "Rosatom" and Zabajkalsky Government decided to resettle 2000 residents to the safer place.

Unfortunately, over quite long-term period, the FMBA of Russia cannot decide the similar problem in Lermontov city of the Stavropol Territory, where about 1000 dwellings are radon-unhealthy, i.e., radon concentration in dwellings are higher than the authorized norms, so, the residents of the first and ground floors are under excessive exposure.

The FMBA of Russia recognizes challenges in radiation protection of workers and the public originated from the former "uranium" legacy of the USSR. Such problems assume to be solved under the inter-state target program of the European and Asian Economic Community (EurAsEC) «Reclamation of Territories of the EurAsEC states affected by impact of uranium mining and milling facilities».

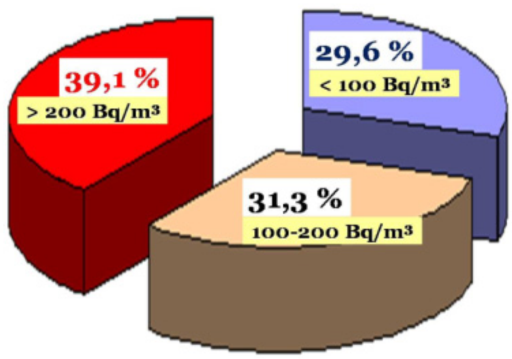

Fig. 2. Radon equivalent equilibrium activity concentration in dwellings, %.

The uranium mines located at the Russian area require the special attention and efforts of the FMBA of Russia. It is well-known that uranium mining and enrichment in mines is one of the most dose forming operations. So, at the Priargunsky mining chemical combine, the permissible annual dose limits established for workers are systematically excessive during uranium mining, mainly, due to excessive contents of radon and its decay products at the working area (the mine). At that, number of workers injured to annual dose higher than 20 mSv increases with years: over 2006 - 30, over 2007- 101 persons. In addition, according to the expert assessments of the FMBA of

Russia, the lung cancer of the uranium miners is 4 times more frequent in comparison with the mean population data.

Consequences of the accident at the Chernobyl NPP

According to data of the United Nations Scientific Committee on Effects of Atomic Radiation, in fact, the single science based consequence of radiation exposure to the public resulted from the accident at the Chernobyl NPP is significant increasing incidence of the thyroid cancer in persons who were children at the moment of the accident. Maximum absorbed dose to the thyroid was 50 Gy. Among those being exposed in childhood, more than 6000 cases of the thyroid cancer have been registered (by 2005, 15 deaths has been registered). Therefore, the FMBA of Russia solves such important health protection problems as arrangement of medical dose register for the Russian residents exposed to emergency radioiodine fallouts of 1986, reconstruction of doses to the thyroid, and maintenance of the register including information on persons participated in the accident consequences mitigation.

Peaceful nuclear renaissance

After the accident at the Chernobyl NPP, the requirements for the NPP safety became much stricter. The main public requirement was to assure guaranteed safety not only for the plant workers, but also for the residents of the NPP impact area. In this light, one of the most relevant scientific and practical tasks is to justify the public dose levels safe in respect to potential induction of late stochastic (cancer and genetic) consequences. For the purpose of such assessment, some large-scale radiation hygienic and epidemiological studies are to be performed at different stages of the NPP operational life. In this light, the FMBA of Russia develops the special unified method for performance of overall monitoring of radiation hygienic situation and public health in the vicinity of nuclear power plants. The methods suggested will help to compare the observed change of the health and environment condition indexes with the ”background” values, to evaluate their dynamical trends, to give quantitative risk assessments of radiation exposure, to justify suggestions on improvement of the public and environmental protection conception and to assure safe operation of the NPP.

Nuclear legacy

The FMBA of Russia jointly with the experts from the Norwegian Radiation Protection Authority participates in environmental remediation of radiation hazardous sites in Murmansk region of the Northwest Russia. These operations include management of the spent nuclear fuel (SNF), solid and liquid radioactive waste (RW) both accumulated over the period of the Navy activity and originated from dismantlement of nuclear submarines and above-water ships equipped with nuclear powered installations. As a result, some regulatory documents have been developed and radio-ecological monitoring is being carried out at the sites for the SNF and RW temporary storage (STSs) located in Andreeva Bay on the Kola Peninsula and in Gremikha village in the coastal stripe of the Barents Sea.

The analysis of radiation-hygienic situation taking account of the data obtained, leads to the conclusion that a long and extensive remediation program is necessary after removal of SNF and RW from the STS’s. Having in mind up-to-date approaches to radiation protection, identification of remediation strategies has been focused on justification of reduction of the occupational and public exposure originated from the residual contamination. The following have been defined (Figure 3):

- Conservation (storage under surveillance) – excludes the potential threat of contamination of the STS territory, water area and air media. A guarded area is arranged and continuous radiation monitoring is carried out.
- Conversion (renovation) – suggests subsequent use of the STS territories and facilities in compliance with the existing regulatory documents regulating the radiation impact on the personnel and public under normal conditions of radioactive source management. Limited use of the territory in combination with remediation measures and radiation monitoring ("brown lawn" concept) is envisaged.
- Liquidation – suggests stage-by-stage dismantlement and removal of equipment, withdrawal of RW, including contaminated environmental media, and assures the limited exposure dose to the critical group of the public at the level 1 mSv/y ("greenfield" or unlimited use conception).

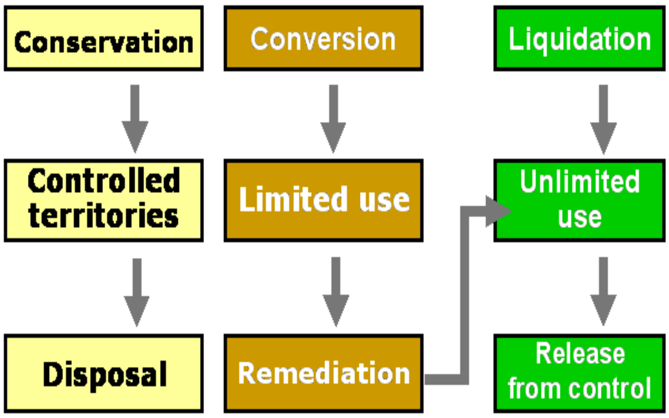

Fig. 3. Restoration options at the sites for the SNF and RW temporary storage.

FMBA of Russia approved the norms for the main options of the STS remediation. They have been developed on the basis of the relevant Russian laws and standards, taking into account the current radiation situation at the STS as well as up-to-date international recommendations and good experience in the field of contaminated area remediation in other States.

Conclusions

The available Russian and international legislative and regulative legal basis as a whole helps to solve problems of radiation safety assurance during the special and hazardous operations, enhances and supplements the principal legislative documents. At the same time, some difficult problems in the regulatory documents are to be solved with respect to operation of the national nuclear industry:

- Remediation of sites contaminated following past nuclear activity and "nuclear legacy";

- Decommissioning of nuclear facilities or justification of prolonged operational life of the functioning ones;
- Radioactive waste management;
- Support of effective emergency response;
- Difficulties in adequate application of the optimization principle.

Russia is not a passive onlooker of the world radiation safety problems to be solved according to the UNSCEAR priorities. They include:

- Medical exposure to patients;
- Radiation levels and consequences of nuclear power production;
- Exposure originated from the natural radiation sources;
- Improved understanding of consequences of radiation exposure at low dose rate.

Today, the accumulated scientific potential of the experts from the FMBA of Russia, the experience in radiation safety regulation and medical sanitary support, as well as the factual materials available enable to solve the most difficult tasks in radiation safety.

Spanish national campaign for the search and recovery of orphan radioactive sources

Carboneras, Pedro[1]; Ortiz, Maria Teresa[1]; Rueda, Carmen[2]
[1] ENRESA, SPAIN
[2] LAINSA, SPAIN

Abstract
This paper aims to describe the main approaches, the steps taken, the experience gained and the results obtained in the campaign for the "Search and Recovery of Orphan Radioactive Sources" that took place in Spain between February 2007 and December 2009. The paper aims to share the experience gained with others who are considering or are already involved in similar campaigns, and to enable opinions to be exchanged with those responsible for such campaigns in other countries. The campaign was initiated by a decision of the Spanish Ministry of Industry, Tourism and Trade (Ministerio de Industria, Turismo y Comercio, MITYC) with the expert assistance of the Nuclear Security Council (Consejo de Seguridad Nuclear, CSN) in compliance with the national legislation currently in force regarding the control of highly active and orphan radioactive sources, and was commissioned to the Spanish National Company for Radioactive Waste Management (Empresa Nacional de Residuos Radiactivos,S.A., ENRESA). The campaign tried to seek and recover the largest possible number of orphan radioactive sources and involved the collaboration of various different agents and organisations where such sources could be found. The paper provides details regarding the number and radiological characteristics of the sources which have been recovered in Spain during the campaign. Experience shows that, even though a suitable regulatory framework exists, as is the case in our country, orphan radioactive sources may still exist for various reasons. Several other actions taken place in Spain previously or in parallel to this campaign were and continue to be very positive in regards to the recovery of control of the majority of radioactive sources existing in the country. It has to be emphasised that in this subject complementary international concerted efforts are always needed and welcome.

Introduction
According to the Spanish regulation, an orphan source is a radioactive source with an activity above the exemption level established in legislation, which is not under regulatory control, either because it has never been or because it has been abandoned, lost, misplaced, stolen, or transferred without proper authorization.

Orphan radioactive sources have caused deaths and injuries in several countries, when members of the public, without knowledge of their potential risk, have found and handled them in an inadequate way. There is also concern that orphan sources may be acquired for malevolent purposes. Finally, the economic impact of an accidental fusion of an orphan source within the metal industry can be considerable. All these reasons have led many countries to consider making efforts to improve the control over them.

Orphan sources are mentioned in the European Union Legislation. The Council Directive 203/122/Euratom on the control of high-activity sealed radioactive sources and orphan sources, Art 9.4, states that "Member States shall ensure that campaigns are organized, as appropriate, to recover orphan sources left behind from past activities".

Orphan sources are also mentioned in Spanish Legislation. The Royal Decree 229/2006 on high-activity sealed radioactive sources and orphan sources, Art 11.4 says that "the Ministry of Industry, Tourism and Trade , with the expert assistance of the Nuclear Safety Council , shall organize, as appropriate, campaigns to recover orphan sources left behind from past activities".

Financial aspects are also mentioned in both legislative documents. According to CE Directive, Art 10, member states "shall ensure that, on the basis of arrangements to be decided by them, a system of financial security is established or any other equivalent means to cover the intervention costs relating to the recovery of orphan sources". Similarly Royal Decree 229/2006, Art 12 says: "the costs stemming from managing orphan radioactive sources, in addition to the measures taken to recover such sources or to deal with radiological emergencies caused by them, shall be defrayed by the last owner of the source, providing that the owner can be identified. If identification is not possible, these costs shall be covered by the owner of the facilities in which the source is detected".

This specific national campaign was launched in Spain as a result of the initiative of the MITYC, with the expert advice of the CSN. The implementation of the campaign was entrusted to ENRESA, and it was developed between February 2007 and December 2009.

The aim of the campaign was the search and recovery of the largest possible number of orphan radioactive sources existing in the country, based on the voluntary cooperation of those agents and organizations where the sources were or might be found, and taking in consideration the Spanish experience and "nuclear" history.

Some of the main characteristics of the Spanish National Campaign were that it was conceived as a preventive action (working in parallel with other on-going corrective campaigns as the metal industries "Protocol"); it focused on past activities, giving preference to radioactive sources of higher activity but covering all type of sources; it was addressed to all sectors of use or potential use; and was geographically broad- based (national). The campaign was funded by the General State Budget but was not free for users or owners. Fares applied were the same as those charged by ENRESA for the management of disused sources in regulated facilities.

Material and working procedure

Since the starting date of the campaign, several core activities were carried out, following a basic initial and very general publicity performed by the MITYC, including the addition of specific information on the campaign in the electronic Web pages of MITYC, CSN and ENRESA.

The initial step taken in the campaign was the creation of an Advisory Committee to support the task of ENRESA, formed by senior members from different organizations, selected for their experience. This Committee was basic for the review of the current and past history of the regulatory control applied, including the management of disused sources in Spain; the detailed analysis of other actions promoted by Spanish authorities in the past regarding orphan and vulnerable sources; the data gathering and evaluation of the historical national information available regarding the uses of the radioactive sources; and the identification of fields of activity likely to have used and continue to posses orphan sources. This Committee met in several occasions during the campaign for a follow up of the action plan established.

a) Review of the current and past history of the regulatory control and management of disused sources in Spain

According to IAEA guidance it is always important for orphan sources campaigns the evaluation of the regulatory history in the country.

Spain has since 1982 a well established Regulatory Agency, the CSN. Before this date, from 1964 to 1982, the Nuclear Energy Board (Junta de Energía Nuclear, JEN) used to act as the Regulatory Agency.

There has always been a rather good degree of control of radioactive sources in the country. Regulations have been implemented and applied since long ago. Licenses granted to users included the identification of the specific radionuclides and activities authorized, as well as provisions for the complete life-cycle of radioactive sources. The facility closure permissions were not granted until it could be demonstrated that the radioactive material was transferred to an authorized final recipient. There were also import controls of sources and regular inspections to users. Of course, the degree of regulatory control of radioactive sources has been stricter since 1982 and even more since 2006 when RD229 was approved.

The collection of disused radioactive sources for their safe management, including disposal, was the initial responsibility of the JEN, until ENRESA was created in 1986. Although the management system was not really “complete” in Spain until 1986, the system and operational capabilities needed to recover such sources have been in existence much earlier and legal requirements and attempts have always been applied to return radioactive sources to the original supplier, although this has not always been possible. Since approval of RD229 in 2006, agreements with supplier and bank guarantees are needed to get approval for the use of whatever high activity sources. Individual inventories of these sources are also fully available.

The conclusion of this evaluation was that the possibility in some degree, of sources existing in the country from past activities, could not be discarded.

b) Analysis of other actions promoted by Spanish authorities in the past regarding orphan and vulnerable sources

The first actions aimed to recover control of orphan and vulnerable sources were initially performed by the JEN since very early (mostly devoted to the radium needles and tubes in the medical sector) and were additionally pursued since the creation of the CSN in 1982. Since 1986 all the field actions were basically assigned to ENRESA.

The following is a brief summary of the most relevant activities promoted in the past:

– The general campaign for the removal of radium-226 sources, being carried out since 1970's, which has resulted to date in several thousand sources collected and finally re-exported to an authorized management facility in USA, after facing many practical difficulties (dispersion, private use, etc).
– The campaign for the removal of lightning rods headers, based on a change in the regulatory system in 1988. This has also faced quite a lot of practical difficulties (lack of reliable information; dispersion; private use, etc) and has collected to date more than 22500 rods. At present it is practically finished but some 100 headers per year are still being removed. The radioactive sources collected after dismantling the headers were basically sent for recycling to UK.
– The campaign for the removal of teletherapy headers, limited in scope and duration (11 headers between 1989 and 1991) and essentially conceived a preventive action. Since then on, disused units are being re-exported as part of the supply process of new equipments.
– The Protocol for the Radiological Surveillance of metallic materials, signed in November 1999 by the Spanish Government and the industrial sectors, most actively involved in the recycling of scrap metal. The protocol was later endorsed by the main trade unions. More than 130 individual companies have signed the protocol to date. By the end of 2008, almost one thousand different radioactive materials had been detected (around 100 per year). Although a great part of them were just material containing Naturally Occurring Radioactive Materials (NORM), several true radioactive sources have been found and removed from the system.
– The Transfer Authorization, which is an administrative procedure used over decades by the Spanish Authorities as needed, to regain control over whatever radioactive material found "uncontrolled", by authorizing the transfer of responsibility over such materials from the existing possessor to an authorized agent for its further management. To date over 200 transfer authorizations had been granted by the end of 2008 and ENRESA has managed to recover 246 radioactive sources.

As a consequence of all these actions carried in Spain since long ago, the expectations in this specific campaign to find a considerable number of orphan sources was low, altough a "confirmation" was considered worthy.

c) Data gathering and evaluation of the historical national information regarding the use of radioactive sources

From the available official documentation and with the help of the Advisory Committee and the individual relevant people identified, who were involved in the first uses of radioactive sources in Spain, a rather good vision of the use of the radioactive sources in the early years (50´s to 80´s, before the CSN was created) was possible.

Since the 1980´s official inventories of the practices and applications of sources in Spain, and the radionuclides and activities within the practices, were available and could be accessed.

In Spain there are about 1300 regulated facilities of different types. Since the objective of the campaign was the collection with preference of the higher activity sources, a review of users of these sources in the different fields was performed, giving priority to the early pioneers. From this study the following uses of radioactive sources were selected: teletherapy, braquitherapy, blood irradiation, irradiators for research, military applications, calibration laboratories, gammagraphy, geophysical and soil controls, and industrial applications.

Spain has not been a producer or exporter of radioactive sources except for some limited production by the JEN in the early years for local use. Most sources used in Spain were (and still are) imported. This is another condition for the results of this campaign expected not to be huge.

d) Identification of fields of activity likely to posses orphan sources

From the data collected, the following group of users likely to have orphan sources was identified:

- Old public and private hospital and clinics
- Old universities with scientific and technical studies
- Old research centres
- Service companies
- Industries
- Manufacturers and suppliers
- Warehouses
- Waste disposal companies

e) National contacts

The approaches to the identified objectives were made using the following channels:

– Government Ministries and Regional Government Authorities responsible for areas, such as Radiation Safety, Nuclear Power, Education, Research, Defence, Health, Environment, Mines, Agriculture, Transport, Industry and Development.
– Non governmental organizations, professional organizations and societies, cooperative institutions, technical service organizations, other technical organizations and trade groups.
– Official Schools related to medical, sanitary, scientific and technological activities.
– Business Associations in the most representative sectors of the industry.
– Industries within the country by sector of activity (chemical, mineral, oil and gas, paper, glass, wood, tobacco, drinks, etc.)
– Service companies importing sources temporally for specific jobs (non destructive testing, geophysical and soil controls)
– Suppliers of radioactive material or equipment, detectors and laboratory equipment. Companies supplying electro medicine equipments and businesses related to radiation protection
– Transport companies and Customs control organizations

– Specific individuals identified by the Committee with historical knowledge of the first uses of radiation sources in the country (mostly in the medical sector)

The contacts with professionals of these organizations were made using all available means: telephone, letter, direct interview, etc. Neither the broadcast media nor the public directly were ever addressed in the campaign. Distribution of the information through medical, scientific, and industrial associations was very useful to achieve a "multiplier" effect in its re-transmission to members and its dissemination via their own regular media (electronic pages, magazines, publications, etc). Additional promotion of the campaign was made in several ordinary fora organized by these associations and societies as well as in courses related (even if laterally) to the topic of the campaign.

f) International contacts

Contacts with international agencies with experience on similar situations were of great value for the campaign. A visit was paid to the International Atomic Energy Agency (IAEA) to know programs being carried out in the field and to search for potential direct contacts. The IAEA is giving technical advice and support all over the world for recovering orphan sources and holds several geographically specific campaigns. A meeting was also held in Madrid with the USA National Nuclear Security Administration (NNSA) with the aim of sharing information about the initiatives being followed by the United States in the world to recover radioactive sources and to study ways of cooperation. The NNSA has been doing enormous economic and human efforts to give many countries all over the world material, means and technical support to recover uncontrolled sources.

g) Other steps taken in the campaign:

– Creation of easily accessible and understandable documents containing graphic information for an easy identification of orphan sources.
– Distribution of graphic and textual material to institutions, organizations, companies and associations.
– Attendance to congresses and meetings for the promotion of the campaign
– Bibliographical searches, Internet searches and consultation of international publications to trace possible locations for orphan sources.

h) Types of search

In the campaign two types of search were performed:

– Non physical or administrative searches, consisted basically in "detective work" for the collection and analysis of information in order to attempt to identify sectors likely to hold orphan sources.
  Some of the key documents analyzed were:
  - Data on orphan sources collected in the past (national campaigns, transfer resolutions)
  - Historical records of disposal of sources
  - Detections of national origin in the metal industry
  - Lists of early supplies in the country (old files).
  - Data on known lost and found sources
  - Historical documents

- Specific examination of sectors of use.
- Lists of attendees to meetings and congresses of interest
- Mailing lists of specialized societies and associations
- Official reports

– Physical searches, using radiation monitors and according to ENRESA searching plans to locate sources, were carried out in a few facilities suspected to have orphan sources and willing to collaborate in the campaign (warehouses in ports or airports, abandoned facilities, etc).

Results

Attention was paid to all contacts, communications and responses received, whether or not related to genuine orphan radioactive sources. In some cases, the demands were redirected to ENRESA's normal answering system for the ordinary management for radioactive waste or other alternative routes, according to the characteristics of the declared material.

Non-specific consultations were received about disposal routes for:

– X-rays equipment. In Spain specific companies make destruction of tubes.
– Smoke detectors, not covered by the campaign because their management is regulated by RD 208/05, transposing the corresponding European Directive, as electric and electronic equipment.
– Lightning conductors, for which a specific campaign was still active.
– Disused regulated sources.
– Exempt sources, not the objective of the campaign at an early stage but with some allowances later on due to specific circumstances.
– Sources found in those industries and field of activity already covered by the "Protocol" in place for the metal recycling industries.

Each recovery of orphan sources included the following actions, performed using the capabilities available in ENRESA as part of its regular business:

– Analysis of the available information and technical visit to complete the detailed description of the radiological (and any other relevant) characteristics of the radioactive sources declared.
– Acquisition of graphical images of the sources and equipments.
– Preparation of the sources for its provisional storage and future transport.
– Collection of radioactive sources from the declaring premises and transport to ENRESA's facilities in El Cabril (Cordoba).

First sources were recovered in the campaign by the end of 2007, after getting from the MITYC the generic transfer authorization (an administrative requirement whenever a "radioactive material" is to be transferred from one to another possessor).

By the end of the campaign more than 300 radioactive sources have been declared and mostly recovered. In addition to these sources, other radioactive materials have also been recovered, including unsealed sources of various radionuclides, equipments with depleted uranium shielding and several other contaminated pieces.

The data below show the results at the end of December 2009. These are not yet fully the "definitive" results as they do not include the sources declared by the end of December 2009, collected in the first months of 2010.

Classification of sources collected by radionuclide

Radionuclide most frequently found in the campaign was Cs-137, followed by Ra-226, Co-57, Sr-90, Ni-63 y H-3.(Table 1.)

Table 1. Classification of sources collected by radionuclide.

Number of sources	Radionuclide	%
80	Cs-137	30,08
40	Ra-226	15,04
35	Co-57	13,16
21	Sr-90	7,89
18	Ni-63	6,77
14	H-3	5,26
10	Po-210	3,76
9	Th-232	3,38
5	Co-60	1,88
4	C-14	1,50
4	Ba-133	1,50
3	Ra-226/Be	1,13
3	Am-241/Be	1,13
3	Pm-147	1,13
3	Sn-119	1,13
14	Various	5,26
266		100

The figure shows expected values with some exceptions: Co-57, a short lived radionuclide used for calibration of gamma cameras in Nuclear Medicine services; Ni-63, included in laboratory equipment for gas chromatography and Po-210 used in static eliminators in the industry.

Classification of sources collected by activity

Most of the radioactive sources collected in the campaign had activities lower than 1MBq when declared. Nearly 100 sources had activities above this value. The highest single activity was 76000 MBq and the total activity was above 100000 MBq.(Table 2)

Table 2. Classification of sources collected by activity.

Activity	Number of sources
< 1 MBq	168
1- 10 MBq	22
10 -100 MBq	31
100 -1000 MBq	36
1000 - 10000 MBq	8
10000 - 100000 MBq	1
TOTAL	266

Most active sources collected in the campaign included industrial gauging sources, Ra-226 tubes and needles, sources for the measurement of humidity and density of soil, braquitherapy eye and surface applicators and many types of checking and calibration sources.

Activities shown are referred to the date of collection of the sources.

Classification by sector of activity

Sources have been collected in the different types of facilities, namely medical, industrial, research, etc. in a similar percentage (Table 3)

Table 3. Classification of sources collected by sector of activity.

Type	Number of facilities	Number of sources	% facilities
Industrial	24	74	32,43
Research	22	73	29,73
Medical	22	100	29,73
Others	6	19	8,11
Total	74	266	100

The the distribution of sources and facilities is similar, but the sources with the highest activities were collected at industrial facilities.

Classification of the sources collected in the campaign according to IAEA categories

Table 4. Classification of sources collected by IAEA category.

Category	nº sources	%
Exempted	70	26,32
Category 5	184	69,17
Category 4	12	4,51
Total	266	100

One fourth of the radioactive sources collected were exempted when declared, although they were not always exempted in origin. In spite of this, they were collected.

Around 200 sources were not exempted, being mainly categorized as 4 y 5, although some of them were category 3 in origin (Table 4)

Geographical distribution of the sources collected

Although the campaign was addressed to the whole Spanish territory, most of the sources were collected in Madrid area, for two basic reasons: a) Spain was a very “centralised” country in those years and historically the first uses of radiation were promoted from the JEN in Madrid; and b) in some case (army) the sources found were firstly collected in their central services in Madrid, before being transferred to ENRESA lately.

Discussion

Reasons for the existence of orphan sources

The analysis case by case of the reasons found for the existence of orphan radioactive sources shows the following results:

- Sources were an historical legacy (used before regulatory control was put in place)
- Costs of disposal were very high
- No disposal routes were available
- Deliberate fears of regulatory requirements (a few cases)
- Sources had been used in regulated installations without having been declared

Other remarks about the orphan sources recovered

- The sources recovered in the campaign did not represent, in any case, a security risk or a high safety risk at the locations in which they were found. No evidence of malicious practice was detected.
- Work was performed in an effective and discrete way. There was not any negative media impact associated to the campaign. Great interest and collaboration was offered by the different sectors addressed.
- In most of the cases owners covered the cost of the management applied regularly in Spain. In some specific cases holders of the sources found it extremely difficult to meet the costs involved. None of the sources was left behind due to the cost issue.
- The campaign was a good opportunity for owners of orphan sources to “clear houses” in a relatively easy way.

Some lessons learned in the campaign

- The usefulness of carrying out physical inventories in the facilities, including most ancient materials, to find out orphan sources.
- The highly recommended prompt disposal by the regulated installations of disused sources, considered “vulnerable” as they may became “orphan” rather easily.
- Exempt sources were not the object of the campaign, but were recovered in quite a few cases for different reasons. Many users expressed their doubts as how to dispose off this type of sources, even when clear rules were available in the country.

The ending date of the campaign, December 2009, refers only to the pro-active actions carried out specifically. From this date on, the Spanish regulatory system maintains mechanisms to allow ENRESA to continue recovering all orphan radioactive sources declared in future, following specific administrative procedures, as it has been doing up to date

Conclusions

Spanish experience showed that, even though a suitable regulatory framework exists and though it is implemented efficiently by the supervisory authorities, as is the case in our country, orphan radioactive sources may still exist. Experience has shown the usefulness of this type of "proactive" campaign in spite of previous related efforts.

International complementary concerted efforts are always needed and are highly recommended to improve control of orphan sources, because, although there may be a well established regulatory system, no country is completely isolated and free of risk with respect to the inadvertent international movement of radioactive material.

Mitigation of exposure to radon by household water treatment

Turtiainen, Tuukka
STUK—Radiation and Nuclear Safety Authority, Finland

Abstract

Water distribution networks are obliged to carry out monitoring of the water quality. Presently they cover over 90% of the water supply in Finland. There are, however, about 500,000 Finns that rely on private wells for their daily water supply. One of the contaminants that impair the water quality of private wells, especially those drilled in bedrock, is radon. There are presently 6,600–9,000 private wells in which radon concentration exceeds the recommended maximum concentration of 1,000 Bq/L. Due to inaccessible water distribution networks household water treatment units remain the only viable option for mitigating the exposure. In this paper, household water treatment principles for removing radon from water are described together with doses and risks related to waterborne radon among Finnish well-owners.

Introduction

Radon is a radioactive gas that originates from naturally occurring uranium that has been present in the earth's crust since its formation. Due to its solubility to water, it is found in all groundwaters. Water supply plants are obliged to carry out statutory monitoring of the water quality and the maximum concentration set for radon is 300 Bq/L (STUK 1994). Decree 401/2001 by Ministry of Social Affairs and Health recommends 1,000 Bq/L as the maximum concentration of radon in domestic wells. Radon causes radiation exposure through ingestion and through inhalation because radon is partly released into indoor air during water usage. These exposure pathways increase mainly the risk of stomach and lung cancer (NRC 1999).

Systematic surveys of the occurrence of radon in Finnish groundwaters began at the end of the 1960s. In the first phase, bedrock water samples from drilled wells in the Helsinki area were surveyed (Kahlos & Asikainen 1973). Radon concentrations were generally high, with a mean of 1,600 Bq/L, which prompted the surveying of waterborne radon throughout Finland. Based on over 1,500 water samples, the mean radon concentrations in groundwater wells and bedrock water wells at that time were assessed as 60 and 630 Bq/L, respectively (Asikainen & Kahlos 1980).

In the 1980s, the surveys were mainly directed at private wells, which were investigated in co-operation between STUK and Geological Survey of Finland, which performed nationwide studies on the physico-chemical and microbiological quality of well waters (Juntunen 1991). Since that time, radioactivity in all new groundwater sources are measured before they are connected to water distribution networks. In a more recent population-based random study, in which 184 water samples from dug wells and 288 from drilled wells were analysed, the observed mean concentrations of radon were 50 and 460 Bq/L, respectively. In dug wells, all measured radon concentrations were below 1,000 Bq/L, but 10.8% of drilled wells exceeded this level (Vesterbacka *et al.* 2005).

The availability of water services has steadily increased, especially in the more densely populated southern Finland, where the highest radon concentrations are generally found. Finland presently has a population of 5.3 million, about 4.8 million of whom have now access to water distribution services. The remaining 500,000 rely on private wells or have formed small co-operatives for abstracting water (Isomäki *et al.* 2007).

The number of drilled wells has steadily increased. In the 1950s, one well out of 1,000 was a drilled well, but by the early 1990s the portion had increased to 23% (Korkka-Niemi 2001). According to a survey conducted in 2007, the portion of drilled wells was already 32.5% (Vienonen 2007). According to data collected by Muikku *et al.* (2009), the portion of drilled wells was 43.9%. From these, we can estimate that the number of users of drilled wells is 160,000–220,000.

At the end of 2007, 1.01 million households with a total of 2.65 million residents were living in one-family houses (Statistics Finland 2008). From these data, we can estimate that the number of drilled wells in permanent use is about 61,000–83,000 and, considering the concentration distribution of radon, the number of wells where radon concentrations exceeds 1,000 Bq/L is 6,600–9,000.

Methods for removing radon from drinking water

Research on radon removal from water supplies was initiated in the 1970s in Czechoslovakia. Aeration was found an effective method for removing radon out of water. A removal efficiency of 99% was reported for 8 minutes aeration time using an air-to-water ratio of 1:8 (Hanslik *et al*. 1978). In the early 1980s, several aeration techniques and activated carbon adsorption were tested in Sweden. Among the tested methods, aeration under atmospheric pressure was found the most effective with a removal efficiency of up to 75% (Hedberg *et al.* 1982). In the USA, similar studies were also begun in the early 1980s. Three methods were tested and found effective: granular activated carbon adsorption, diffused aeration and spray aeration (Lowry 1983).

Removal studies in Finland were initiated in the 1990s in collaboration between STUK, the Finnish Environment Institute and Helsinki University of Technology. From the first project onwards, the main objective was to bring suitable and reliable treatment units to the market. Therefore, companies specializing in water treatment have been invited to participate in the research projects (Myllymäki *et al.* 1999). In 1997, a European research project financed by the European Commission started to investigate removal of naturally occurring radionuclides from ground water (Annanmäki & Turtiainen 2000). In order to obtain long-term experiences of their operation, a follow-up project was initiated and the units mounted during the previous project were monitored until the end of 2002 (Vesterbacka *et al.* 2008).

Aeration technique

As a dissolved gas, radon can be removed from water by aeration similar to e.g. carbon dioxide. Three alternative principles are customarily employed in aeration: a large number of air bubbles are produced in the water (diffused aeration); water is sprayed into air as small droplets (spray aeration); or a large surface is created between water and air on an inert material (tower aeration). Domestic aeration units typically employ a combination of the first two principles and the aeration time needed per water batch is 4–10 minutes. Most commercial systems work under atmospheric pressure and hence a water pump and a pressure tank are needed after the aeration unit to give the water enough pressure to deliver it throughout the plumbing. Water flow from a well through an aeration unit into a pressure tank is electronically controlled (Turtiainen 2009). The cost of acquiring aeration units is two to three times as high as that of an activated carbon unit. This difference, however, will be partly compensated by the higher operating costs resulting from the need to replace the carbon batch every three years (Mäkeläinen & Turtiainen 2003).

Low-cost alternatives where aeration takes place in the bore hole have also been introduced. In total, aeration units from eight manufacturers have been tested as of spring 2010. The lowest radon removal has been recorded for aeration in the bore hole, where efficiencies varied from 3% to 77% (average efficiency during 100 litres flow). More sophisticated aeration units, however, were all able to remove more than 90% of radon (Turtiainen 2009). Presently, four brands are available on the Finnish market, all with adequate radon removal efficiency.

Activated carbon adsorption

As a non-polar gas, radon is effectively adsorbed on activated carbon. Activated carbon units sold in Finland are typically pressure vessels with carbon bed volumes of 39–105 litres. An automatic backwash system is employed in cases where the influent contains large amounts of iron, manganese or humic substances that may cause clogging. The units are always installed to treat all household water so that exposure to radon through inhalation is prevented, as well. The units operate passively under normal plumbing pressure (2–6 bar) and hence require no additional pumps (Turtiainen *et al*. 2000a). Therefore, the acquisition price of the unit remains low compared to the aeration technique.

The maximum amount of radon accumulated on the carbon bed depends on the water flow rate and the radon concentration in raw water, and is reached in about tree weeks after commissioning of the unit. The short-lived progeny of radon that emit gamma radiation are also retained on carbon and reach equilibrium with radon. Due to resultant external gamma radiation from the activated carbon units they cannot be installed inside residential buildings and their use should be limited to radon concentrations below 5,000 Bq/L (Annanmäki *et al.* 2000).

The radon removal efficiency of activated carbon units was followed at ten households for a period of 3 to 9 years. The carbon bed was replaced with a fresh batch in three locations during the follow-up. In the selection of the households, different types of water were covered, including iron- and manganese-rich water and water with a high content of organic carbon. Radon concentrations in raw water were 1,500–7,400 Bq/L (Vesterbacka *et al.* 2008). All units removed more that 90% of radon, and most of them nearly 100%. Some units showed a decline in removal efficiency over time, and hence to ensure adequate removal efficiency it was recommended that the carbon batches be replaced every three years. Water quality, both microbiological and chemical, remained good. Iron, lead-210, polonium-210 and organic substances were partly removed by activated carbon treatment (Turtiainen *et al*. 2000b).

Customer insights on radon removal units

STUK recommends aeration technique as the primary household water treatment for removing radon because the units do not cause external radiation or produce any type of radioactive waste. The maintenance costs of aeration units are also somewhat lower than activated carbon units which require replacement of carbon at three years' interval. Replacement of carbon may sometimes be neglected by the home-owners.

According to a survey among customers that use household water treatment for removing radon, activated carbon adsorption is more widely employed, with a 70% share of all units (Vesterbacka *et al.* 2008). The reason for this is evidently the more affordable acquisition price. Another survey conducted in 2008 among 53 well-owners implied that most people are ready to take required measures against radon when they receive information. Only nine of the interviewed did not intend to react (Turtiainen & Salonen 2010).

Effective doses and related risks

Dose conversion factor for radon ingestion by adults reported by NRC (1999) is 3.5×10^{-9} Sv/Bq. The factor increases with decreasing age being 4.0×10^{-8} Sv/Bq for infants. Drinking water consumption has been investigated among the adult Finnish population in the age groups 25–34, 35–44, 45–54, 55–64 and 65–74 years. The average daily intakes among female and male populations representing these age groups were 0.667–0.929 and 0.441–0.676 litres, respectively (Paturi *et al.* 2008). By assuming even water ingestion during the day and by subtracting time spent outside homes (work, school, travelling, etc.) the annual intake of water at home among female and male population of these age groups has been assessed as 230–260 and 140–190 L/a, respectively (Turtiainen & Salonen 2010). According to the survey by Vesterbacka *et al.* (2005), the mean concentration of radon in those wells where radon exceeds 1,000 Bq/L, is 2,700 Bq/L.

Radon is partly released into indoor air during water usage. The proportion of waterborne radon concentration in indoor air to radon concentration in water is expressed as transfer factor (Nazaroff *et al.* 1987). Parameters, such as ventilation rate, indoor air volume, total water usage rate and proportion of radon released from water during certain types of water usage, affect the value of transfer factor. NRC (1999) recommends that a factor value of 1.0×10^{-4} be used in dose assessments (1,000 Bq/L of radon in water causes an excess radon concentration of 100 Bq/m^3 in indoor air). In Finnish one-family houses, both water usage rate and ventilation rate are lower than those in American houses. The modelled value (0.36×10^{-4}) is supported by actual measurements, which give a mean value of 0.39×10^{-4} (Turtiainen & Salonen 2010). The mean excess radon concentration in indoor air can thus be assessed as 100 Bq/m^3 in houses where the recommended maximum value for radon in water is exceeded. ICRP65 recommends a dose conversion factor of 6×10^{-9} Sv/(Bq h m^3) for radon in indoor air of homes with an equilibrium factor of 0.4 (ICRP 1994). These values together with a 0.8 indoor occupancy factor will be used in the following.

By using the values discussed above, the mean collective effective dose from ingestion can be estimated as 31–42 man Sv/a (weighed by population per gender and age group) among users of drilled well water in which radon exceeds 1,000 Bq/L. By using risk of 5% per Sievert it can be roughly assessed that two additional fatal cancer cases per year are attributable to ingested radon (ICRP 2007). The collective effective dose, 31–42 man Sv/a, is also obtained from dose assessments for inhalation, which may add one or two fatal cancer cases to the previous figure.

The number of household water treatment units installed for removing radon is presently about 1,000. Assuming an average removal efficiency of 95% for the removal units, the effective dose through both ingestion and inhalation of radon has been reduced by 3.4 mSv per year on average among those who have purchased them. Expressed as collective effective dose, the reduction is about 9 man Sv per year.

Discussion

In normal cases, the individual lifetime risks related to radon in drinking water are small. Even among those who use water in which radon exceeds 1,000 Bq/L, the mean lifetime risk is below 1%. Extreme concentrations of radon in well water are, however, occasionally found. Probably the highest concentration of radon ever found in private wells, 130,000 Bq/L, was located in Southern Finland in 2007. The family of five had been using the water regularly for a period of 10 years. The effective dose from ingested radon to the family members was thus about 1 Sv each. Hence, the assessed risk of one of the family members getting cancer attributable to ingested radon is about 30%.

Owing to long distances to water mains from the estate or due to projected low end-point consumption, joining the public water services may not be possible for homes with high radon concentration in the well water. The government has recognised the lack of water services (both drinking water and waste water) in rural areas and has accordingly channelled additional funs to extend the existing networks. There are, however, areas where the networks will not be available in near future. In these cases, household water treatment has provided an effective means to mitigate radon exposure. Acquisition of a water treatment unit is straightforward and the units sold today have generally been reliable and customer satisfaction has been good. This was made possible particularly by engaging the companies in research and development of the techniques from the first phase on.

Statistically, the number of cancer cases related to the radon in well water is only a few per year. Citizens, however, should have the right to be informed about this risk, which is also implemented in national legislation. Radiation is a sensitive issue for many, especially for families with children. Public communication campaigns or newspaper articles about risks relating to well water have always expedited radon measurements at laboratories and subsequently resulted in increased sales of the treatment units. Public memory, however, is short and public communication should be enhanced when the number of water samples sent for radon measurement start to decline. There are still 15,000 to 21,000 Finns that continue to be exposed to waterborne radon without necessarily being aware of it.

Dose assessment for tritium releases during normal operation of NPP

Duran, Juraj[1]; **Malátová, Irena**[2]
[1] VUJE, Inc., Dep. of Accident Management and Risk Assessment, SLOVAKIA
[2] SURO, CZECH REPUBLIC

Abstract

Radiation Doses (RD) codes for estimate of impact of air effluents during normal operation of Czech NPP assume that all atmospheric tritium releases are emitted from ventilation stacks only. Transfer of liquid tritium is modeled by diffusion process in river only. In reality, in the case of Dukovany NPP, cooling water in cooling towers contain significant activity of tritium, as water is coming from reservoir with liquid effluents. Until now no special attention was devoted to the transfer of water vapor with tritium from cooling towers, because it was supposed that the tritium released from NPP was already taken into account in the calculation of doses from hydrosphere; estimation of doses for Dukovany NPP was therefore conservative. The aim of present research is to find out how conservative is the present way of estimation of doses from tritium and a realistic approach will be sought. A computer code MHTO has been developed to assess tritium doses to the general public. The code enables to simulate the behavior of tritium in the environment released into the atmosphere and hydrosphere under normal operation of NPPs. The code can calculate the doses for the four forms: tritium gas (HT), tritiated water vapor (HTO), water drops and organically bounded tritium (OBT). Models in this code consist of the tritium transfer model including reemission of HTO from soil to the atmosphere. The comparison of results obtained from calculations using RD and MHTO codes prove that when taking into account the releases of tritium from cooling towers, codes RD provide a value of maximal individual effective dose from hydrosphere about 30% less and the dose from atmosphere is about 20% higher in comparison to the case without releases from cooling towers. At the same time, the collective dose is approximately 30% lower as in the case without releases from cooling towers.

Work on this project was supported by State Office of Nuclear Safety of the Czech Republic (project SUJB-5200).

The legacy of uranium mines – Pluralist Expertise Group experiment on uranium mines in Limousin (France)

[6] SCK-CEN, BELGIUM
[7] IRSN, FRANCE
[8] Independent expert, ISRAEL

Abstract

Context: In France, as mining and milling operations drew to a close, from the 80s until 2001, AREVA-NC has carried out with the administration important work on remediation and rehabilitation of more than 200 sites to assure the protection of the population and the environment, with continuous monitoring of the environment, which is ongoing. The closure and the remediation over this period have caused some concern in the public and NGOs. This issue is of particular concern in Limousin, the area that most contributed to uranium mining in France. Among actions taken by the French Government and Regional authorities, the Pluralist Expertise Group (GEP) concerning the legacy of uranium mines in Limousin was created after a joint mission letter from Ministries of environment, industry and health (2005).

Method: The group brings together experts from various technical fields including French institutes, the industrial operator, local and national NGOs, independent experts and foreign experts. Four multi-partite working groups (WG) have been set up to discuss the current status and management options for the sites:

– WG1: Inventory of substances and transfers in the environment
– WG2: Impact and surveillance
– WG3: Regulations and long-term control and management
– WG4: Analysis of measurements.

The purpose of this paper is to describe the work of WG2.

Results: At first the WG2 has drawn up a status report of the current situation, both at national and international level, for its topics (risk for the environment, impact

on the population, health and ecological surveillance). Then the experts of the WG2 have put forward some recommendations concerning the actual management of the uranium mines in France. New methods in the field of environmental impact, sanitary screening and dosimetric assessment have been proposed and tested in Limousin. The details of WG2 will be published at the end of this year (*www.gep-nucleaire.org*).

Radiation situation in Moscow and public doses due to man-made radiation exposure

Metlyaev, Evgeny[1]; Filonova, Anna[2]
[1] Burnasyan Federal Medical Biophysical Centre, Moscow, RUSSIA
[2] Burnasyan Federal Medical Biophysical Centre, Moscow, RUSSIA

Abstract

Over 2002-2007, radiation situation resulted from global fallout in Moscow has been assessed in terms of ^{137}Cs and ^{90}Sr contents in more than 500 samples of the environmental media. Such assessment showed that ^{137}Cs and ^{90}Sr contents in atmospheric precipitation complied with the average Russian levels, while annual activity concentration of these radionuclides in common air is six orders of a magnitude lower than permissible values regulated by the radiation safety standards.

^{137}Cs content in foodstuffs intaken by Moscow residents varies over the range from 0.1 up to 1.4 Bq/kg(l), while that of ^{90}Sr - from 0.08 up to 0.13 Bq/kg(l),; this is much lower than permissible specific activities. Over the years under observation, excess ^{137}Cs and ^{90}Sr contents in comparison with the permissible ones have been registered in wild food samples (mushrooms, wild berries). This is due to the fact that such kinds of foodstuffs entered to Moscow from the regions affected by the accident at the Chernobyl nuclear power plant.

The selective individual dose monitoring using thermoluminescent dosimeters showed that annual effective dose induced by external exposure of natural and cosmogenic radionuclides to Moscow residents is not higher than 1 mSv/a. Contribution of man-made radiation exposure is not higher than 5%. Effective dose induced by internal man-made radiation exposure to Moscow residents due to food intake over the inspected time period is 13 μSv/a on average.

Materia Study of global fallouts of nuclear explosion radioactive products at the area of Moscow began in 1957.

At the first stage, the research task was to determine concentration and isotope composition a radioactive aerosols in near-earth layer of atmosphere. Later, te objective of this work was to study radiation situation within Moscow area and to calculate public doses due to the global fallouts.

Development of the methods for radiochemical analysis promoted determination of ^{90}Sr and ^{137}Cs contents in the environmental media. Introduction of gamma-spectrometry methods enabled to specify complex compound of radioactive substances in the environmental media. Learning of methods for identification of radioactive substances in foods helps to evaluate radionuclide intake and to assess dose to the public, which is the main criterion for the radiation situation assessment.

In this light, the following tasks have been set:

1. To collect and analyze different parameters of the radiation situation, in particular, the extent of radionuclide contamination of the prime foodstuffs.
2. To study the site contamination with ^{90}Sr and ^{137}Cs radionuclides on the base of data on their contents in common air and fallouts, as well as gamma background levels in-situ.
3. To specify the food ration structure of the Moscow resident per capita taking into account the age structure of intake.
4. To evaluate ^{90}Sr and ^{137}Cs intake via ration.
5. To calculate effective doses to the public due to global fallouts.
6. To identify the critical age group.

So, our study included determination of radionuclide contents in the environmental media:

– Common air (aspiration samples);
– Atmospheric fallouts (sedimentation fallouts)
– Foodstuffs.

Sampling was being carried out according to the requirements of te regulative and legislative documents.

A value of the atmospheric fallout activity in Moscow was being determined on the base of precipitation analysis being collected using the special dishes (cuvette) (sedimentation filters), as well as radioactivity determination of common air (aspiration filters).

In samples of common air and fallouts, sum of beta active radionuclides was being determined using the radiometry method.

Over the reported period, gross beta activity of atmospheric fallouts on the geological substate varied from 4,0 to 33 Bq/m^2, while gross beta activity of radionuclides in the near-earth atmospheric air was at the level of 110 – 127 µBq/m^3. Results of gamma background measurements varied from 9 to 12 µR/h. Such data are in good compliance with data presented in radiation hygienic passports of Moscow and with data provided by the MosNPO “Radon”.

Samples of foodstuffs and drinking water were being examined using gamma spectrometry, radiochemistry and radiometry methods.

To evaluate intake of radioactive substances via foods by the residents of Moscow, data on food ration structure for Moscow residents have been examined. They resulted from the findings of selective inspections of the domestic budgets being performed by the Goscomstat of Russia.

The prime food groups include: bread and cereal products, milk and dairies, potato, vegetables and melons, meat and meat products, fish and fish products, as well as fruits and berries.

The foodstuffs were provided via the Moscow trade network and markets.

Study of the Goscomstat materials on the food ration structure enabled to conclude that over the recent years the food structure of Moscow residents remained practically unchanged and is still at the same level.

Table 1 includes data on intake of the prime food groups by the residents of different age groups.

Table 1. Mean intake of the prime food groups by the residents of different age groups in Moscow over 2000-2007, kg/days.

Food group	Per capita on average	Adults >17 years old	1-2 years old	2-7 years old	7-12 years old	12-17 years old
Bread and cereal products	0,327	0,392	0,157	0,188	0,441	0,376
Milk and dairies *	0,519	0,622	0,776	0,776	0,467	0,624
Potato	0,183	0,220	0,121	0,133	0,195	0,195
Vegetables and melons	0,192	0,231	0,144	0,216	0,331	0,188
Meat	0,237	0,285	0,119	0,154	0,225	0,237
Fish	0,043	0,053	0,006	0,021	0,032	0,032
Fruits and berries	0,126	0,151	0,094	0,141	0,216	0,123

*except for tallow oil

To evaluate ^{90}Sr and ^{137}Cs contents in foodstuffs included in the food ration of Moscow residents, results of direct examinations performed by the experts from the Burnasyan FMBC have been considered.

Table 2. Average contents of ^{90}Sr and ^{137}Cs in Moscow foodstuffs over the period 2000-2007, Bq/kg,l.

Foodstuffs	2000 – 2007	
	^{90}Sr	^{137}Cs
Bread and cereal products	0,10	0,27
Milk and dairies	0,07	0,39
Meat and meat products	0,14	0,32
Potato	0,07	0,24
Vegetables and melons	0,09	0,08
Fish and fish products	0,14	0,32
Fruits and berries	0,14	0,18
Mushrooms	0,17	2,1
Tea	5,6	4,0
Drinking water	0,002	0,001

Over the full period of surveillance, the specific activity of food samples collected in Moscow for the purpose of analysis was lower than the established regulations.

The level of radionuclide contents in foodstuffs being intaken by the resident of the Moscow region, is at the level of the averaged Russian data, while in some foodstuffs it is even lower (bread, milk, potato) (Table 3).

Table 3. Mean contents of ^{90}Sr and ^{137}Cs in foodstuffs in the Russian regions over the period 2000-2004, Bq/kg, l [12].

Foodstuffs	2000 – 2007	
	^{90}Sr	^{137}Cs
Bread and cereal products	0,13	1,4
Milk and dairies	0,12	0,70
Meat and meat products	0,06	0,30
Potato	0,08	0,70
Vegetables and melons	0,09	0,03
Fish and fish products	0,25	0,28
Fruits and berries	0,12	0,04
Mushrooms	3,7	39,0
Drinking water	0,002	0,001

Contents of ^{137}Cs and ^{90}Sr in foodstuffs and in water being intaken by the Moscow residents, is induced by the global fallouts of ^{137}Cs and ^{90}Sr originated from nuclear weapon tests and the accident at the Chernobyl NPP of 1986.

^{90}Sr and ^{137}Cs intake of the Moscow residents via the foodstuffs has been calculated on the base of mean contents of such radionuclides in foodstuffs collected over 2004 and 2006, and mean food intake by different age public groups over the period 2000-2007.

Table 4. Daily and annual intake of ^{90}Sr and ^{137}Cs via foodstuffs by different age groups of the Moscow residents over 2003-2006.

Age		Years					
		2003		2004		2006	
		^{90}Sr	^{137}Cs	^{90}Sr	^{137}Cs	^{90}Sr	^{137}Cs
1-2 years old	Bq/day	0,131	0,241	0,100	0,243	0,138	0,293
	Bq/day	47,82	87,97	36,5	88,65	50,37	106,95
2-7 years old	Bq/day	0,160	0,274	0,118	0,276	0,167	0,327
	Bq/day	58,40	100,0	43,07	100,6	60,96	119,36
7-12 years old	Bq/day	0,190	0,469	0,150	0,302	0,220	0,364
	Bq/day	69,35	171,20	54,75	110,23	80,30	132,86
12-17 years old	Bq/day	0,174	0,408	0,132	0,303	0,196	0,362
	Bq/day	63,51	148,90	48,11	110,74	71,54	132,13
Adults	Bq/day	0,204	0,437	0,146	0,336	0,219	0,394
>17 years old	Bq/day	74,46	159,50	53,11	122,78	79,94	143,81

When calculating radionuclide intake via the food ration components, thye drinking water intake was taken into account (daily):

1,4 l – for adults and children of 12-17 years old;

0,9 l – for children of 7 - 12 years old;

0,7 l – for children of 2 - 7 years old;

0,5 l – for children of 1 - 2 years old.

Radionuclide intake via drinking water has been calculated on the base of the mean level of ^{137}Cs and ^{90}Sr contents equal to 0,001 and 0,002 Bq/l respectively.

The public dose in Moscow is originated from the natural and artificial sources of ionizing radiation. The main dose-forming factors for the Moscow population are the natural sources.

As for ^{137}Cs and ^{90}Sr, the main pathways of intake are ingestion and exposure originated from fallouts on the geological substate.

When calculating effective internal doses induced by ^{90}Sr and ^{137}Cs, being intaken by the population of Moscow via the foodstuffs and water, annual radionuclide intake values via the foodstuffs by the different age groups of population and dose coefficients for ^{90}Sr and ^{137}Cs for each age group are taken into account.

For persons included in any group, the effective dose calculation assumes:

Intake of only local foodstuffs (provided through the Moscow trade network);

Average food intake by members of the appropriate age group (kg/day).

Annual (committed) effective internal dose ($E_,$) is assessed in terms of radionuclide intake by the local population via the local foods:

$$E = 10^{-3} \cdot \sum_k d_k \cdot \sum_n (M_n \cdot A_{kn}), \text{ mSv/year,}$$

where:

d_k – dose coefficient for food intake of the k-th radionuclide by the adult residents according to Annex II, Sv/Bq;

M_n - mean annual intake of n-th foodstuff, kg/year;

A_{kn} - annual specific activity of the k-th radionuclide in the n-th foodstuff, Bq/kg.

Gross effective internal dose to the adult residents of Moscow over the inspected period is given in Table 5.

Table 5. Gross effective dose to the adult residents of Moscow over 2003 - 2007, μSv/year

Exposure pathway	Radionuclide									
	2003		2004		2005		2006		2007	
	^{90}Sr	^{137}Cs	^{90}Sr	^{137}Cs	^{90}Sr	^{137}Cs	^{90}Sr	^{137}Cs	^{90}Sr	^{137}Cs
Internal exposure via foods	2,31	2,25	1,5	1,6	2,85	2,92	2,24	1,87	2,76	2,59
Internal exposure via drinking water	0,84	0,42	1,09	0,3	0,03	0,07	0,03	0,07	0,03	0,07
Total	3,15	2,67	2,59	1,9	2,88	2,99	2,27	1,94	2,79	2,66

Gross effective dose to the adult public of Moscow due to internal exposure varies from 3,1 to 5,77 μSv/year. Gross effective dose to the critical group – children of 12 – 17 years old – is not higher than 6,5 μSv/year.

Doses originated from the drinking water intake are very low and depend upon the age special features of water intake: minimum - 0,063 μSv/year for children of 1-2 years old and maximum- 0,148 μSv/year for the critical group - 12-17 years old.

Thus, gross effective dose to the Moscow residents due to global fallouts is not higher than 13 μSv. Even taken into account dose induced by external gamma radiation originated from the natural radionuclides, gross effective dose to the Moscow residents is much lower than the public dose limit regulated by the national regulative documents (1 mSv).

Abstract

The radiation exposure of the Belgian population in 2006 was calculated with the methods of the UNSCEAR 2000 report. The annual average effective dose is estimated at 4.6 mSv, of which 2.5 mSv is from natural sources and 2.1 mSv from applications of ionizing radiation; more than 95% from medical imaging. Radiotherapeutic exposures are not accounted for in this overview.

The contribution from diagnostic radiology practice was calculated by multiplying an estimated average dose per type of X-ray examination with the National Health Insurance data on the number of examinations. The exposure is dominated by CT, which provides about 60% of the effective dose; the number of CT-scans increased by 77% between 1997 and 2006 to 155 per 1000 people. An extensive measurement campaign on the patient doses in interventional and cardiological radiology showed effective doses between 5.7 mSv for diagnostic angiography and 15.3 mSv for an average PTCA. The Belgian government has recently launched a project to monitor therapeutic procedures for deterministic effects and to guide optimization in these practices. The effective dose from diagnostic radiology is estimated at 1.88 mSv/y. Better dose estimates will be available after the publication of diagnostic reference levels from the first generalized and legally obliged patient dose survey.

The number of diagnostic administrations of radiopharmaceuticals to patients in Belgium was 52 per 1000 people in 2006 resulting in an effective dose from nuclear medicine of 0.22 mSv/y.The estimated contributions from natural sources in 2006 are the same as in 2001.

The average exposure in Belgium has doubled over the last 110 years, from approximately 2.3 mSv in 1895 to 4.6 mSv in 2006. Of this increase 0.2 mSv comes from natural sources and 2.1 mSv from medical applications. During the same period the average life expectancy in Belgium for man increased from 48 to 77 years and for women from 51 to 83 years resulting in a 3- to 4-fold increase of the lifetime exposure.

The risk perception of the population from ionizing radiation is strongly correlated to the perceived possibility of potential exposure, with a high concern for nuclear waste management and a low concern for medical and natural exposure.

Introduction

Man has always been exposed to natural radiation arising from the earth as well as from outer space (cosmic radiation). Since the discovery of X-rays by Röntgen in 1895 people are also exposed to man-made sources of ionizing radiation. Attention was first drawn to the medical possibilities of diagnosis of bone injuries and imaging of retained bullets received on the battlefield. Diagnostic radiology was in the 20th century supplemented with nuclear medicine and radiotherapy. Outside the medical field industrial and military applications of ionizing radiation were developed, but their collective impact on the population exposure remained limited. Medical uses of radiation continue to increase as techniques develop and become more widely disseminated. As part of this trend, high dose procedures (particularly CT scanning) are increasingly being used to the point that in several countries, including Japan and the USA, medical has displaced natural sources of radiation as the largest overall component of ionizing radiation exposure.

The effective doses to the Belgian population in 2001 were presented at the IRPA 11 conference in Madrid (Vanmarcke 2004) with the methods given in the UNSCEAR 2000 report. In this paper, the assessment is revised using data for 2006.

Medical radiation exposures

Medical imaging has seen the introduction of digital detectors. This has led to 2 main advantages: (1) most detectors can work at a lower dose level than film-screen systems, and (2) digital detectors can be used for new applications, such as high resolution (3D) imaging. This evolution is a logical reply to ever increasing demands for more complex and new imaging procedures and a more efficient use of dose budgets. Next to these arguments, upgrading of technology is governed by financial aspects and work flow issues. Guidance or optimization of dose settings is not yet routine practice in our hospitals. Recent patient dose studies organized in the frame of the medical directive (97/34/Euratom) and its Belgian implementation confirmed a large dose spread.

The amount of radiation per procedure indicates an increasing trend and as a result also the dose to the patient.

- Higher activities can be administered in nuclear medicine to improve image quality. The increasing use of various isotopes with short half-lives, such as technetium-99m (T½: 6 hours), leaves the dose to the patient and the environment within a reasonable margin.
- High doses can be delivered to patients in interventional radiology, sometimes resulting in skin injuries.
- The introduction of digital techniques could reduce the dose provided that the imaging process is strictly controlled. Overexposures that lead to images too dark for interpretation are virtually impossible in digital radiology. The search for better image quality, sometimes introduced without any justification procedure, increases exposure. This is especially the case in CT that has seen the introduction of high resolution cardiac angiography, CT perfusion, dual energy applications, etc..

Very high doses are delivered precisely to tumor volumes in radiotherapy to eradicate disease, mostly cancer, while minimizing the irradiation of the surrounding healthy tissue. The quantity effective dose is inappropriate for characterizing these exposures, in which levels of irradiation are by intent high enough to cause deterministic effects. Radiotherapeutic exposures are therefore not accounted for in this overview. Incidents however have stressed the importance of quality assurance and optimization.

In the frame of these developments, Flemish and Belgian data were collected for the yearly report on the environment and nature in Flanders (MIRA 2007) and were compared to the world average values of the UNSCEAR 2000 report.

Diagnostic radiology

According to National Health Insurance data (RIZIV/INAMI), the average inhabitant of Belgium was subject to 1.2 X-ray examinations in 2006 (excluding dental X-rays) (MIRA 2007). The trend in the annual frequency is shown in fig. 1. The number of examinations remained stable between 1997 and 2006 thanks to efforts of the National Health Insurance to keep the costs under control.

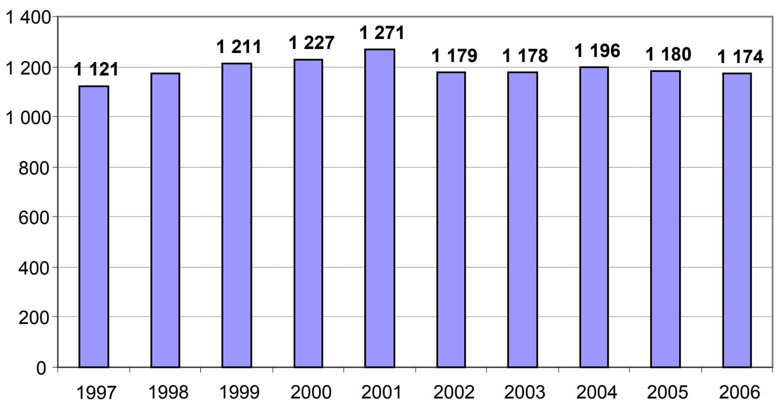

Fig. 1. 10-year trend for total number of X-ray examinations per 1000 inhabitants in Belgium (excluding dental X-rays).

More detailed National Health Insurance data show a shift between the types of examinations (fig. 2). Traditional techniques, such as spine and GI-tract examinations (included in “fluoroscopic examinations”) are being replaced by CT (Computed Tomography) or MR (Magnetic Resonance imaging). The number of CT-scans increased by 77% between 1997 and 2006 to 155 per 1000 people. The figure shows also a significant increase in the use of mammography since 2001, when the Flemish government provided free breast cancer screening for women aged 50 to 69 years. Chest examinations remained constant at a high level. The field of vascular imaging has progressed rapidly over the last decades. Blood vessels are visualized for diagnostic or therapeutic purposes. Diagnostic X-ray procedures are being replaced by non invasive imaging such as MR angiography or CT angiography, but the number of (higher dose) interventional procedures is rising. Vascular imaging should be closely monitored, because the exposure to the patient and the medical team can be very high, especially during interventional procedures. Everyday, doctors improve their skills and knowledge in this field, so that ever smaller vessels or more complex medical problems find a solution. Interventional procedures are considered less risky for the patient than traditional “open” surgery and shorten the duration of hospitalization.

Fig. 2. Trends in diagnostic radiology practice in Belgium between 1997 and 2006 (Bosmans 2007).

As there are only a few data on the doses delivered to patients in radiology in Belgium available, we had to rely partially on data from other sources. The average effective dose per type of examination from four different sources is compared in table 1. In the right column, the effective doses, used for the calculations in the report on the environment and nature in Flanders, are given (MIRA 2007). They were derived from local studies and supplemented by international literature (Bosmans 2007). In Belgium, doses from conventional X-ray examinations are relatively high due to the extensive use of fluoroscopy for positioning of the patient. The selected value for the average CT dose is 7.2 mSv, which is somewhat less than the value from the UNSCEAR 2000 report of 8.8 mSv. The value was calculated from the relative frequency and the effective dose per type of CT examination given in table 2.

The values that were used to estimate the exposure from interventional procedures were retrieved from an extensive national study (Bleeser 2008, Smans 2008, Bogaert 2008). In the frame of this multicenter study, effective patient doses were calculated for diagnostic imaging of the lower limbs and the most frequent cardiac examinations. This study also allowed to estimate effective doses for the other types of frequent examinations. Today, our regulatory authority, the Federal Agency of Nuclear Control, requires that dose data of all dynamic X-ray procedures are registered. How to exploit these data for optimization is not yet clear.

Table 1. Comparison of effective doses from diagnostic X-ray examinations (mSv).

Examination	UNSCEAR 1993	UNSCEAR 2000	Mol 2001	RIVM 2005	MIRA 2007

Table 2. Average patient dose from CT examinations (MIRA 2007).

Type of CT examination	Average effective dose mSv
CT skull	1.5
CT skull base	1.7
CT abdomen and/or chest	12.7
CT spine	5.7
CT limbs and joints including angiography	1.5
Average CT dose	**7.2**

Figure 3 shows the average effective dose distribution of the Flemish population in 2006 from diagnostic X-ray examinations. This distribution is derived from the frequency of the various medical procedures and the average radiation dose for that procedure from table 1 (MIRA 2007). The exposure is dominated by CT, which provides 59 % of the effective dose. The average annual dose from diagnostic radiology in Flanders is estimated at 1.75 mSv in 2006 and in Belgium at 1.88 mSv. The difference is mainly due to a slightly lower number of CT scans in Flanders (142 per 1000 population) than in Belgium (155 per 1000 population).

Figure 4 shows the temporal trends in patient dose from diagnostic radiology in Belgium. The average annual dose from CT increased by 77% between 1997 and 2006. The increase of the CT dose is partly compensated by a decrease in conventional examinations. Most remarkably, the installation of a large number of MR systems has not stopped the expansion of the number of CT examinations.

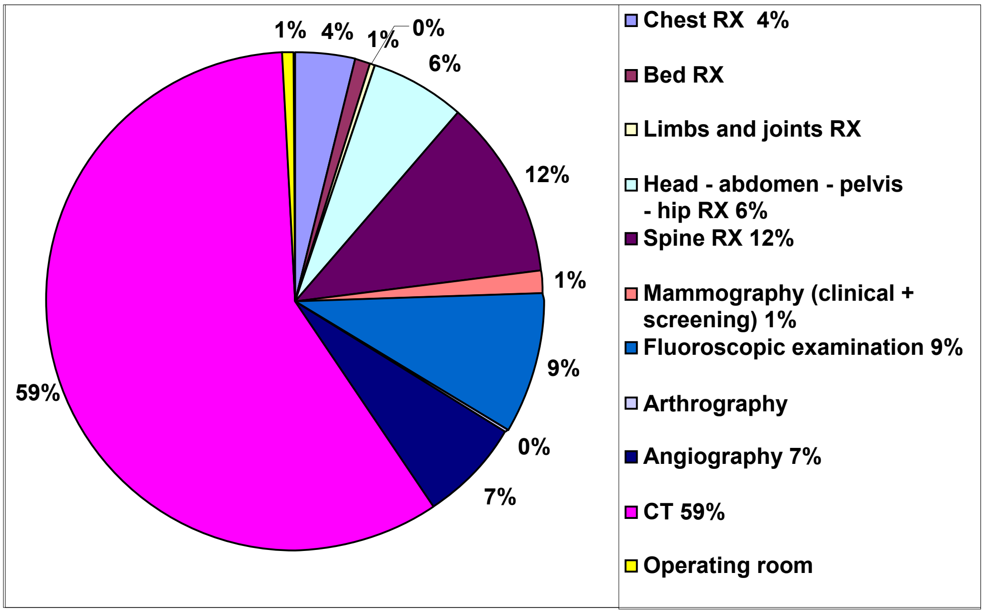

Fig. 3. Dose Distribution from diagnostic X-ray examinations in Flanders in 2006 (Bosmans 2007).

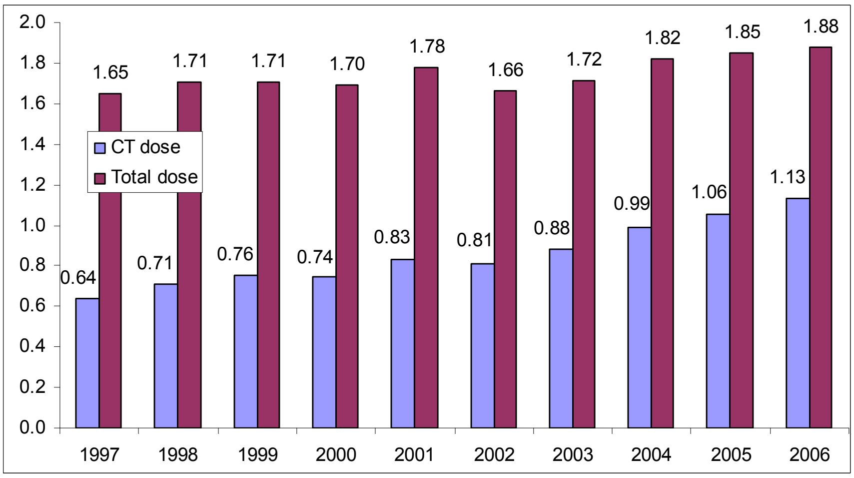

Fig. 4. Trends in annual effective dose (in mSv per year) from diagnostic radiological examinations in Belgium (1997-2006). The large and increasing share from CT is given separately.

Nuclear medicine

In nuclear medicine, radionuclide preparations are administrated to patients for diagnosis or to a much lesser extent for therapy. The number of diagnostic administrations of radiopharmaceuticals to patients in Flanders and Belgium was respectively 40 and 52 per 1000 population per year in 2006 (National Health Insurance data). The large academic hospitals in Brussels, which attract a lot of Flemish patients, could explain the difference. The number of diagnostic nuclear medicine procedures in Belgium is high. The UNSCEAR 2000 estimate for countries with an advanced health care system is 19 per 1000 population per year.

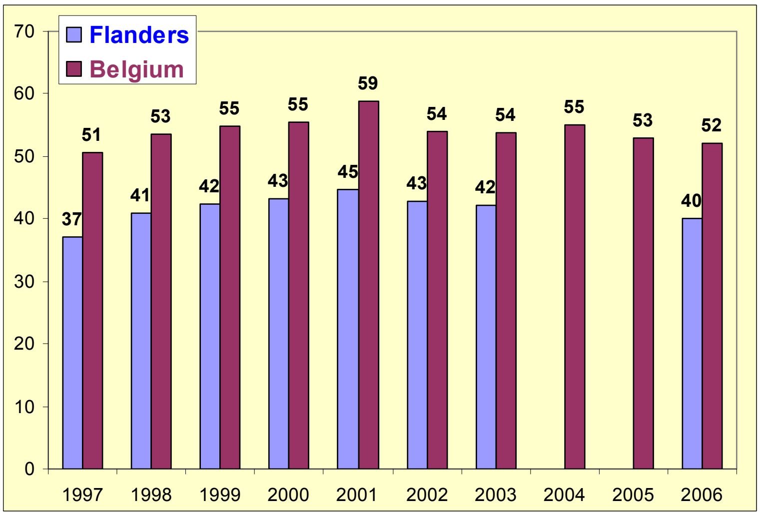

Fig. 5. 10-year trend in diagnostic nuclear medicine practice in Belgium (1997-2006) and Flanders (1997-2003 and 2006).

Positron Emission Tomography (PET), where the radionuclide fluorine-18 (T½: 110 min.) is usually administered in patients, is a relatively new technique, which has proven its value for a number of practices, such as the detection of brain tumors. There are currently several dozen PET scanners in Belgium, including several PET-CT. The dose to the patient from a PET examination varies between 5 and 8 mSv. In case of PET-CT the CT dose has to be added. This CT may be either a full CT, which in most cases replaces another CT, or an examination to improve PET image reconstruction. In the latter case, the dose may be relatively limited. In any case PET-CT is a high dose imaging procedure. A Flemish study showed that technologists who manipulate the F-18 syringes may receive doses to fingers and hands above the limit of 500 mSv/y (Berus 2004).

Technetium-99m dominates the spectrum of the radiopharmaceuticals. The typical dose for an examination is between 1 and 10 mSv and the administered Tc-99m activity between 100 and 900 MBq. The Belgian Society for Nuclear Medicine has published guidelines for the reference administered activities for diagnostic nuclear medicine procedures on their website:

http://www.belnuc.be/images/stories/PDF_guidelines/reference_activities.pdf

A survey at 19 nuclear medicine departments in Flanders estimated the average dose per diagnostic procedure at 4.2 mSv (De Geest 2002). This value, multiplied by the number of examinations in 2006, results in an average dose of 0.17 mSv/y in Flanders and 0.22 mSv/y in Belgium. The corresponding UNSCEAR 2000 estimate for countries with an advanced health care system is 4.3 mSv per procedure and 19 procedures per 1000 population, which corresponds with an average dose of 0.08 mSv/y.

Medical radiation exposures in Belgium in 2006

The average effective dose from diagnostic medical imaging in Belgium in 2006 is estimated at 2.1 mSv/y: 1.88 mSv/y from X-ray examinations and 0.22 mSv/y from nuclear medicine procedures. The corresponding values for Flanders are 1.92 mSv/y:

1.75 and 0.17 mSv/y. The collective medical exposure for the whole population in 2006 is estimated to be:

- Belgium: 0.0021 x 10 511 382 = 22 000 manSv;
- Flanders: 0.00192 x 6 078 600 = 11 700 manSv.

The increasing medical exposure could be responsible for hundreds of excess cancer cases each year in Belgium. It should be noted however that the age distribution of patients differs from the age distribution of the general population on which ICRP-risk coefficients are still based. In digital radiology departments, examination specific age distributions could be retrieved from the image databases, but this is not a routine task in the imaging department.

Exposures from natural radiation sources

The estimated contributions from natural sources in 2006 are the same as in 2001. The average radon concentration in Belgium is estimated indoors at 48 Bq/m³ and outdoors at 10 Bq/m³. With the UNSCEAR dose conversion factor of 9 (nSv/h)/(Bq/m³) (in terms of radon decay products) and a small contribution from radon gas dissolved in blood, a radon dose of 1.35 mSv is calculated. The annual exposure to cosmic radiation is estimated at 0.35 mSv, including a small contribution from air travel and holidays (for instance winter sports). Finally, the external and internal exposures from K-40 and the natural decay series are assessed at 0.4 and 0.3 mSv respectively and the thoron exposure at 0.1 mSv.

Sources and trends of radiation exposure in Belgium

The radiation exposure of the Belgian and Flemish population from natural and man-made sources is compared in table 3 to the average exposure for countries with an advanced health care system from the UNSCEAR 2000 report. The average annual dose in Belgium is 4.6 mSv and in Flanders 4.1 mSv. The largest contribution comes from diagnostic medical examinations, which is estimated, on the basis of social security data, to be 2.10 mSv in Belgium and 1.92 mSv in Flanders. The second largest contribution is from radon exposure.

The average effective dose in Belgium has doubled over the last 110 years from approximately 2.3 mSv/y in 1895 to 4.6 mSv/y in 2006. Of this increase 0.2 mSv/y comes from natural sources and 2.1 mSv/y from medical applications.

- A slow increase of the indoor radon exposure from about 1.15 mSv/y in 1895 to 1.35 mSv/y in 2006. This is due to the reduction in ventilation in modern homes and to the use of building materials with enhanced radium levels, such as phosphogypsum and fly ash. 10 to 100 times higher radon concentrations have been found in some dwellings, mostly located in radon prone areas.
- A small increase of the cosmic radiation of about 0.05 mSv/y from air travel and winter sports. 10 times higher cosmic ray exposures are possible for frequent flyers.
- A strong increase in the medical diagnostic use of ionizing radiation from 0 mSv/y in 1985 to 2.1 mSv/y in 2006. 10 to 100 times higher values are possible for particular patients.
- A small contribution from all other man-made sources of less than 0.05 mSv/y.

During the same period (1895 - 2006) the average life expectancy in Belgium for man increased from 48 to 77 years and for women from 51 to 83 years. The combined effect of these two trends resulted in an increase of the lifetime exposure by a factor of 3 to 4:

- for men from 110 mSv in 1895 to 354 mSv in 2006 and;
- for women from 117 mSv in 1895 to 382 mSv in 2006.

Table 3. Average exposure from radiation sources in Belgium, Flanders and in developed countries with an advanced health care system (Vanmarcke 2004; MIRA 2007; UNSCEAR 2000).

Source	Average annual effective dose Belgium mSv/y	Flanders mSv/y	Worldwide mSv/y
Natural radiation

Total (rounded value)	**4.6**	**4.1**	**3.7**

* Developed countries with an advanced health care system

Risk perception from ionizing radiation

The third risk barometer survey of the perception of the Belgian population (Perko 2010) confirmed that there exists no generalized fear for nuclear activities. Compared to 2006 a slight rise (5%) of risk perception was noticed for most items. Industrial risks (industrial accidents, industrial waste) are evaluated much lower than personal and lifestyle risks. The paradox that the sources with the highest population exposures, such as medical X-rays and natural radiation, are perceived as less dangerous than nuclear power plants, which have a low population exposure in normal operation, continues to exist. However the perception of medical and radon risk is higher than in previous barometers. The risk perception for terrorism, chemical or nuclear waste or accidents was 30 to 40% lower in 2006 compared to 2002. These lower values were for the largest part replicated in the 2009 survey.

The predistribution of iodine for prophylaxis in accidental conditions was widely supported. About 16% of the Belgian population remembers the iodine release incident in August 2008 in IRE, Fleurus. Most people believe the consequences of this release to be more serious than what is communicated by the authorities, and this holds for both the general population and the subset of people who lives near the installation. There remains a significant lack of confidence in the provision of correct information by the authorities on risks related to accidents in nuclear installations or radioactive waste.

Higher confidence exists where authorities have been active and often present in the media.

Sharing an environmental monitoring network: The AREVA Tricastin experience

Mercat, Catherine; Devin, Patrick; Garnier, François
AREVA, FRANCE

Abstract

Set up at the beginning of the site's operations, in 1962, the monitoring of the radiological environmental impact of the AREVA site of Tricastin has evolved over time to more specifically meet the multiple objectives of environmental monitoring: 1) to prove the respect of the commitments required by the authorities ; 2) to be able to detect a drift in the observed levels ; 3) to enable the assessment of impacts of industrial activities ; 4) to ensure the balance between environmental quality and practical uses by local population ; and 5) to inform the public of the radiological state of the environment. Thousands of data were acquired on the radioactivity of all environmental compartments as well as on the functioning of local ecosystems. Today, the Network of Environmental Monitoring of AREVA Tricastin goes beyond the requirements of routine monitoring to provide innovative solutions for monitoring the radioactivity (especially for uranium) in the environment.

Introduction

To assess the potential impact of the nuclear facilities on its environment, AREVA has set up a monitoring network on and around the site, since the start of its activities. Since 1962, numerous data have been accumulated, to know the functioning of local ecosystems, to assess the background of environmental radioactivity and trends in the different environmental compartments. An ambitious collection and structuring of historical data is underway to have a comprehensive vision of the past activities of the site.

Currently, samples and measurements of environmental radiation monitoring are managed by an AREVA common environmental monitoring network. The sampling is made inside and outside the site according to an agreed schedule which is controlled monthly by administrative authorities (ASN[1], DSND[2] and DREAL[3]). In addition to these regulatory requirements, AREVA also performs a targeted monitoring to strengthen the survey and to increase knowledge of the environmental impact of industrial activities on the site, according to its values and environmental policy. Moreover, an increased monitoring program was set up in July 2008 following the

[1] French Nuclear Safety Authority for civil facilities
[2] French Nuclear Safety Authority for military facilities
[3] French Regional Authority for BPI

accidental discharge of SOCATRI. It was gradually alleviated after the demonstration of a speedy return to the original situation before the incident.

Nuclear operations on the Tricastin AREVA site and regulatory commitments

The following institutions - AREVA NC Pierrelatte, COMURHEX Pierrelatte, EURODIF Production, FBFC Pierrelatte, Enrichment Corporation Tricastin (SET) and SOCATRI- are part of the upstream activities of the AREVA Company. They provide services for worldwide electricians: nuclear conversion, enrichment of uranium and nuclear fuel fabrication.

The AREVA Tricastin site now includes five nuclear operators of AREVA Company (AREVA NC -formerly COGEMA-, COMURHEX, EURODIF Production, SOCATRI and SET), a facility of FBFC, some research activities (units of the Atomic Energy Commission and units of the Institute for Radiological Protection and Nuclear Safety) and the facility labelled BCOT of the NPP EDF-Tricastin. To cover all these activities, there are several nuclear plants and a secret nuclear plant, each supervised by regulatory texts which authorise the nuclear releases and require environmental monitoring. In addition, other regulatory texts complete the requirements of environmental monitoring for the BPI of the site. Environmental monitoring of the site is therefore based on a set of texts, sometimes depending on various administrative authorities (ASN DSND, DREAL), and whose release dates are different. Their updates are dependent on the administrative development of each facility; the harmonization of environmental monitoring at the site is therefore a real challenge.

The pooling process initiated in 2005 is now operational. An agreement signed between the various operators of the site and the Head of the Tricastin site governs the operation of a common network of environmental monitoring. A computer database manages all the results which are previously validated by the two laboratories of the site dedicated to the measurement of environmental samples. The overall environmental monitoring network has evolved to be fully compatible with ISO 17025 standards which establish competency requirements for testing and calibrations, including sampling in the environment.

Current results of the environmental monitoring network

As illustrated in Figure 1, monitoring of radioactivity in the Tricastin environment interested in all media (air, water, soils, flora and fauna, food from local agriculture). The samplings are made at frequencies appropriated (daily, weekly, monthly, quarterly, and semi-annually) according to the substance analysed and / or the monitored parameter.

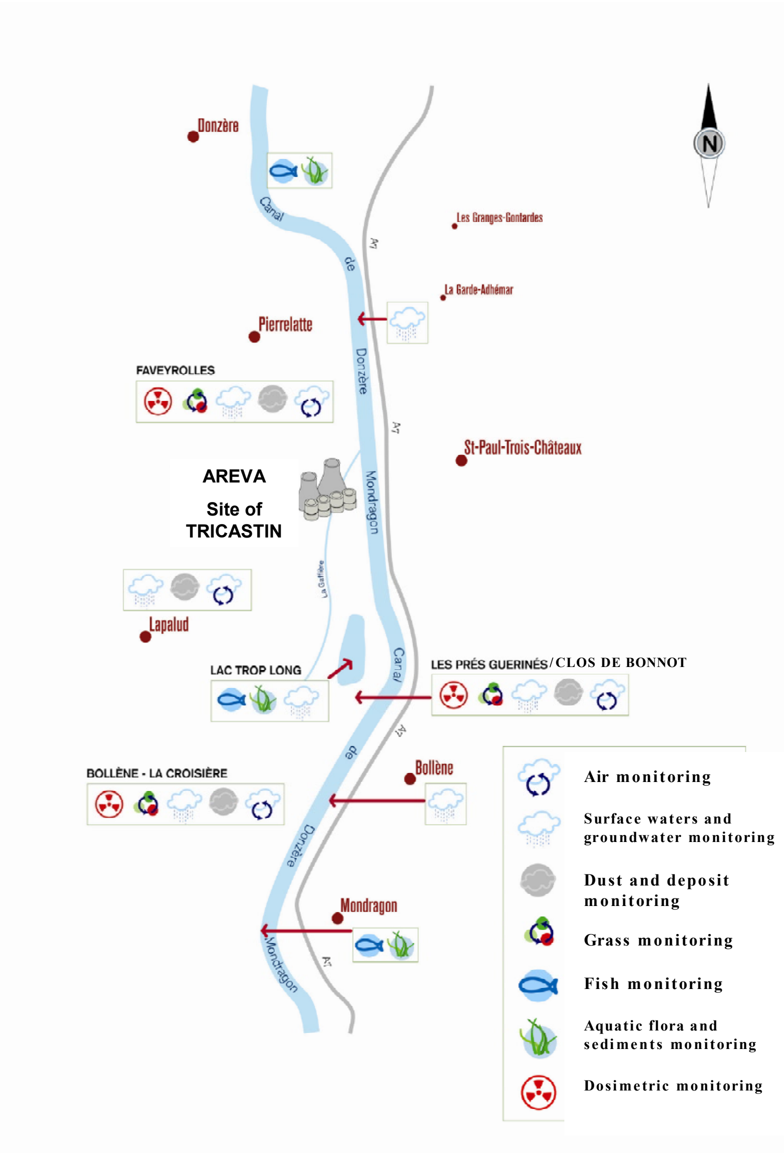

Fig. 1. Simplified diagram of the environmental monitoring network.

a. Air monitoring

The air monitoring network consists of eleven air control stations, including one outlet dust exhaust air and a ground recovery device for the precipitation. Seven of these stations are located within the site and four of them off-site, as close as possible to population groups living along the site. Each station is equipped with an external automatic air sampler for determining the radiological activity; an Owen gauge for the collection of rainfall ; and for two of them, with a bubbling system for the collection of tritium and carbon 14.

Air monitoring allows the measurement of the background radiation naturally emitted by the environment and the detection of possible influence of industrial activities of the Tricastin site. In France, the natural background is about 0.8 mSv per year [IRSN, 2009], due to cosmic and telluric rays. Around the Tricastin site (outside the site fence and at the reference stations), levels are generally measured at the local natural background level (80 nSv / hr or 0.7 mSv per year), excepted for a portion of the road labelled “Chemin des Agriculteurs” (Path of Farmers), at the east of the AREVA site, between the nuclear power plants of EDF and AREVA facilities. At this point, the combined operations of both nuclear sites induced a measurable cumulated dose which however is less than 1 mSv, in the theoretical hypothesis of a permanent stand at this barrier during the entire year (Figure 2).

A meteorological station equipped with a mast height of 100 m completes the air monitoring devices and allows the measurement collection 24/7.

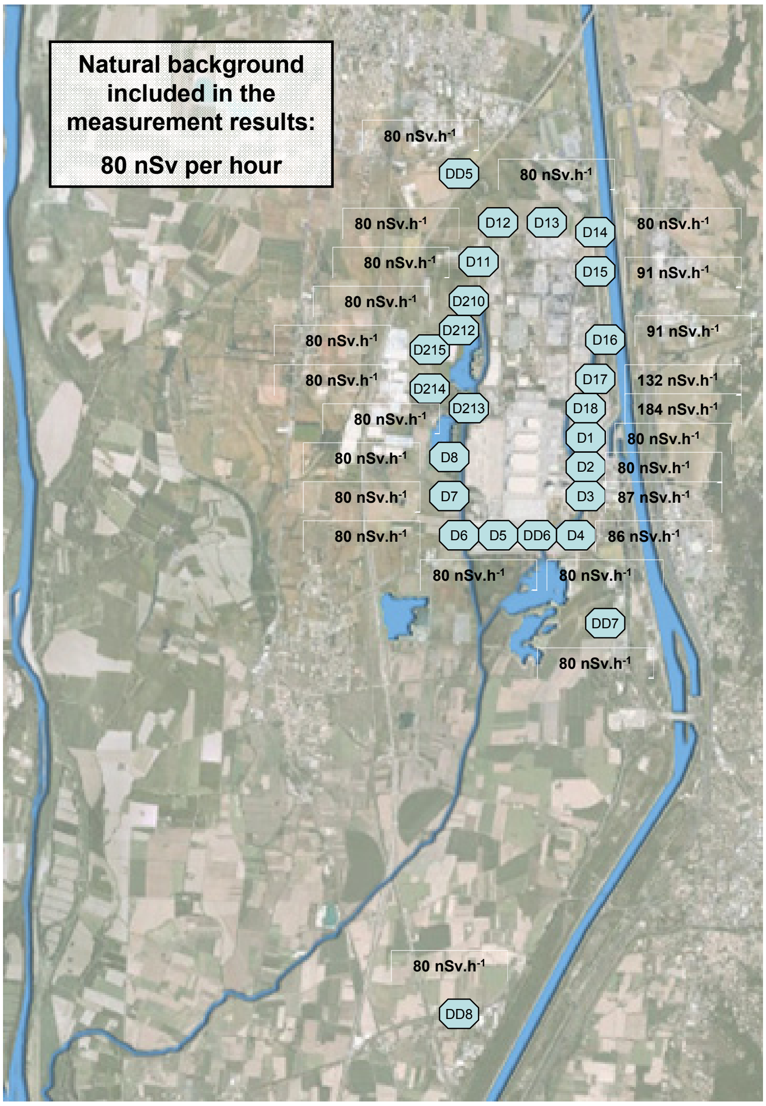

Fig. 2. Map of the mean annual dose rates measured in 2009 (background dose rate included).

b. Terrestrial monitoring

The site provides regulatory oversight of the monitoring of terrestrial radioactivity. At least a monthly analysis of plants (grass), at four points in the vicinity of the site, is performed. A mini-garden has been established for each reference station to ensure the availability of grass. On these samples, monthly measures of gross beta activity, uranium content and potassium-40 activity are performed. In addition, a measurement campaign on major agricultural products and on the land surface layer is made yearly.

The monitoring of radioactivity in the grass allows both to measure the background due to the natural occurrence in plants of radioactive elements (such as potassium 40, uranium and its progeny), and, to detect a possible influence of industrial activities of the Tricastin site. The plants uranium content is naturally very variable. The order of magnitude is of several mg per kg fresh weight but can reach several tens of micrograms per kg fresh weight for certain herbs [Anke, 2009]. Therefore, a possible influence of site operations is difficult to highlight and a PhD in collaboration with IRSN was initiated in 2009 to obtain more detailed background noise in local products.

c. Aquatic monitoring

The monitoring of the aquatic environment concerns (Figure 1):

- Surface waters: upstream and downstream of the Donzère-Mondragon channel, which is the outfall of the mayor discharge processes of the site, upstream and downstream of the rivers Gaffière and Mayre Girarde, downstream of the river Lauzon and in the Lake "Trop Long";
- Groundwater: today some fifty regulatory points are monthly analysed,
- The drinking waters: annual measurements of gross alpha and gross beta activities and concentrations of potassium-40 and uranium are performed for the cities of Pierrelatte, Bollène and Lapalud;
- This monitoring is supplemented by an annual campaign of sampling and analysis of aquatic sediments, flora and aquatic fauna.

Waters monitoring allow measuring the background level due to the natural presence of radioactive elements in water (e.g. uranium and its progeny, and potassium-40) and detecting a possible influence of the site of Tricastin. The rivers have a varying concentration of uranium in their water, about 0.02 to 6 $\mu g.l^{-1}$ [IPSN, 2001], but locally, the groundwater from granites can naturally achieve much higher values, such as 100 $\mu g.l^{-1}$ [ASN / Department of Health and Sports / IRSN, 2009].

For surface waters, the measured values in 2009 show no influence of AREVA Tricastin site on alpha activity measured in the overall Donzère-Mondragon channel and in the Mayre Girarde River (Figure 3). However, traces of the site's activities are visible inside and outside the site, in the Gaffière River. This influence is also visible in the Trop Long Lake and in the Lauzon River. These results are similar to those obtained for uranium and the overall beta activity show broadly similar trends.

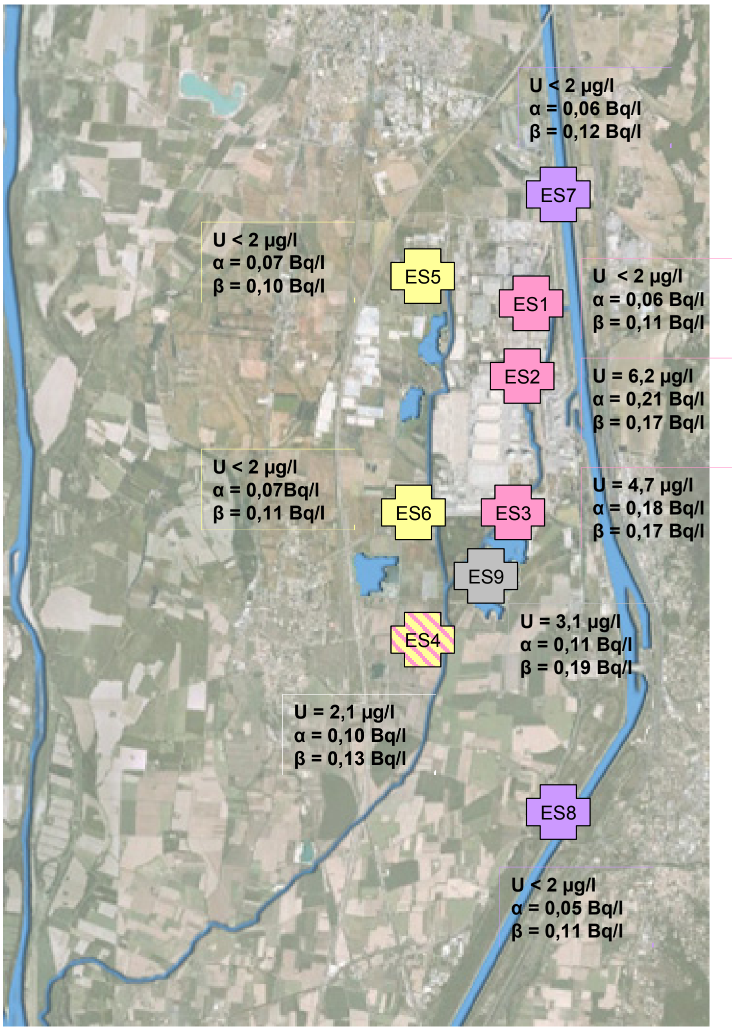

Fig. 3. Results of uranium, gross alpha and gross beta measurements obtained in 2009 in the surface waters.

For groundwater, most regulatory piezometers inside and outside the site show an average of about 1 to 6 $\mu g.l^{-1}$ of uranium, except two piezometers located within the property, with higher values (of the order of several tens of micrograms per litre explained by the past activities of the site.

Regarding the monitoring of the groundwater south of Tricastin, extensive works have been undertaken since 2007 in collaboration with AREVA, ASN, IRSN and DDASS Drome and Vaucluse[4] within a working group which was subsequently extended to other stakeholders. The first measurements campaign has highlighted the existence of a spatial variation of uranium content in the water and the existence of a few points where the uranium concentrations in groundwater exceed significantly the natural background (values between 4 and 10 $\mu g.l^{-1}$ l, instead of about 1 $\mu g.l^{-1}$). The complete inventory of private wells has led to a better spatial definition of the zone with higher levels than the local background and expand the range of values encountered (now values between 1 and 22.7 $\mu g.l^{-1}$).

[4] French regional agencies for Health

AREVA Tricastin invests more than 2 million euros for its regulatory environmental monitoring network, which, in 2009, accounted for 300 monitoring points outside and inside the site, about 14,000 specimens sampled and 27,000 radiological and chemical analyses (water, air, sediment, plants and fish). To carry out and analyze these results, AREVA Tricastin relies on specific teams dedicated to environmental sampling assisted by two laboratories approved by the French Nuclear Authority in the framework of the National Network for Measurement of Radioactivity Environment (RNME).

Beyond knowledge acquisition, AREVA Tricastin sought to reinforce and develop the outline and dialogue with local stakeholders around these issues, by organizing, for example, specific presentations to the attention of the city councils and meetings with nearby residents of the site. Meanwhile, AREVA regularly informs the local Commission of Information (CLIGEET) of the state of the site environment (food survey presented March 21, 2007, state of the water and soil presented July 4 and November 21, 2008, measurement campaign of the radioactivity of private water wells presented July 4, 2008 ...).

In addition, a selection of measurement results representative of the different environmental compartments is updated monthly on the website: http://www.areva.com. Furthermore, the results of measurements of radioactivity into the environment are made available to the public each month via the website RNME established by the ASN and IRSN, at the following address: http:/ / www.mesure-radioactivite.fr

The dosimetric impact on population due to the releases of the site is estimated from the activity of radioactive liquid and gases released during the past year. The computer code COMODORE South-East [Altran, 2007] which includes a dispersion model, is used to assess the transfer of radioactivity into the environment, particularly in the food chain. This assessment is performed according to standards that are the subject of international experts' consensus. For many radionuclides, their level in the environment is well below the analytical detection limits. Therefore, the knowledge of added radioactivity contribution in the environment is not always accessible by measurement. That is why the dosimetric impact can only be assessed by modelling. These calculations take into account all the pathways by which radionuclides can reach humans (air, water, food, etc.) according to the lifestyles and dietary habits of populations. A survey was conducted around the Tricastin site in 2004-2005 to determine precisely the parameters related to dietary habits of these populations.

The evaluation of the dosimetric impact of discharges is made for groups of people likely to be the most exposed among the residents around the Tricastin site. This population group is so called "reference group". For the Tricastin site, because of the plurality of air discharge outlets of different facilities, and because of the local weather conditions, there are several population groups that meet these criteria:

- People in the hamlet of Faveyrolles, north of the site,
- People in the hamlet of Pré Guériné, south of the site,
- Local residents of Bollène-La Croisière, south of the site,
- People in the hamlet of Clos de Bonnot, south of the site.

The establishment of reference stations network of environmental monitoring of the site is perfectly consistent with the location of these groups (Figure 4).

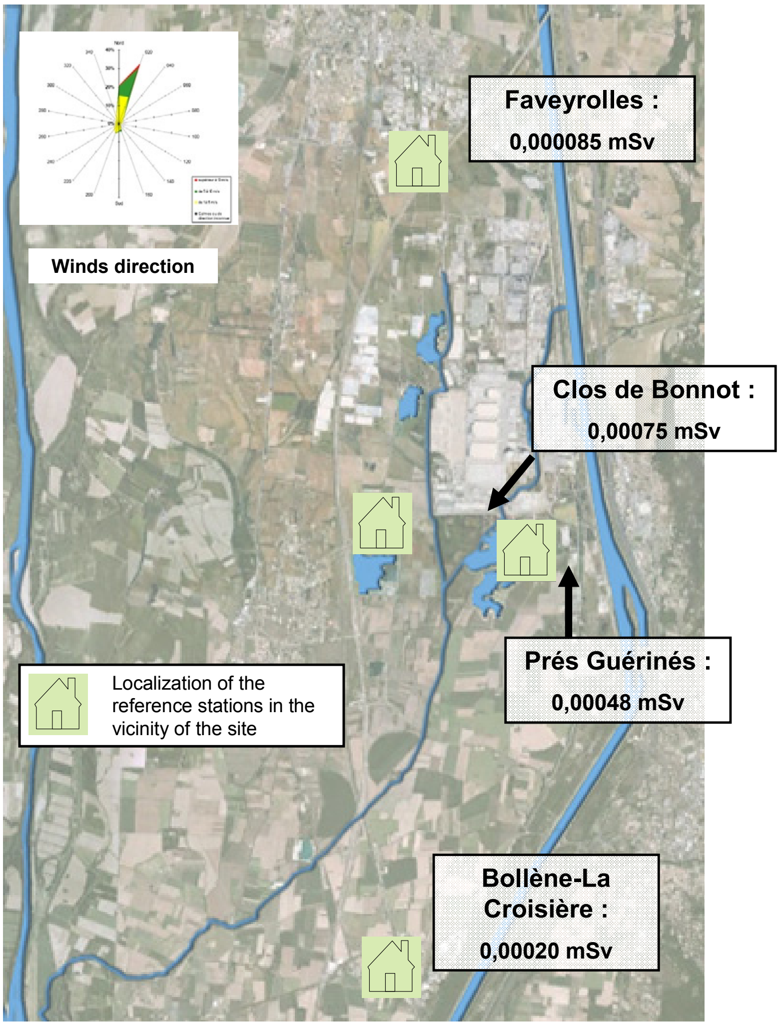

Fig. 4. Map of population groups living along the site and associated doses estimated in 2009.

Historically, in the discharge permits, the reference group labelled “Prés Guériné” was considered as the global benchmark for monitoring the dosimetric impact on people of all the releases of the AREVA Tricastin facilities. Today, although the differences between the calculations for Prés Guériné and Clos de Bonnot hamlets are weak, the population group of Clos de Bonnot shows the highest annual dose.

The annual dose due to actual authorized liquid and gaseous discharge in 2009 was 0.0007 mSv for the population group most potentially exposed (Clos de Bonnot). For other age groups, the doses are lower than those of adults. Considering also the other nuclear facilities nearby, which may contribute to the exposure of these reference groups, these values remain of the order of a thousandth of the limit set by the legislation, which is 1 mSv per year for member of the public.

Future developments

Today, the environmental monitoring network of AREVA Tricastin keep on evolving to go beyond the requirements of routine monitoring and to detect traces of increasingly low radioactivity in the environment. The main projects concern the development of metrology tools to refine as much as possible knowledge of potential impacts on humans and the environment:

- Several research and development projects were launched in 2009 by AREVA Tricastin to develop prototype devices for immediate detection of releases of uranium at concentrations of a few tens of micrograms per litre while the tools currently available only detect, in real time, levels of the order of mg.l-1.

- In autumn 2009, AREVA Tricastin started a research thesis in partnership with IRSN for the measurement of uranium and its progeny in the food chain. In parallel, seasonal campaigns of measurement of uranium in food began in the summer of 2009. The aim is thus to characterize more accurately the background levels in local products but also to respond to societal demands on the levels in the food and agricultural products marketed.

- An inventory of flora and fauna was undertaken in 2009. This study will not only complete the inventory of ecosystems near the site, but also will also define, if possible, species to watch as indicator of the healthy state of the local ecosystems.

Finally, an extensive restoration project of the environmental monitoring records of the site is underway. All these data will be soon structured through a GIS (Geographic Information System) to perform in depth analyses.

Conclusion

Set up from the start of the site in 1962, the environmental monitoring network of the AREVA Tricastin site has evolved over time to meet more and more precisely the multiple objectives of environmental monitoring ; 1) to show compliance with authorities' requirements ; 2) to be able to detect a drift in the observed levels ; 3) to enable the assessment of impacts of industrial activities ; 4) to ensure the balance between environmental quality and industrial practices ; and 5) to inform the public of the radiological state of the environment. Thus, thousands of data were acquired on the radioactivity of all environmental compartments as well as on the functioning of local ecosystems (groundwater piezometric levels, temperatures, flows of rivers ...). Today, the environmental monitoring network of AREVA Tricastin goes beyond the requirements of routine monitoring to provide innovative solutions for monitoring the radioactivity (especially for uranium) in the environment.

The public opening of the national network for measuring environmental radioactivity (RNME) on the 1st of February 2010 helps to enhance transparency and credibility of the operators on the quality and reliability of the measurements made in the framework of regulatory monitoring programs.

^{137}Cs activity concentrations in Polish meats – Current status and dose assessment for consumers

Rachubik, Jarosław
Department of Radiobiology, National Veterinary Research Institute,
Partyzantów 57, 24-100 Puławy, POLAND

Abstract
According to the Commission recommendation and the national law, the Polish Veterinary Inspection implemented a programme of radioactivity monitoring in a wide range of foodstuffs of animal origin. Samples of beef, lamb, pork, poultry, and game meat were taken at meat processing facilities and then transported to regional laboratories for analyses. Radiocaesium activity concentrations were determined by gamma-ray spectrometry using scintillation (NaI(Tl)) detectors. Generally, the radiocaesium activity concentrations in of beef, lamb, pork, and poultry were very low, and, in most of the measurements, reached MDA values. The slightly elevated radiocaesium activity concentrations, observed in several beef samples, may be partly explained by semi-free rearing of these animals. In some game meat samples fairly high levels of ^{137}Cs were still noted. Ingestion of a large portion of game meat in a daily diet by hunters' families may increase ^{137}Cs uptake in this group of consumers. Due to low radiocaesium activity concentrations in meat from domestic animals, the mean effective doses may be considered very low. The annual effective dose received by individuals in Poland and attributed to ^{137}Cs intake with meat was estimated to be a few μSv. Somewhat higher effective dose was calculated for hunters' families as a result of increased game consumption. Therefore, taking into account the permitted annual public dose, consumption of Polish meats are truly safe in terms of contamination with radiocaesium.

Introduction
Atmospheric nuclear weapon tests and accidents at nuclear installations are the main sources of anthropogenic radioactive contaminations of the environment. Radioactive nuclides may affect human beings throughout the food chain. Among the radionuclides released, the most important are considered those of radiocaesium, particularly ^{137}Cs. This radioisotope has a relatively long half-live (30.17 years), and as a chemical and metabolic analogue of potassium is accumulated in muscle tissues regarded as a main food product of animal origin.

An increased level of radiocaesium was noted in many foodstuffs in the early years after the Chernobyl nuclear accident. The radiocaesium levels have remained high in products such as game meat, mushrooms and berries. It is postulated that the transfer of radiocaesium from soil via plants and mushrooms to animals is much higher in forest ecosystems than in agricultural environments, and the radionuclide decrease is very slow (Johanson and Bergström 1994, Kiefer et al. 1996, Kostiainen 2007, Strebl and Tataruch 2007).

One of the most important routes of radionuclide penetration into human organisms seems to be the alimentary tract. Therefore, according to the EU and national law, the Polish Veterinary Inspection implemented a programme of radioactivity monitoring in a wide range of foodstuffs (beef, lamb, pork, poultry, game meat, fish, eggs and milk). Similar programmes are also conducted in other EU member states (Kameník et al. 2009, Madruga 2008, Varga 2006).

The objective of this work was to determine the current levels of radiocaesium in Polish meats, and assess the effective doses for consumers.

Material and methods

Samples were taken at farms or food processing facilities and then transported to laboratories for analyses. The sampling scheme in the regions of Poland in 2008 is shown on Figure 1.

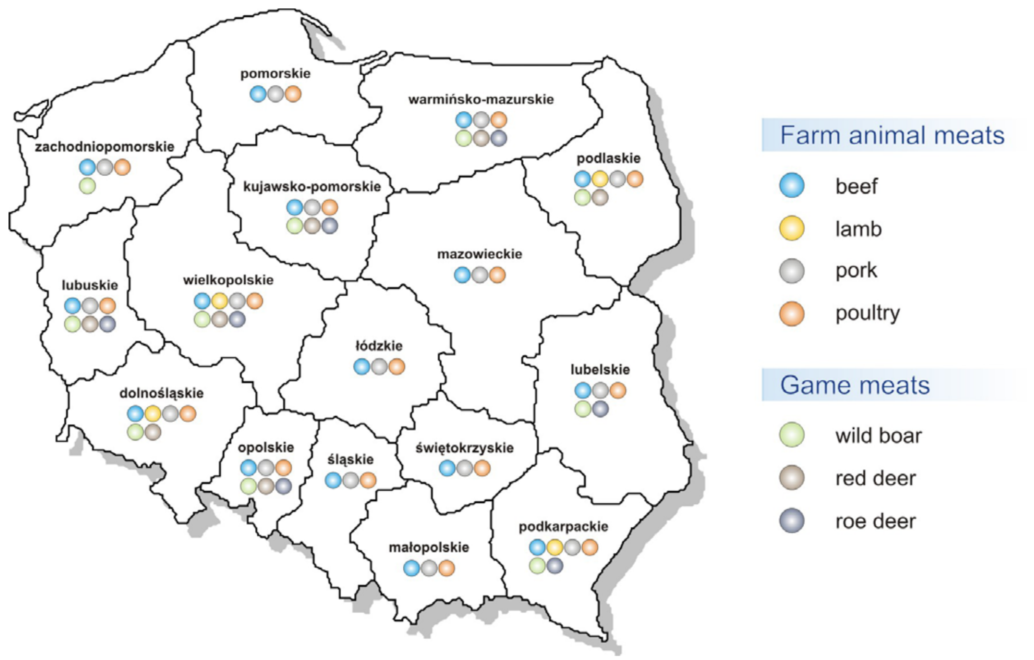

Fig. 1. Sampling in the regions of Poland in 2008.

Muscle samples were chopped, ground and put in 450 cm^3 Marinelli beakers. The sample geometry was similar to that of a source used for the detector calibrations in laboratories.

^{137}Cs and ^{134}Cs activity concentrations were determined by a gamma-ray spectrometry technique using scintillation detectors (NaI(Tl), 2’’) (Scionix, The Netherlands) placed in lead shieldings. Counting time was set to 72,000 s. Gamma-ray spectra were acquired and evaluated using the Genie 2000 software (Canberra, USA).

For radiation dose assessment originating from ^{137}Cs, a dose conversion factor of $1.3 \cdot 10^{-8}$ Sv/Bq was applied to assess the effective doses received by consumers (International Atomic Energy Agency 1996). The effective dose was defined by the equation.

$$H_{\mathrm{E}} = A_k m D_{k\,\mathrm{f}(k)}$$

where H_{E} is the effective dose (Sv); A_k – the concentration of k radionuclide (Bq/kg); m – the quantity of consumed food (kg) and $D_{kf(k)}$ is the dose conversion factor for k radionuclide (Vilic et al. 2005).

Results

Radiocaesium activity concentrations

The ^{134}Cs activity concentrations were negligible (always below MDA values) in all the samples measured.

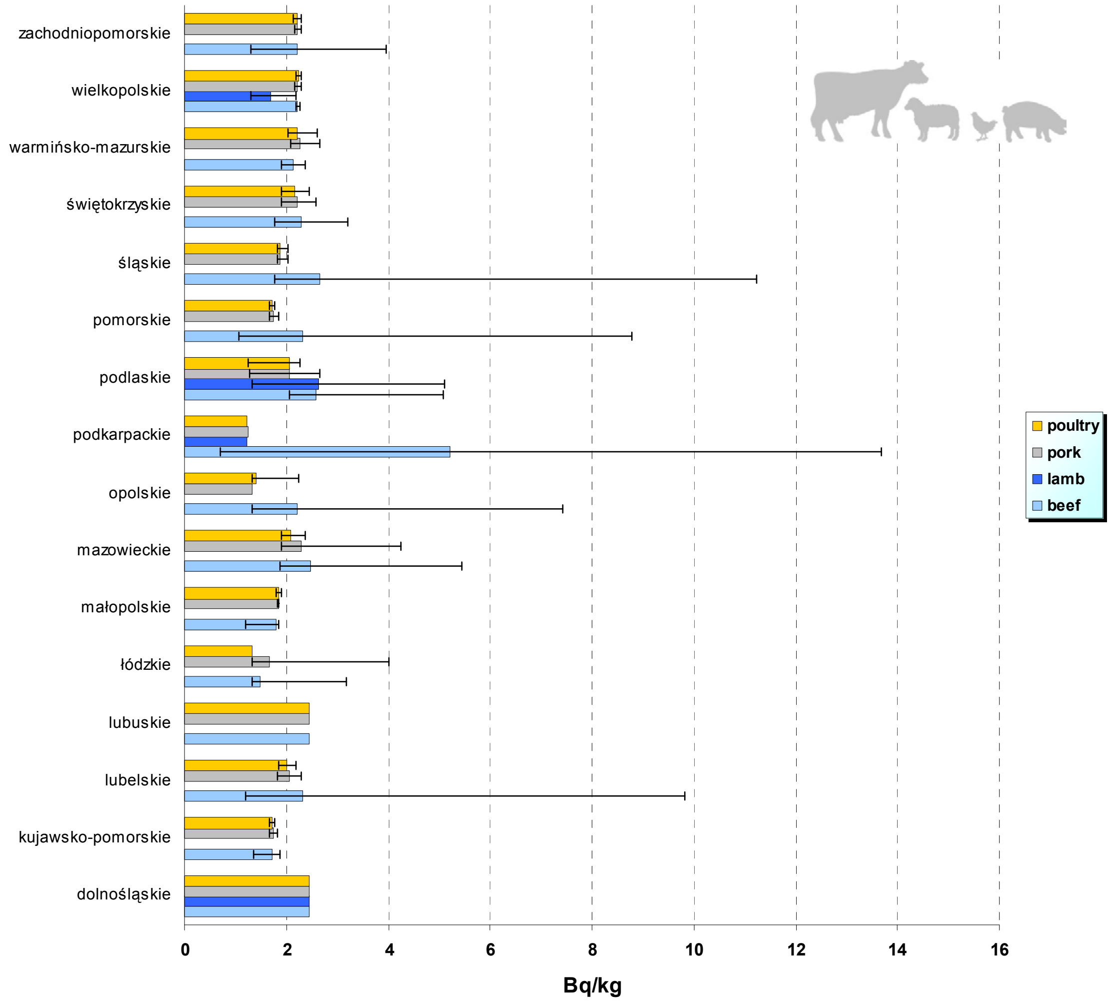

Fig. 2. ^{137}Cs activity concentrations in farm animal meats from the regions of Poland in 2008 (mean and range; no error bars – only 1 sample analysed or all the activity values were below MDA).

The ^{137}Cs activity concentrations were below MDA values in most cases. It should be stressed that because of small differences in analytical equipment, mostly in lead shields, the detection limits for caesium radioisotopes varied between laboratories. The results of ^{137}Cs measurements (averages and ranges) in farm animal and game meats are given in Fig. 2 and Fig. 3, respectively. The results are presented on a fresh-weight basis. As it can be seen, the mean values were about 2 Bq/kg in farm animal meats.

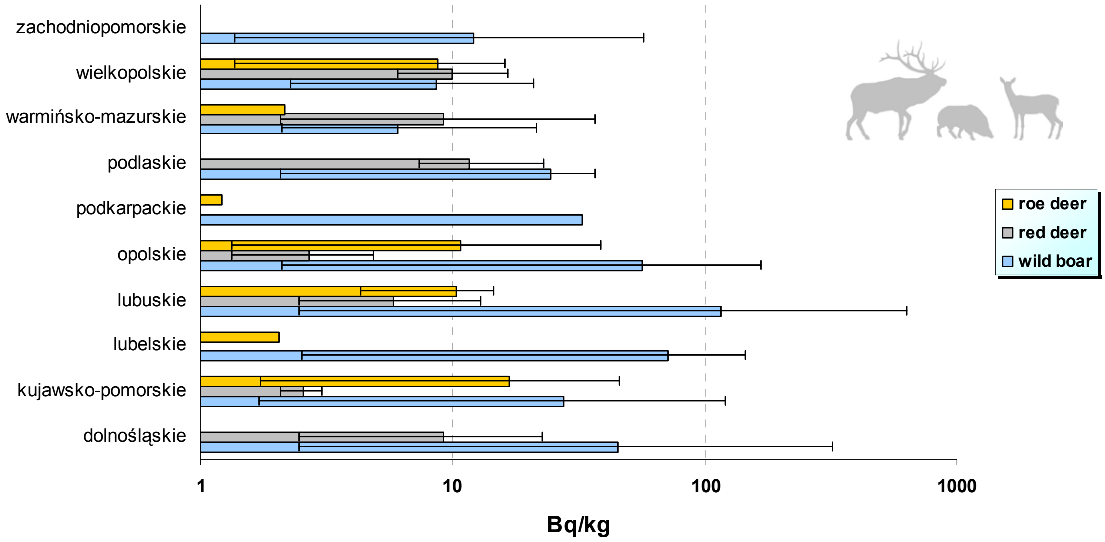

Fig. 3. ^{137}Cs activity concentrations in game meats from the regions of Poland in 2008 (mean and range; logarithmic scale; no error bars – only 1 sample analysed).

The ^{137}Cs activity concentrations were very variable between and among the game meat samples. Even in the same region they ranged from MDA values to more than 100 Bq/kg. The highest ^{137}Cs radioactivity concentration (> 600 Bq/kg) was noted in a wild boar meat sample.

Radiation dose assessment

Since the ^{137}Cs activity concentrations were below the detection limits in the majority of samples, the effective doses originating from meat consumption have been overestimated.

Table 1. Effective doses from consuming 1 kg of farm animal meat.

Farm animal meat	H_E per kg of farm animal meat (μSv)
beef	0.031
lamb	0.026
pork	0.026
poultry	0.025
combined	0.027

Mean effective doses from consuming 1 kg of farm animal meat and game meat are presented in Table 1 and Table 2, respectively. The mean effective dose originating from game meat was almost 10 times higher than that from farm animal meat. The highest mean effective dose was calculated for wild boar meat.

Table 2. Effective doses from consuming 1 kg of game meat.

Game animal meat	H_E per kg of game meat (µSv)
wild boar	0.52
red deer	0.09
roe deer	0.10
combined	0.24

For the wild boar sample with the ^{137}Cs activity concentration exceeding 600 Bq/kg, an effective dose of 8.26 µSv per kg was calculated.

Discussion

Due to a relatively short physical half-life (2.06 years) and a lower deposition after the Chernobyl accident (De Cort et al. 2001), the current radioactivity concentrations of ^{134}Cs in foodstuffs are negligible, and its contribution to the effective doses received by consumers may be omitted.

The highest radiocaesium activity concentrations in meat were observed in the summer of 1986. In subsequent years, contamination with radiocaesium decreased steadily. Since 1994, ^{134}Cs radioactivity concentrations have been below the detection limit in most samples. Mean ^{137}Cs radioactivity concentrations reached a level of 2–3 Bq/kg. Moreover, the differences in radiocaesium activity concentrations among the meats examined were less visible (Muszynski et al. 2003).

The ^{137}Cs activity concentrations in meat measured in 2008 were similar to those noted in previous years. The highest values were found for game meats. There is a significant variation in the ^{137}Cs activity concentrations between and among game animal species. It may be attributed to different contamination levels even in neighbouring areas and different feeding habits of game animals (Vilic et al. 2005).

In Poland after the Chernobyl accident, the highest ^{137}Cs activity concentration (227 Bq/kg – mean, 4–4,357 Bq/kg – range) was observed in roe deer followed by red deer and wild boar. During the next five years, radiocaesium activity concentrations steadily decreased to tens Bq/kg (Grabowski et al. 1994). In our study, the measured activity concentration values were even lower. Similarly to the Austrian findings (Strebl and Tataruch 2007), in recent years the average ^{137}Cs activity concentration in Poland has been higher in meat from wild boar than that in meat from roe deer or red deer.

It is well documented that some mushrooms, readily consumed by animals, show high ability to accumulate radiocaesium (Bem et al. 1990, Grabowski et al. 1994, Malinowska et al. 2006, Mietelski et al. 1994, Pietrzak-Flis et al. 1996). Bay bolete (*Xerocomus badius*), one of the most wide-spread mushroom species in Poland, reveals a unique radiocaesium accumulation feature. Pigments from the bay bolete cap cuticle (badion A and norbadion A) can complex potassium and its chemical analog caesium (Aumann et al. 1989). Deer truffle (*Elaphomyces granulatus*), which also contains particularly high levels of radiocaesium, may be another radionuclide source for game animals, particularly for wild boars (Hohmann and Huckschlag 2005). These authors studied a wild boar stomach content to test the influence of *E. granulatus* intake on wild boar radiocaesium contamination. They found deer truffles in significantly higher proportions in stomachs of animals with maximum contamination levels. Moreover, animals consuming deer truffles might digest contaminated soil components.

Between 1998 and 2008 German and Belarusian researches analysed more than 600 wild boar meat samples from Baden-Württemberg. The muscle radiocaesium levels varied widely from less than 5 to more than 8 000 Bq/kg (fw). The investigators observed maximum values of ^{137}Cs activity concentrations during the winter periods. They connected this pronounced maximum with the consumption of highly contaminated deer truffles available for wild boar in winter (Semizhon et al. 2009). These mushrooms grow in a depth of 6–8 cm in spruce forest soil corresponding to Oh/Ah (organic layer/mineral layer) horizon where the peak of ^{137}Cs activity was observed (Pietrzak-Flis et al. 1996).

The MDA values (1–2 Bq/kg), which were taken for determination of radiation doses, are characteristic for analytical systems used by the laboratories participating in veterinary radioactivity monitoring in Poland. In Hungary, γ-ray spectrometry using NaI(Tl) scintillation detectors are considered as a screening method. For ultimate measurements, γ-ray spectrometry using high purity germanium detectors (HPGe) is applied. The typical limit of detection for meat is in the order of magnitude of 10^{-1} or 10^{-2} Bq/kg fresh weight (Varga et al. 2006). So, a broader implementation of this technique in Poland should produce more reliable results of γ-emitting radionuclide measurements and calculation of the radiation doses for consumers.

Assuming that the mean annual consumption of farm animal meat is around 75 kg and the mean effective dose is 0.027 μSv per kg, an individual in the Polish population may receive the annual effective dose of about 2 μSv.

Lithuanian researchers calculated the average annual effective dose caused by ^{137}Cs at a level of 0.02 μSv, whereas the effective dose derived from natural ^{40}K was 0.14 mSv. So, the main contributors to the total annual effective dose seem to be naturally occurring radionuclides (Butkus et al. 2006). Even in the Ukrainians with the maximum intake of ^{137}Cs, the annual effective dose of 2.7 mSv was estimated (Shiraishi et al. 2008). This value corresponds to the natural radiation dose (2.4 mSv) for worldwide inhabitants (United Nations Scientific Committee on the Effects of Atomic Radiation 1988).

Our studies showed that in some wild boar meat samples the ^{137}Cs radioactivity concentrations may still exceed 600 Bq/kg (maximum permitted level) even more than 20 years after the Chernobyl accident. However, average consumption of game meat in Poland is very low and the contribution of this sort of food to the effective doses received by consumers is negligible, with the exception of hunters and poachers and their families. Supposing that the mean annual consumption of game meat in these populations is around 20 kg (Haldimann et al. 2002), the average annual effective dose of 4.8 μSv was calculated.

Conclusions

Considering the permitted annual public dose at a level of 1 mSv, the consumption of farm animal meat is truly safe in terms of contamination with radiocaesium.

Some precautions may be taken in populations with elevated intake of natural food products.

Public doses due to tritium emissions from Cernavoda NPP

Bobric, Elena; Popescu, Ion; Simionov, Vasile
Cernavoda NPP, Health Physics Department, ROMANIA

Abstract

Heavy water reactors have a large tritium load. In a CANDU reactor most of the tritium is formed in the thermal-neutron-capture reaction, 2H(n,ƒ×)3H which occurs both in the moderator and heat transfer system. Very small amounts of tritiated heavy water may escape from moderator and heat-transport systems of CANDU reactors during maintenance and normal operation. Tritium emissions of Cernavoda NPP were continuously monitored. The tritium concentrations in environmental samples were monitored as part of routine program and public doses were calculated. This paper presents the supplementary tritium doses for a member of public, estimated using HTO concentrations in environmental samples and OBT doses estimated based on Candu Owners Group studies ¡§OBT/HTO Ratio in plants¡¨ and ¡§Contribution of Organically Bound Tritium to total Tritium Dose¡¨ .

New Swedish regulations for clearance of materials, rooms, buildings and land

Efraimsson, Henrik
Swedish Radiation Safety Authority, SWEDEN

Abstract

The Swedish Radiation Safety Authority (SSM) has developed new regulations for clearance of materials, rooms, buildings and land. The new regulations develop and widen the scope of the current Swedish regulations on the release of goods and oil from nuclear facilities. The new regulations put requirement on the procedures for clearance of materials, rooms, buildings and land during all stages of nuclear and non-nuclear practices. The proposed clearance levels are based on recommendations from the European Commission. The regulations are scheduled to enter into force in January 2011.

Introduction

The Swedish Radiation Safety Authority (SSM) is the regulatory and supervisory authority for radiation protection and nuclear safety in Sweden. SSM has developed new regulations for clearance of materials, rooms, buildings and land. The regulations specify under what conditions objects that may have been contaminated[1] by radionuclides in licensed practices with ionizing radiation, can be released from further regulatory control by SSM. Thereby materials and resources can be used and managed in a rational way, in a manner that is acceptable from a radiation protection point of view.

The regulations will replace the current Swedish regulations for release of goods and oil from nuclear facilities, SSMFS 2008:39 (Ref 1) and introduce new rules for clearance of materials from non-nuclear practices as well as new rules for clearance of rooms, buildings and land. The work builds on work performed by the former Swedish Radiation Protection Authority (SSI). A draft version of the regulations was sent for a broad national review in 2006 and a large number of comments were received (see Ref 2 for a description of the draft version). SSM developed the regulations further and a new version was sent for a broad national review in 2009. The regulations have thereafter been adjusted and clarified in some aspects and will soon (spring 2010) be notified to the European Commission (EC) according to the Euratom treaty, before being decided by SSM. The regulations are planned to enter into force in January 2011.

[1] In this paper, the term contamination means any occurence of radionuclides on the surface or in the bulk of an object that is caused by the actual practice.

After the national review in 2006, the Swedish nuclear industry took an initiative to develop a common handbook or code of practice for clearance procedures (Ref 3). The handbook is planned to be issued by the Swedish Nuclear Fuel and Waste Management Company (SKB), following SSM's decision on the regulations.

Background

The work to revise the current regulations for clearance of goods and oil from nuclear facilities (Ref 1) was initiated for several reasons. The main reasons were:

- The methods for management of conventional wastes have changed substantially since the current clearance levels were developed.
- The current regulations were originally not intended for large amount of materials arising from decommissioning of nuclear installations.
- There are currently no general clearance regulations for non-nuclear practices in Sweden.
- A need for harmonization with international recommendations from the EC and the IAEA (Refs 4, 5, 6)

The work was prepared for several years by following the international development of clearance recommendations and regulations. The actual revision project started in 2004 with an evaluation of the current regulations. The evaluation was based on inspections of the clearance procedures at the Swedish nuclear installations (four NPP:s, one fuel fabrication plant and one site with material test reactors, hot-cells for material investigations and radioactive waste management facilities). Another important preparatory work was the investigation of the applicability of the EC recommendations for buildings and building rubble in Sweden (Ref 7). Also, some of the requirements were developed on the basis of experiences from decommissioning projects in Sweden and other countries. During the work, several seminars have been held to discuss specific topics on clearance with the licensees and other interested parties. On several occasions, information and progress reports have been given to radiation protection experts of the licensees. International experiences have been included in the work, by invitation of experts from Germany and Spain to seminars in Sweden, and by participation on international conferences.

The regulations

The regulations contain the following subsections, which will be presented below.

- Introductory requirements
- Area of application
- Clearance
- Measures for clearance
- Clearance levels
- Rules for implementation of clearance levels
- Competence
- Reporting
- Other clearance options and exceptions

Introductory requirements

The introductory requirements describe the purpose of the regulations and give a definition of the term clearance. It is stated that clearance means that the Radiation Protection Act (1988:220) and the Act (1984:3) on Nuclear Activities shall no longer be applied to materials, rooms, buildings and land that may have been contaminated by radioactive substances in such practices with ionizing radiation that are subject to licensing. Thus, it is important to note that the regulations only deal with exemptions from the acts on *radiation protection* and *nuclear safety*, in the case of potentially contaminated objects due to *licensed practices*. Other legislation concerned with hazards from radioactive substances might thus still be applicable, for example legislation on transport of radioactive materials and legislation on non-proliferation of nuclear materials.

Area of application

The area of application is specified both in terms of what is included in the scope of the regulations and what is excluded. Included are: Materials, including waste, rooms, buildings and land that *may* have been contaminated by radioactive substances in practices with ionizing radiation that are or have been carried out under a license according to the Radiation Protection Act or the Act on Nuclear Activities.

Excluded are:

1. releases of radioactive substances to air or water,
2. naturally occurring radioactive substances that are not part of the license for the actual practice with ionizing radiation,
3. practices that only involve naturally occurring radioactive substances and that are carried out without any purpose of use of the radioactive, fissile or fertile properties of radioactive substances,
4. nuclear medicine.

Thus, only radionuclides that have been part of the licensed practice have to be considered when applying the regulations. Nuclear medicine is excluded since contaminated objects from such practice need special consideration and are dealt with in other regulations from SSM (for example contaminated clothes and sheets).

Clearance

Clearance of materials is treated differently than clearance of rooms, buildings and land. For materials, it is stated that a material is subject to clearance when it has been checked in accordance with the regulations and it has been concluded by the licensee that the content of radioactive substances is less than the clearance levels given in the regulations. Thus a mandate is given to the licensee to perform clearance under own responsibility, without any obligatory supervision or decisions by the authority.

For rooms, buildings and land that shall no longer be used for the actual practice, it is stated that the licensee shall take all measures that are needed to achieve clearance. An application on clearance shall thereafter be given in to SSM, who decides on clearance. To allow for some flexibility, the licensee may temporarily use rooms and buildings that have been checked for contamination for other purposes without any decision on clearance by SSM.

Measures for clearance

An obvious requirement is that objects have to be checked for radioactive substances before clearance. The regulations state that the checks shall be based on measurements. Thus it is not sufficient to only estimate the occurrence of radioactive substances based on for example knowledge of the possible ways of contamination of the object. However, it is allowed to apply nuclide vectors or correlation factors between the occurring nuclides if the vectors or factors have been established from measurements on samples that can be considered representative for the actual composition of radionuclides.

It is further stated that the methods and extent of the checks shall be adapted to the risk of contamination, the extent of contamination, and to the characteristics of the potentially contaminated object.

Also, the methods shall correspond with Swedish or international standards, or guiding documents from SSM. Although no such guiding documents are planned by SSM today, they could be issued as a complement to the standards or to override the standards (if some part of a standard for some reason would be considered not appropriate).

Some decontamination efforts may be warranted to keep the amount of radionuclides in cleared materials, and thus also the potential exposure of members of the public, as low as reasonably achievable. It is therefore stated, as an advice attached to the regulations, that decontamination should be considered and that easily removable contamination should be removed before clearance. In another advice attached to the regulation, it is stated that systems, equipment and components should be removed before clearance of rooms and buildings, in order to facilitate decontamination and activity checks of the remaining structures.

An important prerequisite for allowing the licensee to perform clearance under own responsibility is to ensure that it is performed in a well-planned, qualified and systematic manner. In order to achieve this, it is stated that the licensee shall develop a written control program that shall specify the methods and who is authorized to conduct the checks. The control program shall also describe how quality assurance, self-assessment and documentation of results is done. For clearance of rooms, buildings and land as well as for clearance of more than 100 tonnes of materials per year, the control program shall be given in to SSM. Thereby, SSM has the possibility to review the program, judge if it is appropriate and give comments and suggestions for improvements. If needed, SSM can also require the licensee to change or improve the program in a specified manner.

Also, to facilitate supervision by SSM, it is stated that the performing of checks as well as the results of checks shall be documented and that the documents shall be preserved for ten years after clearance. The only exception from this rule concerns tools and equipment that are cleared after temporary use in the practice (se below).

Furthermore, the regulations explicitly forbid dilution of contaminated materials with the purpose to achieve clearance. It is also stated that liquids shall be cleaned from radioactive particles as far as practically achievable, in order to prevent exposure of the public due to accumulation of radionuclides in filters or in sediments.

Clearance levels

As required in the European Community Basic Safety Standards (Ref 8), the clearance levels are based on the basic criteria for exemption (Annex 1 of Ref 8). The criteria are specified as a maximum effective dose to any member of the public of the order of 10 microsieverts per year and a collective effective dose of less than about 1 mansievert per year (or assessment that clearance is the optimum option).

Clearance levels are specified for four different cases:

1. Materials for unrestricted further management (reuse, recycling or disposal)
2. Oil and hazardous waste for incineration or disposal
3. Rooms and buildings for reuse
4. Buildings for demolition

For materials, oil and waste, nuclide specific clearance levels for activity concentration (becquerel per gram) are given for 196 nuclides. For materials for unrestricted further management (category 1 above), the values are those established in European Commission recommendation RP 122, Ref 4. For oil and hazardous waste for incineration or disposal (category 2 above), the values are 10 times higher for all nuclides (except for three nuclides for which the clearance values are the same as those recommended in RP 122 in order to not exceed the exemption values of the European BSS, Ref 8).

Clearance levels are also stated for surface contamination on materials. As in the current regulations (Ref 1), the values are 40 kBq/m2 in total for beta and gamma emitting radionuclides and 4 kBq/m2 for alpha emitting radionuclides.

In general, both the levels for activity concentration and the levels for surface contamination have to be complied with for clearance. The only exception is for tools and equipment that have been used temporarily in the practice and that are intended to be used also after clearance (i.e. not being sent for demolition or recycling). Another prerequisite for this exception is that contamination shall only be expected to be found on accessible surfaces.

For rooms and buildings (categories 3 and 4 above), nuclide specific clearance levels are given for 104 nuclides. The values are those established in European Commission recommendation RP 113, Ref 5, Table 1 (for reuse or demolition) and Table 2 (for demolition only).

No clearance levels are given for land in the regulations. The current approach is that such clearance levels will be decided by SSM on application by the licensee based on site specific considerations.

Rules for implementation of clearance levels

In the regulations, some rules are given on how the clearance levels shall be interpreted and implemented. Firstly, the summation formula shall be used for contamination that consists of several nuclides, see for example Ref 4. Moreover, the activity concentration may be determined as a mean value for up to 1000 kg (in the case of materials) or 1 m^2

(in the case of room and building surfaces, i.e. walls, floors and ceilings) when comparing with the clearance levels.

Surface contamination on materials may be determined as a mean value for up to 0.03 m2 when comparing with the clearance levels.

As mentioned in the beginning of the paper, the Swedish nuclear industry has jointly developed a guiding document for clearance. The document gives further guidance on several different issues that should be considered in the clearance process.

Competence

There is a general requirement that the involved personnel shall have sufficient competence for the measures that they take and the judgements that they make in the clearance process. This is further specified by requirements on knowledge of which radionuclides that occur in the practice and to what extent they may occur as contamination. The personnel shall also be educated in harmful effects and risks with ionizing radiation, in rules and routines for clearance and in methods for sampling and measurement, including inaccuracies and limitations of the methods.

Reporting

A yearly report shall be given in to SSM in order to facilitate SSM's supervision and retrospective follow up on the use of the clearance option for management of materials and waste. The report can also serve the purpose of public insight in the process of clearance. The report shall specify the amounts and kinds of materials that have been subject to clearance, the nuclide specific concentration of radioactive substances in the materials, and, in the case of oil and hazardous wastes, the receivers of the materials. No report is required from licensees that have cleared less than 1000 kg of materials during the past calendar year, in order to reduce the administrative burden on licensees.

Other clearance options and exceptions

SSM can, on a case-by-case basis, decide on other clearance levels than those specified in the regulations. This requires an application by the licensee supported by an analysis of the radiological consequences of the proposed management or use of the object(s) after clearance. If there are circumstances that limit the possible ways of public exposure, higher clearance levels may be accepted.

SSM can also permit exceptions from the requirements in the regulations, if there are special reasons, as long as the purpose of the regulations is not violated.

Discussion

Several difficult issues have to be dealt with when regulating and implementing clearance procedures. A general feature of the necessary considerations is that they include a large portion of judgement.

The derivation of proper clearance levels is a fundamental issue that is based on judgement of the expected or potential exposure that should be accepted from cleared objects. Generally, such judgement leads to the establishment of a dose criterion. In international guidance and legislation, 10 microsieverts per year is commonly used, since it is generally regarded as trivial. In some cases, for example in Ref 6, consideration is also made about low probability exposure scenarios, with the application of higher dose criteria in such cases (1 mSv/year in Ref 6).

To derive clearance levels, considerations must be made about expected and potential scenarios for exposure. This step also includes a large portion of judgement and considerations about the practices that can give rise to contaminated objects as well as about the further destiny of cleared objects (for example in the selection of considered radionuclides, identification of scenarios and choice of parameters and computational models for exposure calculations). Special attention is normally given to such realistic scenarios that would cause a higher exposure than other foreseeable scenarios. This means that the most probable doses to members of the public should be well below the dose criterion and that the dose criterion should only be exceeded in fairly extreme cases.

Internationally, a lot of work has been done on clearance levels for activity concentration in materials, which has been a good help in the development of the new Swedish regulations. However, for surface contamination there is very sparse guidance. Thus, there is a need for international recommendations on general clearance levels for surface contamination. There is also a need for further harmonization between clearance levels and transport regulations (see Ref 9).

The treatment of naturally occurring radionuclides poses a special problem when it comes to clearance. There are practices that involve naturally occurring radioactive materials (NORM) for which the application of the 10 microsievert criterion would cause restrictions on the operations and on the treatment of residual materials that would probably not be motivated from a radiation protection point of view, taking into account the natural abundance of NORM. Instead, higher dose criteria (300 microsieverts per year, Ref 10) or clearance levels corresponding to higher doses (Ref 6) are internationally recommended.

However, for practices in the nuclear fuel cycle, where NORM has been processed in view of its fissile properties, the 10 microsievert criterion should be applied, as for other radionuclides in the nuclear fuel cycle (fission and activation products)[2]. In this case the natural abundance of NORM causes detection problems, which might mean that less confidence level has to be accepted for some nuclides, or even that higher clearance levels can be applied, based on optimization of radiation protection (cf Ref 4, footnote of Table 1).

Once the clearance levels have been established, the question is how to show compliance with the levels. As mentioned earlier, this involves judgement about the potential contamination of the object, selection of appropriate methods for determination of the contamination and proper interpretation of the results. Considerations must be made about which nuclides shall be determined, their expected distribution, the properties of the contaminated materials, confidence levels and detection limits of measurements, logistics, calibration of equipment, quality assurance, etc. Many of these issues have to be solved in a way that is adapted to the actual circumstances. In the new Swedish regulation, this step in the procedure is a

[2] Actually, this is the main reason for the decision to use the clearance levels recommended in Ref 122 instead of Ref IAEA. This is further described in Ref 9.

responsibility of the licensee to a large extent. This emphasizes the importance of skills and competence of the personnel responsible for clearance.

Clearance levels are often regarded as "perfectly safe" levels of contamination which can be disregarded from a radiation protection point of view. However, application of the principle of optimization of radiation protection means that some efforts for decontamination before clearance may be warranted (Ref 9). It could also be warranted to direct the release of materials into the society in such a way that exposure is avoided.

Clearance procedures are closely connected to means and routines for control of radioactive materials and waste within a practice. To avoid exposure of the public or deterioration of public confidence it is crucial that no radioactive material, on false grounds, leaves the practice as cleared material. To prevent this, the clearance procedures should involve additional "lines of defence" to identify and prevent such illicit clearance. This could include random additional checks and gate monitors for goods leaving the site

Conclusions

Over a period of several years, SSM has developed new regulations for clearance of materials, rooms, buildings and land. The work has involved extensive consultation with stakeholders and information to licensees and other interested parties. In parallel, the Swedish nuclear industry has developed a code of practice as a common platform for implementation of the requirements in the management systems of each company. The regulations, the industry code of practice, as well as the awareness and common understanding that has developed during the process, should provide a good basis for robust procedures so that clearance will be done in a reliable and transparent manner.

The approach to assessing doses to humans in the Posiva safety case

Hjerpe, Thomas[1]; Ikonen, Ari T. K.[2]; Avila, Rodolfo[3]; Broed, Robert[3]
[1] Saanio & Riekkola Oy, Laulukuja 4, FI-00420 Helsinki, FINLAND

Abstract

Posiva Oy is responsible for implementing a final disposal programme in Finland for spent nuclear fuel. The next step of the nuclear licensing is by the end of 2012 submit a construction licence application for a KBS-3 type of repository at the Olkiluoto site. Currently, a safety case is produced to support this application, were a preliminary version was completed in 2009. Assessing doses to humans is a key part in order to assess compliance with regulatory requirements on the long-term safety. A prospective deterministic dose assessment, based on the ICRP concept of assessing doses to the *representative person* has been developed. Exposure characteristics are based on site-specific conditions and regional land use. For example, the number of exposed persons is limited by the site-specific capabilities to produce food and drinking water. Due to the temporal scale of the assessment, the surface environment will undergo significant development and many generations may be exposed. This is taken into account by deriving full dose distributions (the dose to each potentially exposed individual) for all generations during the assessment time window. Doses to representative persons, both for the more highly exposed individuals and for the other people in the exposed population, are then identified from the dose distributions. This paper present the methodology applied in the interim safety case to derive annual doses to humans from concentrations of radionuclides in environmental media, resulting dose distributions from the calculation cases analysed, and the doses used when assessing compliance with the regulatory dose constraints for humans.

Introduction

Posiva Oy (Posiva) was established in 1995 by the two Finnish nuclear power companies, Teollisuuden Voima Oyj (TVO) and Fortum Power and Heat Oy (Fortum), to implement the final disposal programme for spent nuclear fuel and to carry out the related research, technical design and development. The spent nuclear fuel is planned to be disposed of in a KBS-3 type of repository to be constructed at a depth of about 400 metres in the crystalline bedrock at the Olkiluoto site. Posiva is currently preparing for the next step of the nuclear licensing of the repository, which involves submitting the construction licence application for a spent fuel repository by the end of 2012. A safety case will be produced to support this licence application; the Posiva plan for conducting the safety case is documented in (Posiva 2008).

A key contributor to the safety case is the biosphere assessment. The overall aims of the biosphere assessment are describe the future, present, and relevant past conditions at, and prevailing processes in, the surface environment of the Olkiluoto site; to model the transport and fate of radionuclides hypothetically released from the repository through the geosphere to the surface environment; and to assess possible radiological consequences to humans and other biota. For the dose assessment, a graded approach based on three tiers has been applied, where Tier 1 and Tier 2 involve conducting generic evaluations to screen out radionuclides that have insignificant radiological consequences. Tier 3 is based on based on site-specific state-of-the-art radionuclide transport modelling and dose assessment.

The regulatory requirements for the long-term safety of a geological repository in Finland are set out in detail in the Radiation and Nuclear Safety Authority's (STUK) Guide YVL E.5 on disposal of nuclear waste (STUK 2009). The criteria for the time window to be addressed in the biosphere assessment and the criteria for protection of humans within this time window are stated as follows (STUK 2009): *"In any assessment period, during which the radiation exposure of humans can be assessed with sufficient reliability, and which shall extend at a minimum over several millennia: 1) the annual dose to the most exposed people shall remain below the value of 0.1 mSv, and 2) the average annual doses to other people shall remain insignificantly low."*. For the larger groups, no fixed dose constraint is set, but the acceptability of the doses depends on the number of exposed people, and they shall not exceed values from one hundredth to one tenth of the constraint for the most exposed people (STUK 2009).

The graded approach to dose assessment has been developed for, and applied in, the recently produced interim safety case (Hjerpe et al. 2010, Posiva 2010). This paper presents the methodology for assessing doses to humans in Tier 3 and selected results from the calculation cases analysed for the interim safety case.

Methodology

The main objective of the assessment of doses to humans is to assess compliance with the above-mentioned regulatory dose constraints defined in terms of annual effective doses. The ICRP (International Commission on Radiological Protection) has provided guidance (ICRP 2007a) on how to assess individual doses for the purpose of establishing compliance with the ICRP recommendations (ICRP 2007b). However, ICRP states that the guidance for the protection of future individuals in the case of disposal of long-lived radioactive waste as provided in (ICRP 2000) remains valid. ICRP (2000) recommends, in the context of assessing doses to those most likely to receive the highest doses, that exposures should be assessed on the basis of the mean annual doses received by the *critical group*. The concept adopted by Posiva is based on the guidance in (ICRP 2007a) on how to assess the dose to the 'representative person'; this is considered to be consistent with the (ICRP 2000), since the 'representative person' is considered to be equivalent to an 'average member of the critical group'. The dose assessment applied in the Posiva interim safety case, below referred to as *the dose assessment*, is presented below and described in detail in (Hjerpe et al. 2010).

The dose assessment is a general process (Fig. 1) for using results from radionuclide transport modelling to make dose estimates that are suitable for assessing compliance with annual effective dose constraints. The methodology for assessing doses to humans described here focuses on three blue middle boxes in Fig. 1.

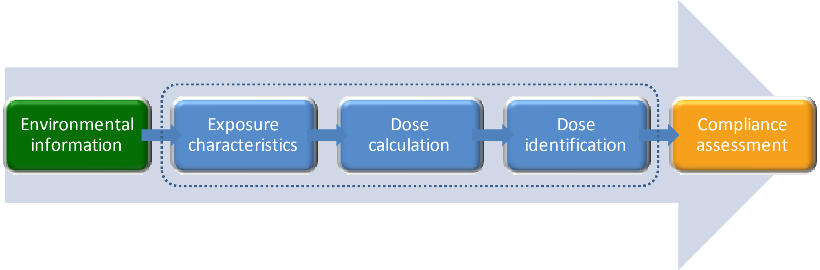

Fig. 1. General process for assessing the doses to humans.

Environmental information

The key environmental information needed for the dose assessments is the time-dependent and radionuclide-specific radioactivity concentrations in environmental media delivered from the radionuclide transport modelling process of the biosphere assessment. This information is given for each biosphere object in the landscape model (the landscape model is the site-specific and time-dependent radionuclide transport model for the surface environment containing connected biosphere objects, where a biosphere object is a sub-area of the whole modelled area described by one, or more, ecosystem types and a data set).

In addition, production rates of individual food products, to derive the total productivity of edibles, and aggregated concentration ratios of radionuclides from environmental media to edible food products, are also needed when calculating food ingestion doses. The productivity of edibles is calculated by summing over all plant parts and animal products normally consumed by man. The aggregated concentration ratios are radionuclide- and ecosystem-specific and derived as the productivity-weighted average of the soil-to-edible concentration ratios for all edibles produced in the ecosystem in question.

Exposure characteristics

A specific set of individual characteristics is selected, including, among others, food and water intake rates. In general, diet, occupancy, and other information needed to estimate exposure can be referred to as ‘habit data’ (ICRP 2007a). When assigning the exposure characteristics, care has been exercised to prevent excessive conservatism. The key features in the selected exposure characteristics, and the selection of habit data, can be summarised as follows:

– the exposure characteristics aim at being reasonable and sustainable, in line with the concept of assessing doses to the representative person (ICRP 2007a),
– all main exposure pathways are considered: ingestion of food, ingestion of water, inhalation and external exposure,
– the number of exposed individuals is limited by the capability of the biosphere objects to produce food and drinking water, by the size of suitable residential areas from a present-day perspective, and by present demography,

– average present-day intake rates are assumed for the representative person,
– cautious assumptions are made for occupancy data (e.g., time spent outdoors),
– a very cautious assumption is made for usage of local resources (i.e., all foodstuffs and water originate from contaminated areas), and
– exposed individuals have no preferences regarding food.

Dose calculation

The dose calculation method applied follows the concept described in (Avila & Bergström 2006), based on values of food energy intake (carbon) and water intake given by the ICRP for Reference Man (ICRP 1975, 2002). The doses arising from intake of contaminated water and food, inhalation of contaminated air, and external exposure from contaminated areas are calculated by using dose coefficients. The dose coefficients used for ingestion and inhalation are based on the values recommended by (ICRP 1996) for adults. The dose coefficients used for external radiation are the values for radionuclides uniformly distributed to an infinite depth and an effectively infinite lateral extent of the contamination in soil from (U.S. EPA 1993). The approach is to calculate *landscape doses*, defined as follows:

– the *landscape dose* (E_{L}) is the pathway-, radionuclide- and biosphere object-specific annual effective dose to an individual.

In the dose calculation, the exposure pathways inhalation and external exposure are combined into the same dose quantity ($E_{\mathrm{L,IE}}$), whereas the dose contributions from food ingestion ($E_{\mathrm{L,F}}$) and water consumption ($E_{\mathrm{L,W}}$) are kept separate. The reason for this is that the exposures from external and inhalation pathways occur simultaneously at the same location, whereas it is not always the case that the consumed food and water originate from the same location. This approach gives the possibility to calculate the dose to an individual who, for example, e.g. lives in a forest, drinks water from a nearby lake and eats food produced on a nearby cropland. For all biosphere objects, landscape doses are calculated for the different pathways as follows:

– *Landscape dose from food ingestion* ($E_{\mathrm{L,F}}$) is the product of the annual intake of a radionuclide from food ingestion and the corresponding dose coefficient for ingestion.
– *Landscape dose from water consumption* ($E_{\mathrm{L,W}}$) is the product of the annual intake of a radionuclide from water consumption and the corresponding dose coefficient for ingestion; $E_{\mathrm{L,W}}$ is calculated for lakes and rivers.
– *Landscape dose from inhalation and external exposure* ($E_{\mathrm{L,IE}}$) is the sum of doses due to inhalation and external exposure from terrestrial objects (forest, wetland and cropland). The contribution from inhalation is the product of the annual intake of a radionuclide via inhalation and the corresponding dose coefficient for inhalation. The contribution from external exposure is the product of the activity concentration in soil and the corresponding dose coefficient for external exposure.

Dose identification

The pathway-specific dose contributions are combined to obtain the "total" dose to each individual in the exposed population. The approach to identifying the dose from all pathways, denoted as the *annual landscape dose*, E_{ALD}, is to identify the dose maxima from each pathway, and sum these. Thus, the dose to the most exposed individual is the sum of the doses from ingestion of the most contaminated food, ingestion of the most contaminated water, and the dose from inhalation and external exposure arising from staying all time in the biosphere object giving the highest dose. When deriving E_{ALD} it is also required that the annual consumption of food and water originates from the exposed area. Thus, the dose may be a sum of contributions from different biosphere objects. For example, if a forest object is producing the most contaminated food, but not enough to satisfy the annual food demand of an individual, it is then assumed that this individual eats everything produced from this forest and the remaining food needed is taken from the biosphere object producing the second most contaminated food.

The approach is to derive E_{ALD} to each exposed individual and the distribution of E_{ALD} between the different individuals of an exposed population is referred to as the *dose distribution*. The highest numbers of people that can satisfy their annual food demand, drinking water demand, and demand regarding residential areas, by utilising contaminated food, water and land are referred to as maximum sustainable populations; these are derived for each exposure pathway. For food ingestion, the carbon content in all contaminated edibles produced during one year divided by the average annual carbon demand by an individual is the maximum sustainable population. For water intake, the population is derived as the available drinking water from all contaminated lakes and rivers divided by the average annual water intake by an individual, taking into account that not all available water is utilised as drinking water. Finally, for inhalation and external exposure, the population is derived by dividing the total suitable residential area by an assumed population density. Here, only forest objects are included and the population density is cautiously selected as the present-day urban density in Helsinki (national maximum).

The derivation of the dose distribution starts by deriving E_{ALD} to the most exposed individual and then subtracting what caused that exposure from the landscape model (one individual's annual demand of food or water, or the size of the residential area). Then, the E_{ALD} to the second most exposed individual is derived, excluding the food, water and residential area the most exposed individual "used" from the landscape. This procedure is performed iteratively until all three exposure pathways have been the dominating pathway E_{ALD} at least once, or until a pre-selected upper limit on the size of the exposed population is reached. This approach to derive the dose distribution ensures that no potentially highly exposed groups are excluded.

The derived dose distribution then forms the basis for identifying annual landscape doses to

– a representative person from the most exposed group, which is the sub-group of the above identified exposed population that receives the highest doses, and
– a representative person for the other people in the exposed population.

For probabilistic assessments, (ICRP 2007a) recommends using the 95th dose percentile as the basis for selection of the most exposed group and that the characteristics of these people need to be explored in the case when relevant dose constraints might be exceeded by a few tens of people or more. Even though the present Posiva dose assessment is deterministic, a similar approach for selecting the most exposed group is applied here since a distribution of doses is derived. The most exposed group is defined as consisting of the smallest of: 1) the 5% most exposed persons in the dose distribution, and 2) a few tens of people, here selected as the 50 most exposed persons. As the final step, the E_{ALD} to two representative persons are identified as follows:

– the annual landscape dose to a representative person within the most exposed group, E_{group}, is the average E_{ALD} for all individuals in the most exposed group.
– the annual landscape dose to a representative person among the other individuals in the exposed population, E_{pop}, is the average E_{ALD} in the exposed population, excluding the most exposed group.

Compliance assessment

In order to assess compliance with the regulatory dose constraints, the whole assessment time window needs to be considered. This is done by identifying, for each generation, the doses to representative persons. Then,

– the highest value, over all generations, of E_{group} is used to determine compliance with the regulatory dose constraints to the most exposed people, and
– the highest value, over all generations, of E_{pop} is used to determine compliance with the regulatory dose constraints to other people.

Results

The methodology described above was applied in the biosphere assessment, summarised in (Hjerpe et al. 2010), in the interim safety case, summarised in (Posiva 2010); this section presents the key results. Dose distributions were derived based on the outcome of the landscape modelling, for which the key input was the derived radionuclide release rates from the geosphere to the biosphere, excluding those radionuclides that were identified from the screening study (Hjerpe et al. 2010) as having insignificant radiological consequences. These release rates are results from nine *repository calculation cases* (RCC), presented in detail in the most recent assessment for a KBS-3V repository (Nykyri et al. 2008). All RCCs addressed have their origin in the same type of repository scenario – assuming releases from a single canister with an initial penetrating defect at the time of emplacement. In addition, each RCC is analysed with three *biosphere calculation cases* (BCC), each using different configurations of the landscape model; the difference is the spatial distribution of the releases from the geosphere, assuming that the releases originates from different repository panels in each BCC. Thus, a total of 27 combinations of calculation cases were analysed. In addition, a number of sensitivity BCCs was analysed to assess the uncertainties introduced in the biosphere assessment process. All results are presented in (Hjerpe et al. 2010); the results presented here are limited to the results from the most realistic cases (the three BCCs in conjunction with the base RCC for the scenario considered) and the cases resulting in the highest doses used in the compliance assessment. The base RCC case, Sh1, assumes (Nykyri et al. 2008) a hole with 1 mm diameter in the copper overpack reaching the insert and the time when water enters a canister through a defect and the dissolution of fuel matrix starts immediately after the emplacement of the canister. The RCC leading to highest doses (see below) are Sh4 Q, in which it is assumed that size of the defect is 4 mm and flow rates are higher for all release routes in the near-field and geosphere. The three BCC are based on the repository panels, denoted as Panels A, B and C, needed for spent fuel from the units currently in operation or under construction, based on the 2006 repository layout, (Kirkkomäki 2007).

The dose distributions for the repository base case Sh1 analysed with the BCC with releases from panel A and for the case Sh4 Q analysed with the BCC with releases from panel are shown in Fig. 2. The annual landscape doses to a representative person for the most exposed group, E_{group}, and to a representative person for other people, E_{pop}, for the RCCs Sh1 and Sh4 Q analysed with the three BCCs are shown in Fig. 3. Table 1 presents the dose maxima, and the year the maxima occur, for the annual landscape doses shown in Fig. 3.

Discussion

The derived dose distributions (Fig. 2) show that the E_{ALD} can be roughly divided into three exposure levels:

1) the E_{ALD} maxima, received only by one or a few individuals. The doses to these most exposed individuals are mainly caused by ingestion of food from forest or wetland objects receiving direct releases from the geosphere (Hjerpe et al. 2010). Since the productivity of edibles is low in these objects, this highest exposure level is only affecting one or a few individuals,
2) an intermediate level, received by some tens to hundreds of individuals. These doses are caused by ingestion of food from croplands, with high productivity of edibles, that are irrigated with contaminated water (Hjerpe et al. 2010), and
3) a lower level, received by some thousands of individuals. The doses to the individuals in this group are totally dominated by ingestion of contaminated water. These individuals do not get any dose from food ingestion, since it is assumed that all contaminated food has been consumed by individuals of the two groups above.

In Table 1, the annual dose maximum to a representative person for the most exposed group, E_{group}, ranges from about 8×10^{-7} to 3×10^{-5} mSv and the dose maximum to a representative person for other people, E_{pop}, ranges from about 2×10^{-8} to 5×10^{-6} mSv.

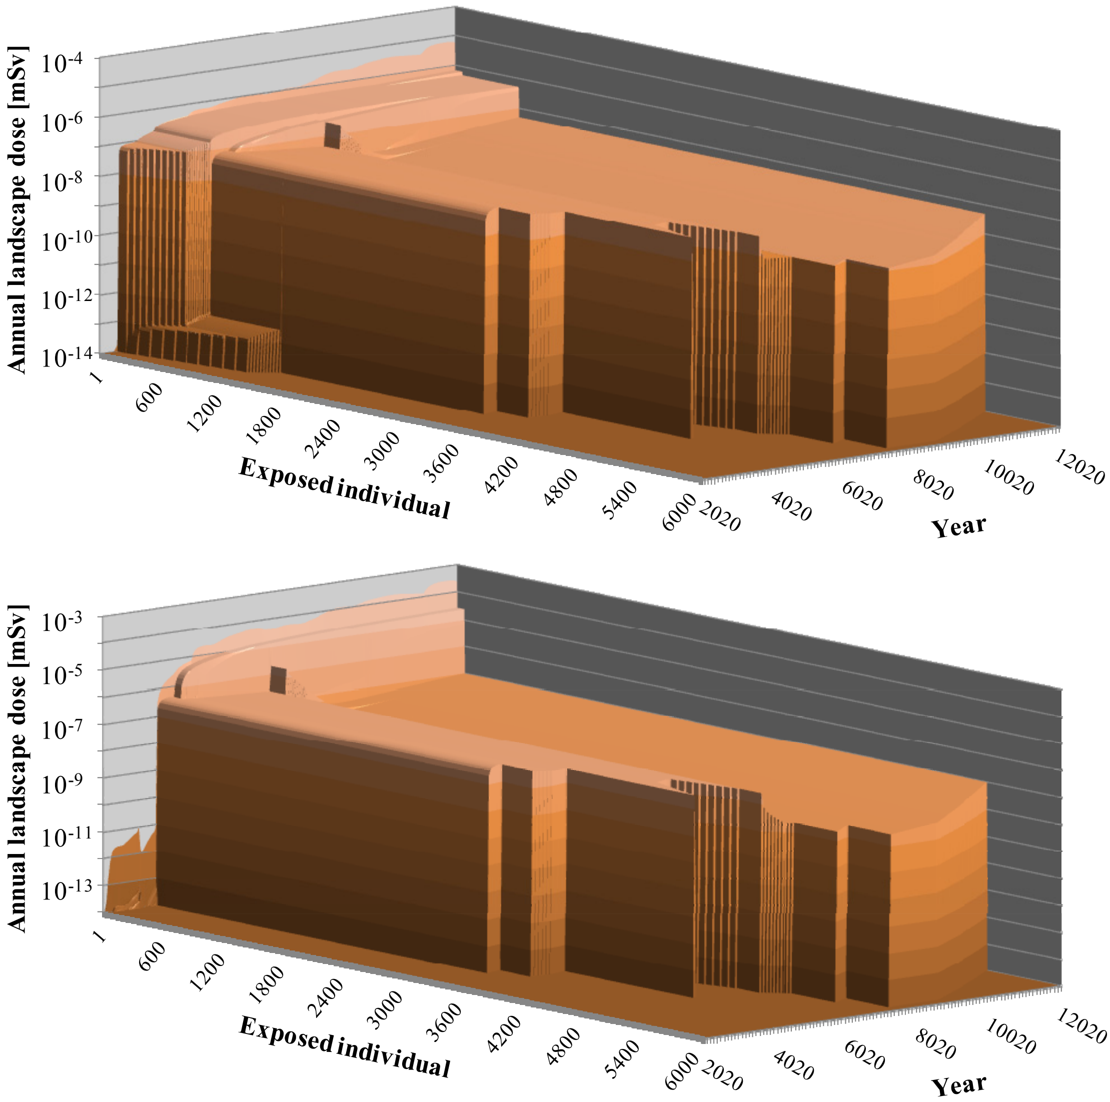

Fig. 2. The dose distributions for the repository base case Sh1 analysed with the BCC with releases from panel A (top) and for the case Sh4 Q analysed with the BCC with releases from panel C (below).

Table 1. Annual landscape dose maxima to a representative person for the most exposed group, (E_{group}) and other people (E_{pop}) for selected RCCs analysed with the BCCs and the year the maxima occur.

RCC	BCC	E_{group} [mSv]	Year	E_{pop} [mSv]	Year
Sh1	Panel A	7.9×10^{-7}	11 920	1.2×10^{-7}	3 970
	Panel B	1.6×10^{-6}	11 870	2.0×10^{-8}	12 020
	Panel C	3.9×10^{-6}	11 870	2.9×10^{-8}	3 570
Sh4 Q	Panel A	1.4×10^{-5}	6 570	4.7×10^{-6}	3 970
	Panel B	1.2×10^{-5}	11 820	2.0×10^{-7}	3 570
	Panel C	3.1×10^{-5}	11 820	4.5×10^{-7}	3 920

Conclusions

This paper has presented the methodology for assessing doses to humans adopted in the Posiva safety case. It is considered that this concept is adequate for the purpose of determining compliance with the regulatory dose criteria. Results from applying the dose assessment methodology in the interim safety case have also been presented. The results show that the derived E_{group} maximum is more than three orders of magnitude below the regulatory annual dose constraint for the most exposed people. Furthermore, the results show that the derived E_{pop} maximum is more than two orders of magnitude below the regulatory annual dose constraint.

Study of the site dose rate of the spent fuel storage facility with add-on shielding

Lee, Kuo-Wie; Lu, Chung-Hsin; Lin, Uei-Tyng; Wang, Jing-Ning; Chang, Shu-Jun; Chang, Bor-Jing
Institute of Nuclear Energy Research, TAIWAN

Abstract
The site dose rate of a spent fuel storage facility is always the focus of public concern in Taiwan. For the strict limitation of the site dose rate committed by the nuclear power plant, an add-on shielding design is needed for the spent fuel storage facility. The purpose of this study is to estimate the site dose rate of the spent fuel storage facility with variant thickness of the add-on shielding design. The simulation model of the storage cask and the add-on shielding was constructed in detail. Neutron and photon sources of the spent fuel in the nuclear power plant was also considered in the simulation. The discrete ordinate code DORT was adopted to calculate the dose rate at the surface of the storage cask, and the SKYSHINE III code was used to estimate the site dose rate according to the fluence results calculated by DORT. Six designed thickness of the add-on shielding were simulated, which include: (1) cask without add-on shielding; (2) 10 cm concrete add-on shielding at side of the cask and 5 cm concrete at top of it; (3) 25 cm concrete at the side of the cask and 20 cm at top of it; (4) 30 cm concrete at the side of the cask and 25 cm concrete at top of it; (5) 35 cm concrete at the side of the cask and 30 cm concrete at top of it; (6) 45 cm concrete at side of the cask and 40 cm concrete at top of it. Besides a single storage cask, a storage facility layout composed of 42 casks was also simulated for the site dose rate estimation. With the simulation results, the tendency of the dose rates at the surface of the cask and those at the distances for different add-on shielding designs were discussed. It is noticed that the dominant contribution of the dose rate at the cask surface comes from the photon source, but in the far distance the dominant dose contribution varies with the add-on shielding thickness. The add-on shielding design provide a simple and practical solution to the spent fuel storage facility for the condition of the nearby site boundary in Taiwan. The simulation results could offer information for the storage facility design in the future.

Introduction
The radiation protection project concerned about the site dose rate of a spent-fuel storage facility is always a major concern for a nuclear power plant. Therefore, the Taipower Company planned to construct an independent spent-fuel storage installation (ISFSI) for the midterm storage of the spent fuel. The strict limitation about the

geographical condition and the site dose rate committed by the nuclear power plant has to be considered in Taiwan. To solve this problem, an add-on shielding design is needed for the spent fuel storage facility. The purpose of this study is to simulate the layout of the storage facility for different shielding designs and skyshine calculations.

Material and methods

For the shielding analysis, a model of an ISFSI storage cask is developed. The ISFSI storage cask includes a canister loaded with 56 spent-fuel assemblies and a vertical cylindrical container. The actual limitation of the site dose rate is 0.05 mSv / yr, which is promised value in the report of environmental impact assessment. Hence, there is additional concrete shielding outside the side and the top of the storage cask to ensure the promised site dose rate. Single cask with different add-on concrete design were simulated, which include: (1) cask without add-on shielding; (2) 10 cm concrete add-on shielding at side of the cask and 5 cm concrete at top of it; (3) 25 cm concrete at the side of the cask and 20 cm at top of it; (4) 30 cm concrete at the side of the cask and 25 cm concrete at top of it; (5) 35 cm concrete at the side of the cask and 30 cm concrete at top of it; (6) 45 cm concrete at side of the cask and 40 cm concrete at top of it. The decay heat calculated by SAS2H/ORIGEN-S simulation code is 9.7 kW per cask. For the site dose rate calculation, the discrete ordinate code DORT was adopted to calculate the dose rate at the surface of the storage cask with the cross-section library CASK-81. The output flux data of the DORT simulation were transferred to equivalent point sources for SKYSHINE III calculation. Figure 1 shows the layout of the ISFSI facility with 13 simulation position, and figure 2 shows the position of the 42 casks in the layout.

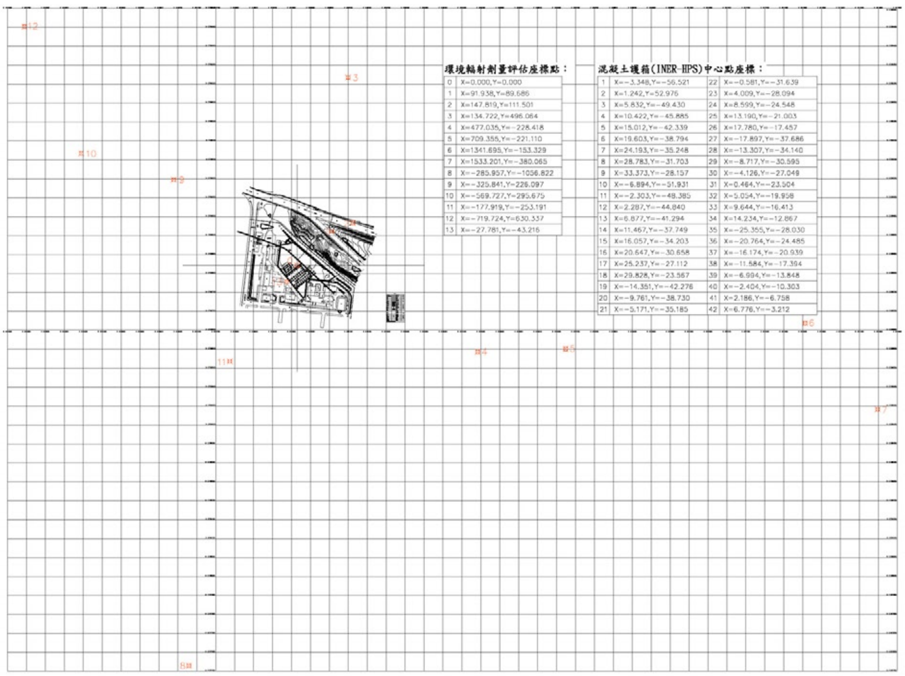

Fig. 1. The layout of the ISFSI facility with 13 simulation position in Taipower Company.

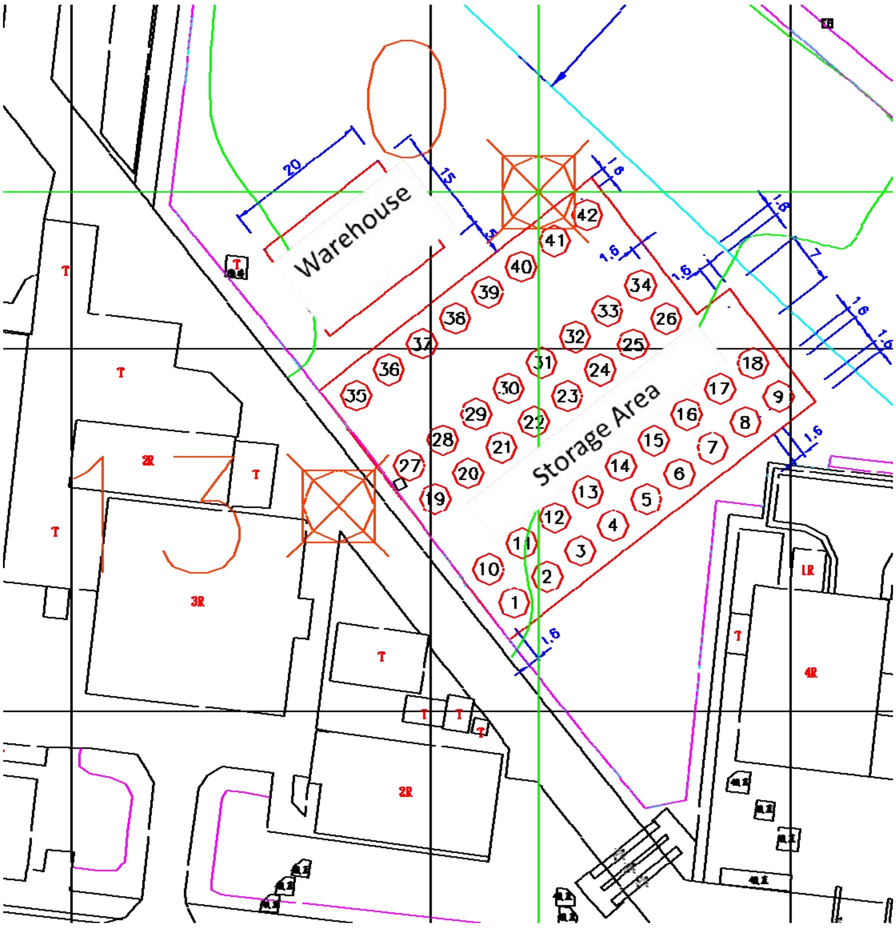

Fig. 2. The position of the ISFSI facility with 42 storage casks.

Results

The maximum surface dose rates at the top and at the surface of the storage cask with six-different shielding thickness design are listed in Table 1. It shows the dose rates contribution from fuel neutron, secondary photon, fuel photon, and structure photon, respectively. On the other hand, a storage facility layout composed of 42 casks was also calculated by SKYSHINE III at various distances. Table 2 shows the side dose rate for 13 estimated positions in Figure 1 with the add-on shielding thickness of 10 cm concrete at side and 5 cm concrete at top. From simulation position 1 to position 12, the side dose rate limitations are complied with the 0.05 mSv/hr. On the other hand, the position 13 is the nearest point from ISFSI facility, and the promised value is 2.5μSv/hr of environmental impact assessment. The total dose rate is 0.166μSv/hr (14.3mSv/yr) in position 13, and it is also complied with the promised value.

Table 1. The maximum surface dose rates calculated by DORT with six-different shielding thickness design.

Additional Concrete Thickness(cm)	Position	Dose rate(mSv/hr)

12	2.28E-05	2.43E-06	2.52E-05	0.05 mSv/yr
13	1.35E+01	8.06E-01	1.43E+01	2.5µSv/hr

Conclusions

In this study, the ISFSI facility was modelled and simulated by DORT simulation code for the radiation protection purpose. In order to satisfy the promised side dose rate limitation, the add-on shielding designs were necessary. Six designed thickness of the add-on shielding were simulated in this study. By analysing the dose rate contribution of the storage casks in the facility layout, the add-on shielding thickness of 10 cm concrete at side and 5 cm concrete at top was the best suggestion for the ISFSI design.

Using equivalent point source to evaluate steel shielding cover for turbine buildings

Lu, Chung-hsin; Chang, Bor-Jing; Shih, Chien-Liang
Health Physics Division, Institute of Nuclear Energy Research, TAIWAN, R.O.C.

Abstract

Skyshine issue is one of major concerns of the public dose in turbine buildings for a BWR nuclear power plant. This paper evaluate the thickness of steel shielding slabs on the top and the side of gas turbines to satisfy the public dose criteria that the power plant committed for an under-construction nuclear power plant in Taiwan.

Included in this work is combination of the QADCG/INER III point kernel radiation transport code and SKYSHINE III procedure. The QADCG/INER III is used to convert volumetric source into equivalent point source. The equivalent point source is applied to SKYSHINE III code to estimate the public dose with the energy spectrum of N-16 under open roof condition. The QADCG/INER III code also used to evaluate the thickness of steel slab between the low pressure gas turbine and the electric generator.

To satisfied the dose criteria, the thickness of steel slabs are 20 cm and 25 cm on the top and the side of the turbine set respectively.

Introduction

For the sakes of routine maintenance and heat transfer, sometimes it will not use fixed material such as concrete to construct the roof of the turbine building in a BWR nuclear power plant. In this case, the skyshine radiation from the top of the turbine building will be the major exposure pathway to the public dose. This project evaluated the thickness of steel slab covered on the top of the turbine sets for an under-construction nuclear power plant in Taiwan to reduce the skyshine effect. The thickness of steel slab located between the low pressure gas turbine and the electric generator was also calculated to avoid direct radiation through the off-site area.

In the aspect of skyshine dose estimation, it was evaluated by the SKYSHINE-III code. This dedicated skyshine code deals with point sources and applies the integral line-beam method for the calculation of skyshine dose. The EPRI NP-243 report provided a procedure to convert the volumetric source into an equivalent point source by using point-kernel code. The turbines and main steam pipes are dealt with independent volumetric sources, and N-16 is the major radionuclide within these equipments. These volumetric sources were converted into equivalent point source via

QADCG/INER III code. Those point sources positions were assumed in the center of the corresponding equipments respectively.

Another issue is to evaluate the thickness of the steel shielding slab between the low pressure turbine and the electric generator. It faced the off-site direction where the public could get close to. The direct radiation is the major concern in this case. The QADCG/INER III point-kernel code was applied to estimate the shielding requirement.

The public dose criteria committed by the nuclear power plant is 0.05mSv/y per unit.

Material and method

There are one high pressure turbine and three low pressure turbine in the turbine building. The main steam pipes concerned in this work are one cross-under pipe and three cross-over pipes connected upon the high and low pressure turbines respectively. Table 1 shows the geometry and activity of those equipments.

Table 1. The source terms geometry and activity.

Equipment	Radius (cm)	Length (cm)	Steam density (g/cm3)	Specific activity (µCi/g)	Total activity (Ci)

The QADCG/INER III is applied to calculate dose values caused by the volumetric source on relatively large distance above turbines in different polar angles while the steel slab is present. In the same detecting points, dose values are calculated for point source of unit activity without steel cover. Both the average dose values are obtained by integrating the dose value for each detector over angle and then dividing by the length of the angle interval. The source strength of equivalent point source is the ratio of average dose of volumetric source to the average dose of unit activity point source. The equivalent point source strength is applied to SKYSHINE III code to estimate the public dose with the energy spectrum of N-16 (6.2MeV) under open roof condition. Figure 1 shows the simplified illustration to convert volumetric source into equivalent point source.

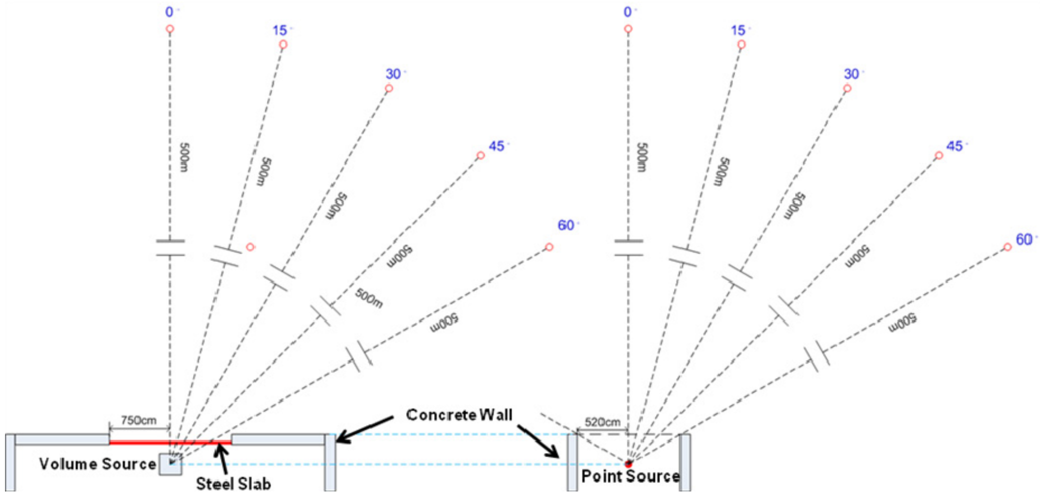

Fig. 1. A simplified illustration to convert volumetric source into equivalent point source.

The ratios of volumetric source to point source with 20 cm steel slab covered on the top and the activities of the equivalent point sources are listed in Table 2. Figure 2 is the schematic diagram applied to the Skyshine III simulation geometry model. On the right side of the Figure 2 is the 3-D model, and the left one is the side view diagram. The low pressure turbine (TLB3) is toward the off-site directory. Figure 3 shows the relative location of turbine set and assessing points in off-site.

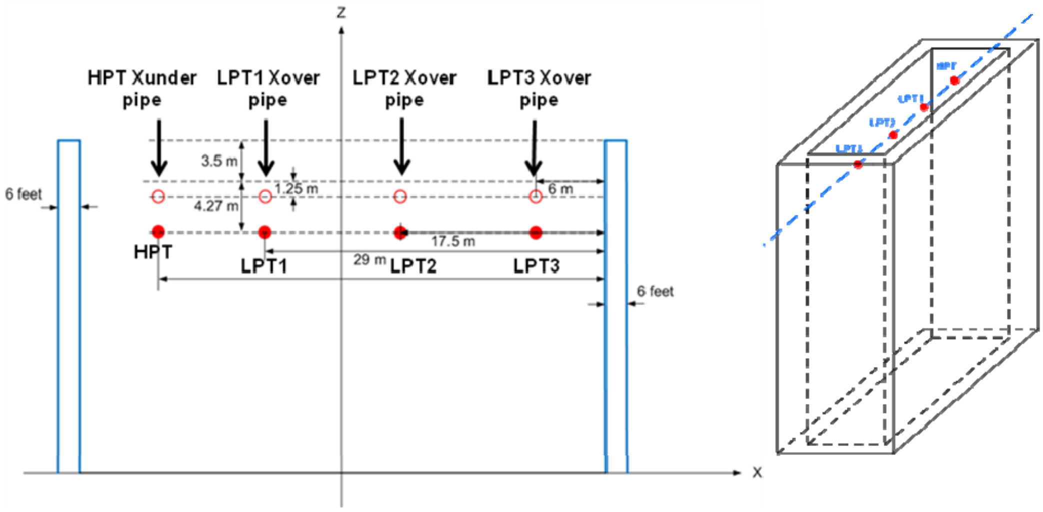

Fig. 2. The geometry model applied to Skyshine III simulation.

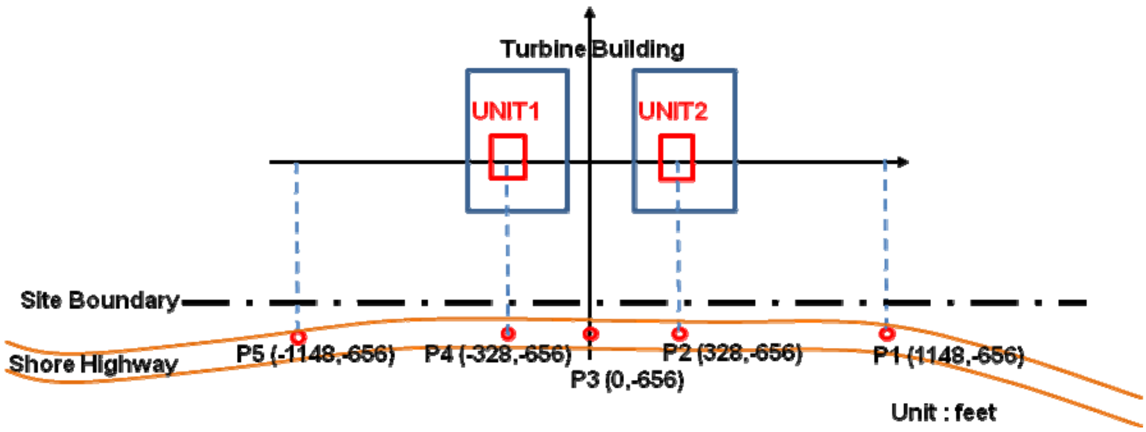

Fig. 3. The relative location of turbine set and assessing points.

Owing to the self-shielding effect and the shielded by the electric generator, the direct radiation from turbines is negligible. The considered source terms for direct radiation evaluation are the main steam pipes upon the turbines. Figure 4 illustrates the side view and top view of the geometry model applied to the QADCG/INER III simulation. Both the turbine set and the electric generator are simplified to homogeneous rectangular solids with density of 2.62 g/cm3 steel material.

Results and discussion

Unit 1 and unit 2 are geometric symmetry to the five off-site assessing points for skyshine dose evaluation. Unit 2 was applied to simulate the skyshine dose for the public in this work. Table 3 is the skyshine dose rate estimating results for unit 2 with 20 cm shielding steel slab on the top. It includes the dose contribution caused by turbines and the main steam pipes. The total shyshine dose of all source terms lists at the bottom of the table. The maximum value 0.0237 mSv/y lies in the assessing point 2.

The thickness of steel slab between low pressure turbine and the electric generator is 25 cm. The direct dose rates of all main steam pipes in different distance along the centerline of the turbine set shows in the second column of Table 4. The distance of 150 m indicates location on the shoreline highway in off-site. The third column is skyshine dose rates of turbines and main steam pipes with 20 cm steel slab on the top in the same distance. The total dose to the public including skyshine and direction radiation lists in the fourth column.

In the distance less the 180 m, the direct radiation will be shielded by the electric generator, floor and the building wall as illustrated in Figure 5. The dose rate is quite small in the near side. The maximum direct dose and the total dose are occurred in about 220 m, and the dose decreases with increasing distance farther than that. Considering both the dose contributions of skyshine and direct radiation, the maximum total dose rate 0.0489 mSv/yr are not appeared in the nearest distance from site boundary.

To satisfy the requirement of dose criteria (0.05 mSv/yr per site) that committed by the nuclear power plant, the thickness of steel slab covered on the top on the turbine set needs 20 cm. The steel slab located between the low pressure turbine and the electric generator needs 25 cm in thickness.

Table 4. The direct radiation dose rate with 25 cm side steel slab, skyshine dose rate with 20 cm top steel slab and the total public dose rate.

ALL PIPES	Side steel slab thickness 25 cm	Top steel slab thickness 20 cm	Total Dose (mSv/yr)

Shielding analysis for Proton Therapy Center in Prague, Czech Republic

Urban, Tomas; Kluson, Jaroslav
Department of Dosimetry and Application of Ionizing Radiation, Faculty of Nuclear Sciences and Physical Engineering, Czech Technical University in Prague, Brehova 7, 115 19, Prague, CZECH REPUBLIC

Abstract
The study of radiation fields around the cyclotron room has been made for the proton therapy center in Prague. The proton cyclotron of energy 230 MeV will be installed there as well as additional components located along the beampath. The ambient doses have been computed by taking into account 3 major neutron and photon sources - cyclotron, energy degrader and its collimator.

The fluxes of neutrons/photons produced by protons have been computed using Monte Carlo code MCNPX^{TM} 2.5.0. Energy and angular distributions have been computed for various targets and proton beam energies. Different physical models of high-energy proton interactions have been studied too. The annual charge at the cyclotron exit has been based on "patient model" (distribution of treatment type) established for similar therapy center in Essen (Germany). The cyclotron extraction efficiency of 50% has been assumed; the beam losses inside the cyclotron amount to 82200 nA.h/year. By convention, it has been considered no beam losses in the degrader, i.e. all the losses of degrader and collimator have been attributed to the absorption in the collimator.

As the cyclotron room is located underground, the outside concrete walls of the cyclotron room (West and South walls) have reduced thickness followed by soil. The annual doses have also been computed inside the fixed beam room (towards East), at the maze exit (towards North), inside the main control room (North, next to the maze), and above the cyclotron room roof. Calculated 3D dose distributions have been used to verify the radiation shielding design and the radiation protection optimalization.

Introduction
Proton therapy is becoming an increasingly popular modality in radiation therapy, most often for the treatment of malignant and non-malignant tumours. Known advantages of proton therapy is its ability to deliver radiation dose with high precision to the tumour while surrounding healthy tissue and organs are irradiated minimally. The cost of the building can be over 100 million EUR and the shielding can have a significant impact on the cost, on the other hand must be designed to adequately protect personnel

and the public. The primary purpose of the study is to design a shield that will be in agreement with the current legislation requirements.

The design of the Prague Proton Therapy Center is similar to the existing facility in Essen, Germany. Thus, some calculations in this article are also independent assessment of proven shielding design.

In this work, the statistical approach has been used for verification of the shielding design. The fluxes of secondary radiation (neutrons and photons) produced by protons have been computed using Monte Carlo code MCNPX^{TM}, version 2.5.0. The ambient dose equivalents at selected critical points around the shielding structure have been calculated using fluence-to-dose conversion factors from the International Commission on Radiological Protection (ICRP) Report No. 74. Influence of the high-energy nuclear interaction model choice has been tested as well.

Material and methods

Shielding design aims

The primary design aims are to limit annual dose equivalent behind the shielding walls to <1mSv (outside of proton therapy facility) and <20mSv (inside of the proton therapy facility, i.e. in control rooms, in corridors, etc), respectively. Dose equivalents have been estimated assuming a 16 hours daily shift, 6 working days per week; all year round (Stichelbaut, 2008). All calculations have been also based on technology contractor information as well as model of patient and distribution of treatment type according to the intended operation of the Therapy Center (Stichelbaut, 2007; Stichelbaut, 2008).

Main sources of radiation and spectra of secondary radiation around them

This work is aimed to verified shielding barriers around the room with accelerator – cyclotron - accelerating protons to the energy of 230MeV. Thus, the main sources in the cyclotron room are cyclotron and energy selection system. The energy selection system is composed of two main components - degrader and its collimator. The degrader is made of graphite (density 1.8 g/cm^3) and is designed to slowing down the proton energy to energies that are indicated for the treatment (190MeV, 150MeV, 110MeV, and 70MeV). The collimator is made of tantalum (density 16.6 g/cm^3) and is used for narrowing the scattered proton beam after the degrader (Stichelbaut, 2007; Stichelbaut, 2008).

The cyclotron - The cyclotron extraction efficiency is assumed to ~50%, i.e. ~50% of the beam is lost in the cyclotron (Stichelbaut, 2007). All beam losses in cyclotron have been assumed at the extraction radius, i.e. at the full energy 230MeV, where the proton beam interacts with a copper material. The thickness of a copper layer (in all directions) in simulations is more than range of protons of energy 230MeV in a given material/copper. Cyclotron itself is shielded in all directions at least of 40 cm of iron (density 7.86 g/cm3), i.e. a iron layer of 40 cm thickness has been considered in simulations as well.

The graphite degrader - Secondary radiation spectra have been calculated for the narrow proton beam of energy 230MeV incident perpendicular the middle of the base of the graphite cylinder. Dimensions of these targets/cylinders are shown in Table 1. In all cases the radius of cylinder is greater than range of protons of energy 230MeV and the length of the cylinder is designed so that the proton beam energy at the exit of the cylinder is equal to the desired energy (used for treatment).

Table 1. Parameters of the cylinder target used in simulation instead of graphite degrader.

Energy of protons at the end of the target/cylinder	190 MeV	150 MeV	110 MeV	70 MeV
cylinder radius [cm]	22,385 cm	22,385 cm	22,385 cm	22,385 cm
cylinder lenght [cm]	5,686 cm	10,634 cm	14,739 cm	17,865 cm

The collimator - Dimensions of target/cylinder substituting for the purposes of simulation the collimator are shown in Table 2. In this case radius and length of the target/cylinder are equal to each other and both dimensions are greater than range of proton incident a tantalum target/cylinder. Also in case of collimator, the proton beam has been considered as narrow and as a perpendicular incident a base of the target/cylinder.

Table 2. Parameters of the cylinder target used in simulation instead of tantalum collimator.

Energy of protons entranced the target/cylinder	70 MeV	110 MeV	150 MeV	190 MeV	230 MeV
cylinder radius [cm]	0,5599 cm	1,2122 cm	2,0515 cm	3,0503 cm	4,1877 cm
cylinder lenght [cm]	0,5599 cm	1,2122 cm	2,0515 cm	3,0503 cm	4,1877 cm

In simulations, the geometric center of a cylinder/target has been places to the origin of coordinate system. A cylinder axis coincides with the x-axis as well as proton beam incident the target/cylinder in the middle of cylinder base. The cylinders were surrounded by air. At the sphere of radius of 1 meter have been registered secondary particles emitted from the target. As the main components of the secondary radiation have been identified neutrons and photons. In Figures 1 and 2 there are shown multiplicities of particles emitted from targets. Examples of some energy and angular spectra of neutrons from various sources of radiation are shown in Figures 3 - 5. Generally, neutron spectra cover the entire energy interval from zero energy up to energy of proton impinging on a target. As can be seen in Figures 6 and 7, energy spectra of photons are not so wide – spectra finished, maximally, at several tens of MeV. Also multiplicity of photons are lower than neutron ones. All simulations there were three different interaction models of high energy particles included in MCNP 2.5.0 – Bertini, CEM2K and INCL4 (Pelowitz , 2005).

In all other (not shown in this paper) cases (different energy of incident protons) have had energy and angular spectrum a similar character, for both neutrons and photons as well. Energy and angular spectra suggest that selection of an appropriate model for shielding calculation/verification is not so easy with these results. Use of any of nuclear interaction model has its pros and cons. One leads to a greater multiplicity of secondary particles in the entire energy spectrum, while another just only at high energies (hundreds of MeV). Thus, all mentioned nuclear interaction models have been tested and compared for shielding calculations/verifications as well.

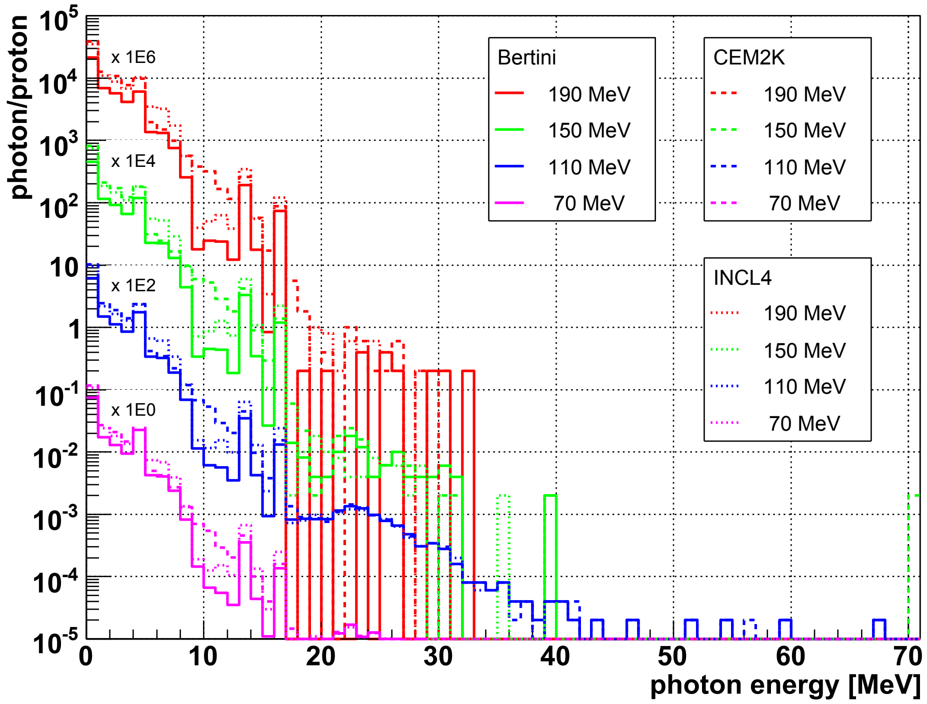

Figure 7. Examples of energy spectra of photons emitted from graphite target (degrader) for various nuclear interactions calculation models.

Shielding calculations

Figures 9 and 10 show the 2D distributions of the calculated values of ambient dose equivalent H*(10) [mSv/year] around the room (see 3D drawing of the object Proton Therapy Center in Prague) with cyclotron, etc. Cross-sections are located in a vertical plane perpendicular to the walls. In the calculations has been included only neutron component of the secondary radiation. Photon component gives only approximately 1 percent of contribution to the ambient H*(10). For evaluation of the dose equivalent have been used fluence-to-dose conversions factors for neutrons from ICRP-74. For results has also been taken into account an expected annual capacity of the Proton Therapy Center due to the number and types of therapeutic interventions (Stichelbaut, 2008).

Three main sources of radiation have been taken into account for shielding verification – cyclotron, degrader and its collimator. These components and their simplification for simulation have been described above. Accelerator efficiency is considered to 50 percent. Conservative approach where beam losses are uniformly disturbed around the cyclotron at extraction radius has been used. Measured transmission factors for degrader and collimator have been used for calculation. By convention, it has been considered that there are no beam looses in the degrader (it means transmission of the degrader is equal to 100 percent) and all beam losses of the degrader and collimator have been attributed to collimator transmission. This transmission depends on the energy of proton beam after degrader as well as on the beam delivery mode during treatment. In the Proton Therapy Center will be for treatments used both active scanning and passive scattering. According to the information from contractor, use of collimator transmission factors for active scanning is more conservative approach (Stichelbaut, 2007; Stichelbaut, 2008).

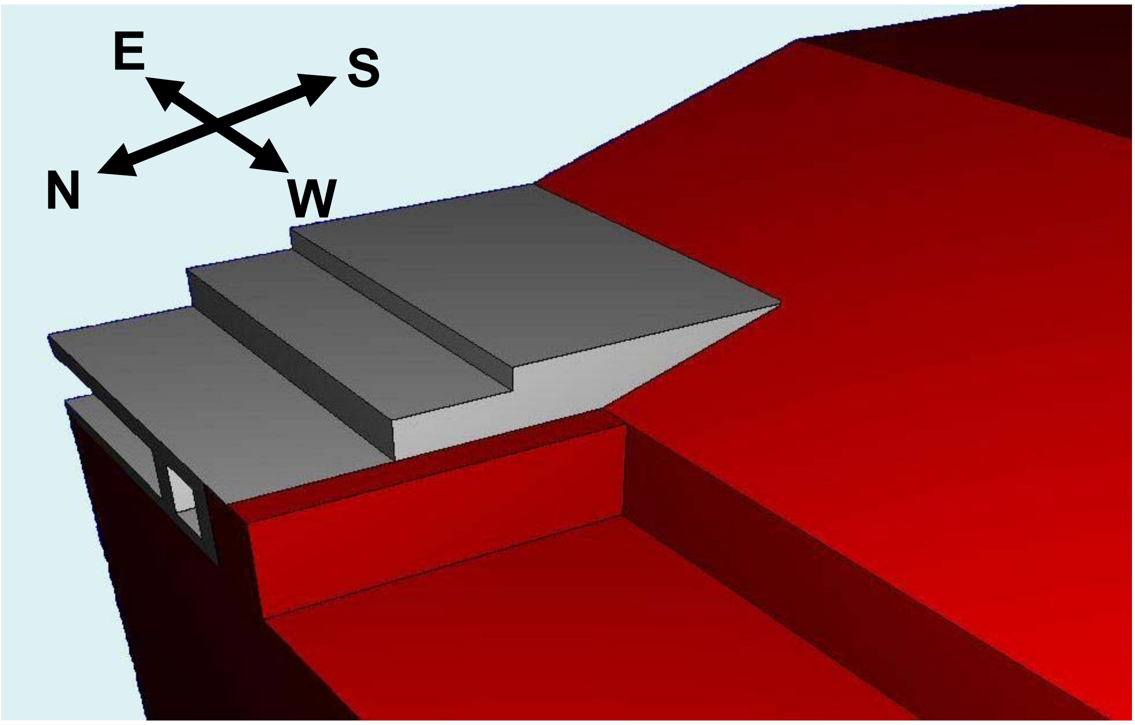

Figure 8. 3D model of the room with a cyclotron and its accessories (grey = concrete, red = soil).

As was mentioned above, for verification of shielding have been used all three models of interaction of high energy particles in the MCNP - Bertini, CEM2K and INCL4 – (Pelowitz, 2005). All models give comparable/similar results with any major deviations from the relevant radiation protection with an impact on legislative requirements compliance.

Discussion

Shielding barriers (concrete and eventually soil) of the cyclotron room in the Proton Therapy Center in Prague are according to the simulation sufficient. There are also some border-line cases in a few localized areas, for example terraces above the entrance maze or place behind the east wall. In these critical areas will be no permanent presence of persons, but it is recommended that they should be properly labelled.

The area directly above the cyclotron and the energy selection system (degrader and collimator) requires also special attention. The area above cyclotron is constructed as a removable cyclotron hatch which must be provided for lowering the accelerator into the building. That means there is not concrete plate, but only some concrete blocks. So, it should be paid attention when imposing these blocks and try to compose these blocks without large air gaps and/or to fill gaps with another shielding material. The area directly above degrader and collimator is also problematic. To achieve the annual dose equivalent <1mSv/year a wall of thickness 4.20m of concrete is needed and space available in this area is only 2.20m. To increase the ceiling it should be possible to use iron or steel material as a shielding. The NCRP Report No. 144 (2003) recommends that any iron or steel shielding should be backed by at least 0.61 m of concrete (since the cross section for the interaction of neutrons with iron falls rapidly below about 5MeV).

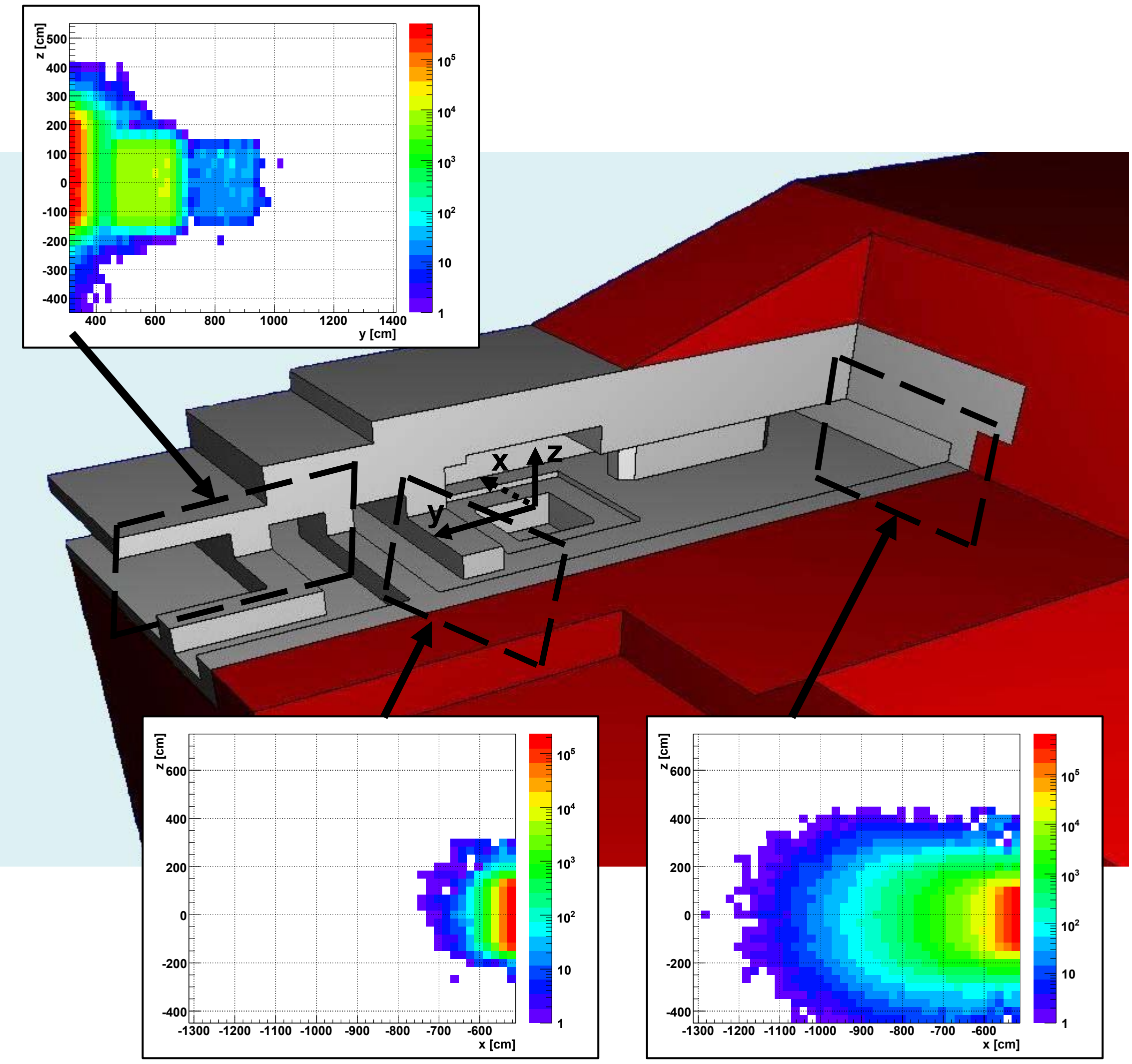

Figure 9. H*(10) [mSv/year] in selected areas of west wall and maze of the cyclotron room.

Conclusions

Shielding barriers of the room with cyclotron and energy selection system have been verified. Thicknesses of the concrete wall proposed in the project are sufficient and meet the requirements of current legislation in the Czech Republic in almost all areas. The problematic areas are described above, in section Discussion.

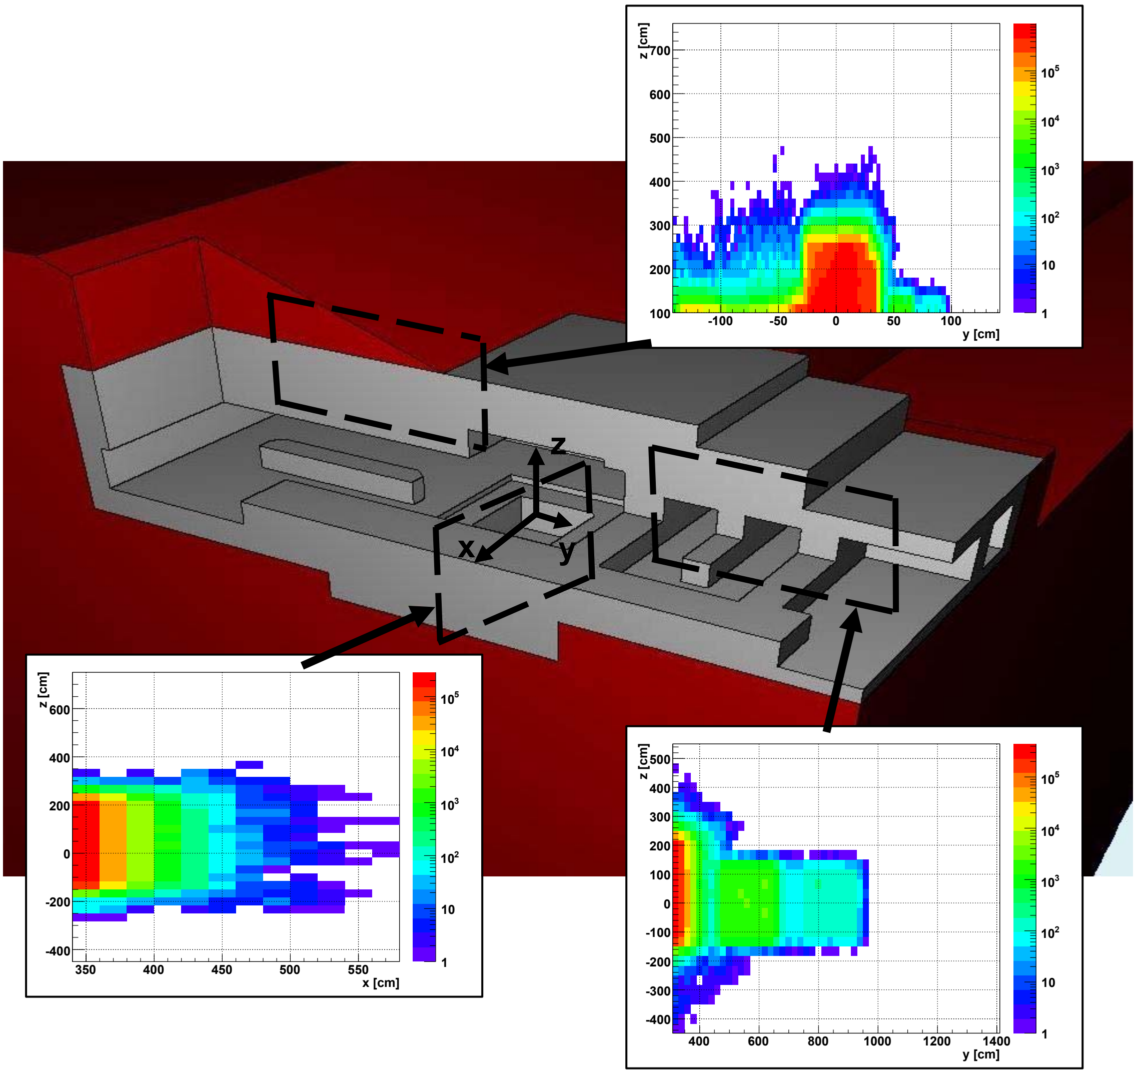

Figure 10. H*(10) [mSv/year] in selected areas of east wall, maze and ceiling of the cyclotron room.

Abstract

Real-time monitoring used of high sensitivity detectors to measure radiation levels in public access area at the Nuclear Medicine Department (NMD) is the prime interest of this investigation. The results of this study are used to verify and to improve the facility layout, patient routings and administrative control measures. The NMD outpatients, with an initial dose of up to 740 MBq (20 mCi) per case, may wait around and incidentally congest in one place that could cause an unexpected higher exposure level in public access areas. In this surveillance study, the ambient radiation time-profile and peak dose rates have been characterized for the transit hallway or corridor where non-NMD medical staff or patients' relatives may present with the source-bearing patients. In order not to interfere with daily NMD operations, a high sensitivity, collimated NaI(Tl) gamma spectroscopy system is deployed at the far end of the hallway to monitor the ambient radiation levels. The time-profile of the radiation levels were derived from a video-taped gamma spectroscopy using time-stripping, consecutive unfolding method. Another digital G-M dosimeter, which has peak rate locked-in capability, is also adopted for tracking the highest ambient radiation dose rate in this transit hallway to alert the medical staff whenever unexpected NMD patients are crowded at one place. Typical 10-min average count rates, based on a 12-hour observing time from 7am to 7pm, are evaluated from this remote collimated detector. From these 10-min average count rate data, we found the ambient radiation levels at some time intervals can reach up to more than 35 times of the natural background level. Also, the peak-rate dosimeter at this corridor has once registered to a peak value of 40.4 micro-sievert/hr. Based on these radiation monitoring data, suggestions to improve the NMD daily operation and the needed administrative changes have been reviewed and accepted by the management of the hospital. Some of these recommendations had been implemented, including waiting time reduced for the patients, less chairs and more satellite waiting areas and permanent survey meters installed with preset light/audio alarm features.

Introduction

Ambient radiation levels in a corridor patients waiting area have been greatly reduced after being remodelled, of our Nuclear Medicine Department (NMD) based on the ALARA consideration. The NMD outpatients, with an initial dose of up to 740 MBq (20 mCi) per case, may wait around and incidentally congest in one place that could cause an unexpected higher exposure level in public access areas. Completed ambient radiation monitoring of our NMD before remodelling had been characterized and published earlier by the same authors elsewhere. (Lai 2001; Lai el al.2003) In this new surveillance study after remodelling, the ambient radiation time-profile has been re-evaluated by using a video-assisted, high sensitivity collimated NaI(Tl) detector system. The peak dose rates in hourly basis and the accumulated daily dose are also demonstrated by real-time, hand-held digital survey dosimeters.

Material and methods

The NMD corridor is situated at the first floor of the six-story Medical Technology Building with a reception room located near the main entrance of the building. A public elevator and a stairway for the whole building are next to the reception room across from the hallway. Before remodeling, the building hallway or transit corridor, measured about 3 meter wide and 40 meter long, has been provided with seating chairs for patients and their relatives to use. The transit corridor divides the first floor into three gamma scan rooms on one side and the drug-administered room and a 4th-scan room on the opposite side. (see Figure 1)

In order not to interfere with daily NMD operations, a high sensitivity, collimated NaI(Tl) MCA gamma spectroscopy system is deployed at the far end of the hallway which is used for emergency exit only. The ambient radiation imposed by the NMD patients is determined by an MCA integral counting mode with a region of interest (ROI) from 60 keV to 2 MeV. In this surveillance study, the ambient radiation time-profile and peak dose rates have been characterized for the transit hallway or corridor where non-NMD medical staff or patients' relatives may present with the source-bearing patients. This MCA detector system is converted from a conventional thyroid up-take probe that can remotely monitor the ambient radiation at a greater distance. The viewing solid angle of the detector through the collimator, which has to cover most the hallway and seated patients, can be verified by a laser pointer shining through the detector assembly with it's detector temporarily removed. The gamma spectroscopy system is energy-calibrated using an americium-241 and a cesium-137 sources for low energy at 60 keV and high energy at 661 keV, respectively. The NMD patients waiting corridor and radiation monitoring instrumentation layout is depicted in Figure 2.

After remodelled, we have removed all the seating chairs from the hallway and divided patients that are waiting for gamma scans into two separate waiting rooms. We also redesigned our facility with a 0.5-cm thick Pb wall and larger space separations between rooms that include a PET/CT scan room, two separated 18FDG i.v. injection rooms, and a delayed-phase patient waiting room. The time-profile of the radiation levels were derived from a video-taped gamma spectroscopy using time-stripping, consecutive unfolding method. An internet-based video-exposure technique has also been used for this ambient radiation measurement. (Huang 2005) Energy-compensated, hand-held digital G-M survey meters are used to measure accumulated environment doses during the surveillance day. One of the G-M dosimeters, which can perform a peak rate locked-in feature and pre-set alarm capabilities, was also adopted for tracking the highest ambient radiation dose rates in the corridor hallway area. New look of the public transit corridor at the same location is shown in Figure 3 for comparison.

Results

With our newly improved facility in operation, we have demonstrated the NMD corridor area average daily count rate has dropped from 16,140 cpm to 3,333 cpm on one Wednesday surveillance study, before and after remodelling, respectively. Detector absolute efficiency calibration data, using a standard Tc-99m point source, at various distances are listed in Table1. During a benchmark testing of the same collimated detector, typical natural background is at about 900 cpm that gives a detection sensitivity of about 4.5 mCi when a Tc-99m point source is located at 30 meters distance. Real-time, radiation time-profile measurements during the surveillance day are illustrated in Table 2.

The hourly peak dose rate detected in patient waiting areas has also reduced to a factor of about two, from maximum dose rate of 40.4 micro-Sv/h to 23.4 micro-Sv/h, during one worst scenario. (See Table 3) Bold fonts in this table denote the exposure dose rates exceed 10 micro-sievert per hour.

10.2	3pm - 4pm	0.36	0.23
0.61	4pm - 5pm	0.21	0.28

*Note: Patients awaiting room increases to two separate rooms after remodelling.

Discussion

In the past, the environmental dose assessments within our hospital were based on a monthly integral dose measurement only. Due to mobility nature of the NMD patients, it is difficult to predict collectively the true radiation levels in public access areas at a given time. In this report we have demonstrated with a much higher sensitive detector in a real-time basis to quantify this radiation level at our work environment and measured peak dose rates at specific interested spots that may be occupied by the general public. Based on these radiation monitoring data, suggestions to improve the NMD daily operation and the needed administrative changes have been proposed and reviewed by the management of the hospital. Some of these recommendations include waiting time reduced for the patients, less chairs and more space separation provided in the hallway and permanent survey meters installed with preset light/audio alarm capabilities, etc.

Conclusions

The great reduction of the environment dose was achieved mainly by using larger room space with thicker lead wall, from previous 2-mm to new 5 mm in lead thickness, and by increasing patient waiting rooms/areas with less chairs available in each seating location. Other NMD administrative control measure of our dose reduction program has also been emphasized in better patient routing, scheduling and less waiting time for the diagnostic patients.

Abstract

EC Medical Exposure Directive 97/43/EURATOM requires in the Article 12 that the Member States will determine the distribution of individual dose estimates for relevant groups of the population. Large differences in the published data from various countries are mainly the consequence of variations in the equipment used, in the adopted choice of the examination categories, in the measured dose quantities and in the limited sample size due to the financial problems with the collection of the data for such survey. Even the dose values collected for one certain examination type show large uncertainties following the imaging technologies and mistakes in protocol standards. The recently published "Guidance on Estimating Population Doses from Medical X-ray Procedures" (EC Report No.154/2008), helped also in Slovakia to specify examination types and to harmonize the methodology for gathering the representative effective doses and annual frequencies, in the framework of the professional bodies involved in public health and radiation protection, for the first stage of the population dose estimates. The poster presentation will show the preliminary results for several examination categories (starting with mammography).

Introduction

The European Commission initiated a study for reviewing the situation regarding implementation of *Article 12* of 97/43 EC Directive [1]: „Estimation of patient dose" where it is proposed that Member states shall ensure that the distribution of individual dose estimates from medical exposure should be determined for the population and for relevant reference groups of the population, accepting exposures from medical X-ray imaging procedures.

Following European legislation, all radiological facilities should regularly supply information on patient doses, to be able to check reference levels and to determine the contribution to the collective dose. For determination of the trends in collective dose and for estimation of per caput doses from medical X-ray examinations was recently published European Guidance on Estimating Population Doses from Medical X-ray Procedures [2].

Objectives of population dose estimation in agreement with EC 154/2008 are:

- to observe trends in collective dose and/or per caput dose from medical X-ray examinations
- to determine the contribution of different imaging modalities to the collective dose
- to determine the relationship between the frequency of different types and their contribution to the collective dose
- to compare the contribution of medical X ray with that of other sources to population exposure

Similarly to the published population dose assessments from medical X-rays in several European countries (3, 4), also in Slovakia initial surveys of information about the population exposures from various types of diagnostic examinations has been collected. This information was available mainly due to the activities of the Slovak Commission of Quality Assurance in Radiology, working by the Slovak Ministry of Health. The main objective of the activities of the Commission are presented in realization of quality audits for reaching the same level of clinical image evaluations and equal technical quality program implementation.

In our presentation we haw collected the results of radiation load of patients undergoing mammography examinations, as an example of our procedure by assessing the patient doses for national dose inventories. In the cohort of 7 934 patients we show the age distribution, distribution of breast thickness and differences between organ doses in conventional and digital mammography examinations.

Material and methods

Establishment of average absorbed glandular doses of mammography patients was realized in a group of 7 934 women from two films screen and two digital mammography units in the period of March 2009 to February 2010 (Table 1). For collection of all parameters (x-ray tube output, exposure conditions, relevant patient parameters, etc.), used for the mean glandular tissue doses estimation a special software has been prepared in the case of film-screen mammography and for digital mammography units the required data has been collected from Central Hospital Information Systems.

Table 1. Number of monitored patients, monitoring period and useded mammography units.

Mammography units	Number of monitored patients	Monitoring period
Sophie Planmed F1 (Film-Screen)	2000	March 2009 – October 2009
Siemens Mammomat 3000 F2 (Film-Screen)	2000	June 2009 – November 2009
Hologic Selenia D1 (Digital)	2000	October 2009 – January 2010
Hologic Selenia D2 (Digital)	1934	October 2009 – February 2010

Results

Due to the wide variation in radiation risks with age at exposure, for the group of monitored patient we have determined the age distribution. The data were divided in to five years age bands (Table 2). For conversion into effective dose two expositions in both breasts were taken into account. The new tissue equivalent weighting factor for the breast (0,12) allowed to convert the mean glandular dose to both breasts into effective dose (ICRP 103). On the Fig 1 is presented the age distribution in all monitored mammography units and the average of the all units shows that the highest number of mammography examinations was observed in age interval form 50 to 55 years.

Table 2. Age distribution of monitored patients.

Age (years)	Number of monitored patients			
	D1	D2	F1	F2
under 40	9	7	7	5
40 – 45	269	313	394	296
45 - 50	350	318	408	457
50 - 55	392	460	400	439
55 - 60	421	380	343	320
60 - 65	273	235	199	237
65 - 70	177	146	143	144
70 - 75	61	47	73	69
75 - 80	29	19	25	29
over 80	19	9	8	4

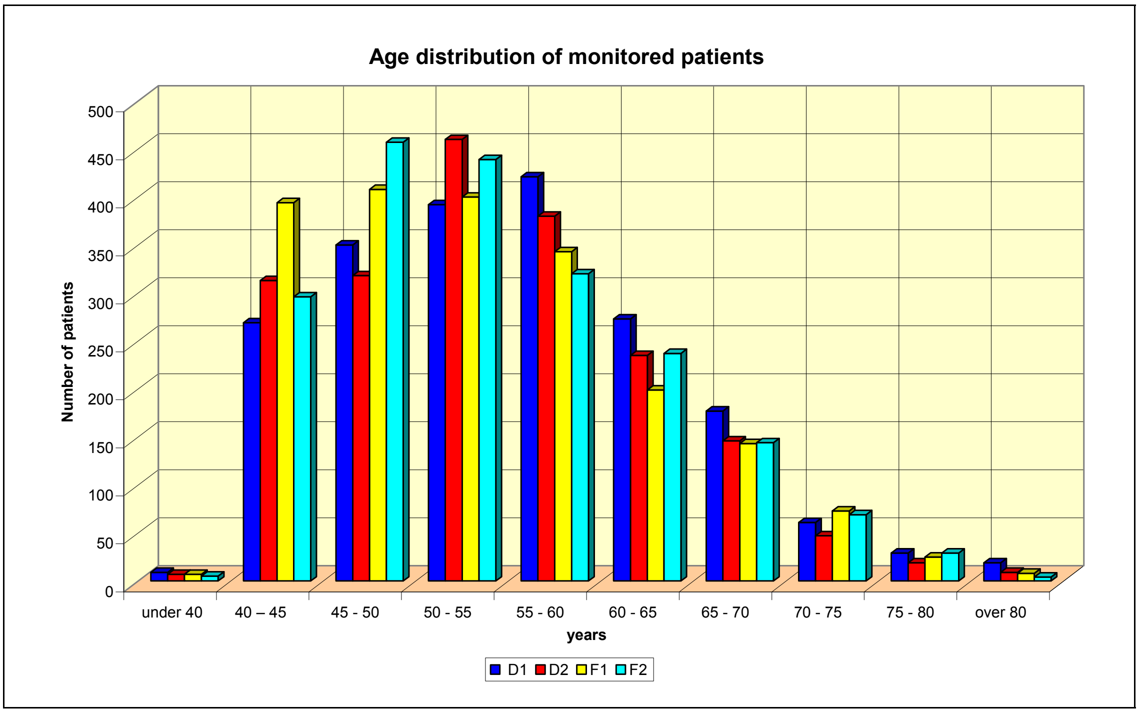

Fig. 1. Age distribution of monitored patients.

One of the most important factors that can significantly influence the absorbed dose to the breast is its volume and composition. As can be seen from the Table 3 there are significant differences in breast thicknesses, showing that in Slovakia the majority of examined patients has the thickness between (50 – 60) mm.

Table 3. Thickness distribution of monitored patients.

Thickneess of breast (mm)	Number of monitored patients			
	D1	F1	D2	F2
under 20	33	0	2	40
20 - 30	176	10	29	161
30 - 40	453	58	136	349
40 - 50	636	245	357	633
50 - 60	476	590	564	574
60 - 70	193	712	562	217
70 - 80	33	326	231	26
over 80	0	59	53	0

Average thickness distribution from all monitored mammography units are presented in Fig.2

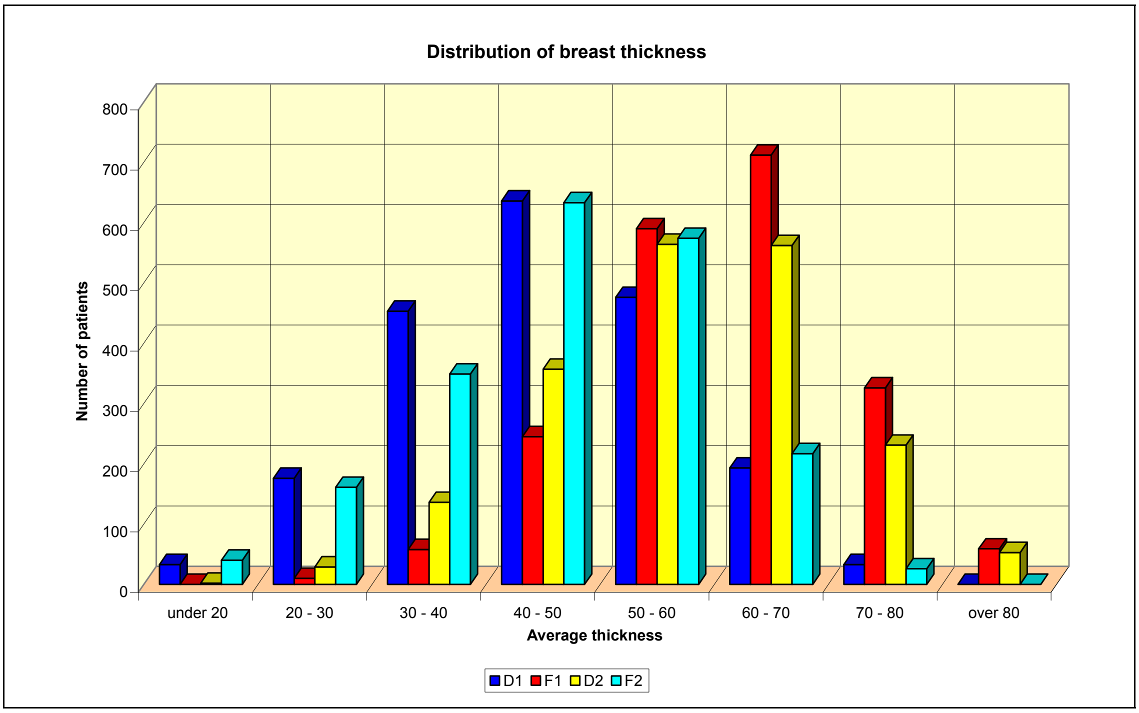

Fig. 2. Distribution of breast thickness.

Table 4. Absorbed doses in the breast for various thicknesses.

Thickneess of breast (mm)	Absorbed dose in glandular tissue (mGy)			
	D1	**F1**	**D2**	**F2**
under 20	1,188	-	0,611	0,465
20 - 30	1,509	1,264	0,88	0,530
30 - 40	1,66	1,415	1,099	0,621
40 - 50	1,816	1,604	1,245	0,718
50 - 60	2,05	1,693	1,405	0,883
60 - 70	2,25	1,669	1,496	1,188
70 - 80	2,08	1,80	1,57	1,646
over 80	-	1,95	1,777	-

Absorbed doses in glandular tissue were measured for thicknesses of breast from 20 mm to 80 mm with 10 mm step (Table 4). In the Fig. 3 are given the average values of glandular tissue doses for monitored mammography units.

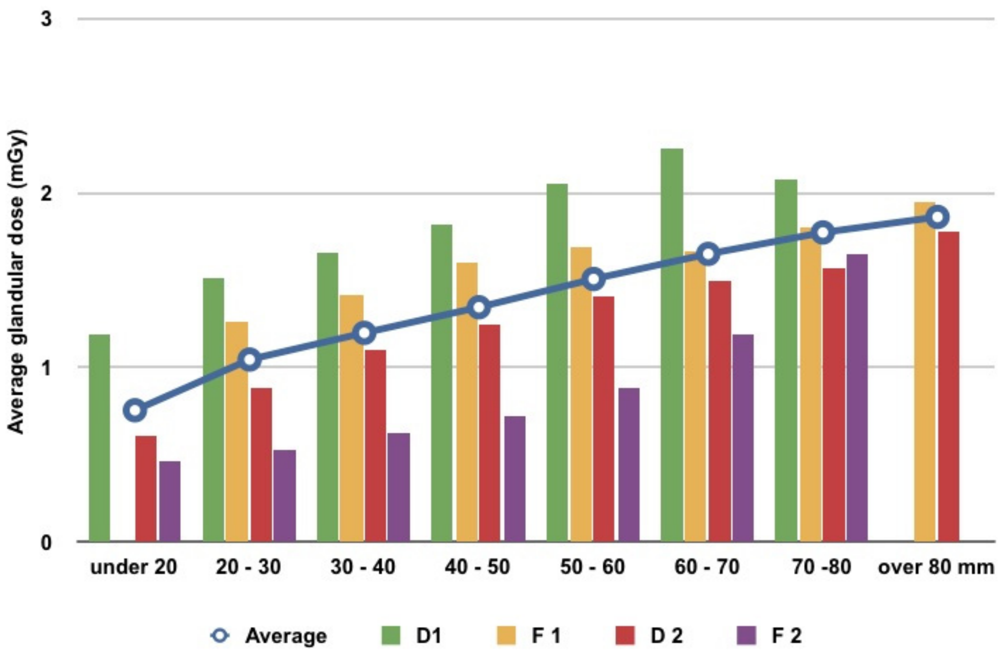

Fig. 3. Comparison of breast thicknesses and average glandular doses.

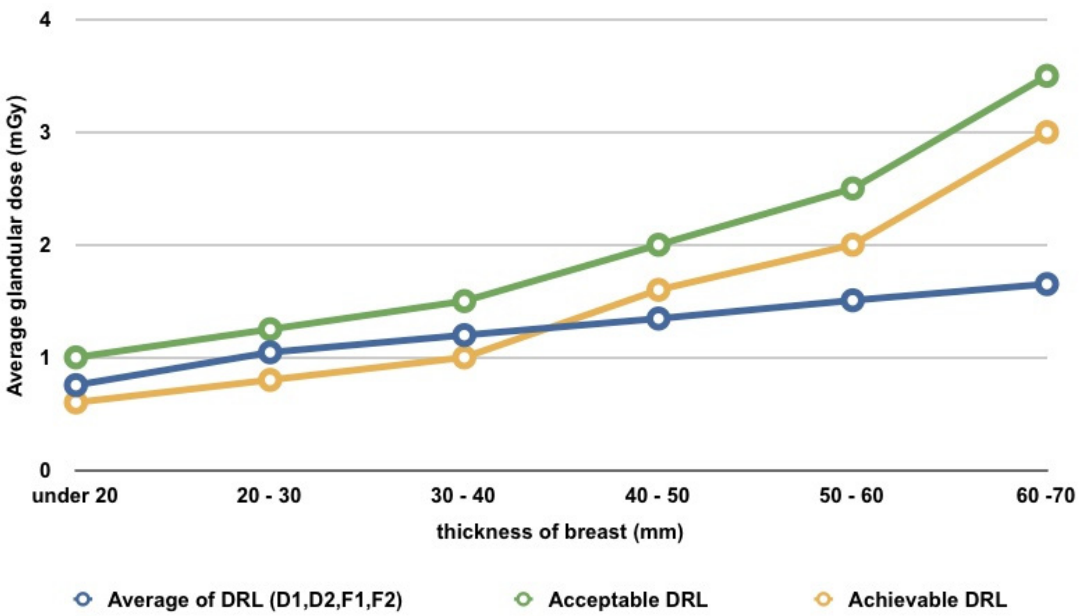

Fig. 4. Comparison of average glandular tissue doses with international diagnostic reference level.

Evaluated mean glandular tissue doses as a function of breath thickness has been compared with internationally accepted diagnostic reference level and with achievable level (Fig.4). On the basis of these results it can be proposed reducing of diagnostic reference levels in the monitored mammography units.

Discussion and conclusions

In our presentation we tried to compare the survey of patient doses on digital and conventional mammography units. In spite of the fact that we monitored two equal digital mammography units the differences in the average mean glandular doses reached up to 45% taking into account the breast thickness. The differences are higher for small thicknesses of breast.

The advantage of digital mammography is shorter time of whole examination by reducing time for developing the film, better storing of imaged, reduction of repeating examinations, it means, great potential in better cancer detection. On the other site, the radiation dose of the patients can be potentially increasing.

Due to the new tissue weighting factors recommended in the ICRP 103 the significant increase of effective doses calculated for the breast examinations compared with the past are observed. In the Table 5 are given the calculated effective dose ranges for two digital mammography units.

Table 5. Comparison of effective doses of two digital mammography units Hologic Selenia.

Mammography units	Effective dose (mSv)
Hologic Selenia D1	0,252 – 1,152
Hologic Selenia D2	0,504 – 0,957

In similar way we continue in the collecting of the information about population doses from medical exposure in the selected types of the X-ray examinations recommended in the European guidance No. 154.

Utility of a web based data survey for a national MDCT radiology practice survey

Wallace, Anthony; Hayton, Anna; Edmonds, Keith; Tingey, David
Medical Physics Section, Australian Radiation Protection & Nuclear Safety Agency (ARPANSA) AUSTRALIA

Abstract

Purpose: To develop a robust and simple Internet based survey form for national MDCT dosimetry surveys. To provide participating practices with a site specific practice reference level (PRL) report for submitted protocols and to use submitted and collated PRL data to construct national diagnostic reference levels (DRLs) for MDCT.

Methods and Materials: As part of a national MDCT dose survey project, a web based MDCT protocol survey form is being developed to record appropriate parameters for dosimetry calculations. The initial draft Excel®[1] version requested responders to provide practice contact and registration information. They were also asked to submit 20 sets of patient scan data for the 7 generic adult protocols chosen. These included integral protocol DLP (mGy.cm), patient weight, patient height and patient slice diameter at a specified anatomical landmark. Fifteen practices were invited to participate of which 11 responded. With version 2 of the survey form, more instructional detail was provided and the slice diameter data point was removed. Data sets are to be kept in an SQL database and transferred to a commercial spreadsheet program for additional analysis.

Results: Initially 15 radiology practices were invited to participate in the survey of which 11 responded. Practices were given 4 weeks to submit data and the survey response was poor. No practice managed to complete the survey with 20 patients per protocol (140 data points). Of the 77 protocols submitted (11 practices x 7 protocols) only 6 protocols were submitted with all 20 patient data fields satisfactorily populated. These were spread across 4 of the 11 practices. However, sufficient data was submitted, in most cases, for a generic dose report to be generated and a survey DRL to be calculated.

Conclusion: This pilot MDCT data survey has shown that the application of a web based MDCT protocol survey should provide sufficient data for accurate dosimetry calculations and comparative intersite surveys to be performed. When released nationally, it should serve as a useful data source for the development of national MDCT DRLs.

Introduction

It is well recognised that the greatest source of patient dose from diagnostic imaging is from multi-detector computed tomography (MDCT) (NCRP 2009). The rapidly increasing growth of applications of MDCT scanning has the unwanted outcome of a significant increase in population cumulative effective dose (Brenner and Hall 2007). The Australian Radiation Protection & Nuclear Safety Agency (ARPANSA) estimates that growth in MDCT scans, based on Medicare Benefits Schedule data, is increasing at approximately 9% per annum with over 2 million MDCT scans being performed in 2009 (Fig.1) (Hayton, Wallace et al. 2009).

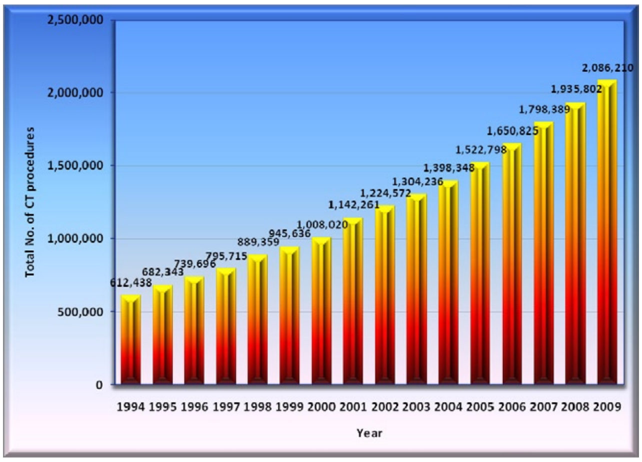

Fig. 1. MDCT procedures in Australia 1994 – 2009.

While the application of MDCT to diagnosis and therapy should always be applied in the sound knowledge of benefit outweighing risk, its application does increase the probability of stochastic detriment to the population e.g. expression of cancerous disease (Brenner, Elliston et al. 2001). Radiobiology research also points to the increased risk of stochastic effects in the paediatric population compared with adults (Hall and Brenner 2008). MDCT has many advantages to offer radiological investigations and its uses and applications are increasing. The development of the technology in terms of its power, flexibility, and utility, ease of use and diagnostic image quality has resulted in an exponential increase in its application in virtually all fields of clinical practice. While the dose to the individual and the consequent individual risk is relatively low, the population risk is compounded by the increasing number of imaging and therapeutic applications undertaken in current medical practice. This may result in an increasing public health concern due to the escalating risks of the expression of stochastic effects. As the expression of stochastic detriment takes many decades to appear, we may only be at the threshold of an increasing MDCT induced cancer rate (Larson, Rader et al. 2007). To address this increasing population health risk ARPANSA has developed a Code of Practice and Safety Guide for the application of ionising radiation in medicine (ARPANSA 2008; ARPANSA 2008). The Code of Practice has been taken up by state regulators and its provisions are now a necessary compliance requirement for statutory radiation safety acts, regulations and conditions of license.

To obtain a clearer assessment of this potential risk, it is imperative that a review of the doses delivered from common radiology procedures is undertaken both at the site of practice and consolidated into a regional or national analysis. DRLs can then be constructed and used as a comparative indicator of radiation efficiency at the practice, regional and national levels. Once site DRLs are established, they can be regularly reviewed and used as a baseline for the implementation of an optimisation program to maximise the efficient use of radiation while maintaining diagnostic image quality. Regional and national DRLs can be obtained and reviewed over a longer period and used as a dose benchmark that, by definition, 75% of practices will be able to achieve. As multiple iterations of the DRL review are undertaken it is expected that the spread of doses per procedure should decrease and the resultant 75th percentile value would diminish.

To assist with the efficient application of ionising radiation in medicine it has become common practice for regional dosimetry surveys to be undertaken to measure the spread of doses that are used for similar radiological investigations across various institutions. This spread of dose is statistically analysed and a 75th percentile (3rd quartile) value is calculated and used as an indicative measure of reasonable practice. The agreed percentile value is termed the Diagnostic Reference Level (DRL) and is conditional upon its dose delivered to the patient providing a diagnostic image of sufficient quality for diagnosis.

The development of dose reference levels for common radiology procedures has been ongoing for the past 2 decades. They provide a simple, comparative dose metric of the indicative, 75th percentile, dose delivered from common radiological procedures. Their application is through the comparison of individual mean or median site dosimetry with the 75th percentile value of the spread of doses for similar radiology procedures from multiple practices, regional or national estimates. Individual site dosimetry is established by recording and calculating, for a range of similar procedures, the mean or median value of the recorded doses for that procedure from a reference or general population of patients. The DRLs provide practices with a measure against which to compare their own practice doses with those of their peers and, if consistently exceeded without clinical justification, will provide an indication for the need of some modification of acquisition protocol to reduce dose. This process of individual site and regional/national comparison is undertaken on a regular basis.

It is important to understand that **DRLs are not dose limits**; they are simply indicators of common practice and are expected to vary over time depending upon changes in technology, acquisition protocols and clinical application. If a practice, after due consideration and optimisation, can justify a local DRL that is higher than what is commonly accepted then they have met the requirements of the DRL philosophy.

The UK introduced dose reference levels in 1990 as an indicator of ‘abnormally high doses’. They used the 3rd quartile value of the mean dose distributions taken from a national dose survey in the mid-1980’. If the practices’ mean dose consistently exceeded the reference dose then an investigation should have been undertaken to establish the cause and take corrective action if the doses are found to be clinically unjustified. The UK data have been updated periodically, every 5th year, for the past 20 years and each review has led to a reduction in the previously published MDCT DRL (Wall and Shrimpton 1998). Their next review (2009/10) will be their 5th iteration of the process. Unfortunately, the development of DRL data in diagnostic radiology within Australia is still at an early stage, as no national surveys have been carried out for any radiological examinations for the express purpose of establishing national DRLs. However, various organizations, regulatory authorities and individual practices have carried out limited CT dose surveys (Boal, Hedt et al. 1999).

ARPANSA had not undertaken a national MDCT dose survey since 1997 (Thomson and Tingey 1997; Wise and Thomson 2004). To estimate contemporary caput effective dose (mSv), Australian MDCT scanning episodes were combined with European MDCT dose data from the recent DOSE DATAMED surveys (EC 2008). The following graph shows the 3 estimates of extrapolated caput effective dose using the DOSE DATAMED cohorts of their low, medium and high ranges of survey doses. Unfortunately this estimate indicates that the Australian extrapolated doses closely fit the highest European cohort. The data estimate is that in 2009 the caput effective dose contribution from MDCT scanning is approximately 1.2 mSv.

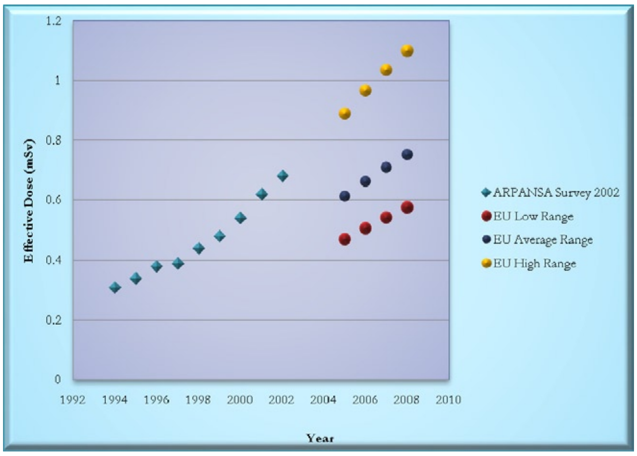

Fig. 2. Estimated caput effective dose (mSv) for Australian MDCT scanning 1994 – 2008.

Material and methods

The ARPANSA MDCT survey was based on the metrics of dose length product (DLP - mGy.cm) available from all MDCT consoles, plus patient weight, height and width, defined at a specific anatomical landmark. Patient weight and height, was to be obtained from questioning the patient and slice diameter was taken from review of the acquired image set. These parameters were recorded for 20 patients, for 7 common protocols. Fifteen radiology practices were invited to initially participate. The 7 common MDCT protocols are (i) head, (ii) cervical spine, (iii) chest, (iv) chest-abdomen, (v) abdomen-pelvis, (vi) lumbar spine and (vii) chest-abdomen-pelvis. Further protocols may be added to the survey as required. The survey forms will be accessible from the web via the ARPANSA website [www.arpansa.gov.au] and are expected to be posted towards the end of 2010.

To test the utility of the proposed web based program a draft survey was developed using Microsoft Excel (Microsoft Office 2003) and sent to selected radiology practices for completion and comment. Excel was chosen, as it is a readily recognisable, user-friendly program with which most scientifically educated users would be expected to have some experience. To minimise potential problems with data and worksheet corruption, due to participant 'editing', each worksheet was password protected.

The survey workbook was made up of a number of information and input worksheets that required participant response. These were a (i) general information page, (ii) radiologist, radiographer and practice registration page, (iii) protocol management page, (iv) data entry page per protocol, and a (v) data report page per protocol. Participants had full flexibility to choose the protocols that they wished to populate. For the initial draft survey it was hoped that all protocols would be fully completed. They were expected to provide a full data sheet for each protocol response. For each protocol it was requested that 20 sets of patient data points were logged. Each data set comprised of the integral dose length product (DLP, mGy.cm) recorded and displayed at the end of the investigation acquisition. This was usually to be found on the 'protocol page' that most systems generate at the end of a patient scan. Many practices 'screen grab' this page and send it to PACS as a formal dosimetry record of the investigation. As well as the integral DLP they were also requested to record the patients weight and height. It was not thought necessary to physically measure these parameters as a high degree of accuracy was not thought important. Participants were informed that a verbal questioning of the patient would be sufficient and would supply a sufficiently accurate indicative measure. It was also requested that the width of the patient at a defined anatomical landmark should also be recorded. This required the review of reconstructed images and has since been deleted as a survey data point. As each data set was added, the report page graph, which provided a histogram of DLP spread, the median DLP of the spread of input DLP and the maximum and minimum input DLP was updated. Participants were strongly requested to complete the protocol data with 20 patients to improve statistical accuracy.

To clearly distinguish between the all practice DRL and the individual practice or, local DRL, it was decided to use the term 'practice reference level' (PRL) which is defined as the median of the spread of all submitted DLPs per protocol.

At the completion of the survey period of 4 weeks each practice was also provided with a written report which included a letter of appreciation, including a table of European DRLs (Tsapaki, Aldrich et al. 2006) and graphs of all practice data for each protocol showing the individual practice PRL, the all practice DRL and the 95% confidence interval for the all practice DRL. This graph was also presented in a slightly different manner with all practice DRL, individual practice PRL and the maximum and minimum spread of individual practice DLP. A histogram of the spread of the practice DLPs per protocol separated into bins of 100 mGy.cm were also included with the survey DRL shown.

All submitted practice data was treated as strictly commercial-in-confidence. Participants only received their own practice data or anonymised all practice data for comparison.

Results

Of the 15 practices approached for participation in the survey only 11 responded, of these only 2 practices managed to submit 20 heads and 2 practices managed to submit 20 abdomen-pelvis scans. One participant provided information on 2 MDCT scanners but used retrospective data that did not include all patient weight, height or any slice diameters. The following table shows the author defined acceptable data responses from the participating practices per protocol.

Table 1. Acceptable Data Response per Practice per Protocol for a 4 week Survey Period.

Practice	Head	Neck	Chest	Chest and Abdo	Abdo and Pelvis	Lumbar Spine	Chest, Abdo and Pelvis	All (140)
A	6	3	5	2	13	1	17	47
B	1	2	3	0	2	4	18	30
C	1	8	14	0	20	0	0	43
D	20	6	8	0	15	3	6	58
E	12	4	8	0	11	5	9	49
F	16	10	10	0	1	10	13	60
G	20	5	13	0	20	12	8	78
H	20	0	14	1	20	0	6	61
I	0	2	0	0	0	4	0	6
J	0	0	0	0	0	4	0	4
K	4	6	8	2	11	0	12	43

However, even with the restricted data input it was still thought necessary to calculate an all practice DRL for the purpose of practice comparison. Recognising the limitation in the statistical accuracy of this calculation it still provides an indicative DRL value against which all practices could compare. The following table shows the European DRL, all practice survey DRL and practice reference level (PRL) spread (min – max).

Table 2. European DRL, All Practice Survey DRL and PRL spread per Protocol.

Protocol	European DRL (mGy.cm)	Survey DRL (mGy.cm)	PRL Spread (mGy.cm)
Brain	1050	1022	392 – 1692
Cervical Spine		815	190 – 1280
Chest	650	784	30 – 1488
Chest-Abdomen		659	324 - 723
Abdomen-Pelvis	780 (abdomen only)	837	143 – 1555
Lumbar Spine		1031	267 – 1879
Chest-Abdomen-Pelvis		1338	265 - 3028

Embedded within the survey forms was a report page where a scattergram was shown and updated after each data input for each protocol. It displayed a calculated PRL with noted minimum and maximum DLP values. As previously discussed, the participant was encouraged to input all 20 data points to increase the statistical accuracy of the displayed PRL. This PRL protocol report page could be sent to a printer as required for a hardcopy record.

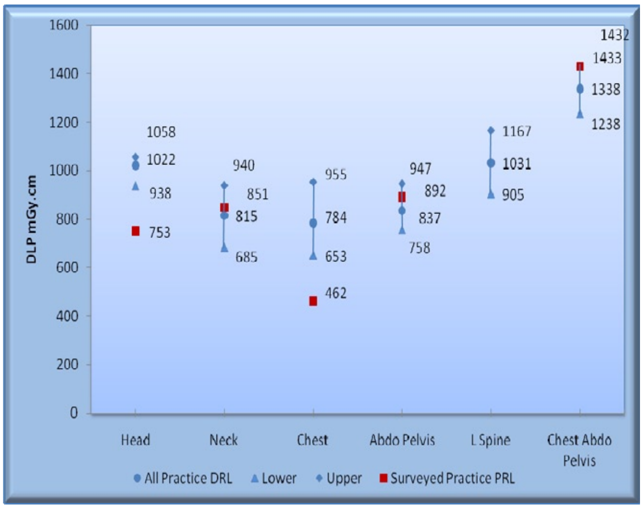

Fig. 3. All Practice DRL with 95% confidence limits and Surveyed Practice Local PRL.

As well as the embedded survey PRL protocol reports ARPANSA also generated a more detailed individual practice report that was sent post-survey. In the covering letter of the report was a table of European DRLs for reference (Tsapaki, Aldrich et al. 2006). This report provided the practice with additional information including DRL values per protocol with 95% confidence interval and their own practice PRL (Fig. 3).

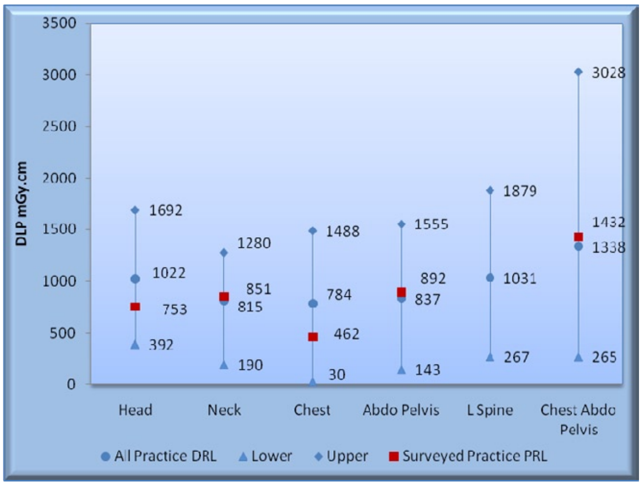

Fig. 4. All Practice DRL with max - min PRL spread values and Surveyed Practice Local PRL.

To provide the practice with information on where their protocol PRL sits in comparison to the spread of submitted PRL values a graphical presentation was attached (Fig. 4). These two graphs enabled each practice to clearly see where their practice stood in terms of the overall dosimetry for the generic protocol data submitted. If the practice did not perform the protocol or chose not to provide any data then a surveyed practice PRL data point could not be displayed.

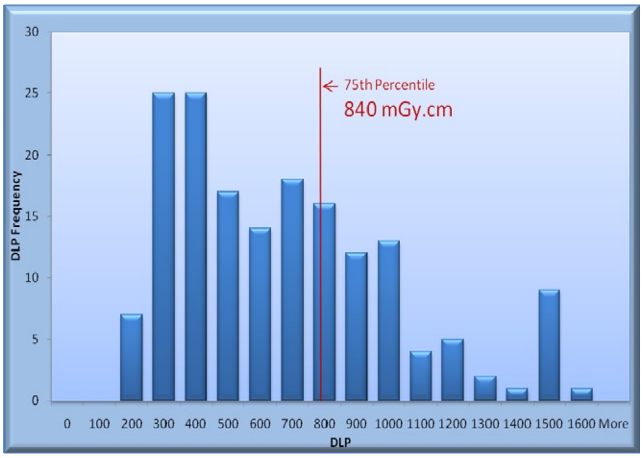

Fig. 5. All Practice Abdo-Pelvis DLP Spread.

Each practice was then provided with two graphs per protocol. The first histogram presented the all practice spread of DLP separated into 100 mGy.cm bins. The DRL was also shown (Fig. 5).

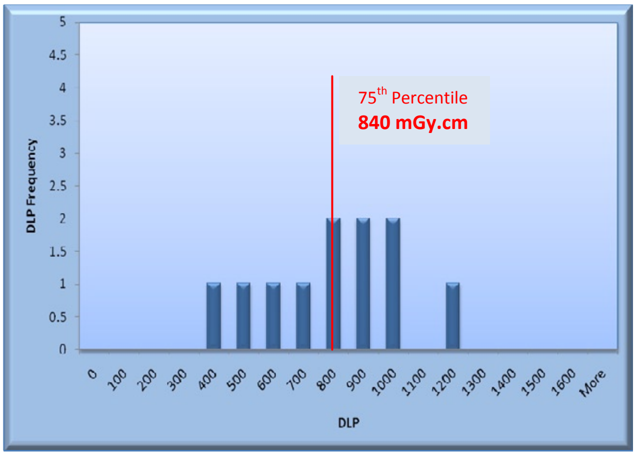

Fig. 6. Example Surveyed Practice Abdo-Pelvis DLP Spread.

The second histogram (Fig. 6) presented the spread of the practice DLP with the DRL. These graphs were displayed one over the other on the same page making it easier to visually compare the practice spread with the overall spread of all practice DLP. Any practice protocol with a significant spread of DLP values to the right of the DRL should indicate to that practice that an optimisation strategy should be undertaken.

Discussion

The initial survey period was for approximately 4 weeks. There was a variety of responses ranging from a complete 20 patient data point submission for some protocols to quite poor data submission compliance. Many practices were unable to submit the 20 patients for many of the protocols. Some practices did not submit all DLP, weight, height and slice diameter data sets. The paucity of complete responses necessitated a review of the survey forms and participant instructions.

Participant feedback from the first draft survey has led to the following modifications for future surveys. To remove any confusion concerning the scan range for each protocol a phantom graphic with red scan box defining the acceptable acquisition region has been included. Any patient volume scanned within the red box and meeting the appropriate protocol indications can be submitted. There was some confusion with the assumed accuracy required for the weight and height data. Indicative data was all that was required and it was not expected that patient measurement should be undertaken but a simple questioning of the patient would suffice. Weight within ±2 kg and height within ±3 cm was required. Provision of a pdf print paper ruler for door entrance and imperial to metric height convertor for older patients has been supplied for ease of use. The ruler can be taped to the entrance door at the required height and patients quickly 'eye-balled' for height estimation as they walk through. Participant response clearly indicated that the chest-abdomen protocol was not used as a common acquisition and due to its poor utility has been removed from the set of standard protocols for DRL assessment. Withdrawal of the slice diameter requirement, deemed to be an impediment for survey completion was removed to improve the ease of response for participants. This removes the requirement of the radiographer to retrospectively seek the appropriate anatomical plane to measure the patient diameter from the acquired image data set. Consequently, all data can be entered at the time of acquisition with no retrospective data mining required. As mentioned above a clearer definition of reference level terms with the inclusion of the defined 'practice reference level' (PRL) as the median of the spread of protocol DLPs was included. To provide information for appropriate feedback to participating practices concerning any excessive dose submissions, all protocol data pages now request the submission of their generic acquisition parameters at the top of the protocol data entry page. This should enable the survey team to communicate potential dose saving strategies to any practice that is clearly giving inappropriate doses. The feedback to the practices will be based on their need for the implementation of an optimisation strategy concentrating on the relevant acquisition parameters.

ARPANSA will use the accumulated practice data to calculate and publish, in consultation with stakeholders; Australian national DRLs. It is hoped that around one third of MDCT practices will respond in the 1st year of the survey. This should equate to approximately 300 practices from which DRLs could be published. Initially, practices will be provided with common European DRL data for comparison (Tsapaki, Aldrich et al. 2006)

It is expected that as the survey will be posted on the web and always available, it will be used as an optimisation tool for dose reduction when required. While this project does not profess to be an MDCT optimisation program, it does provide a robust metric tool for MDCT dose assessment and adjustment. As the optimisation of acquisition protocols is an iterative process, this survey provides a useful and easy to use tool for dose comparison. The acquisition of data for national DRL assessment is a passive outcome of a radiology practice investigating their own patient dosimetry. It is expected that other protocols will be added to the survey as required, e.g. CTCA, CT colonography, etc.

As an additional driver for survey participation it has recently been recognised by state and territory regulators as an approved method to provide compliance with the ARPANSA Code of Practice RPS 14 which requires;

'*3.1.8 The Responsible Person must establish a program to ensure that radiation doses administered to a patient for diagnostic purposes are:*

(a) periodically compared with ***diagnostic reference levels (DRLs) for diagnostic procedures for which DRLs have been*** *established in Australia; and*

(b) if DRLs are consistently exceeded, reviewed to determine whether radiation protection has been optimised.' (ARPANSA 2008).

When the MDCT survey is satisfactorily rolled out ARPANSA will then develop survey documentation to establish DRLs for interventional fluoroscopy, PET-CT, mammography, general radiography and fluoroscopy.

Conclusions

The future provision of this web based survey will provide MDCT radiology practices with a tool to assist them in recording their median dose metrics for MDCT procedures in units of DLP (mGy.cm). It will also generate a protocol report which may be used as a comparative metric for any optimisation program undertaken in response to dosimetry concerns. The survey report will also be taken as meeting the compliance requirements of ARPANSA RPS 14 which has been taken up as a regulatory requirement for all state and territory jurisdictions within Australia. ARPANSA will additionally provide the radiology practice with a written report comparing their protocol dosimetry with, initially European, and eventually, Australian generated, national DRLs.

The multi-disciplinary support of the survey by the various radiology professional societies, the ready availability of the survey via the internet and its acceptance by the regulators as a compliance tool should ensure its take up by radiology practices across the country. It is expected that after approximately 300 practices have responded ARPANSA will be able to generate an accurately determined set of DRLs for MDCT practice in Australia.

Application of the European DOSE DATAMED methodology and reference doses for the estimate of Australian MDCT effective dose (mSv)

Hayton, Anna; Wallace, Anthony; Edmonds, Keith; Tingey, David
Medical Physics Section, Australian Radiation Protection & Nuclear Safety Agency (ARPANSA), AUSTRALIA

Abstract

Purpose: To calculate the indicative effective dose (mSv) per individual per annum to the Australian population from current MDCT procedures using DOSE DATAMED MDCT dosimetry as a reference.

Methods and Materials: DOSE DATAMED was a multinational radiology dosimetry project with contributions from ten European countries with extensive experience in undertaking national dosimetry surveys (http:/ec.europa.eu/energy/nuclear/radioprotection/publication_en-htm). The lack of contemporary Australian MDCT dosimetry survey data post-2002, required the application of a recognised European dosimetry data set for current generic caput effective dose calculation. Utilising Medicare Benefits Scheme[1] (MBS), CT procedure data, plus an additional 31% gross-up factor for data not captured by MBS, an indicative caput dose calculation was made based on the current European DOSE DATAMED dosimetry data.

Results: DOSE DATAMED grouped all MDCT procedures into 7 generic scans with the following doses; Head (2.4 mSv), Neck (2.8 mSv), Chest (8.2 mSv), Spine (6 mSv), Abdomen (13.5 mSv), Pelvis (8.8 mSv) and Trunk (24.4 mSv). MBS MDCT categories were rendered down to fit into these broad categories and a resultant effective dose of approximately 1.2 mSv per individual per annum was calculated.

Conclusion: Previous ARPANSA CT surveys have shown the per caput dose has grown from 0.37 mSv (1994) to 0.9 mSv (2002) The current per caput dose contribution is approximately 1.2 mSv (2008). As the number of MDCT procedures in Australia is growing at approximately 9% per annum, the MDCT dose contribution to the Australian population background radiation dose is also steadily increasing.

Introduction

A 2009 report by the National Council for Radiation Protection (NCRP) showed that in the United States, Medical sources contribute 48% of the total dose received by the public every year. Of the total dose from Medical sources it was found that CT

[1] Australian Government National Health Insurance Scheme

contributed 50% of the dose while only making up 17% of the procedures (NCRP 2009). In Australia in 2009, Computed Tomography accounted for approximately 12% of all diagnostic imaging procedures recorded by Medicare Australia (Medicare 2010).

Material and methods

The numbers of CT procedures recorded by Medicare Australia are available via their website (Medicare 2010). Data is grouped according to 10 discrete categories. Category 5 – Diagnostic Imaging Services covers Ultrasound, Computed Tomography, Diagnostic Radiology, Nuclear Medicine Imaging and Magnetic Resonance Imaging. Data from category 5 was analysed as a whole and the data specifically for Computed Tomography was analysed for gender, age group, state and category break downs. Data on the age and sex structure of the Australian population was also obtained from the Australian Bureau of Statistics website (ABS 2010).

Results

Growth in CT

Over the 16 year period between 1994 and 2009 the number of MDCT procedures recorded by Medicare Australia has increased 240% from 610 thousand to 2.1 million (Medicare 2010). The Australian population increased only 23% in the same period (ABS 2010). The average per annum growth in MDCT procedures is 8.53% which is 6 times larger than the annual growth in the population which is 1.36% (Medicare 2010) (ABS 2010). Figure 1 shows the annual percentage growth rate of MDCT procedures and the Australian population.

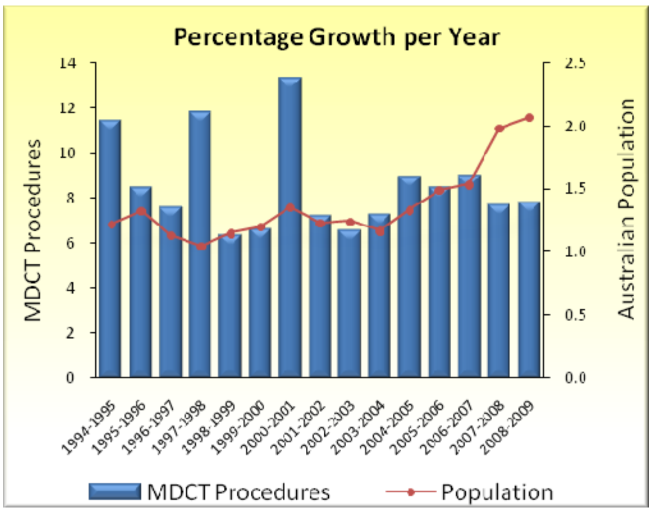

Fig. 1. Percentage growth in MDCT procedures and the Australian population 1994-2009.

Data Gap

Medicare Australia does not capture all MDCT procedures performed. A survey conducted by ARPANSA in the mid nineties estimated that Medicare Australia only captured 76% of all procedures actually carried out (Wise and Thomson 2004). This number is thought to be much lower for paediatric procedures (to be published by Brady).

Procedures that are not captured by Medicare Australia include – Public Patient Radiology (funded directly from state and territory governments), WorkCover referrals, Department of Veterans' Affairs referrals and Traffic Accident Commission referrals.

If this estimated data gap is accurate the number of MDCT procedures performed in Australia in 2009 would increase from 2.1 million to 2.7 million.

Age group breakdown

Medicare Australia breaks down procedure data into 10 separate age groups. Figure 2 shows this data for 2009 normalised to the population structure. The age group with the greatest number of MDCT procedures per person is the 75-84 year olds, closely followed by the 65-74 year olds.

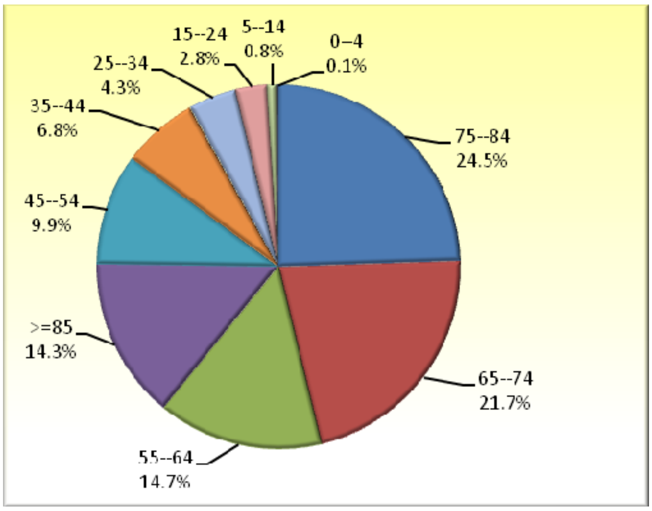

Fig. 2. Age break down of CT procedures for 2009.

Gender breakdown

The data from Medicare Australia shows that the majority of MDCT procedures performed each year in Australia are on females. MDCT procedures performed on females account for 54% of all procedures consistently over the past 16 years. This discrepancy is not accounted for by normalising to the gender structure of the population. However, females do not have the majority across all ten age groups. Both paediatric age groups are dominated by procedures on males. Figure 3 shows the gender breakdown for all age groups.

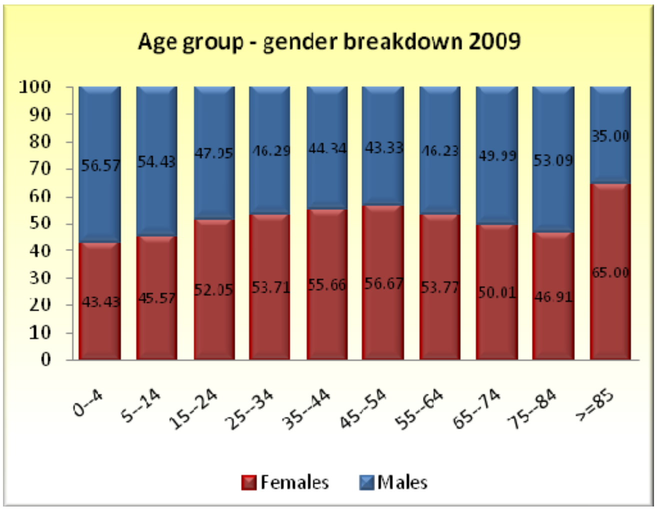

Fig. 3. Age group - gender break down of CT procedures for 2009.

Category break down

Medicare Australia records data on MDCT procedures according to the item number the procedure was billed under. Each item number indicates which anatomical region of the body was scanned and whether a contrast agent was used. These item numbers can be grouped according to general anatomical region. Currently the item numbers can be grouped into sixteen separate categories. Figure 4 shows the percentage of scans in each category for 2009. The five most common categories in 2009 were – head, abdomen and pelvis, lumbar spine, chest/thorax and neck, chest, abdomen and pelvis.

The rate of growth is not constant across each category. In the five years from 2004 the category with the highest percentage growth is interventional. Both the pelvimetry and abdomen category have negative growth. The total percentage growth of all 15 categories over the past five years is shown in figure 5.

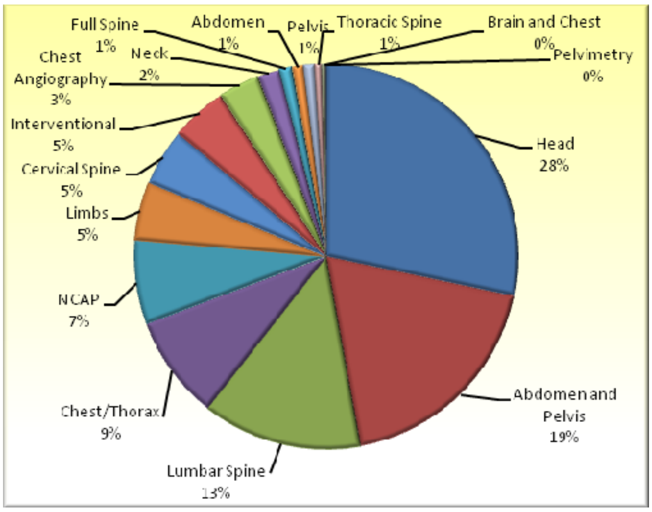

Fig. 4. Category break down of all CT procedures for 2009.

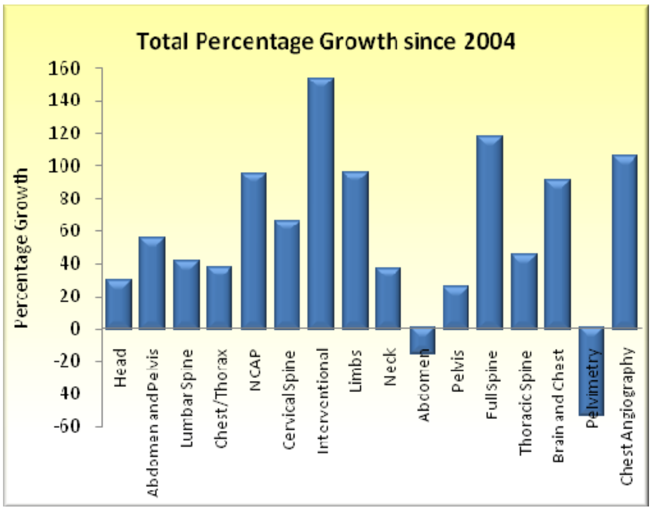

Fig. 5. Total percentage growth 2004-2009.

DOSE DATAMED: European Dose Survey

The European Commission has given advice on estimating the population dose from medical X-ray procedures (EC 2008). They use a list of "Top 20" most common procedures involving x-ray procedures. MDCT procedures make up 7 of this list of 20, they are – CT Head, CT Neck, CT Chest, CT Spine, CT Abdomen, CT Pelvis and CT Trunk. Low, average and high doses per procedure for each of these seven categories have been established via a survey of ten European countries. Thirteen of the sixteen current Medicare Australia Item number categories were grouped to form the seven CT categories as defined by DOSE DATAMED. The number of procedures performed in Australia in each of these categories from 2003 onwards was calculated. This data was then multiplied by each of the low, medium and high doses per procedure as obtained from the DOSE DATAMED Survey. Figure 6 shows this data combined with procedure number and dose level data from a previous 2002 ARPANSA survey. The data indicate that Australia would be considered a 'High' Dose level country. The population dose for Australia for 2009 based on the DOSE DATAMED method is represented in Table 1.

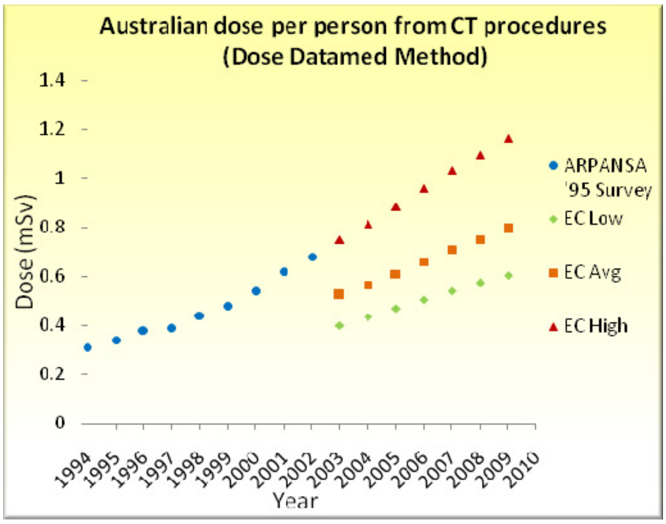

Fig. 6. Dose Per Capita calculated using the DOSE DATAMED method.

Table 1. CT procedure numbers and doses for Australia.

CT Procedure	Dose Level			Procedures 2009	Dose (mSv) (calculated using 'High' Dose Level)
	Low	Avg	High		
CT Head	1.6	2.0	2.4	776525	1863659
CT Neck	2.4	2.5	2.8	145247	406691
CT Chest	6.6	8.0	8.2	349025	2862002
CT Spine	3.6	5.3	6.0	399467	2396801
CT Abdomen	10.2	12.0	13.5	26577	358796
CT Pelvis	8.7	8.7	8.8	27168	239078
CT Trunk	10.4	14.0	24.4	710013	17324322
				Total Dose (mSv)	**25451349**
				Population	**21874920**
				Dose per Person (mSv)	**1.163**

In the Future

If current trends in MDCT procedure and population growth continue we can estimate that the annual dose from MDCT per person will reach 1.53 mSv in 2012. This will overtake the annual estimated natural background radiation dose of 1.5 mSv (ARPANSA 2010).

Discussion

The "Gross Up" Factor

In using the DOSE DATAMED method to calculate a dose per person from MDCT procedures in Australia we have used a single "gross up" factor to account for the procedures that are not captured by Medicare Australia. This "gross up" factor was obtained from a survey that was conducted in the mid nineties. The range of applications for CT scanning as a diagnostic imaging tool has dramatically increased over the past 16 years. This can, in part, be related to technological advances that have enabled faster, more complex, longer and interventional MDCT scanning to be undertaken. We expect the true “gross up” factor to also have changed in the past 16 years.

Our application of the DOSE DATAMED doses to our Medicare Australia numbers provides a calculated estimate of dose to the Australian population, it is not definitive. In aligning the Medicare Item numbers with the seven DOSE DATAMED categories there were a number of item numbers that were left out completely. These item numbers related to interventional CT, brain and chest CT, limbs CT and some item numbers relating to neck and cervical spine CT. Overall, the percentage of procedures recorded by Medicare Australia that have not been included in the seven DOSE DATAMED categories has been steadily increasing from 4% in 1994 to nearly 12% in 2009.

Despite Medicare Australia not providing definitive data, our generic calculation does provide a reasonable estimate of the population dose from MDCT procedures for Australia. The estimate of 1.2 mSv per person for 2009, and the current rate at which procedure numbers provide strong support for the implementation of a national survey to establish the true dose to the Australian population.

Conclusions

MDCT scans in Australia are increasing at approximately 9% per annum, which is more than six times greater than the growth in the population. On average more women are undergoing MDCT procedures than men. In 2009 more than 75% of all MDCT procedures were carried out on persons over the age of 55, with the most MDCT procedures per person occurring in the 75-84 year age group. MDCT scans of the head account for the largest portion of procedures but also has the second lowest positive percentage growth per year. The highest percentage growth per year was seen in the ‘interventional’ category of 31.7% which in 2009 only accounted for 3.4% of all procedures. Applying DOSE DATAMED dosimetry data to the calculation of population dose from MDCT procedures, Australia falls in to the “High Dose” category, which in 2009, resulted in an average dose to the population of 1.16 mSv per person.

Comparison of spectroscopic investigation and computer modelling of lanthanide(III) and actinide(III) speciation in human biological fluids

Barkleit, Astrid; Heller, Anne; Baraniak, Lutz; Bernhard, Gert
Forschungszentrum Dresden-Rossendorf e.V., Institute of Radiochemistry, P.O. Box 510119, 01314 Dresden, GERMANY

Abstract

Radionuclides represent a serious health risk to humans in case of incorporation. To get a first insight into the transport and metabolism in the human organism, we compared the speciation of Eu(III) and Cm(III) in human biofluids calculated by thermodynamic modelling with spectroscopic results obtained by time-resolved laser-induced fluorescence spectroscopy (TRLFS) with regard to the lanthanide/actinide analogy.

For TRLFS measurements, fresh human whole saliva and urine samples have been spiked in vitro with europium or curium. To identify the dominant species the measured spectroscopic data were compared to reference spectra with single organic and inorganic constituents of the biological fluids. The TRLFS spectra with saliva were all similar in the pH range between 6.8 and 7.4. The TRLFS spectra with urine showed that all samples with pH below and all samples with pH above 5.8 each exhibit strikingly similar spectra. Comparing the measured spectra with the reference data, we found that in urine at lower pH citrate complex species dominate the speciation of both metals while at higher pH and in saliva the spectra were identical to those of a mixture of inorganic and organic components.

The speciation calculation for saliva results for both metals in a predominant phosphate coordination with a small amount of coordination with citrate which reflects the experimental results not exactly.

The speciation calculation for urine shows up to pH 6.5 a dominating citrate speciation for both metals and only for higher pH values additionally phosphate coordination. However, spectroscopic investigations signed of a more complex speciation behaviour which cannot be described with single inorganic complexes.

To conclude, the comparison of experimental speciation investigation and computer modelling shows that because of their simplifications models cannot always image the complex natural processes correctly.

Introduction

In case of incorporation, radionuclides represent a serious health risk to humans due to their (radio-)toxicity. To understand their transport, metabolism, deposition and elimination in the human organisms it is crucial to determine their speciation and transport on a molecular level. Unfortunately, only little is known about the metabolism of trivalent actinides (An(III)). To address this lack of knowledge, in this study the speciation of curium (Cm(III)) and europium (Eu(III)) in saliva as the first contact medium at oral incorporation and urine as the main elimination medium was investigated spectroscopically with time-resolved laser-induced fluorescence spectroscopy (TRLFS). Additionally the speciation of the metal ions in the biofluids was calculated by thermodynamic modelling. Speciation calculation can be a helpful tool to simulate biokinetic processes when it is too risky to obtain experimental information (Webb et al. 1998). Another option is using non-radioactive analogues like trivalent lanthanides (Ln(III)) instead of An(III) to obtain experimental data. The aim of our study is to compare the results of both alternative methods, the speciation modelling and experiments with Eu(III) as a non-radioactive Ln(III) analogue with the experimental results of the speciation of the trivalent radioactive actinide Cm(III) in saliva and urine.

TRLFS is a useful tool to investigate the chemical environment of luminescence emitting ions like Cm(III) and Eu(III) at trace metal concentrations. The luminescence emission bands and the luminescence lifetimes provide information about the first coordination shell of the ions. For Eu(III), the emission bands $^5D_0 \rightarrow {}^7F_0$ (at 580 nm), $^5D_0 \rightarrow {}^7F_1$ (at 590 nm), and $^5D_0 \rightarrow {}^7F_2$ (at 615 nm) are of special interest. The first transition is formally forbidden and appears only under deformation of the first coordination shell of Eu(III). Whereas the magnetic dipole transition $^5D_0 \rightarrow {}^7F_1$ is hardly influenced by complexation, the relative intensity and the splitting pattern of the hypersensitive electric dipole transition $^5D_0 \rightarrow {}^7F_2$ show changes in the local environment of the Eu(III) species. The luminescence signal of the $^6D_{7/2} \rightarrow {}^8S_{7/2}$ transition of Cm(III) shows significant shifts with changes of the coordinative environment (Edelstein et al. 2006; Kim et al. 1991). From the lifetimes of both luminescent species, Eu(III) and Cm(III), the number of coordinating water molecules can be determined (Kimura and Choppin 1994).

Materials and methods

Sample collection

Unstimulated whole human saliva was obtained in absence of any gustatory or masticatory stimulation from healthy adult volunteers by spitting in a dry plastic tube. Samples (about 25 mL each) were collected at the same time of day (between 10:00 and 11:30 a.m.), at least one hour after the last intake of food or drink. Before using, the saliva samples were centrifuged (10 min, 4000 g).

Human urine samples were obtained from healthy adult volunteers as 24-hours-collecting-samples to eliminate fluctuations of the composition due to eating and drinking and used without further treatment.

A total of 5 saliva and 9 urine samples were investigated. All investigations were performed immediately (4-5 h), or otherwise saliva and urine samples were cooled stored at 4 °C (up to 24 h) or -20 °C (more than one day).

Analysis of the saliva and urine composition

The inorganic composition of all samples was determined using mass spectrometry with inductive coupled plasma (ICP-MS) and ion chromatography (IC). The content of cations was measured using the ELAN 9000 system from Perkin Elmer and the content of anions was determined using the Metrosep A Supp 4 column and a HPLC system from Metrohm. The total organic carbon (TOC) was measured with a multi N/C 2100 S from Analytik Jena AG. The pH values were determined with a BlueLine 16 pH electrode (Schott).

Speciation calculation

The calculation of the Eu(III) and Cm(III) speciation in saliva and urine was determined with the computer program MEDUSA (Make Equilibrium Diagrams Using Sophisticated Algorithms, version 2004), combined with the associated Hydrochemical Equilibrium-Constant Database HYDRA (version 2004). The stability constants for Eu(III) complexes were compared with the NAGRA database (Hummel et al. 2002) and, if necessary, readjusted. For the analogue Cm(III) complexes, the stability constants were taken from the NEA database (Guillaumont et al. 2003). If no stability constants for Cm(III) complexes are available (phosphate species), the values of Eu(III) complexes were applied.

Time-resolved laser-induced fluorescence spectroscopic measurements

For TRLFS measurements, the saliva and urine samples (3 mL each) were spiked with $3x10^{-5}$ M Eu^{3+} (Eu_2O_3, Aldrich) and $3x10^{-7}$ M Cm^{3+} (from a stock solution of the long-lived ^{248}Cm isotope in 1 M $HClO_4$; isotope ratio ^{248}Cm 97.3 %, ^{246}Cm 2.6 %, ^{245}Cm 0.04 %, ^{247}Cm 0.02 % and ^{244}Cm 0.009 %), respectively. All treatments with Cm(III) were carried out in a glove box.

The time-resolved laser-induced fluorescence spectra were recorded at 25 °C using a pulsed flash lamp pumped Nd:YAG-OPO laser system (Powerlite Precision II 9020 laser equipped with a Green PANTHER EX OPO from Continuum, Santa Clara, CA, USA). The optical parametrical oscillator (OPO) used to tune the wavelength of the emitted laser beam was pumped by the second harmonic oscillation of the Nd:YAG laser (532 nm). The doubled signal output wavelength can be varied between 330 nm and 500 nm. The laser pulse energy, which was between 1 and 2 mJ, was monitored using a photodiode. The fluorescence emission spectra were detected using an optical multi-channel analyzer-system, consisting of an Oriel MS 257 monochromator and spectrograph with a 300 or 1200 line mm^{-1} grating and an Andor iStar ICCD camera (Lot-Oriel Group, Darmstadt, Germany). The europium(III) and curium(III) emission spectra were recorded in the 440-780 nm (300 line mm^{-1} grating) and 570-650 nm (1200 line mm^{-1} grating) ranges. A constant time window of 1 ms was applied, and two excitation wavelengths, 395 nm (Eu) and 398 nm (Cm), were used. For time-dependent emission decay measurements, the delay time between laser pulse and camera grating was scanned with time intervals between 10 µs and 50 µs.

The TRLFS spectra were analyzed using origin7.5G. The single spectra were normalized to the same peak area (Cm) and of the $^5D_0$-$^7F_1$ transition peak (Eu), respectively. The lifetimes of luminescent species were determined according to the equation of exponential decay:

$$E(t) = \sum_i E_i \cdot \exp(-t/\tau_i) \qquad (1)$$

E is the total luminescence intensity at the time t, E_i the luminescence intensity of the species i at t, and τ_i the corresponding lifetime.

With the luminescence lifetimes the numbers of water molecules in the first coordination spheres of Eu(III) and Cm(III) were then calculated applying Kimura´s equations (Kimura and Choppin 1994):

$$nH_2O \pm 0.5 = 1.07 \cdot \frac{1}{\tau} - 0.62 \qquad \text{for Eu(III)} \qquad (2)$$

$$nH_2O \pm 0.5 = 0.65 \cdot \frac{1}{\tau} - 0.88 \qquad \text{for Cm(III)} \qquad (3).$$

Results

Analysis of selected components in saliva and urine

The composition of the main components of saliva and urine are summarized in Tables 1 and 2. We concentrated on the main cations sodium, potassium, magnesium (only urine) and calcium and the anions phosphate, sulphate (only urine), and carbonate as relevant potential complexation agents. The determination of chloride concentration was omitted because Eu- and Cm-chloride complexes are very weak and are not expected to play any role in the speciation.

The determined values are in good agreement with other studies on the composition of saliva (Edgar 1992; Rehak et al. 2000) and urine (Kirchmann and Pettersson 1995; Putnam and Thomas 1969).

Table 1. Concentrations of selected components of whole saliva.

Analyt	Range	Mean
Sodium (mmol/L)	2.98 – 6.57	4.00
Potassium (mmol/L)	3.35 – 21.46	9.39
Calcium (mmol/L)	0.99 – 1.14	1.03
Phosphate (mmol/L)	0.55 – 5.52	4.11
Carbonate (mmol/L)	3.10 – 8.00	4.87
TOC (g/L)	0.85 – 0.98	0.91
pH	6.78 – 7.43	7.05

Table 2. Concentrations of selected components of urine.

Analyt	Range	Mean
Sodium (mmol/L)	9.13 – 305.22	133.43
Potassium (mmol/L)	8.29 – 107.93	45.86
Calcium (mmol/L)	0.57 – 4.29	2.16
Magnesium (mmol/L)	0.70 – 6.54	2.42
Phosphate (mmol/L)	0.12 – 28.80	7.71
Sulfate (mmol/L)	0.08 – 16.03	4.97
Carbonate (mmol/L)	0.12 – 26.58	4.41
TOC (g/L)	2.24 – 7.86	4.71
pH	5.25 – 6.74	6.00

Additionally the total organic carbon was determined. It is well-known from the literature that the main organic substances in human saliva are proteins (e.g. mucin or enzymes). The major digestive enzyme of saliva, α-amylase, is present in concentrations of about 0.6-1.2 g/L (Edgar 1992). Citrate as the typical organic substance of many biofluids plays with a maximum of about 0.05 mmol/L (Zipkin and McClure 1949) only a minor role in saliva. In human urine, the main organic component is urea with about 0.2 mol/L (Putnam and Thomas 1969). An important organic substance for heavy metal complexation is citrate with an amount of about 3.2 mmol/L in urine (Putnam and Thomas 1969).

Speciation calculation of Eu(III) and Cm(III) in saliva and urine

For the computer modelling of the speciation of Eu(III) and Cm(III) in simulated saliva and urine, the mean values for inorganic components from Table 1 and 2 were used. Additionally mean values for citrate were included (0.05 mmol/L for saliva (Zipkin and McClure 1949) and 3.20 mmol/L for urine (Putnam and Thomas 1969)). The complexation of Eu(III) and Cm(III) with urea, the matrix substance of urine, was determined previously (Heller et al. 2009) and showed that the Eu(III) and Cm(III) urea complexes are very weak. Normally they do not influence the speciation of heavy metal ions in urine, therefore they were omitted. Also the complexes of Eu(III) and Cm(III) with various amino acids, which are present in saliva and urine, were investigated at neutral and slight acidic pH (Heller et al. 2010) and can likewise be omitted because they are also very weak.

The calculated speciation for Eu(III) and Cm(III) in simulated saliva shows at pH 7.0 a predominant coordination with phosphate (more than 80 %) with a small amount of citrate coordination. Figure 1 (left) shows the speciation diagram for Eu(III), the Cm(III) speciation looks similar. It is worth to mention that because for Cm(III) phosphate complexes no stability constants are known those of the analogue Eu(III) complexes were used for calculation instead. Therefore the Cm(III) speciation is doubtfully.

The speciation for Eu(III) and Cm(III) in simulated urine is pH dependent. In the pH range between 5.0 and 6.5 we observe nearly 100 % citrate coordination. At higher pH additionally phosphate coordination appears. Figure 1 (right) shows the speciation of Eu(III) in urine at pH 7.0. Here we observe still more than 50 % citrate coordination and about 40 % phosphate coordination. To Cm(III) speciation calculation in urine the same constriction does apply like to Cm(III) speciation calculation in saliva considering the stability constants of the phosphate species. The speciation calculation of Cm(III) in urine is therefore also doubtfully.

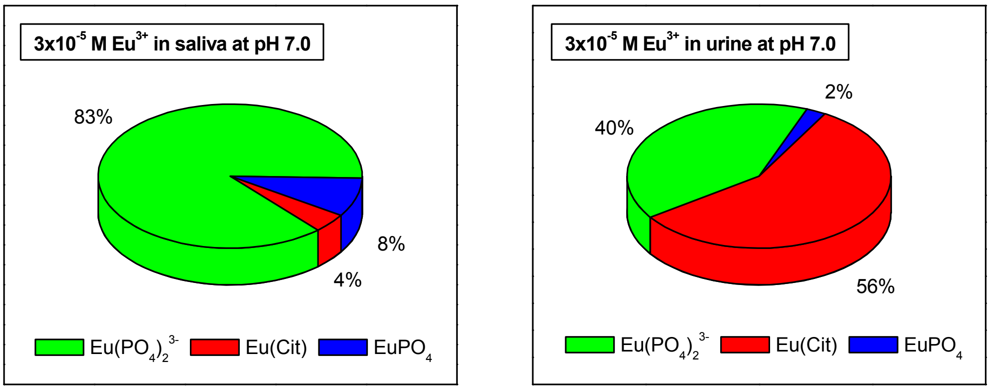

Fig. 1. Calculated speciation of europium in simulated saliva (left) and urine (right) at pH 7.0 with component composition of Table 1 (inorganic components) and additional citrate (0.05 mmol/L for saliva, 3.2 mmol/L for urine).

TRLFS measurements of Eu(III) and Cm(III) in saliva

A total of 5 measurements each of Eu(III) and Cm(III) in natural saliva samples with pH values in the range of 6.8 to 7.4 have been carried out. Figure 2 (left Eu, right Cm) shows that they are all similar. The luminescence decay of these mixtures is always mono-exponential for both, Eu(III) and Cm(III).

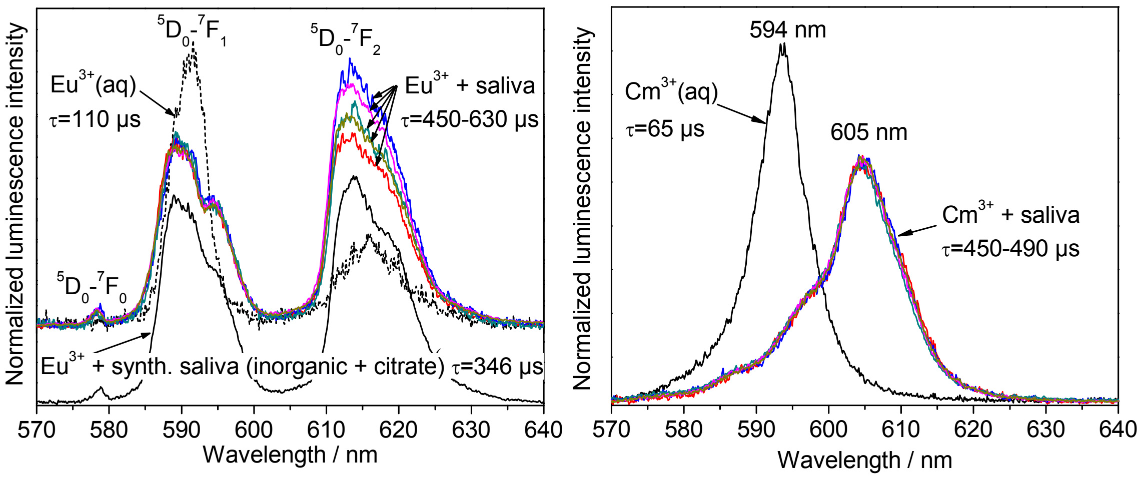

Fig. 2. Luminescence spectra of Eu(III) (left) and Cm(III) (right) in saliva.

In case of Eu(III) (Figure 2 left), the relative intensity of the $^5D_0 \rightarrow {}^7F_2$ transition is higher in comparison to the aquatic Eu^{3+} ion, both emission peaks, $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$, are split and additionally the $^5D_0 \rightarrow {}^7F_0$ emission peak appears due to complexation with the saliva matrix. The luminescence lifetimes were determined to be between 450 and 630 µs (mean: 530 ± 75 µs) which corresponds to 1 - 2 remaining water molecules (applying Eq. (2)). For comparison, the Eu^{3+}(aq) ion has 9 water molecules in the first hydration shell. Consequently, 7 - 8 water molecules are exchanged through coordination sites of the saliva matrix.

For comparison, several synthetic saliva model solutions spiked with Eu^{3+} were investigated: with only the inorganic components according to Table 1 and with additionally the organic ingredients citrate, lactate and α-amylase, and also all single inorganic and organic components. Only the synthetic saliva with inorganic components plus citrate fits the static spectra correctly (see Figure 2 left) and fits additionally nearly the luminescence lifetime. All other tested models (spectra not shown here) show either different static spectra or considerably shorter lifetimes or even both.

The luminescence spectra of Cm(III) in human whole saliva are depicted in Figure 2 (right). The complexation of the Cm^{3+}(aq) ion with saliva causes a strong red shift of the luminescence signal of about 12 nm from 594 nm (Cm^{3+}(aq)) to 605 nm. The luminescence lifetime increases from 65 µs (Cm^{3+}(aq), according to 9 water molecules) to 450 – 490 µs (mean: 474 ± 16 µs), which corresponds to 1 remaining water molecule. Similar to Eu(III), about 8 water molecules of the first hydration shell of Cm(III) are exchanged through ligand coordination sites of the human whole saliva matrix.

Just like for Eu(III), for comparison several synthetic saliva models with only inorganic components and additionally with organic components and also the single inorganic and organic components, spiked with Cm^{3+}, were determined. In contrast to Eu(III), the synthetic saliva model with inorganic components plus citrate does not fit the spectra of human whole saliva, neither the peak maximum (600 nm) nor the luminescence lifetime (90 – 120 µs). Only with additionally α-amylase the peak maximum (603 nm) and luminescence lifetime (300 – 610 µs) fit nearly the values of human whole saliva.

TRLFS measurements of Eu(III) and Cm(III) in urine

Figure 3 depicts the luminescence spectra of Eu(III) samples in human urine at different pH values and also in several model solutions for comparison. In both cases, the spectra are different above and below pH 5.8. Like for saliva, also for the urine samples synthetic urine models as well as several single inorganic and organic components were investigated for comparison. Below pH 5.8 the static spectra and luminescence lifetimes are similar to those of the citrate complexes of Eu(III) (see Figure 3) and Cm(III) (peak maximum: 600 nm; lifetime: 121 µs). Above pH 5.8 the Eu(III) urine spectra corresponds to synthetic urine with only inorganic components (Figure 3). For Cm(III), neither the inorganic synthetic urine (peak maximum: 596 nm, lifetime: 70 – 80 µs) nor the model of inorganic synthetic urine with citrate (peak maximum: 600 nm, lifetime: 90 – 120 µs) fits the spectral data for human urine (see Figure 4). Therefore, no assured assignment is possible at the moment.

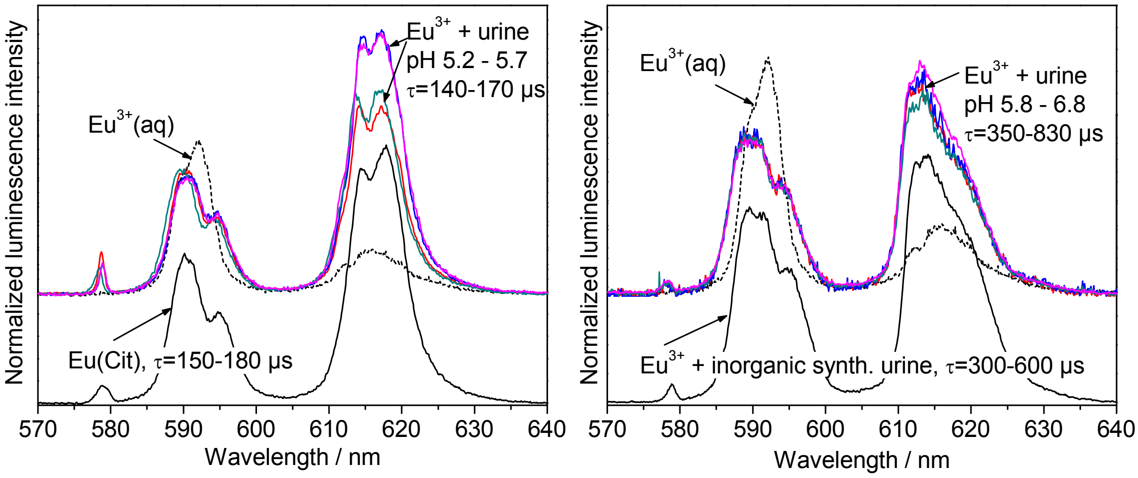

Fig. 3. Luminescence spectra of Eu(III) in urine and related model spectra. Left: Urine samples with pH values 5.2-5.7 and for comparison Eu-citrate. Right: Urine samples with pH values 5.8-6.8 and for comparison inorganic synthetic urine.

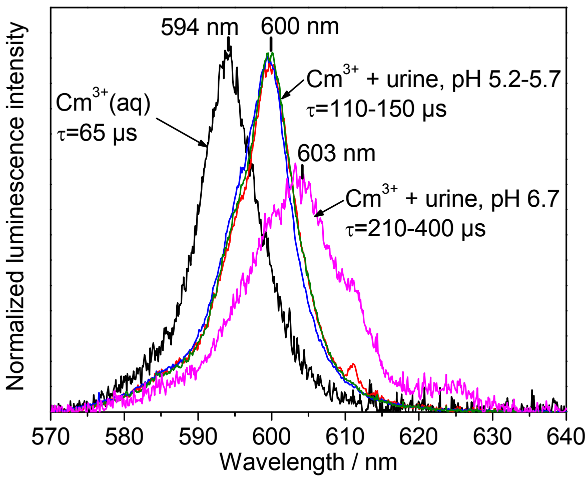

Fig. 4. Luminescence spectra of Cm(III) in urine.

Discussion

The comparison of speciation calculation of Eu(III) and Cm(III) in human whole saliva and human urine with the spectral data of Eu(III) and Cm(III) in original human whole saliva and human urine samples shows some analogies but also some discrepancies.

For saliva, the speciation calculation predicts predominant phosphate coordination with a small citrate fraction. The spectral analysis of the complexation of Eu(III) in human saliva in comparison to several synthetic saliva models and single saliva components results in a more complicated speciation. Beside a small citrate fraction not only phosphate coordinates the Eu^{3+} ion, but a mixture of inorganic anions. For Cm(III), even more organic components like α-amylase seems to be involved in complexation.

For urine, in the pH range between 5.2 and 5.7 the spectral results support the speciation calculation. Both trivalent metal ions are completely complexed with citrate. But in the pH range between 5.8 and 6.8, the results from spectral analysis differ strongly from the calculated speciation. The speciation calculation predicts even at pH 7 predominant citrate coordination and less than half phosphate coordination. In contrast, spectral data show for Eu(III) above pH 5.8 a mixed coordination with only inorganic anions present in urine. For Cm(III) a mixed coordination with inorganic and organic anions seems to be present.

The discrepancies between theoretical and practical results are due to a big lack in data for complex stability constants of single components, especially for Cm(III). Furthermore, no data about the stability constants of mixed ternary or higher complexes with two or more inorganic and/or organic anions are available for Eu(III) and Cm(III). One can assume that such ternary or higher mixed complexes are present in biofluids with a high variety of different inorganic and organic anions for metal ion complexation.

Conclusions

Time-resolved laser-induced fluorescence spectroscopy (TRLFS) is a useful tool to investigate the complexation behaviour of metal ions in biofluids. The spectroscopically determined speciation of Eu(III) and Cm(III) in human saliva and urine showed discrepancies to the computer modelled speciation due to a lack of complex stability constants, especially for Cm(III), and for ternary or higher mixed complexes for both metal ions. For better speciation calculation further investigations to determine complex stability constants are necessary.

The comparison of the complexation of Eu(III) as a selected trivalent lanthanide Ln(III) with Cm(III) as an example for a trivalent actinide An(III) shows less analogies than expected. Especially at nearly neutral pH the speciation in saliva and urine each differ between Eu(III) and Cm(III). This can possibly be due to the different metal ion concentrations used. However, this comparison shows that a prediction of the complexation behaviour of An(III) on the basis of results with Ln(III) should only be used as rough estimation. For precise conclusions, selected experiments with An(III) are necessary.

[2] BOKU – University of Natural Resources and Applied Live Science Vienna, Low-Level Counting Laboratory Arsenal, AUSTRIA

Abstract

Most building materials, especially of mineralogical origin, contain natural radionuclides. Generally radioactivity in building material originates from radionuclides of the natural decay chains U-238, Th-232, U-235 plus progenies as well as the primordial radionuclide K-40. External radiation exposure by gamma-radiation and beta particles emission plus internal exposure due to inhalation of radon cause chronic exposure of the public. Due to increasing indoor habitation of persons – in average about 80% of time persons stay indoor – external and internal exposure caused by natural radionuclides in building materials are of increasing importance. Additional the rising production of building materials using industrial by-products and residual materials from NORM industry necessitate the consideration and regulation of this radiation protection issue in regard to chronically public exposure. In this paper historical and recent basic concepts of dose estimation, radioactivity measurement methods including metrology and calibration of instruments are given. Examples of building material evaluations are discusses with regard to approaches of regulatory standards and experiences with implemented legal guidelines and provisions. The result of this research could act as effective fundamental basis for harmonised guidelines in Europe to limit chronically public exposure due to natural radionuclides in building materials.

Mapping of aerosol releases from Forsmark nuclear power plant

Bohl Kullberg, Erika
Forsmarks Kraftgrupp AB, Safety and Environment – Radiological Safety, SWEDEN

Abstract

Forsmark NPP has set a goal to reduce discharges of radioactive aerosols, mainly airborne particles of corrosion products such as cobalt-60, ^{60}Co, by 50% by 2011. To reach this goal we have run a project to map when and where aerosol discharges take place. We started by correlating aerosol discharges, measured in the stack, with events, such as reactor pool cleaning, in the plant. This has given us indications regarding which jobs release more aerosols. To further clarify the relationships of from which events and locations aerosol discharges emanate we have developed an instrument that measure aerosols in ventilation ducts, using the same millipore/coal filter cassettes that are used in the stack monitoring system. Our approach has been to confirm findings from the event-mapping project and further clarify which sections of the ventilation system that transport most radioactive aerosols.

By analyzing data from the event- release correlation study and the duct-measurement study we conclude that pool cleaning is the single major source of aerosol discharge and by introducing new work methods and air filtering systems during identified jobs aerosol discharge should be significantly reduced. We have also identified that the majority of aerosols comes from the reactor building, especially when small leaks occur - more optimized use of the filter banks might reduce the discharge of radioactive aerosols. In the end this will help lower the discharges of radioactive substances from Forsmark NPP making clean energy even cleaner.

Introduction

Even though nuclear power is a clean energy source, small discharges of radioactive substances to air and water occur. These discharges contribute only negligibly to the normal background dose. At Forsmark NPP the dose from the background radiation is estimated to be 1 mSv/y and Forsmark contribute to this dose with approximately 0.0002 mSv/y.

95-99% of the dose from the discharge of radioactive substances comes from ^{14}C produced in the cooling media during operation. We are currently unable to reduce this contribution to the dose since there are no suitable carbon-capture options available. The remaining 1-5% of the dose is made up of radioactive noble gasses, iodines and aerosol particles, mainly made up of radioactive corrosion products such as ^{60}Co. All discharges to air are measured in the stack monitoring system. At unit 1 and 2 (F1 and F2), all discharges go through the main stack, at unit 3 (F3) there are additional separate stacks for the waste department and the active workshop.

Forsmark NPP, striving to reduce our environmental impact, has a goal to reduce discharges of radioactive aerosols by 50% by 2011. To reach this goal we have performed a study to map when and where aerosol releases take place, this to find out how to avoid and reduce discharges.

Material and methods

To map aerosol discharges from Forsmark NPP we have used two tracks:

Our first approach has been to correlate aerosol discharges, measured in the stack, with events in the plant. We have looked at the years 2006-2009. From the stack monitoring system we have gathered monthly and weekly readings on the discharge of aerosols, which we have compared to listed events. To know what to look for in log-books and listings we compiled a list of possible events, which we then compared with discharges on a monthly basis. If a closer look was needed the weekly readings were used. This approach has given us indications regarding which jobs release more aerosols. We have chosen to concentrate on the release of the corrosion product ^{60}Co since this is the most prevalent nuclide and also the most dominant contributor to the dose from aerosol discharge.

Our second approach has been to develop an instrument that measures aerosol content in ventilation ducts. Ventilation air is sampled through a nozzle inserted in the duct and led through a filter cassette using an isokinetic flow. Aerosols are collected on a Millipore filter, the same type of Millipore/coal filter cassettes that we use in the stack monitoring system. The cassette has been connected to the airflow in the duct for approximately one week after which the Millipore filter was analysed for aerosol content using gamma spectrometry. This approach was developed to be able to verify the findings in the correlation study. We have only recently started the measurement program so more detailed data should come later.

By analyzing data from the event- discharge correlation study and the duct-measurement study we should be able to optimize where new aerosol filters could be introduced and point out which jobs can benefit from actions to help reduce the release of radioactive aerosols.

Results and discussion

Correlation aerosol discharge – events in the plant

Below are figures of the monthly discharges of ^{60}Co through the stacks at each unit. Red rectangles symbolizes months when planned outages have taken place. For F2 and F3 this correlates with high aerosol discharges (figure 1 B,C), for F1 the discharge occurs more uniformly over the year (figure 1A). For F2, major remodelling work occurred late 2009 where major components in both the reactor and turbine plant were replaced. This rendered, not unexpectedly, quite a large release of aerosols.

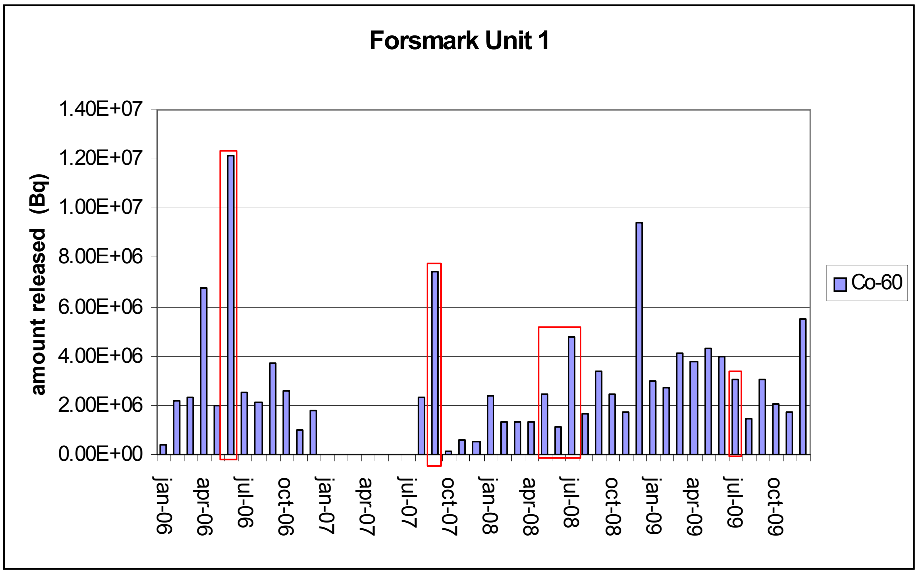

Figure 1A. Discharges of ^{60}Co from Forsmark 1.

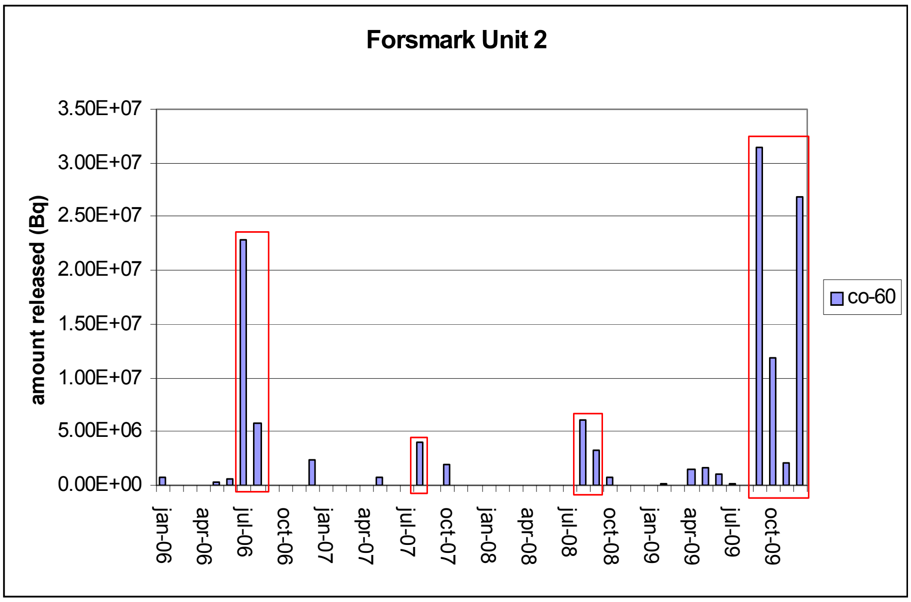

Figure 1B. Discharges of ^{60}Co from Forsmark 2.

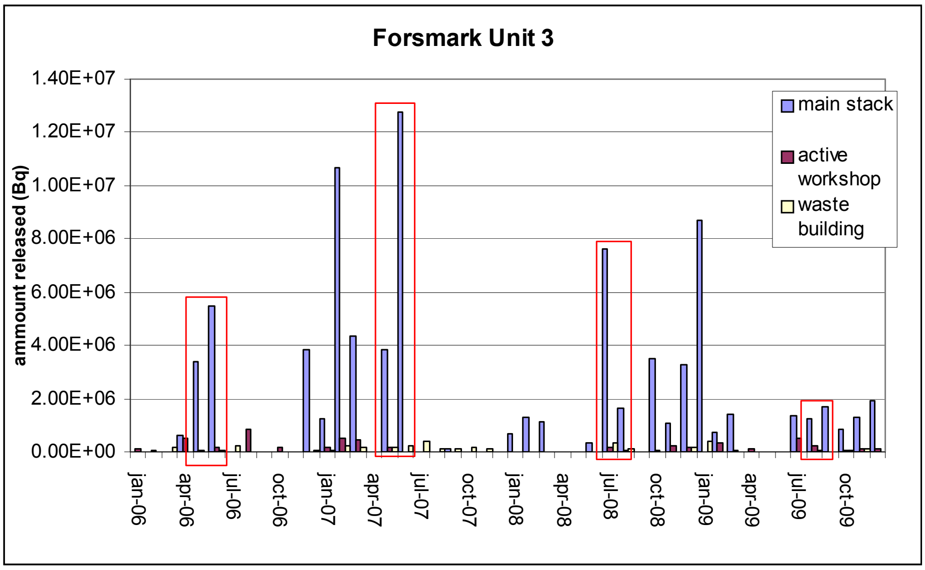

Figure 1C. Discharges of ^{60}Co from Forsmark 3.

Pool cleaning

During each outage the reactor-pool is emptied and cleaned before opening the reactor and before closing. These actions have been assumed to result in aerosol release. Cleaning of pools, some times using high-pressure washers, result in particles collected on the walls being released into the air of the hall. No filtration of the ventilation of the hall takes place before discharge through the main stack. In the correlation study it is shown that aerosols are discharged during outages, pool cleaning and opening of the reactor probably contributes to a large extent.

It is not only the reactor-pool that might give rise to aerosol release during cleaning. The fuel-flask pool is sometimes used as a waste pool where contamination ends up after work is done on control-rods, fuel elements and internals. Cleaning of the flask pool is shown to give rise to aerosol discharge if there have been aerosol generating work going on in the pool. The high peak at F3 in januari 2009 is an example of that. It probably comes from cleaning of the flask pool after control-rod segmentation during the latter part of 2008.

Ion exchange columns - flushing

Flushing of ion exchange columns was prior to more detailed study thought to be a source of aerosol release. No correlation has however been found and this might be attributed to the fact that the ventilation from the flushed tank is going through particle filters before being discharged into the air.

Waste handling

The more continuous discharge of aerosols from F1 was earlier thought to be attributed to the fact that ventilation from the waste department for solid waste went through the F1 stack but the results from our measurements in the ventilation canals (se below) show that no significant aerosol discharge emanates from the waste department. The ventilated air is filtered before the ventilation canal and it appears that the filtration works as planned.

Leakages

One other significant source for aerosol release is when leaks in the primary system occur. Leaks in the steam system might also contribute to aerosol discharge but only to a lesser extent since carry-over of aerosols to the vapour phase is very low. If a leak appears in a system carrying warm pressurized water in contact with the reactor, the possibility to steer the ventilation from that room to filter banks exist. This is not very often done with small leaks mainly because of the difficulty to identify when and where small leaks occur. The new measurement tool described above might help improve this work; it has recently been used to identify a leak in F1. Until the leak can be fixed the ventilation is now steered to the filter banks and thus the discharge is reduced.

Aerosol measurements

We have used the aerosol measurement instrument to determine from which part of the ventilation system most aerosols come. So far we have tested ventilation from the waste department at F1, the unfiltered ventilation from the reactor building at all units, and the waste department at F3. One instrument has also been used to trace a leak to a certain room at F1.

Waste department at F1

Contrary to our previous beliefs it seems as though no aerosols emanate from the waste department. All air is filtered before entering the ventilation canals and this filtration appears to work satisfactory.

Reactor building F1

The nuclides ^{60}Co, ^{58}Co and ^{51}Cr were detected on the filters sampling unfiltered air from the reactor building (Figure 2A), and the ratio between the nuclides correlates very well with the ratio between the same nuclides discharged in the stack (figure 2B). Since the nuclide distribution is slightly atypical, we can conclude that the majority of the aerosol discharge during the period at F1 has come from the reactor building, probably from the small leak recently identified.

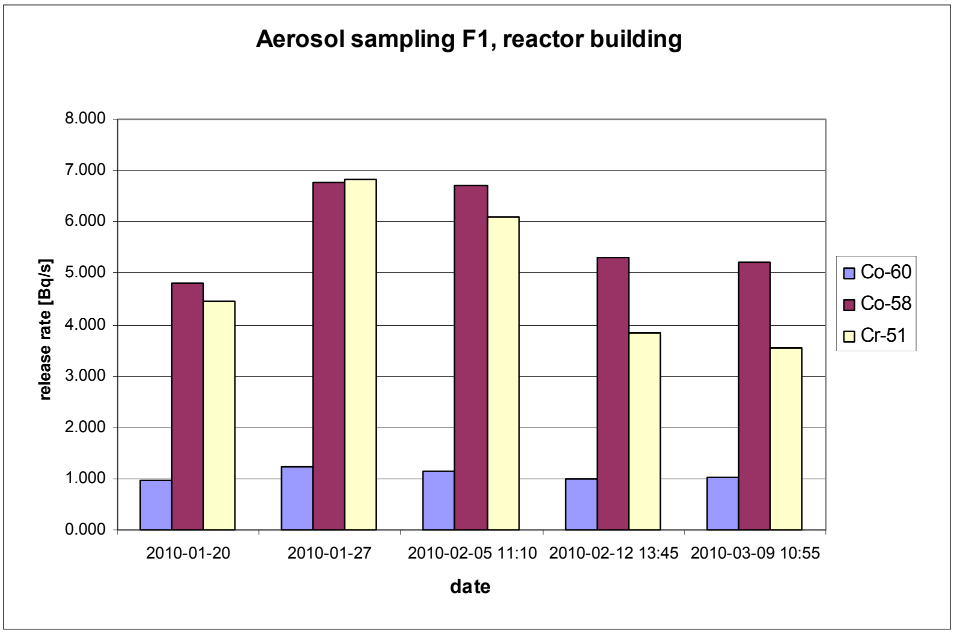

Figure 2A. Aerosol Sampling at the ventilation ducts from the reactor building at Forsmark 1.

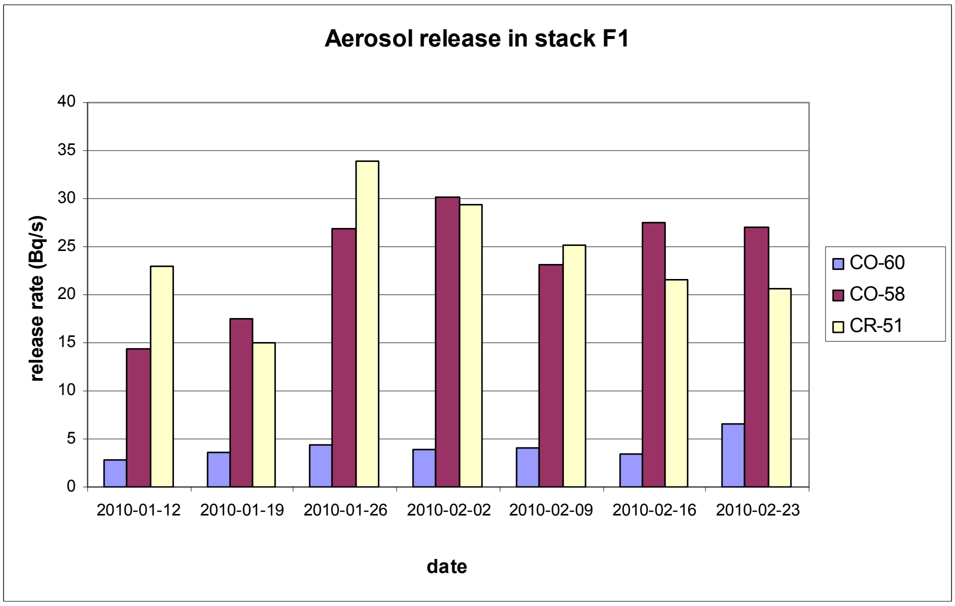

Figure 2B. Aerosol discharge from Forsmark 1.

Reactor building F2

No aerosols have been detected on the filters, which is expected since there have been no detectable aerosol discharge in the stack during the period.

Reactor building F3

Only very small amounts of ^{60}Co have been detected, which correlates with low discharges in the stack during the period.

Waste building F3

No aerosols were detected.

It has been a slight disappointment that we only detected aerosols on two instruments, but we can attribute this to the fact that there have been very low aerosol discharges from F2 and F3 during the period, which of course is positive

Conclusions

We have so far identified that pool-cleaning is a major contributor to aerosol discharge and will change the way we perform this task to reduce the release of aerosol-particles to the ventilation system. This will probably include the use of local air filters and some sort of "vacuum cleaning" of the pool walls.

It is also important that small system leaks are identified and fixed promptly, if this is not possible then ventilation should be steered to filter banks to make sure that no more elevated release of aerosols than necessary reach the environment.

It is good to note that no aerosol discharge seems to come from the waste department at F1. This is proof that the filter-banks work as intended. It is of utter importance that it is ensured that filter banks in the ventilation systems have a good filtering capacity.

We have now finished the initial study and have identified some actions that will be implemented to help lowering aerosol discharges but the work to map the ventilation system with regards to aerosols will continue to further improve our knowledge in how aerosols are produced and discharged.

A nation wide survey on drinking water radioactivity in Estonia: facts, risk assessment and remedial actions

Forte, Maurizio[1]; Ruut, Jyri[2]; Aro, Tiiu[2]; Rusconi, Rosella[1]; Trotti, Flavio[3]; Caldognetto, Elena[3]; Risica, Serena[4]; Realini, Franco[5]; Airoldi, Riccardo[5]

[1] ARPA Lombardia, Dipartimento di Milano, ITALY
[2] Health Protection Inspectorate, ESTONIA
[3] ARPA Veneto, Dipartimento di Verona, ITALY
[4] National Institute of Health, ITALY
[5] CGIAM, ITALY

Abstract

Within the frame of a Twinning Light Project sponsored by European Union, a cooperative study between Estonia and Italy has been carried out to assess the actual radiological exposure of Estonian population due to the natural radioactivity of drinking water. Actually, about 22% of people is exposed to doses higher than 0.1 mSv/y (reference value for the Total Indicative Dose according to EU Directive 98/83) due to high concentrations of Ra-228 and Ra-226.

Estonian authorities were facing the problem of finding a feasible solution, but both a comprehensive overview of the situation and a deep cost benefit analysis were still missing.

Available radiometric data (nearly 1,000), as provided by Estonian institutions, were fully analysed in order to assess their representativeness and to identify the most critical situations. Though highest radioactivity values were found in the North of Estonia, where Cambrian Vendian waters are used, the few available data for the remaining part of the country cannot definitely assure compliance of drinking water, as previously supposed. On this basis, a new monitoring program has been proposed and the most suitable analytical tools have been suggested.

The effectiveness in radium removal of presently operating Fe/Mn treatment plants has been assessed. Since the resulting removal efficiency (about 15 %) was inadequate, a thorough cost benefit analysis of commercially available treatment plants for radium removal has been carried out, the main constraint being the small size of Estonian aqueducts (59 % serving less than 500 people).

Production and management of radioactive wastes and effluents in water treatment plants was examined on the basis of the technical documents issued by EU and IAEA (RP 122 and 135, IAEA RS-19).

A review of existing international guidelines was provided, and regulatory proposals were given in the light of proper risk assessments.

Regularities of long-term changes in artificial radionuclides content in the Barents Sea ecosystem

Matishov, Gennady[1]; Matishov Dmitry[1]; Solatie Dina[2];
Kasatkina Nadezda[1]; Leppänen Ari-Pekka[2]

[1] Murmansk Marine Biological Institute of the Kola Science Center of RAS, RUSSIA

[2] STUK – Radiation and Nuclear Safety Authority, Regional Laboratory in Northern Finland, FINLAND

Abstract

The comparative analysis is performed for the radiation contamination of the Barents Sea ecosystem in the 1980s and 1990s and in the first decade of the 21st century. Natural purification processes in the marine environment are the main factors of the decrease in the intensity level of artificial radioactive isotopes. These processes include repeated dilution, nuclear decay, sorption by sediments and suspended solid material, and accumulation by aquatic inhabitants. A stable decreasing trend is observed for the intensity level of artificial radioactive isotopes in the Barents Sea.

Introduction

The phenomenon of artificial radioactivity has been observed for the natural environment since the first nuclear tests in 1940s and continues at present. The disposal and dumping of both solid and liquid nuclear waste were typical for the Arctic and the northern seas. Radiological hazard sites can be observed in the coastal area, which are concentrated in Kola and Motovsky bays; the city of Murmansk, as well as towns: Severomorsk, Polyarny, and Gadzhievo; and the following fjords: Saida, Olenya, Pala, Zapadnaya Litsa, Ura, and Ara. Gaseous, liquid, and solid nuclear wastes are being stored there. The European reprocessing plants are the most significant producers of nuclear waste in the Arctic Ocean. The Sellafield factory (Great Britain) is the biggest one amongst them. The total activity of radionuclides discharged by these plants was 160×10^{15} Bq. Around 10–20% of ^{137}Cs discharged in Sellafield and around 30% of ^{90}Sr enter the Barents Sea. The plume of west European discharges crosses the shelf area of the Barents Sea and reaches the Central Polar Basin in six years (Nikitin et al., 1991; Nies, Nielsen, 1996; Matishov, Matishov, 2004). The input of Chernobyl accident provided from 10 to 20% of the radioactive pollution of the Kara and Barents seas in the 1990s.

The concentration of radioactivity has decreased an order of magnitude in the Arctic marine ecosystems from the 1960s to the 1990s as a result of water self-purification, natural decay of ^{90}Sr and ^{137}Cs, and the reduction of nuclear waste dumping. At the same time, with the time passed after the Chernobyl accident and the moment nuclear tests on the Novaya Zemlya and adjacent shelf were ceased, it is reasonable to follow the evolution of anthropogenic radioisotopes in the first decade of the 21st century. Of vital importance are also the problems of radiation safety, ecological standardization and forecast of the long-term effect of low doses on the marine biota. Not less important is the forecast of ecological security in case of nuclear energy installations' application while oil and gas development and extraction on shelf, in particular, at the Stockman gas condensate deposit.

Murmansk Marine Biological Institute of the Kola science center of the Russian academy of sciences (MMBI KSC RAS) has been carrying out regular monitoring of artificial radionuclides in the environment and organisms of the West Arctic seas since 1990 (Matishov 1994, 1995, 1996; Smith et al. 1995; Matishov, Matishov, 2004). In 1992-1999 radiation monitoring was carried out by MMBI in co-operation with Radiation and Nuclear Safety Authority (STUK, Finland). This co-operation got new development in 2006-2007.

Material and methods

Materials for radioecological investigations were collected during both coastal and marine multi-disciplinary expeditions of MMBI KSC RAS.

Preliminary concentration of cesium isotopes from water samples (100 l volume each) were performed by the cellulose-inorganic sorbent *ANFEZH*. The measurements of ^{137}Cs, ^{40}K, and ^{226}Ra activity were made by the *Canberra* gamma-spectrometer. To determine the specific activity of ^{90}Sr oxalate-radiochemical preparation was applied with subsequent measurement of counting sample at the *Beckman LS-6500* alpha-beta-scintillation counter by Cherenkov radiation of daughter radionuclide ^{90}Y. The anion exchange method was applied to analyze the Pu isotopes, when ^{242}Pu was used as a tracer agent. To determine Polonium samples were treated by tracer ^{209}Po and isotope ^{210}Po was deposited on a silver disk (Vesterbacka, Ikäheimonen, 2005). The activity of ^{238}Pu, ^{239,240}Pu, and ^{210}Po isotopes was measured by the alpha-spectrometer *Canberra Alpha Analyst.* The standard *Genie-2000* software was used for spectrum analysis.

The gamma-emitting isotopes and ^{90}Sr activity were measured at the certified radioecological laboratory of MMBI KSC RAS. The ^{238}Pu, ^{239,240}Pu isotope activity was measured at the laboratory of STUK. The inter-calibration, which gave good concordance of results obtained at two laboratories, was carried out during the joint activities.

Results and Discussion

The radioecological pattern of the Barents Sea at the end of the twentieth century was quite patchy. The ^{137}Cs activity concentration in the waters was relatively high at the end of the 1980s, from 10 to 40-90 Bq/m^3. The concentration of this isotope decreased in the middle of the 1990s an order of magnitude and did not reach more than 2-15 Bq/m^3. The content of ^{137}Cs in the waters of the Zapadnaya Litsa Fjord was 4.9 Bq/m^3, of the Ara Fjord – 4.7 Bq/m^3, in the entrance of the Kola Bay to the Barents Sea – 8 Bq/m^3. The volumetric activity of ^{90}Sr varied from 1 to 7 Bq/m^3 in the 1990s. The ^{239,240}Pu activity decreased from 13-18 to 6-11 Bq/m^3 from the 1980s to the 1990s. The waters close to the radioactive waste treatment plant RTP «*Atomflot*» were enriched by ^{239,240}Pu of 18-70 Bq/m^3 at the end of the 1990s (Matishov et al. 1996, 1997; Matishov, Matishov, 2004).

The specific activity of ^{137}Cs in the bottom sediments of the Barents Sea varied from 10 to 30 Bq/kg dry weight. The coastal areas of Spitsbergen, the Kola Peninsula, Novaya Zemlya, Franz Josef Land, and the shallow waters of the Pechora Sea were characterized by lower activity of ^{137}Cs, from 0.6-3.0 to 6.0 Bq/kg. Relatively higher concentrations of ^{137}Cs (5-11 Bq/kg) are typical for bottom sediments in all troughs and trenches in the open areas of the shelf. Clayish sediments covering the bottom of the Central Trench (300-380 m deep) contained 5-9 Bq/kg of ^{137}Cs and 0.2-0.8 Bq/kg of ^{90}Sr (Matishov et al. 1994, 1995, 1996; Matishov, Matishov, 2004). ^{239,240}Pu was found everywhere in the sediments of the Barents Sea shelf, from 0.1 to 20 Bq/kg. The distribution of this isotope depends on the sediment type and geographical distance to the nuclear weapons range. The silts of the Central Trench contain from 0.9 to 3.2 Bq/kg of ^{239,240}Pu. The concentration of this isotope is quite low in sands and aleurites of the shallow waters (0.1-1.0 Bq/kg); it may increase up to 3.2–4.3 Bq/kg in some trenches and downwarpings, and it is as high as 13 Bq/kg in the South-Novozemelskaya Trench to the south of Chernaya Guba (Matishov, Matishov, 2004). The bottom sediments of the Zapadnaya Litsa, Saida, Pala fjords (Kola and Motovskii bays) are characterized by a concentration of 2 to 9 Bq/kg of ^{239,240}Pu, and higher concentrations of ^{137}Cs (30-120 Bq/kg) and ^{60}Co (from 4-10 to 80 Bq/kg) (Matishov et al. 1996; Matishov, Matishov, 2004). These fjords are the nuclear-power submarine depot complexes.

Macroalgae, mostly *Fucus* spp. and *Laminaria* spp., accumulate the isotopes in the coastal waters. The maximal activity of ^{137}Cs was found in the early 1980s (up to 10 Bq/kg) and after the Chernobyl event (up to 7 Bq/kg) (Matishov 1995; Matishov, Matishov, 2004). In the 1980s and 1990s, the macrophytes contained up to 0.4-5.0 Bq/kg of ^{137}Cs, 0.3-3.0 Bq/kg of ^{90}Sr, and 0.02-0.3 Bq/kg of ^{239,240}Pu. The local contamination was focused on the water area close to the vessel «Lepse» belonging to RTP «Atomflot». This vessel is used as a spent-fuel storage; the concentration of isotopes in the macrophytes here was as high as 20–46 Bq/kg of ^{137}Cs, 1.2 Bq/kg of ^{134}Cs, 1.6 Bq/kg of ^{60}Co, and 4.6 Bq/kg of ^{152}Eu (Matishov, Matishov, 2004). However, this contamination is several orders lower than that observed in other areas after the Chernobyl event.

To ascertain the contemporary degradation regularities of anthropogenic radioactive substances, the Barents Sea water, bottom sediments, and algae – bio-indicators of radioactive contamination – were analyzed in 2005-2009. It is quite obvious that a natural decrease of artificial radionuclides' content is typical of all elements of marine ecosystem for the last decade (Matishov et al. 2004, 2005, 2007). Obviously, all the ecosystem elements are characterized by decrease in the anthropogenic isotope concentrations for the last decade.

The volumetric activity of the radionuclide ^{137}Cs in the Barents Sea in 2005-2007 is quite equable for all the investigated areas. The isotope activity is low and varies from 1-2 to 3.6 Bq/m^3, decreasing an order of magnitude compared to the 1970s. The maximal ^{137}Cs content of 6.5 Bq/m^3 was registered in Kola Bay waters near the area of RTP «Atomflot» outfall. Relatively high concentrations were found in the coastal area on the way of the Murmansk costal current. The activity of ^{137}Cs in Dalnezelenetskaya and Teriberskaya bays varied about 3.4-3.6 Bq/m^3. The activity of the same isotope constituted about 2 Bq/m^3 in the waters off the Novaya Zemlya western coast and, thus, was close to average for the Barents Sea. The ^{90}Sr comes from the Norwegian Sea by the warm currents, according to the data of 2005-2009. The Atlantic warm waters are characterized by increased concentration of ^{90}Sr, reaching up to 6-8 Bq/m^3. The concentration of ^{90}Sr is several times lower and is about 1-4 Bq/m^3 in the south-eastern sector of the Barents Sea, where the waters are already transformed. The activity of this isotope is 1.2-3.9 Bq/m^3 along the Novaya Zemlya coast.

The present-day contamination level of the bottom sediments in the Barents Sea is quite low. The average specific activity of ^{137}Cs is 1-3 Bq/kg and ^{90}Sr is 0.2-2.0 Bq/kg in the bottom sediments for the period of 2005-2009 (Fig 1a). The predictable activity of the isotopes is usual for all the bottom sediments of the Barents Sea with some exceptions for the coastal areas. The minimal activities of ^{137}Cs (0.5-2.9 Bq/kg) and ^{90}Sr (0.1-2.0 Bq/kg) were found in the open areas of the sea, where quartz is the main rock-forming mineral. Quartz is characterized by a low sorption capacity. The local increase of ^{137}Cs activity (5-8 Bq/kg) was observed in troughs near the Franz Josef Land. The bottom sediments there are mostly formed by silts. The bottom sediments off the Novaya Zemlya coast contained up to 4.7 Bq/kg of ^{137}Cs. The specific activity of ^{238}Pu in bottom sediment along the standard section No. 6 was 0.02-0.04 Bq/kg. ^{239}Pu activity was 0.4-1.3 Bq/kg. The analyzed ratio ^{238}Pu/^{239}Pu in the sediment samples showed that the plutonium is from global fallout from the atmospheric nuclear weapons testing.

The main part of system radioecological studies is the establishment of balance mathematical models. The obtained data on radionuclide distribition in waters was applied to calculate the current balance of artificial radionuclides in the Barents Sea. The calculation results show that the input of ^{137}Cs and ^{90}Sr is largely determined by the radionuclides exchange on the western boundaries of the Sea, where the resulting transfer is always directed from the Norwegian Sea to the Barents Sea. The contribution of atmospheric fallout and river runoff into the total radionuclides input is negligible at present as compared to radionuclide input with the Atlantic waters which is about 64 TBq/year of ^{137}Cs and 271 TBq/year ^{90}Sr.

The bottom sediments sampled from the station on the north-western slope of the Murmansk Bank, which is affected by the Norwegian Current, were characterized by the presence of ^{125}Sb (half-life period 2.77 years). This anthropogenic radionuclide, together with ^{99}Tc, is usually associated with liquid discharges of the nuclear industry plants. Its presence in the Barents Sea indicates that a small amount of radioactive wastes of the Sellafield Plant comes with Atlantic waters.

Some of the Barents Sea coastal areas, including Kola Bay, are characterized by increased concentration of the anthropogenic radionuclide in the bottom sediments. These areas belong to the local sources of pollution, such as numerous depot complexes of atomic submarines and icebreakers, the places of the moorings and waste reclamation of these vessels, and radioactive waste storage sites. Bottom sediments within the territory of RTP «Atomflot» are characterized by the highest levels of ^{137}Cs up to 20 Bq/kg (Fig 1b). Besides ^{137}Cs and ^{90}Sr some other anthropogenic radionuclides, such as ^{152}Eu, ^{60}Co, ^{134}Cs, were found in this sample. The presence of these isotopes is not typical for the open parts of the Barents Sea.

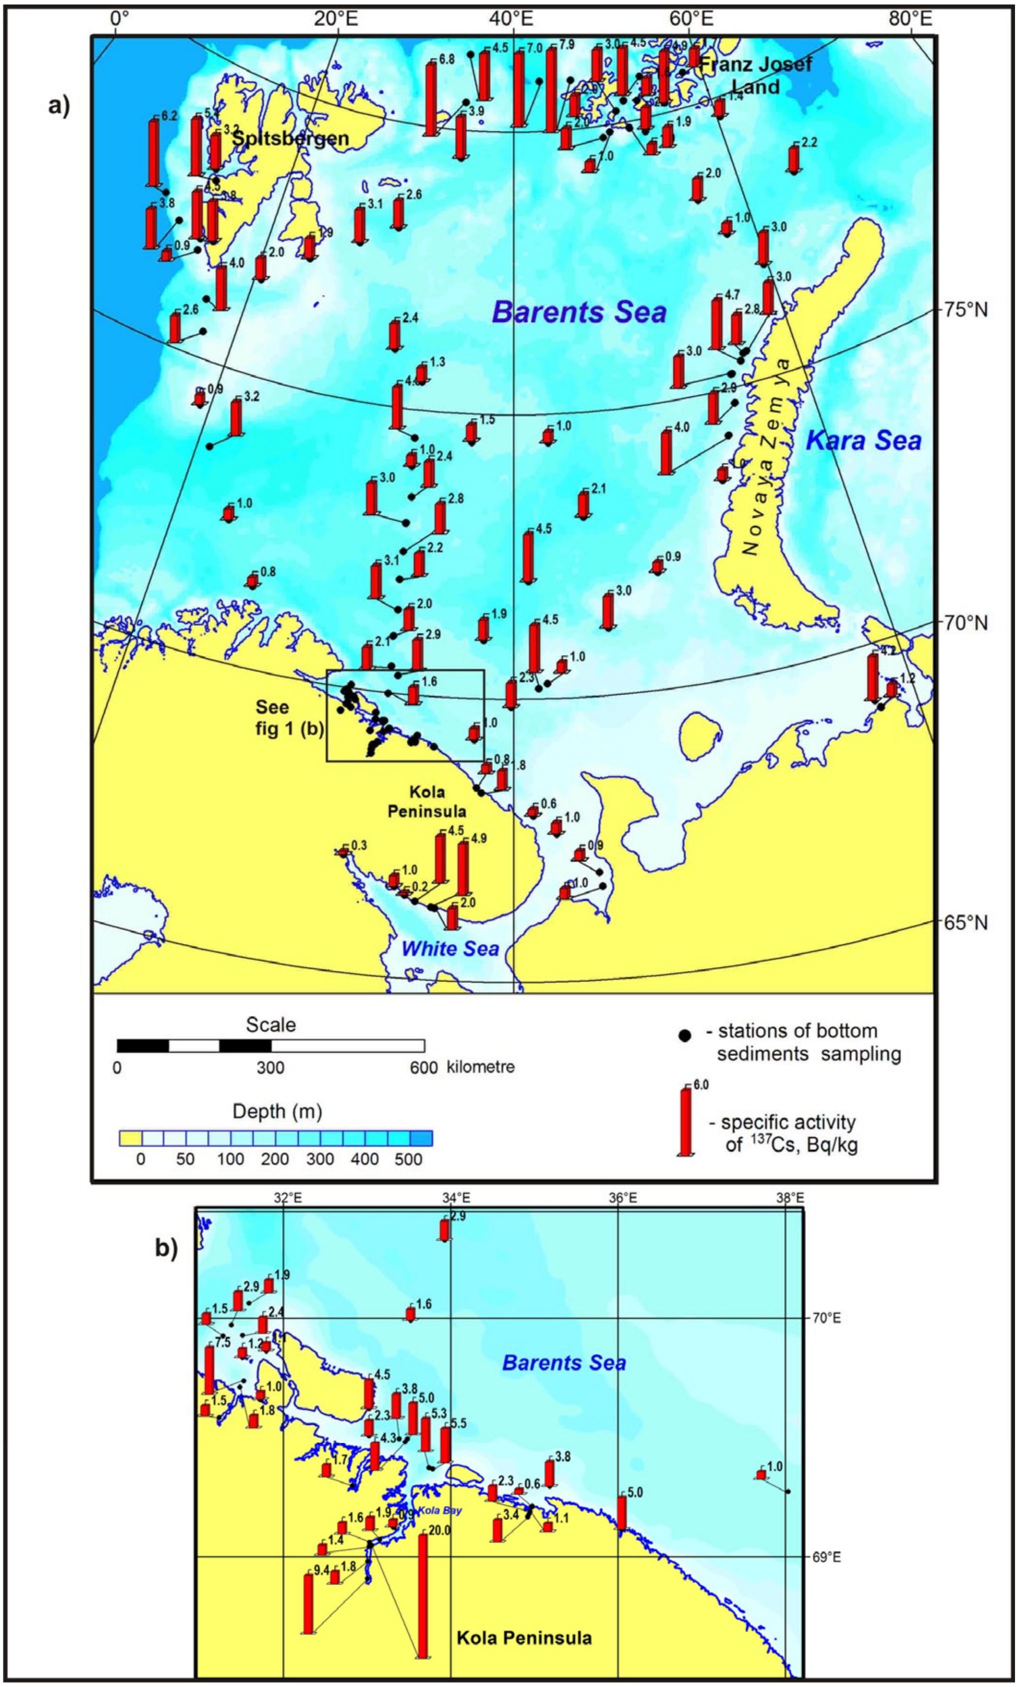

Fig. 1. Specific activity of ^{137}Cs in bottom sediments of the Barents, Greenland and White Seas, 2005-2009.

The activity of ^{137}Cs in contemporary macrophytes (Fucus vesiculosus. being mainly studied) varied from 0-1.2 to 8.4 Bq/kg dry weight and 90Sr, from 0.6 up to 4.0 Bq/kg (Table 1, predominantly *Fucus vesiculosus*). The maximal concentration of ^{137}Cs of 8.4 Bq/kg was found for the littoral macrophytes near the settlement of Mishukovo close to «Atomflot» Enterprise.

Table 1. Specific activity of artificial and natural radionuclides in *Fucus vesuculosus* of the Barents Sea, 2007.

Sampling area	Coordinates		Specific activityof of radionuclide, Bq/kg dry weight		
	N	E	^{137}Cs	^{90}Sr	^{40}K
Kola Bay, Abram-Mys settlement	68° 58' 53"	33° 01' 41"	<1,2	0,8±0,3	958±51
Kola Bay, Retinskoe settlement	69° 06' 48"	33° 22' 00"	4,7±1,0	2,3±0,9	591±70
Kola Bay, Min'kino settlement	69° 59' 36"	33° 01' 36"	<1,27	—	840±100

Kola Bay, town of Severomorsk	69° 05' 00"	33° 25' 42"	<2,1	0,6±0,3	748±9
Kola Bay, Mishukovo settlement	69° 02' 39"	33° 02' 42"	8,4±1,7	1,8±0,7	707±9
Ura-Guba	69° 18' 08"	32° 50' 43"	<1,66	4,0±0,5	558±68

Radioecological studies of the Barents Sea commercial fish showed that the present-day activity of artificial radionuclides is extremely low. All investigated species (Atlantic cod, haddock, long rough dab, spotted wolfish) contained ^{137}Cs of less than 0.2 Bq/kg raw weight. Thus, the radioactivity of the Barents Sea ichthyofauna nowadays is primarily determined by the presence of natural radionuclide ^{40}K.

Temporal changes in the ^{137}Cs content have been best studied in Atlantic cod from the Barents Sea (Fig. 2). The average ^{137}Cs concentrations are known for the period beginning from 1979. The maximum ^{137}Cs content in cod (2.2 Bq/kg raw weight) was observed in 1982, which may have been accounted for discharges from radiochemical enterprises of the Western Europe. The maximum ^{137}Cs content in cod from the Barents Sea was delayed by four to five years with respect to the maximum amount of this nuclide in water (Matishov et al. 2001). The ^{137}Cs content in cod of the Barents Sea after 1982 was diminished exponentially with a seven-year half-life period. In 2005-2009, the ^{137}Cs concentration in cod did not exceed 0.2 Bq/kg raw weight. Taking into account the current composition of food consumed by human beings, the dose of radioactive cesium received through eating fish falls into the «radioactively safe zone».

In summary, the present-day concentrations of the anthropogenic isotopes in the ecosystem elements are evidence of the absence of high-energy sources of artificial radioactivity after the cessation of nuclear weapons tests on Novaya Zemlya and the adjacent shelf in 1950-1960s and the Chernobyl global emission in 1986.

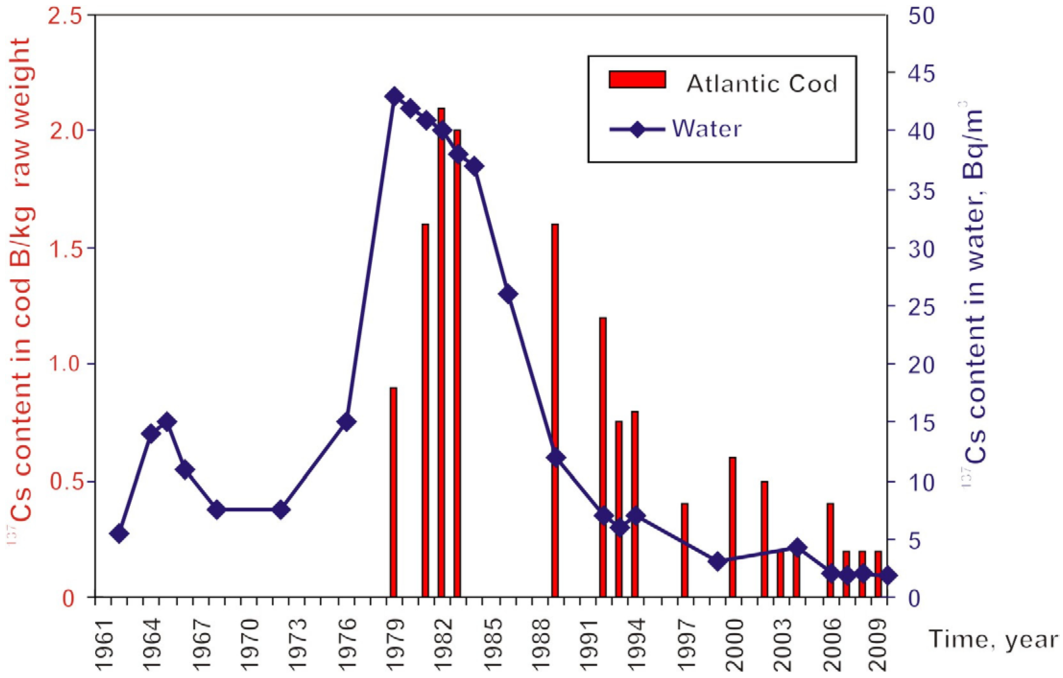

Fig. 2. Average ^{137}Cs concentration in water and in Atlantic cod from the Barents Sea (1979-2009).

Conclusions

The major source of the present-day radioactive pollution in the Russian Western Arctic are still the long-living isotopes of ^{137}Cs, ^{90}Sr, and ^{239,240}Pu, emitted during nuclear weapons tests in the middle of the twentieth century. Some artificial radionuclides originating from the Sellafield factory are coming with the Atlantic waters. The impact of local atomic power fleet and transport complexes is registered in sites 10-20 km apart.

Natural purification processes in the marine environment, such as repeated dilution, nuclear decay, sorption by sediments and suspended solid material, and accumulation by aquatic inhabitants, are the main factors of the decrease in the intensity level of artificial radioactive isotopes. Against the background of radioactive pollution decrease, studies on other natural previously unexamined radionuclides (^{40}K, ^{226}Ra, ^{228}Th, ^{210}Po and others) may become a question of interest.

Human dose pathways from forests contaminated by atmospheric radionuclide deposition

Rantavaara, Aino; Ammann, Michael
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

After radionuclide contamination of forests, the potential health risk of both the early and late phase radiation exposure of people using forests needs to be assessed. Radionuclides vary in their exposure characteristics. Short-lived ^{131}I can be a significant source of internal and external radiation in the first weeks. Long-lived ^{137}Cs may call for long-lasting surveillance of forest products, and ^{134}Cs contributes to human doses for a few years. ^{90}Sr is seldom a significant contributor to the radiation doses from forests unless there is a high surface contamination of berry plants and mushrooms. Radiation doses depend on the ways people use forests and forest products. Consumption rates of wild foods and the time spent in forest vary by countries and population groups. Dose pathways that need attention are the ingestion of wild foods, the handling and use of wood ash, and the exposure to external radiation in forests particularly in the first weeks after radionuclide deposition.

A hypothetical contamination scenario was used to demonstrate the importance of the different pathways to the human doses. The forest food chain and dose model of RODOS, a European emergency response system, was used for scenario assessment. The assessments show that the highest annual doses arise from the ingestion of wild foods from the first harvest after deposition of ^{131}I, ^{134}Cs, ^{137}Cs and ^{90}Sr in early July. Exposure of adults to external radiation from ^{131}I in forest vegetation and ground is important in the first weeks. Small scale users of fuel wood are exposed via an additional dose pathway through the use of contaminated ash for enrichment of garden soil. Regular ash fertilization accumulates ^{137}Cs in soil year by year. A maximum annual dose of 60 $\mu Sv\ a^{-1}$ was estimated to residents due to stay in ash-fertilized garden, as late as seventy years after the hypothetical contamination event (100 $kBq\ m^{-2}$). Of course, actual doses will depend on the details of exposure situation. Nevertheless, the presented assessment may help in understanding the relevant pathways. Such an understanding is important when giving advice on the safe use of contaminated forests as are regionally adapted assessment models and knowledge of the local forestry practices.

Introduction

Atmospheric release and the consequent distribution and deposition of radioactive material in rural areas may present a threat to radiation safety of people using forests. The deposition pattern can vary substantially due to the characteristics of the release, weather conditions during the passage of the plume, and the distance from the source of release. Environmental and ecosystem related processes change the initial distribution of radionuclides in forests. In addition, radioactive decay reduces the overall activity in forest.

Radionuclide contamination of forests has been a concern of experts on radioecology, radiation protection and forestry since the Chernobyl accident in 1986. In recent decades long retention times of radioactive caesium in the nutrient cycle of forest became evident. Only insignificant losses of radionuclides through surface runoff or fixation in soil minerals were detected in boreal forests on podzolic soil horizons (Tikhomirov and Shcheglov 1994; Bergman 1994, Dahlgaard et al. 1994). Relatively high uptake of radioactive caesium from soil to forest vegetation and further to wild foods was also confirmed (Aarkrog 1994; Rantavaara 1990).

The aim of the present study was to clarify human dose pathways after radionuclide contamination of forests. Comparative model predictions of the potential doses to different users of forests were assessed and factors modifying the doses were referred to.

Dose pathways from contaminated forest

Radionuclides distributed in trees, understory, ground layer vegetation and soil are sources of external exposure to people spending time in contaminated forests. Sawn timber and logs used as building material can expose people to external radiation in residential and working environments. Living year-round (7000 h a^{-1}) in a wooden house made of 15-20 cm thick logs requires that the activity concentration of ^{137}Cs is less than 1700-2000 Bq kg^{-1}(80% dry matter) in order that the dose from building material to residents remains below 1 mSv a^{-1}. For sawn timber used in a timber-framed detached house the respective ^{137}Cs concentration level would be 2400 Bq kg^{-1} (80% dry matter). The dose assessment model MATERIA (Markkanen 1995) was used for this estimation. Various other wood products in residential environments, for instance furniture, are causing considerably lower doses than wood used as building material (IAEA 2003).

Wood ash concentrates those radionuclides that are not released to the atmosphere during combustion, e.g. isotopes of Cs and Sr. The concentration factor for the combustion of wood ranges from 50 to 200, and corresponds to mass ratio of dry fuel and ash. Workers involved in disposal and recycling of ash may receive the highest individual doses amongst the workers in the production chain of wood energy (Vetikko et al. 2004).

Ingestion of radionuclides in wild berries, mushrooms and game meat is often the most significant dose pathway from forest, mostly due to the consumption of large amounts of wild foods. Mostly minor doses are received from the inhalation of airborne radionuclides during the passage of a radioactive cloud or from resuspended particles, soil or ash dust, if the instructions for protection of workers and the public are followed.

About assessment data

The radiological significance of a contaminating event depends on the characteristics of deposited radionuclides, their decay rates, type and energy of radiation and their chemical behaviour in natural ecosystems and human metabolism. Site conditions and forest management practices govern the radionuclide dynamics in forests.

The dose that is received within the first year depends crucially on the season during which the radionuclide deposition occurred. Furthermore, the time from deposition to the actual radiation exposure needs to be taken into account. The longer the delay, the lower is the dose contribution from short-lived nuclides and from foliar contamination of plants. The ways people are using forests and forest products varies and requires surveying. For instance, berry and mushroom pickers und hunters have distinctive consumption patterns. Forestry workers were assumed to be exposed to radiation during working in forest only; they may still belong to other subgroups of users of forests.

It is challenging to quantify radionuclide flow in forests, a continuously changing ecosystem with a rotation period of about 80 years in Central Europe and even longer in sub-arctic conditions. Of great value to radioecology has been the experience gained in forest research and the collaboration with organizations that have comprehensive knowledge of forest. State-of-the-art sampling methods are essential for obtaining reliable field data on radionuclides in forest (Aro et al. 2009). There exist several assessment models for forests. The validity of some of them was compared in the BIOMASS programme of IAEA and reviewed by Shaw et al. (2005).

Two nuclear accidents in the past caused widespread contamination and had also an impact on forests in boreal and temperate Eurasia and America. These were the accident at the Chernobyl nuclear power plant in Ukraine in 1986 and the chemical explosion in the nuclear fuel processing plant Mayak near Kyshtym, Cheliabinsk province, Siberia in 1957 (Trabalka et al. 1980; Jones 2008). These accidents were widely studied and provided important radioecological field data on radionuclide behaviour in forests. Another valuable data source were studies related to the global fallout from atmospheric nuclear testing during 1945-1980. Also some smaller events have contaminated forests, albeit on a limited scale, and were subject to radioecological studies (Auerbach 1987). Radionuclide transfer in forests was one of the topics in a literature review published by IAEA (2009) and in a handbook on transfer parameters (IAEA 2010), which, regarding forests, was summarized by Calmon et al. (2009).

Dose assessment model

The forest food chain and dose assessment model FDMF, which is part of the European emergency response system RODOS, was used for the dose assessments (Rantavaara et al. 2001). The parameters of FDMF were derived from Finnish and other European data from experimental field studies, survey data on people's outdoor activities and consumption of wild foods. The compartment structure and transfer processes considered in FDMF allow assessment of the radionuclide flow in forests (Fig. 1).

Using the RODOS system, predictions for large affected areas can be provided. Through regional parameters the assessment results represent the conditions in calculation area. During dry weather the time-integrated air concentrations are used in the calculation of the initial activity densities of radionuclides on different surfaces within the forest. These surfaces are the forest soil, understory vegetation, and crown and trunk of trees. The deposition onto these surfaces during rain depends on the development stage of the canopy, the amount of rain and the total deposited activity. The result of a prognosis calculation depends on the choices made during the setup of a model run. The choices can be, e.g. the type of forest, the population group, the species of plants and animals providing wild foods, the type of fuel wood and the details of the use of wood ash. The model takes into account height and biomass density of the forest type chosen, regional consumption rates of wild foods and losses of radionuclides during cooking.

FDMF calculates the time-dependent radionuclide contents in forest compartments, activity concentrations in forest products and radiation doses to various population groups (hunters, pickers, public). The need for intervention and availability of acceptable wood and wild food products can be further assessed with another RODOS model, LCMforest (Rantavaara, Ammann 2005).

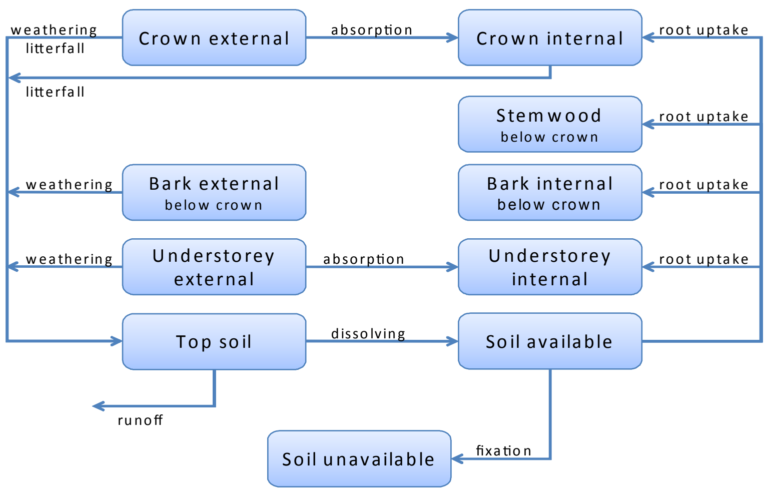

Fig. 1. Compartments of the dynamic module of the forest model FDMF and the processes changing their radionuclide content with time.

Calculation scenario

A hypothetical contamination of two forest types was assumed to have happened in July. The activity inventories of the forests contained the following four radionuclides: ^{90}Sr, ^{131}I, ^{134}Cs and ^{137}Cs (Table 1). The initial contamination exceeded manyfold the average activity densities of these radionuclides in most countries after the Chernobyl accident. The activity ratios of the radionuclides were roughly those found in Fennoscandia in early May 1986. Dry deposition was assumed to happen on the 8th of July. An advanced Scots pine *(Pinus sylvestris L.)* forest was chosen to represent the Northern Europe and a coniferous forest type the Central Europe.

Wild food species were blueberry *(Vaccinium myrtillus L.)*, moose *(Alces alces)* and mushrooms corresponding to an aggregated transfer coefficient of 0.05 m^2 kg^{-1} for isotopes of Cs. For Central Europe this uptake category included *Cantharellus cibarius, Boletus edulis, Collybia sp.*, several *Lactarius* sp., *Leccinum* sp. etc. and for Northern Europe *Cantharellus tubaeformis Cratellus cornucopioides*, some of the *Russula sp.* etc.

Table 1. Radionuclides included in the assessment, their half lives and activity inventories in forest at the end of radionuclide deposition.

Radionuclide	Half life[1)]	Inventory (Bq m^{-2})
^{90}Sr	28.79 y	10^3
^{131}I	8.02 d	5×10^5
^{134}Cs	2.065 y	5×10^4
^{137}Cs	30.07 y	10^5

[1)] Chu SYF, Ekström LP, Firestone RB. The Lund/LBNL Nuclear Data Search, Version 2, February 1999.

Potential doses of adults from external radiation exposure were calculated from air kerma in boreal Scots pine forest. In FDMF the conversion from kerma to effective dose of an adult takes into account the source compartments in forest and a correction for the size of a subject to obtain effective dose for a five years old child. Doses from ingestion of wild foods were estimated for Central Europe (CE) and Finland (FI).

Activity concentrations in timber for building (logs, sawn timber) and fuel wood (split firewood) were assessed. The dose pathway of using wood ash for soil enrichment was assessed with FDMF. Doses to residents were derived from ^{134}Cs and ^{137}Cs accumulating in soil due to a regular distribution of ash from fireplace to kitchen garden. The fuel wood from an affected area was used. Other assumptions were:

- delay since felling of trees until distribution of ash: 1 year
- ash application rate: 0.2 kg m^{-2} in a year
- surface soil was managed after each ash application, denoting a radiation attenuation factor of 0.3
- exposure time of adult residents to radiation from ash in garden: 300 h/year.

Results of scenario calculations

In the first week after radionuclide deposition ^{131}I in crown layer and in the entire forest contributed to the dose rate more than ^{134}Cs and ^{137}Cs together (Figs. 2 and 3). After the first week the ground layer contributed most to the dose rates in forest.

The activity concentrations in logs and split firewood (Fig. 4), the activity density accumulating in garden soil via regular ash application (Fig. 5) and the annual effective dose from additional ^{134}Cs and ^{137}Cs in garden (Fig. 6) due to ash mixed in soil indicate a gradual increase of the annual doses to residents during decades. The dose from the external exposure to radionuclides in ash distributed in the garden soil was approaching 0.04 mSv a^{-1} forty years after the deposition. The contribution of ^{134}Cs to the dose was negligible. The maximum annual dose to adult residents was estimated to be 0.06 mSv a^{-1} about seventy years after deposition.

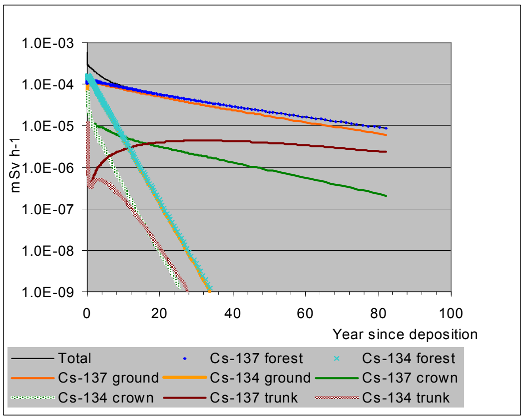

Fig. 3. Effective dose rate (mSv h^{-1}) due to radiation from ^{134}Cs and ^{137}Cs in ground, trunk and crown layers, and the total dose rate in forest. Region FI.

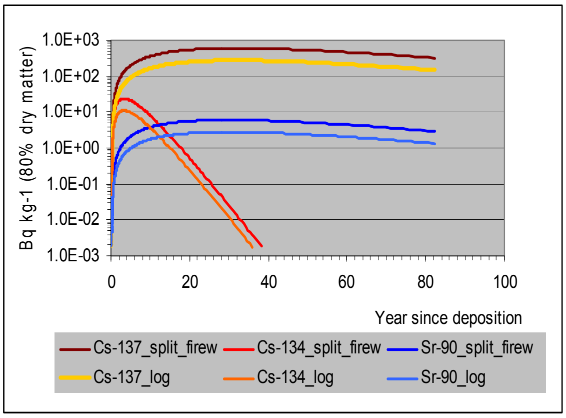

Fig. 4. Activity concentration in timber(Bq kg^{-1}, 80% dry matter) for building (logs) and in split firewood.

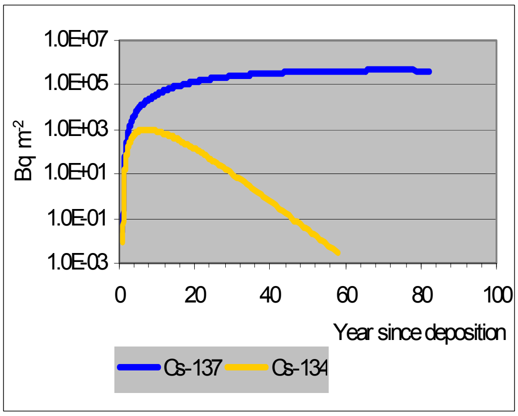

Fig.5. Activity density of ^{134}Cs and ^{137}Cs in kitchen garden due to soil enrichment with wood ash.

The doses to adults from external exposure in forests (Fig. 6) were used to give an idea of the differences between population groups. Adults in Central Europe received 33% and hunters and pickers 44% of the dose that adults in Finland would receive. Within the Finnish population the doses to different population groups were, again compared to adults, 33% for children (5 years of age), 140% for hunters and 110% for pickers. Forest workers were assumed to work 150 hours per month in forest without shielding from a harvester or other machines. Annual doses during 11 months per year were 15-fold compared to the dose of an adult (Fig. 6).

Wild foods contributed to the dietary dose significantly more in Northern (Fig. 7) than in Central Europe (Fig. 8). The doses differed mainly because of lower consumption rates in Central Europe (Fig. 9). Children (5 y) were not assumed to consume wild foods or go to the forest in CE. Radionuclides deposited on plant surfaces close to harvest or hunting seasons contributed significantly to the first year doses from blueberry and moose meat.

Discussion

The various dose pathways contribute to the human dose from forests in relation to radionuclide, region, population group, and the time since forest contamination. The ways people use forests and forest products are changing in time. Consumption rates of wild foods and the time people spend in forests should be surveyed regionally at intervals of a decade or so. A suitable survey methodology should be used, the types and species of wild foods specified and cultural and other sources of regional variation considered. All parameters determining the effective dose from external radiation or dose commitment from radionuclides ingested in wild foods are important independent of the nature of data.

Natural processes and forest management are changing the radionuclide distribution in forest vegetation and soil. Together with consumption rates they are contributing to temporal variation in radiation doses received from wild foods. The dominant dietary pathway to the public is seldom via forest during the first years after a contaminating event. Later this may change, and the exposure to slowly declining ^{137}Cs concentrations in wild foods will prevail while other foodstuffs are practically clean. An example on such changes was obtained via assessment of systematic foodstuff surveillance data collected in Finland in 1960-2005. Percentage contributions of terrestrial wild foods to dietary ^{137}Cs increased in time during periods of global nuclear fallout and after the Chernobyl accident (Rantavaara 2008). Essential was the simultaneous decrease in the total dietary intake, caused mostly by environmental processes in agricultural production systems. Substantial dietary changes did not hide the effect of environmental processes on doses from ingestion of ^{90}Sr and ^{137}Cs during these periods. The doses received in the first year after radionuclide deposition were the higher the closer to consumption of foodstuffs of the season the deposition occurred.

Timber used for building, actually stemwood, is the least contaminated part of a harvested tree, whereas fuel wood can contain also more contaminated parts of a tree. Particularly wood ash needs attention of experts on radiation protection, energy industry and small scale use of firewood. Bioenergy production based on forest biomass as fuel can be a pathway of concern in the future. Intensive harvesting of felling residues has been supposed to involve detrimental removal of mineral nutrients from forest. If carried out, a condition would develop where increased root uptake of radioactive caesium and strontium occurs, whereas returning nutrients to forest floor through wood ash fertilization could have a reducing effect on ^{137}Cs contamination of forest vegetation (Rantavaara and Aro 2009).

Radiation safety guidance is needed in energy industry for protection of workers handling with wood ash. The wood ash surveys in the 1990's (Rantavaara and Moring 1999) and early 2000's (Vetikko et al. 2004) clarified the need for site-specific measurements of industrial ash in Finland. The studies probably facilitated safe handling of ash and following the related radiation safety guide (STUK 2003).

Conclusions

Radionuclide contamination of a forested area should be assessed for the potential health risk. Providing local people and other concerned population groups with information and advice can help avoiding unnecessary radiation doses. Due to the complexities in radionuclide contamination of forests assessment models are needed to prepare the preliminary advice. Nevertheless, decisions on remedial measures and restrictions for the use of forests need to be based on qualified measurements because of their socio-economic consequences. For correct interpretation of the measurement results scientific design of measurement and sampling strategies are fundamental. Experts on forestry should be involved in the planning and implementation of intervention programmes.

Stem wood will be contaminated with delay, slowly accumulating long-lived isotopes ^{137}Cs and ^{90}Sr, and is the least contaminated part of a tree. Timber that is used for buildings and originates in other than the most contaminated areas of Europe is not supposed to cause to residents an effective dose higher than 1 mSv a^{-1}.

Doses from the treatment, transport and use of wood ash can occasionally exceed 1 mSv a^{-1} to e.g. long-range truck drivers. The small scale users of contaminated fuel wood and ash may need guidance to avoid unnecessary radiation exposure.

Acknowledgements

The European Union partially financed the development of the forest modules of RODOS during past Fission Safety programmes. P. Calmon, IRSN, Institut de Radioprotection et de Sûreté Nucléaire, France, participated in the development of the first version of the model. M.I. Balonov, A.N. Barkovski and V. Yu. Golikov from the Institute of Radiation Hygiene, St. Petersburg, Russia, derived the algorithms for air kerma in forest.

Occurrence of plutonium in the terrestrial environment at Thule, Greenland

Roos, Per; Jernström, Jussi; Nielsen, Sven P.
Risø National Laboratory for Sustainable Energy, Technical University of Denmark, P.O. Box 49, DK-4000 Roskilde, DENMARK

Abstract
Samples of air, resuspended particles, water, soil and precipitation were collected in an area 10 km south of the Thule 1968 impact point and analysed for their content of ^{241}Am and plutonium. The results from the soil sampling show a very inhomogeneous distribution with hot spots ranging up to several hundred kBq per m^2 of Pu. Although concentrations in surface soil can be very high the concentration in analysed air filter samples and passive aerosol collectors are very low. Exposure to plutonium due to inhalation of airborne plutonium particles in the area is of little importance according to this study. To further assess the risk of inhaling resuspended material particles isolated from the different hot areas have been subject to investigation on stability and leaching behaviour.

Introduction
On the 21 of January 1968 an American B52 bomber carrying nuclear weapons crashed on the sea ice in Bylot Sound, about 15 km west of Thule Air Base, northwest Greenland, Fig.1. On impact the plane caught fire and the jet fuel as well as the weapon's chemical high explosives detonated causing a local dispersion of radioactive material. Part of the weapons plutonium was distributed over some square kilometres of the ice in the explosive fire that followed. Plutonium-contaminated ice was recovered and shipped back to the US, as was the plutonium-contaminated wreck. The underlying sea sediments received a fraction of the weapons plutonium when the sea ice melted the following summer and probably also during the accident as the impact caused the ice to break up (U.S. Air Force, 1970).

Flames from the fire reached heights of around 850 m and the smoke pillar even higher. Based on observations from eyewitnesses, metrological data and radar observations it was concluded that the contaminated cloud from the fire drifted south to southwest. At the time of the accident an inversion layer existed at around 830 m and the atmosphere was thermally stable up to around 2200 m. At a height of 1000 m the winds came from the north, higher up, at 3500 m winds were from the west. Wind speed was around 3 m s^{-1} at all heights. It was anticipated that from these observations, finer particles from the fire could have been transported far away from the crash site and reached land south of Bylot Sound, although at low concentrations. It was consequently expected that measurable concentrations of contamination could be found in the direction of the Inuit settlement site Narsaarsuk on the coast some 8 km south of the crash site and further in on land. Contaminated material on the crash site was also anticipated to have been resuspended and dispersed westwards towards Sounders Island due to the storm which followed on the 24 and 29th of January (U.S. Air Force, 1970).

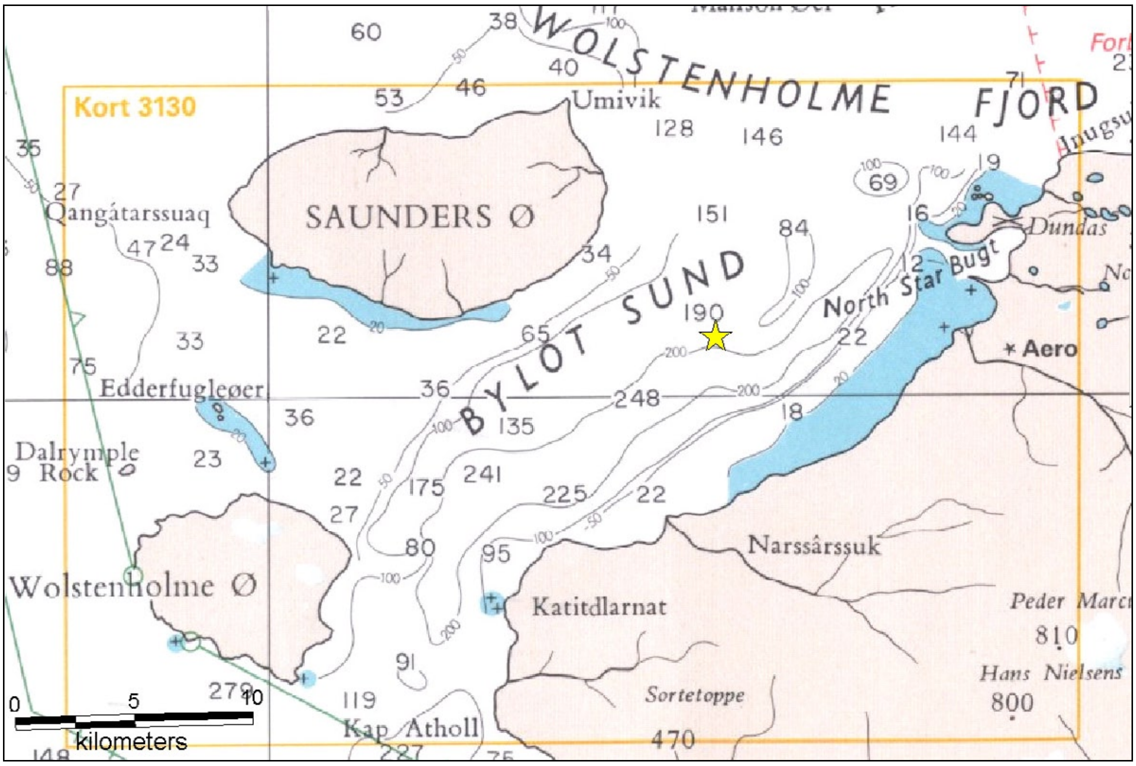

Fig. 1. Map of Bylot Sound showing the site of the aircraft accident (star).

Due to the frequent storms, melting snow and running surface water the contaminated material initially residing on the snow surface may to some extent have been redistributed in the months and even years following the accident. This redistribution may be anticipated to have taken place locally.

The distribution of plutonium on land was initially investigated only weeks following the accident by the analysis of snow samples. In general two zones with contaminated material was identified, one in direction towards south of the crash site, the primary fallout zone, and one towards west which most likely was due to redistributed resuspended material from the crash site in connection with the violent winds following the accident. The contaminated areas on land south of Bylot Sound showed maximum levels of around 9 kBq m^{-2} close to Narsaarsuk.

In connection with the Thule-2003 project concerning investigation of plutonium in the environment around Thule (Nielsen og Roos, 2006) soil samples were collected from 8 localities at Narsaarsuk. At all 8 sites plutonium from the accident could be quantified at different levels in the top soil layers. The spatial variation in plutonium concentrations is very un-even due to the presence of small particles. Detailed analysis of the soil samples collected in 2003 have shown particles with a ^{239,240}Pu content up to 150 Bq. In connection with a pilot study carried out in august 2006 at Narsaarsuk, soil samples were collected which further confirmed the presence of weapons plutonium as well as a large spatial variation of the contamination.

Occupancy at Narsaarsuk, where elevated plutonium levels have been found on the ground, may include a risk of inhaling radioactive particles if these are resuspended from the ground. This resuspension may be caused either by wind or by some mechanical action of the soil. Depending on the level of exposure to these radioactive particles there is a potential risk to human health.

Material and methods

During 2006-2008 a comprehensive field expedition was conducted in the Kap Atholl area at Thule. Soil samples were collected using a 10 cm diameter PVC-tube. At each sampling location 5 individual samples were taken in order to assess deposition variability. A total of about 500 soil-samples were collected over an area of about 20 km2. Overview of the ^{241}Am deposition in the area was obtained using a portable NaI-detector system. Air sampling was done using a Staplex air sampler with a flow rate of about 1 m^3/min. Passive collectors ('sticky vinyl') were placed on wooden frames or on to walls of the shacks in Narssarssuk in order to further assesse the presence of plutonium in air. Rain was collected using a 0.25m^2 funnel located close to the air sampler. Assessment of resuspension of plutonium from soil was done using a simple vacuum-cleaner on areas of about 1 m^2. In the laboratory soil samples were screened in 5-15g aliquots to quantify the total amount of ^{241}Am in each soil sample. The presence of particles and thus inhomogeneous soil samples made this procedure necessary. Passive collectors were analysed first using a digital autoradiography system and later analysed by radiochemical methods and solid state alpha spectrometry for Pu-isotopes. Air filters and rain samples were first analysed by gamma spectrometry and later by solid state alpha spectrometry for Pu-isotopes.

Results

The results from analysed soil samples shows that the Pu contamination is very unevenly distributed over the Kap Atholl area. Several so called 'hot spots' ranging from less than a meter in size to several tens of meter exist in the area around Narssarssuk. Deposition density of Pu in these areas are in the order of 10-100 kBq m^{-2} or even more but is difficult to determine due to the areal Pu density in many cases being determined by a few larger particles. Outside the high deposition areas concentration of Pu is more likely to be found in the 0.1-1 kBq m^{-2} range. A figure showing the frequency distribution of Pu from analysed soil samples are shown in figure 2.

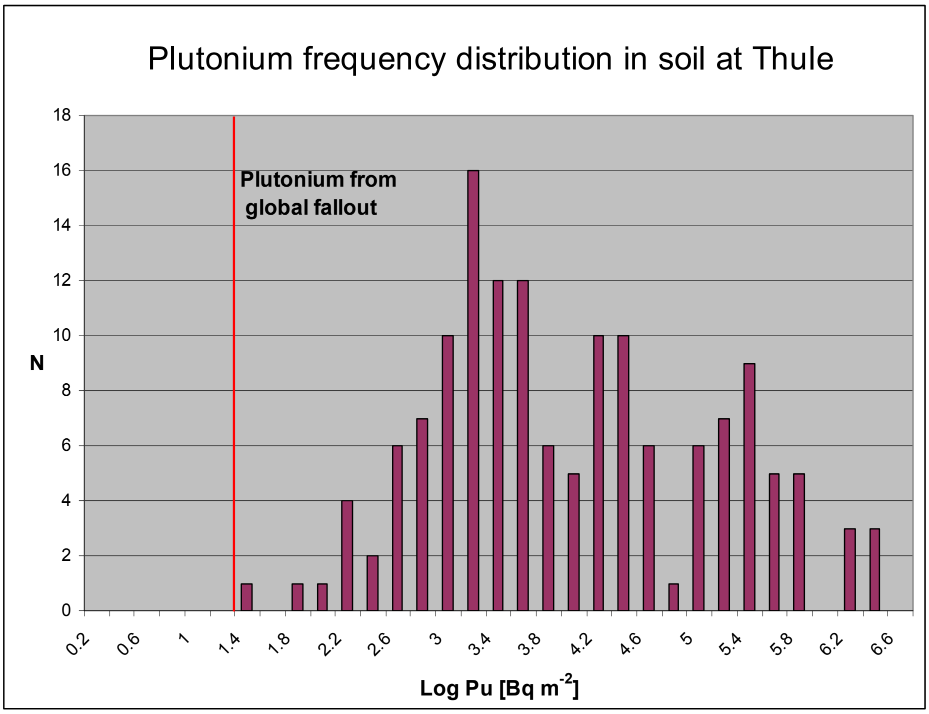

Fig. 2. Frequency distribution of Pu from analysed soil samples.

Results from the resuspension experiments using a simple vacuum-cleaner shows that Pu can be found in nearly all samples (figure 3). In spite of the relatively large amount of resuspended material even during a single exposure to vacuum cleaning the levels of plutonium in air was found to be very low during this study. From the air filters analysed no concentration higher than 5 nBq m^{-3} was observed. Similarly the passive particle collectors showed no sign on digital autoradiography of particles attached during the exposure period. Radiochemical analysis of plutonium on the passive collectors resulted in concentrations in the range 0.1-3 mBq. The conversion of these numbers to corresponding air concentrations is not straightforward and has been omitted.

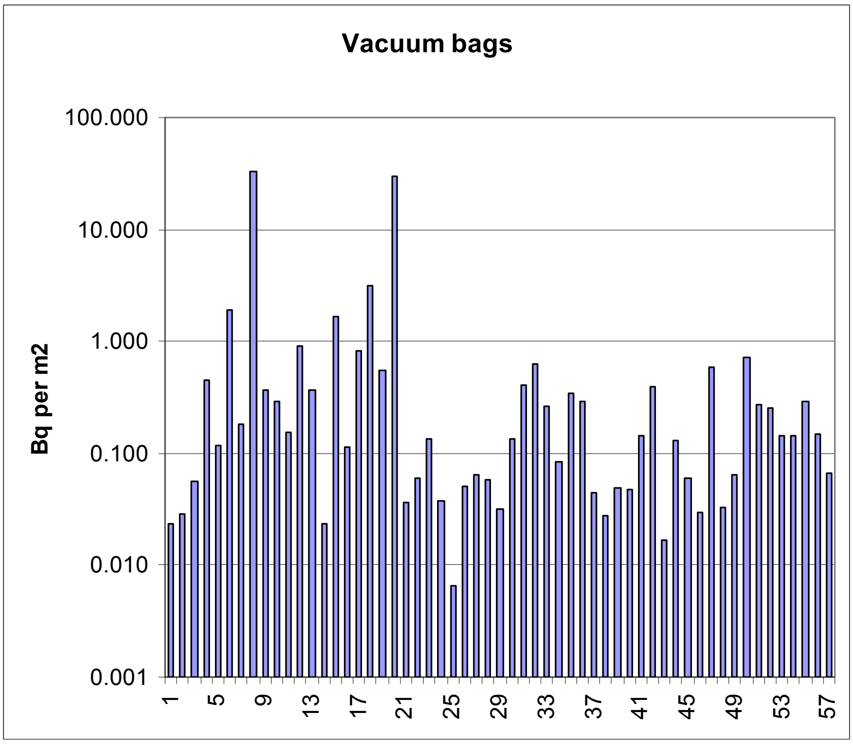

Fig. 3. Results of ^{241}Am from analysed vacuum cleaning bags. Corresponding ^{239}Pu levels can be obtained by multiplying the numbers by six (^{239}Pu/^{241}Am ratio in the Thule material is about 6).

Discussion

The deposition density of plutonium found in the terrestrial environment south of the impact point is of the same order of magnitude as the most contaminated sediments in Bylot Sound. While relocation of contaminated sediments to accumulation bottoms is an important process explaining the spatial distribution of plutonium in Bylot Sound similar mechanisms probably can explain the spatial variability of plutonium on land in the Narssarssuk area. The Thule area is classified as an arctic desert and large areas in the Kap Atholl peninsula is stony, rocky or sand terrain. The annual amount of precipitation is very low and in combination with violent storms it is evident that areas not sheltered from wind will be heavily eroded. Any material initially deposited on such areas will thus likely reside there only for a short time before being relocated successively to areas with wind shelter and/or areas having a high water content or vegetation. Since most areas with vegetation receive their water through nearby deposited snow melting during the summer a view over the area showing pockets of snow in summertime also reveal the potential areas where redistributed plutonium has finally ended up. Probably most of the initially deposited material on snow was relocated to their final destinations during the storm that took place a few days after the accident. All the hot spots identified in the Narssarssuk area are located close to snow patches but not all snow patches are associated to elevated plutonium areas.

The risk of resuspending the deposited material is depending on surface properties such as presence of vegetation, water and how exposed the area is for wind. Although the landscape has been exposed to more than 40 y of strong winds it is clear that the risk of resuspending deposited plutonium is significant according to data in figure 3. Air filter data however showed very low concentrations and the maximum observation of 5 nBq m^{-3} corresponds to doses due to the inhalation pathways which is in the order of 1 nSv y^{-1}. Possibly ingestion may be the dominating pathway of the terrestrial Thule plutonium to man in the area.

Conclusions

Although locally deposition densities of plutonium in the Narssarssuk area may reach close to 1 MBq m^{-3} concentrations of plutonium in air is very low and does not constitute any severe health problems according to this study.

Environmental radioactivity assessment at nuclear legacy sites in the Republic of Tajikistan

Nalbandyan, Anna; Hosseini, Ali
Norwegian Radiation Protection Authority, Emergency Preparedness and Environm. Radioactivity, NORWAY

Abstract

The impressive number of extant nuclear and radiological sources in the Central Asia is a major environmental concern as they pose a potential threat of radioactive contamination to the whole region. Key sources of concern are technologically enhanced levels of naturally occurring radionuclides (TENORM) due to uranium mining and milling. Uranium ore mining and processing in the former Soviet Republic of Tajikistan resulted in origination of huge amounts of uranium tailing materials and waste rock deposits, often dumped near inhabited areas. Given the absence of a proper waste management in most of those areas, there is a considerable potential for the spread of contamination beyond existing contaminated sites. A joint field mission to Tajikistan was conducted in 2008 as part of the project: Environmental impact assessment of radionuclide contamination of selected sites in Kazakhstan, Kyrgyzstan and Tajikistan, coordinated by the Norwegian University of Life Sciences. The present work focuses on the assessment of radiation exposure and radioactivity levels in the former uranium mining and tailing sites at Taboshar, and Digmai, both located in northern part of Tajikistan. Gamma-dose rate surveys were carried out on each site. Generally, the dose rates measured at the uranium mining site in Taboshar varied between 0.70 and 4.4 µGy/h. However, this excludes some hot spots where dose-rates as high as 20 µGy/h were measured. On the tailing site which contains 1.2 mln tons of radioactive wastes the measured dose rates varied 0.7 – 1,9 µGy/h. It is noteworthy that the tailing site lies just 1 km far from the local school in Taboshar where we also did measurements. The highest level of radioactivity was exhibited by Digmai – 18.8 µGy/h. From each site soil samples were taken for subsequent lab analyses for radioactivity and track detectors placed on-site for determination of Rn concentration. The analyses are in progress and the results will be available by the end of 2009.

Improved model for estimation of fallout from atmospheric nuclear testing

Abstract

Estimation of global fallout is still important when establishing background values for many radionuclides. Even where deposition measurements have been made, there is a limit for how comprehensive they can be or can have been. Using a model makes it possible to put the available data in a better framework. Two types of models for global fallout have often been used, one assuming that the variation in deposition is a function of latitude, the other assuming that the deposition can be described as the product of radionuclide concentration in precipitation and the amount of precipitation. The former has a meteorological basis for dividing global data into latitude bands and the quantitative estimate is based on the UNSCEAR compilation of deposition data, even though the original sources clearly state that the compilation is for the latitude band as such and should not be used as a model for individual sites. The latter has been used successfully for individual countries and regions, but the same parameters cannot be expected to hold for all conditions. The global model presented here uses the concentration function as a basis, but includes also latitude dependency and contribution of dry deposition through making the average annual deposition one of the parameters used in the model. The parameters of this new model have been determined using the data from the comprehensive global EML network and the model was validated with good results using data from other networks and data from the Nordic countries.

Reduction of radioxenon emissions from radiopharmaceutical facilities – A pilot study

Braekers, Damien[1]; Camps, Johan[1]; Paridaens, Johan[1]; Saey, Paul R. J.[2]; van der Meer, Klaas[1]

Abstract

The Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) is building an International Monitoring System (IMS) in order to verify that the state signatories of the treaty fulfil their commitments of not performing any kind of nuclear explosion. The atmospheric noble gas monitoring is a part of this verification system and focuses on the measurement of short-lived radioxenon isotopes in the atmosphere. In order to improve the sensitivity of the IMS noble gas network, the radioxenon background should be decreased. Previous research has shown that a very limited number of radiopharmaceutical facilities are responsible for the major part of the radioxenon background [Saey 2009]. In addition xenon routine releases from such facilities can hide the release of radiological more important nuclides like iodine during on- or off-site gas monitoring. Reduction of radioxenon release will consequently decrease the global background and enhance the basic safety of such nuclear facilities.

This study reports on several techniques that could be installed in a radioisotope production facility to reduce the discharge of radioxenon in the atmosphere. This pilot study was centred on the Institute for Radioelements (IRE) facility in Fleurus, Belgium – the worldwide third largest Mo-99 producer. Each production step was analysed to determine the amount and the isotopic composition of a possible xenon release. Many techniques (e.g. adsorption on solid materials, cryogenic processes…) will be discussed in terms of performance and practical aspects for the filtration and/or delay of xenon fission gas emissions.

It has been demonstrated in this work that significant reductions of radioxenon atmospheric discharges from Mo-99 production facilities are theoretically possible. Nevertheless it requires a complete inventory of each pathway of xenon release during separation and purification steps of medical radionuclides.

Introduction

The Comprehensive Nuclear-Test-Ban-Treaty Organisation (CTBTO) is operating for verification purposes an International Monitoring System (IMS) based on four different techniques (seismic, hydroaccoustic, infrasound and radionuclide (particulate and noble gas) measurements) to detect if an explosion in nature is nuclear or not. The objective of the IMS is, according to the CTBT: "…At least 90% detection capability within 14 days after a nuclear explosion in the atmosphere, underwater or underground for a 1 kton nuclear explosion". The global monitoring of noble gases measures the activity concentration in air of four radioxenon isotopes (Xe-133, Xe-133m, Xe-135 and Xe-131m) with a limit of detection below 1mBq/m^3 for Xe-133 [Saey 2007]. However the global radioxenon background which has mainly an anthropogenic origin (nuclear power plants, hospitals and radiopharmaceutical facilities) is in certain areas up to 2 orders of magnitude above the detection limit of the IMS network. It has been demonstrated that the largest contribution to the radioxenon global background by far is coming from the four most important medical radioisotopes production plants that are producing 95% of the Mo-99 world demand by neutron irradiation of highly enriched uranium [Saey 2009]. Mo-99 is the precursor of Tc-99m which is used in 80% of the medical applications with radioisotopes involved world-wide. By consequence, reduction of the radioxenon discharges from these radiopharmaceutical production plants will decrease the global radioxenon background and thus increase considerably the sensibility of the noble gas monitoring network.

On the other hand reducing the radioxenon routine discharges of such kind of nuclear facilities can have another interesting impact regarding the nuclear safety of these installations. Even if the radioxenon nuclides are not important from the radiological point of view, the huge noble gas activity released can mask other more dangerous nuclides such as iodine during on- or off-site gas monitoring. Reduction of radioxenon emissions will consequently decrease the global background and enhance the basic safety of such nuclear facilities in case of an accident but also during the routine monitoring.

This pilot study of the reduction of radioxenon discharges coming from a radiopharmaceutical facility was focused on the case of the Institute for Radioelements at Fleurus in Belgium which is one of the largest Mo-99 producers.

Review of the noble gases retention-scrubber techniques

Xenon is part of the group of noble gases - its interactions with other elements or matter are, therefore, very limited. Except a few uncommon chemical reactions with strong reagents, xenon is chemically "inert". Xenon interactions with matter or other elements are limited to the van der Waals forces (more specific dispersion or London forces). Consequently only physical separation processes have been proposed and investigated for the recovery of radioxenon from gaseous effluents like adsorption on solid material, cryogenic distillation or diffusion through membranes. The cryogenic distillation process has already been studied extensively and tested for the treatment of krypton and xenon present in the off-gases coming from a nuclear waste reprocessing plant [Collard et al. 1982]. This technique is said to be promising, however it has been rejected because of the higher operational costs and the potential fire hazard caused by ozone accumulation [Geens et al. 1985]. Gas diffusion through thin polymer membranes technology has been already studied in the nuclear sciences field for the purification of a reactor building contaminated air with radioactive noble gases [Stern et al. 1980]. Despite the high efficiency of a multi-stage permeation system, this technique hasn't been selected because of its lower throughput and the sensibility of the thin membranes to the chemically reactive substances that could be present in the off-gas (e.g. iodine, volatile acids, nitrogen oxides…).

The adsorption process on activated carbons (A.C.) or zeolites is an easy-to-install and reliable process with limited expected operational costs. Several authors have already studied and tested this technique for the treatment of radioactive noble gases effluents coming from different nuclear installations [Moeller et al. 1981, Mondino et al. 2002]. Despite the fire hazard in presence of NO_x, activated carbons are a very effective type of adsorbents for the retention of xenon until the radioactive decay has reduced sufficiently the radioxenon activity at the output of the system. The off-gas from a radiopharmaceutical facility contains several radioactive gases (Xe, Kr, I and Rb) as well as non-radioactive gases (Xe, Kr, N_2, O_2, NO_x, CO_2, iodine and water vapour) that requires a multi component adsorption approach [Munakata 1999]. Moreover, a pre-treatment of the carrier gas will be necessary in order to remove the most important impurities (water vapour, iodine and carbon dioxide) that could interfere with xenon for the adsorption. Noble gas adsorption depends mainly on several parameters as nature and flow rate of carrier gas, temperature and pressure that can be optimized to obtain the maximal retention time for radioxenon. Finally, xenon breakthrough curve models taking into account the radioactive decay [Lee et al. 1971, Madey et al. 1981] or with an advanced description of the dynamic process [Munakata et al. 2001] can be used on a set of experimental data to extract some important parameters like effective adsorption coefficient and/or diffusion coefficients. In our study these models have been used as a prediction tool to determine the xenon retention time and the decontamination factor of a given adsorption system with the help from experimental data already published in the literature.

Pilot study → The Institute for Radioelements

The main radionuclides currently produced from irradiated uranium targets (up to 93% of U-235) at the IRE institute are Mo-99, I-131, Xe-133 and Y-90. About 15-20% of the worldwide production of Tc-99m is performed in the Fleurus radiopharmaceutical plant [Kidd 2008].

In order to understand the xenon discharges into the atmosphere by such a facility in detail, a complete analysis of the chemical processes of separation and purification of radionuclides is required. Furthermore, the quantitative simulation of fission products with the ORIGEN code based on target and irradiation specifications can allow us to estimate the amount of radioxenon released for each discharge pathway during the production.

Investigation of the xenon emissions during the radiochemical process of separation and purification of radionuclides

The chemical processes for the recovery and the purification of the medical radioisotopes play a major role in the dynamics of the radioxenon emissions in the atmosphere from a radionuclides production plant. For the clarity of the following discussion, the radioxenon released has been split in two categories:

- Xenon from dissolution is the xenon accumulated in the targets (by direct fission production or decay) at the time of dissolution and released during the targets dissolution step.

- Xenon from decay is coming from the radioactive decay of the other uranium fission product like iodine or tellurium after the dissolution step.

The isotopic ratio of these two categories is different with a important contribution to the xenon total activity of shorter half-life radionuclides (Xe-135 and Xe-135m) for the xenon from dissolution while Xe-133, Xe-133m and Xe-131m account for the major part of the activity released by radioactive decay of the other fission products. The general process taking place in the IRE institute for the separation and the purification of the medical radioisotopes is based on [Salacz 1985]. The flow sheet is shown in Fig.1 and the critical steps of the process in terms of potential radioxenon emissions are presented in yellow.

The target dissolution by a sodium hydroxide solution releases all fission gases that have been produced during the irradiation and the cooling time over a short period of time. There are about 30h between the end of irradiation and the beginning of the dissolution. Radioactive noble gases such as xenon and krypton account for the major part of the gaseous inventory and are carried out of the dissolver by a helium flow to a cryogenic trap at liquid nitrogen temperature for the recovery of Xe-133. An additional charcoal trap also working at low temperature is installed after the first one to reduce the radioxenon discharges in the ventilation system. The trapped xenon is transferred to MDS Nordion for purification and concentration by gas chromatography. The efficiency of the xenon recovery line and the purification step has been estimated by monitoring at 99% [Verboomen et al. 2009].

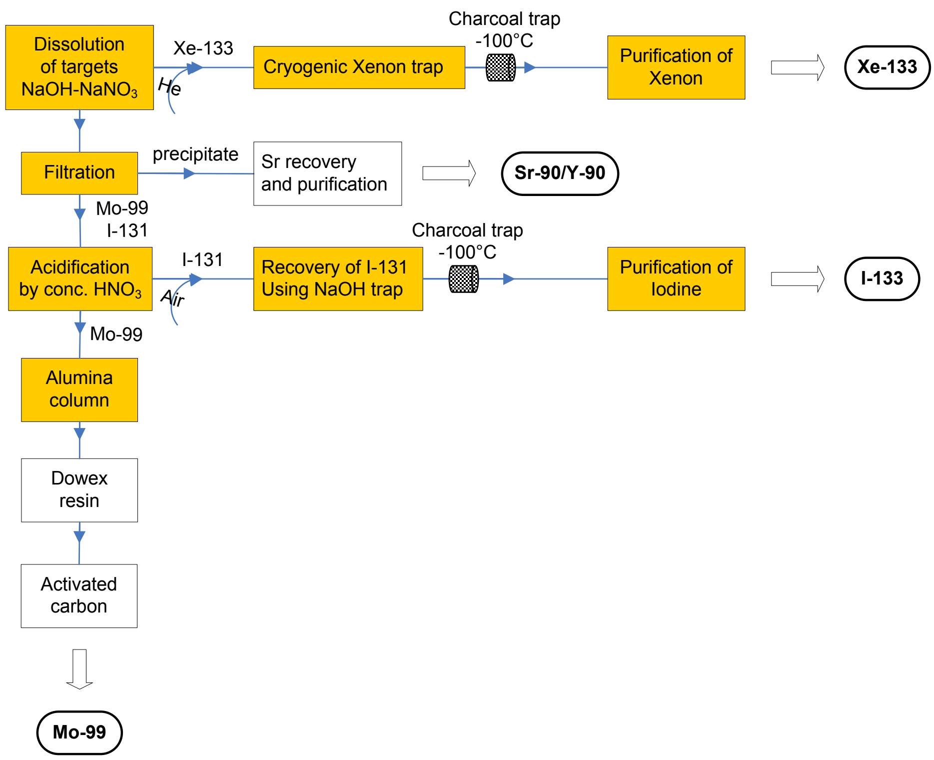

Fig.1. The process flow sheet for the recovery and the purification of Y-90, Mo-99, I-131 and Xe-133 medical radioisotopes at the Institute for Radioelements.

The precipitate containing the unfissioned uranium and some insoluble fission products like strontium is removed from the liquid phase by filtration. Radioxenon that is still present in the dissolver after the dissolution is released during this step. The next phase of the recovery and the purification of Sr-90 from the solid residue can be considered as free of radioxenon because of the time interval of years between the filtration and the beginning of the strontium production. However the precipitate continues to release radioxenon that is still contained in the solid material but also from the radioactive decay of iodine and tellurium traces.

The oxidation of I^- into I_2 by nitric acid induces the release of iodine in the gas phase. Iodine is trapped on a sodium hydroxide trap and stored until its purification. To reduce the discharge of xenon, a small charcoal trap has been installed after the iodine trap. The efficiency of the iodine recovery is maximum 90% [Salacz 1985]. About 10% of the total amount of iodine stays in the liquid phase and will be transferred on the first chromatography column for the continuation of the Mo-99 purification. The time between the end of the acidification and the beginning of the iodine purification is about 7 days for reaching the good isotopic ratio between I-131 and I-133. During this 7-days interval, the radioactive decay of iodine is producing continuously radioxenon (mainly Xe-133 and Xe-131m). The first alumina chromatography column of the Mo-99 purification step is also a potential source of radioxenon emission because iodine and tellurium traces are removed from the bulk solution and sent in the liquid waste tanks.

Finally, the liquid waste tanks and charcoal filters of the ventilation system that are containing iodine which has not been trapped or treated before, continuously produce some radioxenon isotopes by radioactive decay.

The profile of the radioxenon emissions from a radionuclide production facility is very complex because of the diversity of the emission sources in the process with a xenon isotopic ratio changing over the time. Contrary to a nuclear fuel reprocessing plant where the Kr-85 is mostly discharged all at once during the cutting and the dissolution of the fuel rods [Winger et al. 2005], the treatment of off-gases released only during the dissolution won't be good enough for obtaining a significant radioxenon decontamination factor. All the other critical steps in terms of potential radioxenon emissions in the process also have to be taken into account.

Estimation of the xenon source term using Origen code simulation

The quantification of the xenon contained in the uranium targets after irradiation has been done by using the Origen code simulation tool [Bowman et al. 1999]. The irradiation of the high enriched uranium targets used by the IRE is actually performed in three different research reactors: in the BR-2 reactor at Mol (Belgium), in the HFR reactor at Petten (the Netherlands) and in the OSIRIS Reactor at Saclay (France). The average irradiation conditions of the uranium targets in these three facilities are shown in Table 1.

Table 1. Input data for Origen calculations.

Target type	U-Al alloy (93% U-235)
Amount of U-235	4 g per target
Irradiation time	150h
Thermal Neutron flux	1.5 10^{14} n/cm^2.s
Cooling time	30h

Actually, 12 targets (48g of U-235) are irradiated and treated in one batch per production and there are 3 productions per week [Verboomen et al. 2009]. The time dependence of the activity for the main five radioxenon isotopes after the end of the irradiation is shown in Fig.2. The total xenon activity that is released from the targets during the dissolution step has been estimated to 438 TBq. If we consider an efficiency of 99% for the Xe-133 recovery and purification lines, a discharge of 4.4 TBq of "fresh" radioxenon (xenon from dissolution) per dissolution can be expected. The main contributions to this activity are coming from the Xe-133 and the short half-live xenon isotopes (Xe-135 and Xe-135m). This graph shows clearly that the xenon isotopic ratio of a discharge happening during the dissolution of the targets can be very different of one coming during the iodine purification step (7 days later). All the radioxenon discharges (puffs and constant releases) that are coming from different places in the facility at different times since the end of the irradiation merge together in the ventilation and reach the atmosphere by the same stack. The complete attribution of each signal detected by a single monitoring system at the level of the stack is virtually impossible because of the overlapping of all kind of radioxenon emissions.

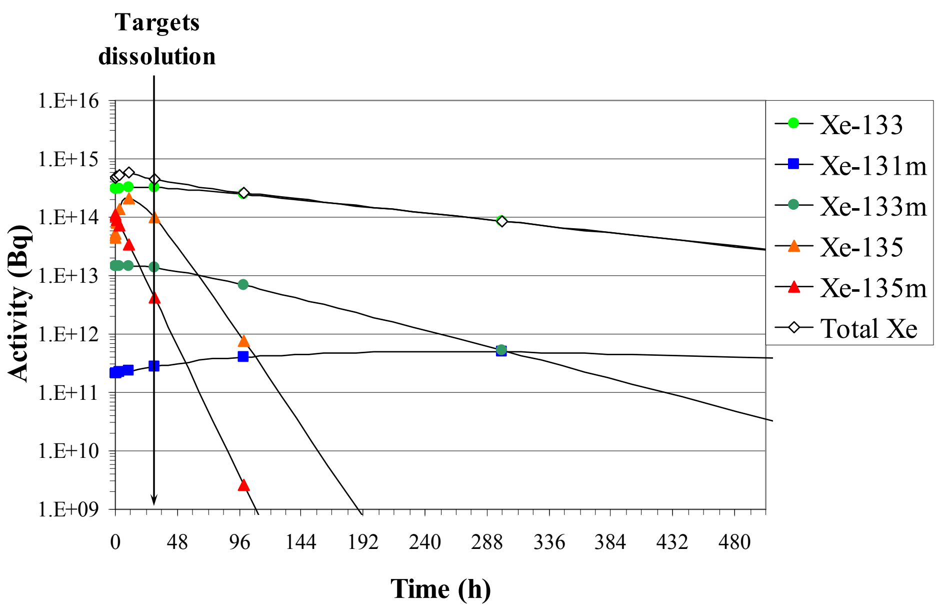

Fig. 2. Activity (Bq) versus time (h) for the main xenon radioisotopes produced during the irradiation period.

Another interesting point is to compare the contribution of the xenon activity released during the dissolution to the xenon activity produces by radioactive decay of the other fission products. The evolution of the xenon activity in function of time is shown in Fig.3. in terms of the sum of both types of xenon emissions. The xenon activity that can be released from fission products decaying is about 32 TBq after 100 hours. This contribution accounts for 12.5% of the total activity if all xenon is discharged at that moment. Although this part of radioxenon is generated over several days and probably not released during a short period of time, the amount produced from these decay chains is split during the acidification step between the first Mo-99 purification column (10%) and the purification of iodine (90%) (See Fig.1.). At the end about 10% of the xenon activity produced by radioactive decay of the fission products (3.2 TBq over 4 days) is sent to the liquid wastes storage facility. It illustrates clearly that an untreated xenon discharge can rapidly account for several percents of the total radioxenon emissions and thus can mask the effort put in treating other release pathways.

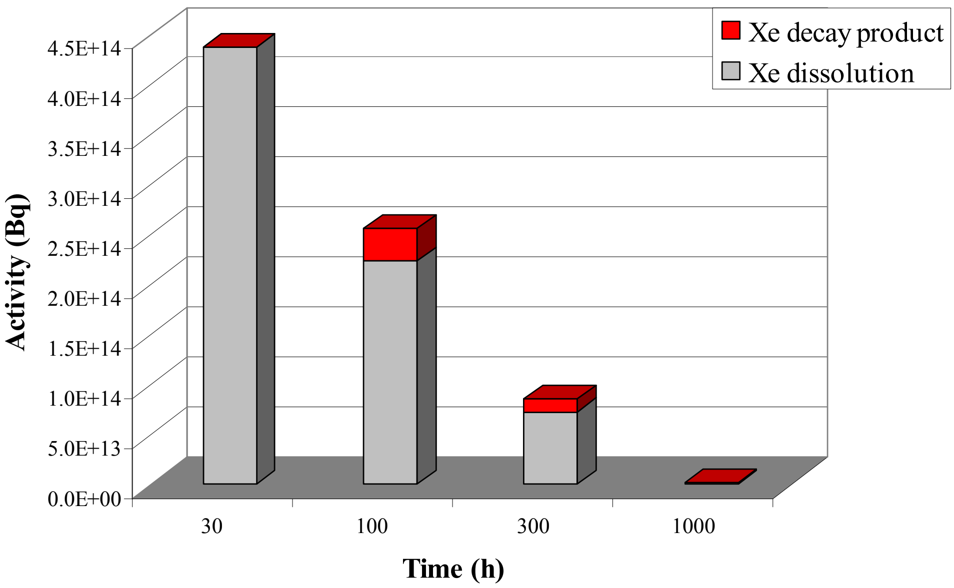

Fig. 3. Evolution of xenon activity (Bq) in function of time (h) (grey: Xenon released during dissolution; red: Xenon produced by radioactive decay).

Example of a xenon adsorption delay system

The scheme of the example presented below is shown in Fig.4. This system has been designed for the treatment of gaseous effluents with a relative small flow rate (up to 4l/min) and helium is used as the carrier gas to minimize its influence. Two preconditioning steps have been planned to remove most of the impurities before contact with the adsorbent bed. The first one is relative to the removing of nitrogen oxide by catalytic reduction with ammonia. The second is a pressure swing adsorption (PSA) system for the elimination of water vapour and the carbon dioxide. Four activated carbon packed bed columns (length=100cm, radius=10cm) installed in parallel are the adsorption part for the retention of the xenon.

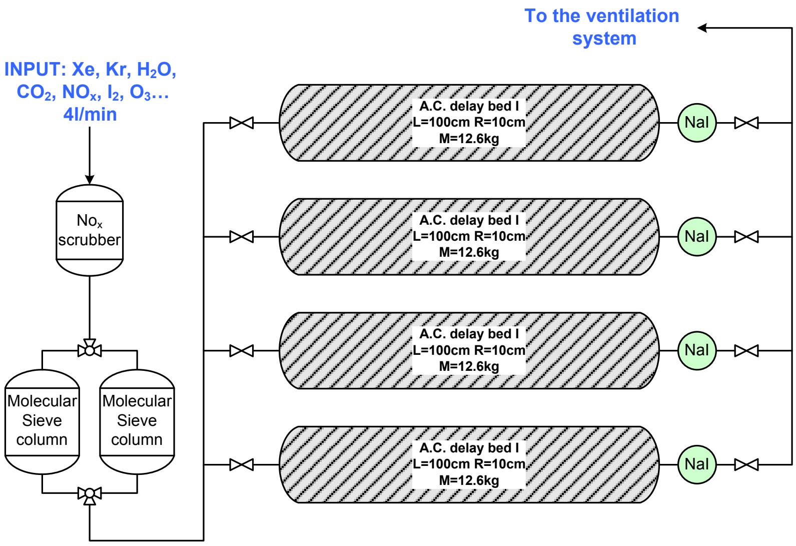

Fig. 4. Example of a xenon delay system for the treatment of contaminated gaseous effluents up to 4l/min.

A parallel multi-column adsorption system has two advantages:

- To reduce the linear velocity of the carrier gas in each column, which is an important parameter that can seriously affect the retention time;
- Increase the basic safety of the installation with the principle of redundancy.

The monitoring of the radioxenon activity is done by a sodium iodine detector on top of each column and each column can be isolated for decay if needed. The input and output parameters of the xenon breakthrough curve simulation, based on the experimental data of [Munakata et al. 2001], are listed in table 2.

Table 2. Input and output parameters for the breakthrough curve simulation of the example.

Parameters	Value
Flow rate	4 liters/min.
Temperature	195K
Column length	100cm
Column radius	10cm
Linear velocity	0.53 mm/s in each column
Bed density	0.40g/cm^3
Amount of A.C.	12.6kg/column → 50.4kg
Xenon partial pressure	100 Pa
Effective adsorption coef.	~6500 cm^3/g
Retention time	56.7 days
Decontamination factor (Xe-133)	> 1000

This example has shown that a small system with only 50kg of A.C. is able to treat a helium flow contaminated with radioxenon up to 4liters/min. We can imagine that each critical step, pointed out from Fig.1, can be treated with this system or that all the contaminated gaseous phases will be sent into a single tank connected to the delay system for a global treatment to reduce the operational costs.

From the radioprotection point of view, this kind of retention system can raise some problems for the protection of workers because of the high specific activities of short-life radioxenon isotopes and the important amount of radioxenon which is going to accumulate inside the adsorption beds.

Conclusions

The possible reduction of the atmospheric radioxenon discharges from a radioisotope production facility like the Institute for Radioelements at Fleurus, Belgium has been investigated. The review of the noble gases filtration/mitigation processes has pointed out that the adsorption on activated carbon is the most suitable technique for this purpose. The analysis of separation and purification steps of the radioisotopes, combined with quantitative estimation by using the ORIGEN code have shown that the dynamics of the xenon emissions are very complex and can not be attributed to only one process but to the entire process flow taking place in the facility.

A small adsorption system working at low temperature has been designed with four parallel activated carbon columns for the retention of radioxenon. Breakthrough curve models have shown that a decontamination factor of more than 1000 for Xe-133 can be expected. However the installation of such a system for the treatment of all possible sources of radioxenon from inside the facility could raise some problems of radioprotection due to the high radioxenon activity present.

Acknowledgments

The authors would like to thanks Dr. H. Miley and Dr. J.C. Hayes from the Pacific Northwest National Laboratory (PNNL) for their advices all through this research. We are grateful to Dr. B. Verboomen, Dr. B. Deconninck, Mr. N. Paquet and Dr. J.-Y. Binamé from the Institute for Radioelements (IRE) for their help and their permanent support.

Abstract

In Austria the legal framework to "Exposure by natural radionuclides in drinking water" is the Austrian Drinking Water Ordinance (Trinkwasserverordnung BGBl. II 304/2001) which implements exactly the European Drinking Water Directive 98/83/EC. The minimum requirements on the quality of drinking water and water intended for human consumption are appointed in it. For radioactivity two indicative standard parameter limits are established – tritium activity concentration of 100 Bq/l and total indicative dose TID (effective dose from radionuclides in drinking water except ^{3}H, ^{40}K, radon and radon progenies) of 0.1 mSv/a. The appointment and the evaluation of the TID are specified in the Austrian Standard OENORM S 5251:2005. Generally only the radionuclides ^{226}Ra and ^{228}Ra, dose conversion factors for adults and a yearly water consumption of 730 l are taken into account for dose calculation.

In the paper the estimation of the TID according to the drinking water directive and the OENORM standard is compared to dose estimations for other age groups and other nuclides based on measurements carried out in Upper Austria. The dose contributions of ^{210}Po and ^{210}Pb clearly preponderate the dose contributions of the radium isotopes. An alternative model for dose estimations has been developed, which takes into account a daily water intake and a continuous excretion of activity from the body. The presented dose assessment clearly yields lower annual effective doses for the population. Present regulations and guidelines for drinking water monitoring and surveillance are discussed and evaluated with regard to the results of this study.

Disagreement persists on methods and applied parameters for estimating total doses caused by natural radionuclides in drinking water within Europe, its individual countries and experts. This paper contributes supporting facts and feasibilities to yield a good basis for future guidelines.

Introduction

Drinking water is the most important food. Therefore its availability, quality and regulation are delicate and important topics. For this purpose it is fundamental to have an overview and hence reasonable regulations about natural radioactivity in drinking water. In the European Drinking Water Directive 98/83/EC (European Commission, 1998) a minimum requirement on the quality of drinking water and water intended for human consumption is appointed. For radioactivity two indicative standard parameter limits are established – Tritium activity concentration of 100 Bq/l and total indicative dose TID (effective dose from radionuclides in drinking water except ^{3}H, ^{40}K, radon and radon progenies) of 0.1 mSv/a.

Radon and the radon progenies are excluded from the European directive (European Commission, 1998). The European commission (European Commission, 2001) recommends for ^{222}Rn, that a reference level should be appointed above an activity concentration of 100 Bq/l, and with radon activity concentrations above 1000 Bq/l measures are justified. For the radon progenies ^{210}Pb and ^{210}Po the Commission recommends (European Commission, 2001) that above an activity concentration of 0.2 Bq/l and 0.1 Bq/l respectively, it should be tested whether any measures are necessary.

^{238}U were not taken into account in the European commission recommendations, but the World Health Organisation (WHO) recommends a guidance level of 15 µg/l natural uranium, which corresponds to a 0.19 Bq/l ^{238}U activity concentration in the drinking water guidelines (WHO, 2004). These guidance levels are applied to chemo-toxic effects of uranium, not on the radioactive exposure. The WHO defines guidance levels for several radionuclides in drinking water (artificial and natural) and says that no deleterious radiological health effects are expected from consumption of drinking water if the concentrations of radionuclides are below the guidance levels (equivalent to a committed effective dose below 0.1 mSv/a). This corresponds with the European directive 98/83/EC (European Commission, 1998).

For radon the WHO guidelines recommend that controls should be implemented if the radon concentration of drinking-water for public water supplies exceeds 100 Bq/l, which corresponds basically with the European Commission recommendation (European Commission, 2001) but is stricter.

All these recommendations afford high responsibilities of the countries to establish their individual and detailed limitations and regulations.

In Austria the legal framework for exposure from natural radionuclides in drinking water is the Drinking Water Regulation – TWV (Republic of Austria, 2001) which implements exactly the European Drinking Water Directive 98/83/EC (European Comission, 1998). The appointment and the evaluation of the TID are specified in the Austrian Standard OENORM S 5251 (OENORM, 2005). The required measurement techniques (e.g. detection limit), sampling site and the evaluation methods including examples are specified there. Generally only the radionuclides ^{226}Ra and ^{228}Ra with dose conversion factors for adults and a consumption rate of 730 l/a are taken into account for dose calculation of drinking water in Austria. Beside this standard there is a lack of regulation concerning other radionuclides e.g. ^{222}Rn, ^{210}Po and ^{210}Pb.

For taking of an inventory of radionuclides in drinking water a drinking water pilot study was carried out in Austria. Based on these measurements dose calculations were implemented according to the Austrian Standards and compared with other dose models and evaluated. The paper yields to provide a basis for further discussions because of disagreement on methods and applied parameters for estimating total doses caused by natural radionuclides in drinking water within Europe, its individual countries and experts.

Material and methods

A drinking water research project was carried out between 2004 and 2006 in Upper Austria (area: 12 000 km^2, population: 1.4 million) funded by the Government of Upper Austria in which 350 water samples were taken in water supplies, wells and at consumers' houses. All water samples were analyzed for different radionuclides (^{222}Rn, ^{226}Ra, ^{3}H, ^{238}U) and gross-alpha-beta-activity concentration by LSC and ICP-MS. A collection of the water samples were additionally analyzed for ^{228}Ra, ^{210}Po and ^{210}Pb by LSC. The detailed sampling methods and the project in whole is discussed in (Gruber et al., 2007, Gruber, 2009) and the detailed measuring procedures are also given in Landstetter & Katzlberger (2005).

For the analyzed radionuclides activity concentrations in the water samples (c_i) dose calculations were carried out. The total indicative dose (TID) was calculated according to the Austrian Standard OENORM S 5251 (OENORM, 2005). The total dose is the sum of the dose contributions of the single radionuclides (GD_i) (according to OENORM S 5251 basically only ^{226}Ra and ^{228}Ra), which are calculated from the activity concentrations (c_i) with the legal valid dose conversion factors ($h(g)_i$) for adults (age >17a) respectively and an annual consumption (KM) of 730 l/a (according to OENORM S 5251) (Formula 1). Activity concentrations below detection limit are set to zero. Uncertainties are calculated by error propagation without taking into account an uncertainty contribution of consumption and dose conversion factors.

$$GD = \sum_i GD_i = \sum_i h(g)_i \cdot c_i \cdot KM \qquad (1)$$

For the compliance of a reference value for the total indicative dose (RGD – e.g. the total indicative dose (TID) according to the drinking water directive (Republic of Austria, 2001)) the following requirement has to be proved, whereas ΔGD is the uncertainty of the total dose (Formula 2).

$$RGD \geq GD - \Delta GD \qquad (2)$$

The total dose (Formula 1) was additionally calculated regarding other measured nuclides (^{238}U) and also for nuclides excluded in the drinking water directive (European Commission, 1998) like ^{210}Pb, ^{210}Po. Besides the dose contribution of the different radionuclides and the total dose were estimated with dose conversion factors for other age groups (babies, children), because they are applied for dose assessments in some countries and this topic is still under discussion within the experts. The dose conversion factors are the values of the committed effective dose per unit intake via ingestion for members of the public at different age groups according to the Basic Safety Standards (IAEA, 1996, see Table 1). The annual water intake values were chosen by the Article 31 working party on radioactivity in drinking water after overview of different intake values by different organisations, including the WHO. The age group 12–17 a was not considered for dose calculation because of no defined water intake for that age group (Risica & Grande, 2000).

Table 1. Dose conversion factors for different age groups and nuclides (IAEA, 1996) and annual water intake (European Commission (1998), Risica & Grande (2000)).

Age group	Dose conversion factors (Sv/Bq)					Annual water intake (l)
	^{228}Ra	^{226}Ra	^{238}U	^{210}Pb	^{210}Po	
<1	3.0 E-5	4.7 E-6	3.4 E-7	8.4 E-6	2.6 E-5	250
1–2	5.7 E-6	9.6 E-7	1.2 E-7	3.6 E-6	8.8 E-6	350
2–7	3.4 E-6	6.2 E-7	8.0 E-8	2.2 E-6	4.4 E-6	350
7–12	3.9 E-6	8.0 E-7	6.8 E-8	1.9 E-6	2.6 E-6	350
(12–17	5.3 E-6	1.5 E-6	6.7 E-8	1.9 E-6	1.6 E-6)	
>17	6.9 E-7	2.8 E-7	4.5 E-8	6.9 E-7	1.2 E-6	730

Additional dose assessments were carried out based on a model by Bronzovic et al. (2006) taking into account a continuous daily water intake and a continuous excretion of the radionuclides from the body. Therefore the m(t) value according to IAEA (2004) was applied, which describes the fraction of a unit intake retained in the whole body at time t after intake. The major part of the radionuclide is excreted from the body within a few days after the intake (e.g. for Ra, Figure 1). A daily total radionuclide activity in the body was calculated for different radionuclides by a daily 2 litre drinking water intake with a constant activity concentration and a daily excretion specified by the m(t) value. The effective dose for the total body (without distinguishing between tissues and organs, related to a 70 kg reference person) was estimated taking into account the absorbed fraction, the energy emitted in the body by the radionuclides and the radiation weighting factors.

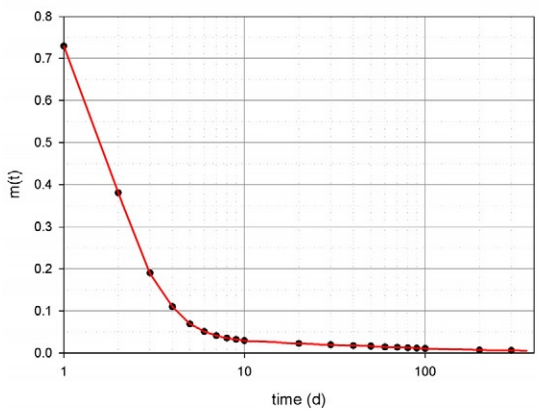

Fig. 1. The fraction of a unit intake retained in the whole body at time t after intake (m(t) value, for one year) for the radionuclides ^{226}Ra and ^{228}Ra.

Results and discussion

The calculated total dose according to formula (1) according to the Austrian standard OENORM S 5251 (OENORM, 2005) – considering only ^{226}Ra and ^{228}Ra is below the parametric value of total indicative dose (TID) of 0.1 mSv/a for all analyzed drinking waters in Upper Austria (Fig.2). Corresponding to the cumulative frequency distribution in Figure 2 for 90 % of the Upper Austrian drinking waters a total dose below 0.01 mSv/a is expected.

The dose calculations considering other nuclides show, that the dose contribution of ^{238}U is in general insignificant, but preponderate the dose contribution of ^{226}Ra and ^{228}Ra in some particular samples. The total dose caused by the radon progenies ^{210}Pb and ^{210}Po is clearly higher and 10 % of the water samples exceed the parametric value of the total indicative dose of 0.1 mSv/a (Figure 3). These radionuclides should therefore not be disregarded in guidelines and regulations for radiation protection purposes.

Only samples with both activity concentrations above detection limit (DL) are displayed in the figures.

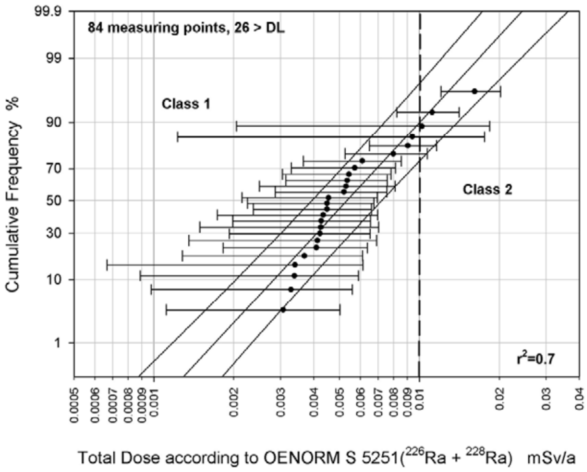

Fig. 2. Cumulative frequency of the total dose according to OENORM S 5251 (OENORM, 2005).

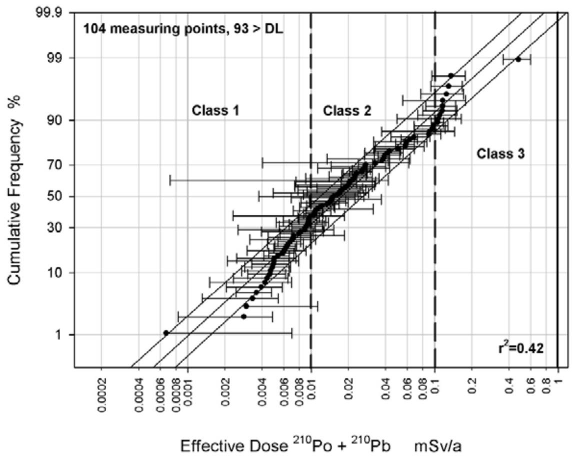

Fig. 3. Cumulative frequency of the total effective dose by ^{210}Po and ^{210}Pb calculated for adults.

The total doses for ^{226}Ra and ^{228}Ra are also clearly below the parametric value of 0.1 mSv/a for the other age groups (children). For about 10 % of the Upper Austrian drinking waters a dose above 0.1 mSv/a is expected for babies (< 1a) (Fig.4). No analyzed water sample has a dose caused by ^{238}U higher than 0.1 mSv/a for all age groups. The dose caused by ^{210}Pb and ^{210}Po for babies (< 1 a) exceeds 0.1 mSv/a for about 50 % of the analyzed Upper Austrian drinking waters. Also for the other age groups doses above 0.1 mSv/a occur for these nuclides (Figure 5).

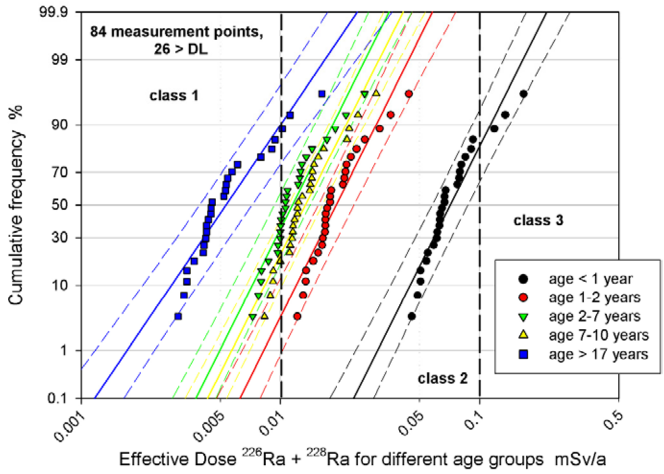

Fig. 4. Cumulative frequency distribution of the sum of the effective doses in drinking water caused by ^{226}Ra and ^{228}Ra for different age groups.

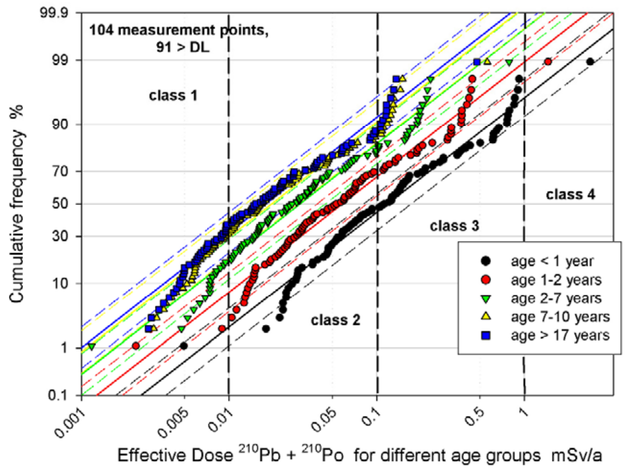

Fig. 5. Cumulative frequency distribution of the sum of the effective doses in drinking water caused by ^{210}Pb and ^{210}Po for different age groups.

Figure 6 illustrates the dose contribution of each nuclide to the annual total dose for adults (> 17a) estimated for each analyzed drinking water sample. For most of the samples the dose contribution of ^{210}Po dominates (up to 80-100 %) because of its high dose conversion factor (Table 1). The activity concentration of ^{228}Ra is below detection limit for most of the samples, but if the activity concentration is above detection limit, it contributes clearly to the total dose because of its high dose conversion factor (Table 1).

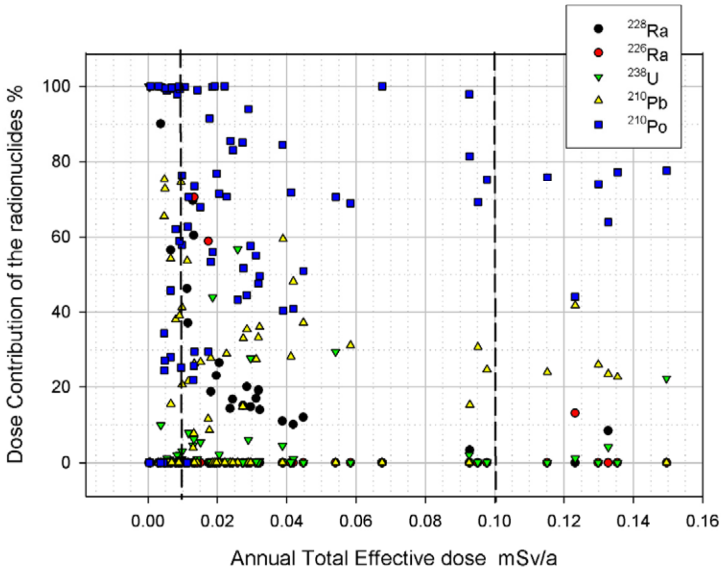

Fig. 6. Dose contributions of the nuclides to the annual total effective dose for adults (>17a).

The effective doses calculated with the above discussed alternative method, taking into account a daily water intake and a continuous excretion of the radionuclides from the body (m(t) value) are at least 2 magnitudes lower for adults than calculated with the conventional method (formular (1), Austrian Standards Institute, 2005) with the same activity concentration in drinking water. So it has to be proofed, if dose calculations according to formula (1) overestimate the radiation exposure of the public caused by radionuclides in drinking water and if the parametric value of the total indicative dose of 0.1 mSv/a is too conservative.

Conclusions

Dose assessments of radionuclides in drinking water are an issue of steady discussion within countries of the European Union and others and also within experts of one country. There are discussions about the legislative regulation and implementation of dose parameters or of reference activity concentrations. As discussed and explained in this paper, the European drinking water directive (European Commission, 1998) only states a total indicative dose and a tritium activity concentration, which was one-to-one adopted in various national laws (like Austria and Germany for example). For other radionuclides like the radon progenies ^{210}Po and ^{210}Pb only (activity concentration related) recommendations exists. As shown above the dose caused by ^{210}Po and ^{210}Pb is not negligible compared to the dose contribution of the radium isotopes. So these nuclides should be taken into account in applied regulations and dose calculations.

The survey in this paper should illustrate that in Upper Austria risk for the population caused by natural radioactivity in drinking waters only occurs in individual cases and for most of the Upper Austrian drinking waters no hazards for the population exist. Nevertheless drinking water should be controlled and surveyed regarding radioactivity, but drinking waters with little enhanced radioactivity concentrations according to different standards, recommendations and guidelines should not be set disabled for drinking water purposes without further surveys and dose assessments. For this purpose guideline values were developed in the framework of this project to simplify and standardize experts' activities in drinking water affairs. These recommendations are already adopted and published in the "Austrian food and drinking water codex", Codex alimentarius Austriacus, Chapter B, drinking water (BMGFJ, 2008) and are based on a differentiation between a monitoring level (indicative parameter of TID 0.1 mSv/a) and an intervention level of a total indicative dose of 1 mSv/a. If this intervention level is exceeded appropriate remedial actions should be recommended. In the codex also intervention levels for the activity concentration of ^{222}Rn (1000 Bq/l) and its progenies ^{210}Pb (2 Bq/l) and ^{210}Po (1 Bq/l) are included. The codex is not a regulation, but an important implement which proclaims terms and definitions, technical names and research in Austria. The worked out recommendation could also yield an extension of the Austrian drinking water regulations.

Impact of facilities under the nuclear fuel cycle on the public health: SUE “Hydro Metallurgical Plant” (LPO “ALMAZ”) case study

Titov, A. V.; Tukov, A. R.; Bogdanova, L. S.; Yatsenko, V. N.; Korzinkin, M. B.
Burnasyan Federal Medical Biophysical Center, Moscow, RUSSIA

Abstract

Over the full period of the nuclear power engineering and industry development, comprehensive radio-ecological inspections are carried out in the Russian Federation to reveal and evaluate potential negative consequences of past activity of facilities under the Nuclear Fuel Cycle (NFC).

The Project No 3003 of the International Science and Technological Centre (ISTC) «Radiation Impact of the Facilities under the Russian Nuclear Energy Complex on the Environment and Human. Development of the Scientific Basis for Radiation Protection of the Environment» integrated efforts of several key international organizations involved in the radiation safety examinations. The Burnasyan Federal Medical Biophysical Centre under the FMBA of Russia (ex-Institute of Biophysics) is one of the participants of this project. The Centre accumulated the great experience in evaluation of the public doses originated from radioactive discharges and effluents; it also developed some methods for assessment of radiation impact on the human health. Following this work, the available results of the radiation situation monitoring have been summarized and analyzed; doses resulted from man-made radiation exposure to the public living nearby the Krasnoyarsk Mining Chemical Combine (MCC), LPO “Almaz” and Novovoronezh NPP have been assessed, and their contribution has been evaluated into dose due to the natural background at such areas.

At the same time, epidemiological inspection was being performed to identify potential connection between the radiation situation at the area of the facility impact and the public health. Data on incidence of malignant neoplasms have been collected over the period from 1991 to 2006 in respect to the residents of the areas studied. The special attention was paid to leukemia, which is the first response to over-exposure. The development took into account indexes of patients with cancer of lymphoid, blood-forming (hematoplastic) and their nested tissues, as well as cancers of other critical human organs. Finally, the database on epidemiological data has been arranged and treated.

Analysis of morbidity with malignant neoplasms helped to reveal significant differences in the morbidity statistics of male and female residents of Lermontov city

situated at the area of the LPO "Almaz" impact, in comparison with the control area in respect of common morbidity and incidence of the trachea, bronchus and lung cancers.

Material and methods

Three methods are used in epidemiology to answer the question about potential association between radiation situation at the area inspected and malignant neoplasms of the residents at this area. These are: *cohort examination*, when the morbidity risk of persons under radiation exposure is being evaluated in comparison with the control group; *case-control study* – risk connected with exposure is calculated by means of comparison of the diseased person group ("cases") with that of healthy individuals ("control") by their radiation exposure index; *territorial comparison*, when areas are chosen with different radiation exposure level.

Generally, case-control studies are less reliable than randomized control examinations or cohort ones.

The main requirement for application of the cohort or "case-control" study is availability of the personal dose data for each resident studied. Today, it is impossible to provide such kind of information. Therefore, we applied the method of territorial comparison in this work.

Obninsk city was selected as the control territory and its population was under examination. The town-forming facility is located in Obninsk – the Institute of Physics and Power Engineering (IPPE) equipped with the first Russian nuclear power plant – nevertheless, inspection aimed at risk assessment of leukemia incidence in the IPPE experts being carried out by V K Ivanov ea. [1], did not find any excessive risk, so the conclusion can be made on its absence for the rest residents of the city as well. In addition, «…long-term experience of nuclear facility operation in Obninsk shows that man-made radioactivity is low and does not impact significantly on doses to the public and environmental species» [2].

Having in mind that leukemia is generally the first response to over-exposure, our development included firstly indexes of the number of persons diseased with cancers of lymphoid, blood-forming and their nested tissues, as well as cancers of other critical human organs which are more frequent at the areas inspected.

The database arranged includes the areas being inspected over the period from 1991 to 2006. To improve the information validity, data have been treated by two-year cycles of study. For this purpose, all absolute indexes were being summed each two years.

Intensive indexes of morbidity were calculated according to the equation:

$$P=\frac{a \cdot k}{n}, \qquad (1)$$

where P – intensive index,

a – number of persons diseased,

n – number of the relevant serviced contingent,

k –for malignant neoplasms = 100 000.

The standard error is calculated for the intensive indexes (m) according to the equation:

$$m = \pm\sqrt{\frac{P \cdot Q}{n}}, \quad (2)$$

where m – standard error,
P – intensive index,
$Q = k - P$,
n – number of the relevant serviced contingent.

The standard error is included into the lists of the intensive indexes. Then, tables of morbidity indexes are being arranged for different nosologies and cycles of study.

To evaluate validity of difference between two indexes (the t – Student criterion), the mean error of this difference has been calculated, equal the square root from the sum of squares of the mean errors for these indexes

$$s.e.difference = \sqrt{(s.e.C_1)^2 + (s.e.C_2)^2} \quad (3)$$

If difference (C_1-C_2) is at least twice higher than its mean error, then some to the some extent we can say that the difference in the indexes is valid (non-random) and depends on some certain reason. If otherwise, this difference is less than twice higher than its mean error, then this difference is not valid (random).

The confidence probability specifies result reliability of the sampling study. We use 95% confidence probability in this work.

Results and Discussion

In the course of operation of the hydro-metallurgical plant (HMP), maximum doses originated from the current effluents took place near Ostrogorka village, subsidiary plots of which located near the border of the health protection zone. Table 1 shows annual effective dose to the residents of Ostrogorka village via each pathway of effluent-induced exposure over 1979 - 1991, being calculated according to [3].

Table 1. annual effective dose to the residents of Ostrogorka village originated from the current effluents, µSv.

Yar													
1978	1979	1980	1981	1982	1983	1984	1985	1986	1987	1988	1989	1990	1991
2,8	1,9	0,8	2,6	2,6	2,6	2,6	4,0	4,0	4,1	3,3	2,4	2,7	0,12

Data from Table 1 confirm that radionuclide release into atmosphere during the uranium ore milling at the HMP did not impact significantly on the public living to the leeward relating to the effluent sources. Internal exposure due to ingestion radionuclide intake via the local foods made the main contribution into annual effective dose to the public - 98 %. ^{210}Pb and ^{210}Po made the highest contribution into internal dose due to ingestion.

Effective doses of potential internal and external exposure to the public because of contamination of water in the surface ponds with the mine water

Self-leaked mine water from Gallery 32 at Beshtau hill passes to Zolotushka River and left tributary of Podkumok River through discharge 5. In summer, the residents use water from discharge 5 without purification to irrigate their gardens and vegetable gardens located close to the gallery. In addition, contamination of water reservoirs with mine water causes the external exposure to the public in the course of swimming and staying at the parts of contaminated floodplain.

The internal public doses have been evaluated hypothetically assuming that food intake received from the personal gardens was 211 kg/year for 1 person. In addition, in some cases small cattle is ranched at the subsidiary plots (goats, sheep, pigs, nutrias, rabbits, birds etc.), and fishing is undertaken in the ponds. Taking into account these factors of potential radionuclide intake via foods, the calculations included milk and meat intake at the 10% level of the value averaged over the Stavropol Territory, i.e. 20.3 l/year and 5.3 kg/year, respectively, while fish intake- at 5% level of the averaged value – 0.56 kg/year.

Table 2 includes assessment of effective internal doses to the critical population group due to food intake issued from the subsidiary plots, while Table 3 includes effective external doses originated from staying at the contaminated soils (plots) and swimming in the ponds.

Table 2. Internal public doses, mSv/year.

Radionucide	Fish	Potato and other agricultural products	Meat	Milk	Gross dose
^{238}U	1,6E-04	2,3E-03	6,1E-05	3,5E-04	2,9E-03
^{234}Th	1,1E-04	4,4E-06	1,2E-06	1,1E-07	1,1E-04
^{230}Th	1,5E-02	3,3E-03	2,1E-04	2,1E-05	1,9E-02
^{226}Ra	2,8E-03	7,3E-04	6,4E-03	6,0E-03	1,6E-02
Gross dose over all radionuclides	1,8E-02	6,3E-03	6,7E-03	6,4E-03	3,8E-02

For the part of residents who provide themselves fully with meat and milk from personal domestic animals, internal doses can reach 0,16 mSv/year. Internal doses to the critical group - «fishmen», who intake fish from the local ponds in 100 % volume, will be 0,39 mSv/year.

Table 3. External doses, mSv/year.

Radonuclide	Swimming	Staying at the area of the floodplain	Gross dose due to both exposure pathways
^{234}Th	1,5.10-6	2,5.10-9	1,5.10-6
^{230}Th	0	2,2.10-5	2,2.10-5
^{226}Ra	1,0.10-5	3,2.10-3	3,2.10-3
Gross dose over all radionuclides	1,2.10-5	3,2.10-3	3,2.10-3

In case of permanent living at this territory and full provision with the agricultural products, meat and milk originated from such personal plots, effective internal doses will be 1,7-2,5 mSv/year. At that, only 7-10 % of this dose are resulted from irrigation of the personal gardens with the mine water. External dose from radionuclides containing in soil will be 0,84 mSv/year.

The area of the village sitting is considered as radon hazardous territory. Additional exposure to the public can be resulted from inhalation intake of radon fission products, airborne in dwellings. Direct measurements of the radon EEC in the village are not being carried out. However, there are data on the neighbor Lermontov city. The more representative data [4, 7] are from the FMBC (ex-SRC Institute of Biophysics) experts under the FMBA of Russia and CSEN under MSCh-101. They carried out their measurements in 213 dwellings over the period since April 1995 till March 1996. The findings of inspections showed high EEC levels in the cottage-type houses, and revealed the season dependency of the radon EEC in dwellings. The EEC levels over the autumn-winter period were 2 and more times higher than those in summer. The evaluated annual effective doses to the residents of individual design dwellings were about 28 mSv. At that maximum doses about three times differed from the mean values. According to measurements of 2006, the mean radon EEC value was 230 Bq/m^3 in the cottage-type houses (85 measurements); this corresponds to about 17 mSv annual effective doses to the public.

Having in mind that the lung cancer is generally the first response to over-exposure of radon and its daughter products, our development included firstly the persons diseased with this nosology, as well as cancers of other human organs, which are more frequent at the areas inspected (Table 4)

Table 4. Distribution of persons diseased with malignant neoplasms over Lermontov and Obninsk cities by different nosologies and sex.

Sitting of malignant neoplasm	Sex	Totl number of diseases registered	
		Lermontov	Obninsk
1	2		
Malignant neoplasms – total including:	M	838	2528
	F	823	2955
Ventricle	M	75	343
	F	60	254
Trachea, bronchus, lung	M	240	458
	F	38	59
Breast	F	143	615

	F	30	162
Leukemia	M	21	70
	F	20	57
Leukemia except for CLL	M	12	51
	F	14	36

Figure 1 demonstrates dynamics of total morbidity with malignant neoplasms of the male residents of the cities by the examination periods

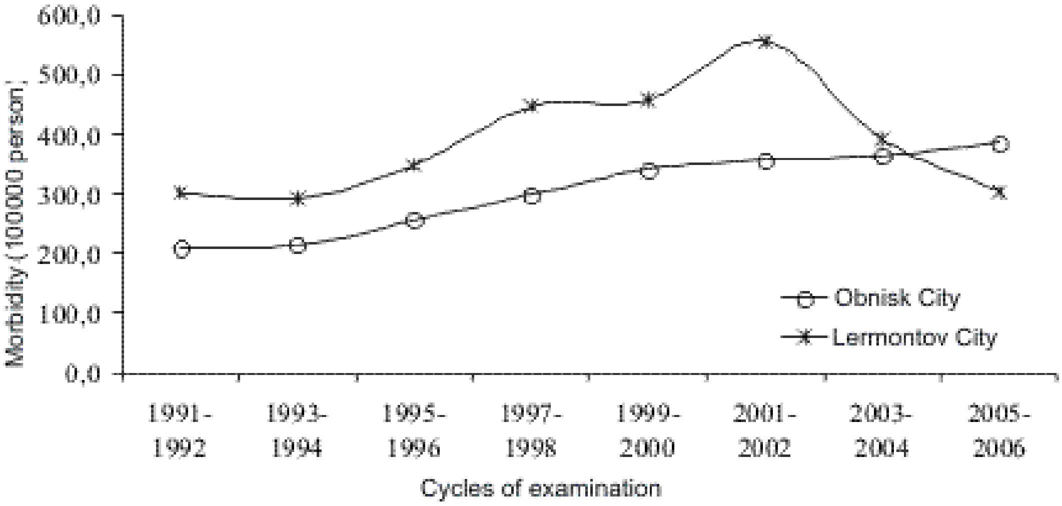

Figure 1. Dynamics of malignant neoplasm morbidity of male residents of Lermontov and Obninsk cities, by the examination cycles.

Such data demonstrate increasing index of common morbidity with malignant neoplasms of males with years in Obninsk city from 208,99 to 385,29 per 100000 males, i.e., 84 %. The indexes for the boundary periods for Lermontov city, such increasing has not been registered, but, for some cycles of examination, they reached rather high values – up to 554,59 per 100000 males over 2001-2002.

Over all periods of surveillance except for 2005-2006, male morbidity indexes for Lermontov are higher than the similar indexes for Obninsk city, and valid differences have been found for 6 cycles of examination of 8: 1991-1992, 1993-1994, 1995-1996, 1997-1998, 1999-2000, 2001-2002.

The most interesting is morbidity with cancer of trachea, bronchus and lung of males over Obninsk city increased with years a bit, while over Lermontov city it has increased up to 2001-2002 inclusively, reaching 153,13 per 100000, but over two last cycles of examination it decreased to 85,5 and 72,6 respectively.

Over each cycle of examination, the male morbidity indexes over Lermontov city were higher in comparison with those over Obninsk, and differences in the indexes were valid, except for two last cycles of examination (2003-2004 and 2005-2006).

The morbidity trend with cancer of lymphoid, blood-forming and their nested tissues was unstable both for Obninsk and for Lermontov. It has increasing tendency for Obninsk data, while for Lermontov it firstly increased, then decreased up to 4,27 per 100000 males over the last cycle of examination (2005-2006).

Comparison of indexes by cities showed that generally there were not valid differences by the cycles of examination.

Male morbidity with leukemia in Obninsk was wavelike. As for Lermontov, increasing morbidity is registered with years of inspection; rather high indexes of morbidity have ben registered over 2003-2004: it reached 27,01 per 100000 male residents of the city, nevertheless over the next period, 2005-2006, there were not registered leukemia events among them.

The most interest can be connected with data on leukemia morbidity except for the CLL, because they confirm unhealthy radiation impact of the environmental factors on the population. Over males in Lermontov, such kind of pathology has not been registered in 3 cycles of examination.

In two cycles (2001-2002, 2003-2004 гг.), the morbidity indexes over Lermontov city were higher than the similar values over Obninsk, but number of diseased persons was small, so differences in the morbidity indexes were invalid.

Thus, of all examined indexes of male morbidity with malignant neoplasms over Lermontov city in comparison with the Obninsk population, higher total cancer morbidity has been found as well as morbidity with the trachea, bronchus and lung cancers.

The female cancer morbidity in all malignant neoplasms both over Lermontov and over Obninsk generally trends for increasing with years of examination. It became 68 % higher for Lermontov, and 78 % for Obninsk.

Figure 2 demonstrates the comparative assessment of malignant neoplasm morbidity for females of Lermontov and Obninsk cities by the cycle of examination (per 100000 females).

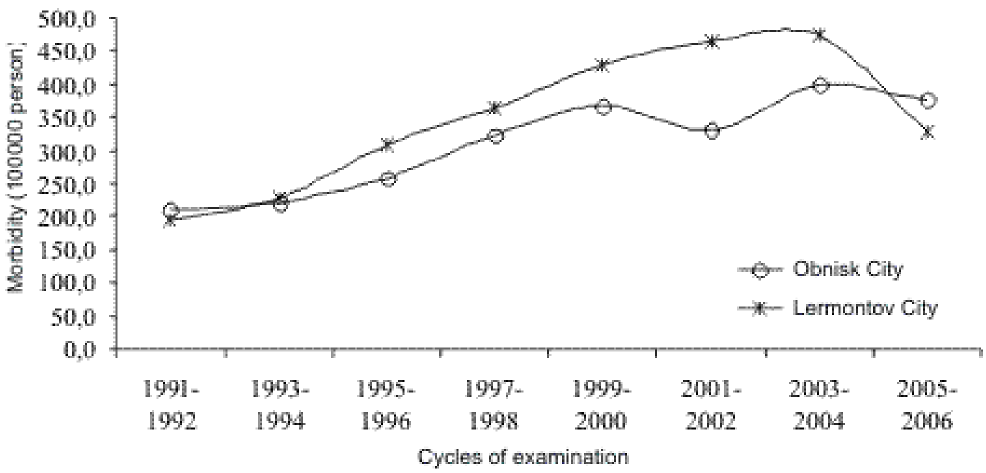

Figure 2. Dynamics of the female malignant neoplasm morbidity over Lermontov and Obninsk cities, by the cycles of examination.

Over some cycles of examination, the morbidity over Lermontov is a bit higher than over Obninsk, except for the last period. Differences in common malignant neoplasm morbidity is invalid, except for 2001-2002 period, when such difference is significant. Recently, the morbidity in Lermontov became lower in comparison with the Obninsk one.

Morbidity with the trachea, bronchus and lung cancers in both cities varies over the cycles of examination; this is more evident for Lermontov.

Over all cycles of examination, indexes for Lermontov are higher that for Obninsk. Differences in indexes are valid in two cycles – 1995-1996 and 2003-2004.

Comparative assessment of the breast cancer of females in Lermontov and Obninsk by the cycles of examination demonstrates their unstable difference by the cycles of examination.

For Obninsk, the morbidity increased slowly from 45,2 to 98,1 per 100000 females, while for Lermontov it reached maximum of 95,7 (period 1999-2000) and decreased significantly over the following cycles of examination up to 25,3 (2005-

2006). Regardless the fact that over two cycles (1997-1998 and 1999-2000) the breast cancer morbidity over Lermontov was higher than the similar index over Obninsk, this difference is invalid.

The female morbidity with the lymphoid, blood-forming and their nested tissues cancers is instable by the cycles of examination in both cities.

There were no valid differences of such kind of pathology over cities.

The excessive leukemia morbidity has been registered of females in Lermontov in comparison with that of Obninsk over 2001-2004, but because of small number of female diseased with leukemia this difference in indexes is invalid.

The female morbidity with leukemia except for the CLL has the same trends as the leukemia morbidity, but at the lower digital level, and over three cycles of examination in Lermontov such kind of disease has not been registered at all.

Thus, comparative analysis of female morbidity with all forms of malignant neoplasms in Lermontov demonstrated exceeding of this index in comparison with the similar index for Obninsk. Valid difference between them has been found only for the cycle of examination 2001-2002. The trachea, bronchus and lung cancer morbidity is notable in Lermontov, where in two cycles of examination (1995-1996, 2003-2004) in validly differs from that for Obninsk.

The above mentioned enables to make the following conclusions:

Morbidity with malignant neoplasms (by all analyzed forms) of residents in Lermontov city, especially the trachea, bronchus and lung cancer is higher than the similar indexes over the control area.

Excessive morbidity with malignant neoplasms (common by the analyzed forms) of the Lermontov population, especially the trachea, bronchus and lung cancer in comparison with the similar indexes over the Obninsk population can be explained by radiation exposure originated both from excessive contents of airborne radon and its daughter decay products during work of males in mines, and from living and staying in dwellings and public buildings being constructed over 1950-70s using the constructive materials with excessive contents of natural radionuclides.

Conclusions

Dose evaluation of man-made radiation exposure to the public living at the LPO "Almaz" impact area demonstrated that maximum effective dose via the meat and milk chain is 2,5 mSv/year. ^{226}Ra is the main dose-forming radionuclide in both cases; its contribution for both exposure pathways exceeds 90%. Maximum potential internal public dose due to intake of foods being produced at the subsidiary plots and gardens varies from 37 μSv/year to 470 μSv/year. On another hand, results of radiation survey in the city demonstrated the presence of high levels of radon and its progenies contents in dwellings of the city, especially in the cottage-type buildings. The evaluated annual effective doses to the public living in the individual design houses were 28 mSv over 1995-1996; according to measurements of 2006 - 17 mSv. Comparative analysis of doses demonstrates prevailing of the natural component above the man-made.

The above mentioned permits to conclude that inhalation intake of radon and its decay products is the main radiation factor affecting the public health in Lermontov city.

The analysis of malignant neoplasm morbidity helps to find some statistical domination over male and female residents of Lermontov in comparison with the similar index over Obninsk city in respect to common cancer morbidity and morbidity with the trachea, bronchus and lung cancer.

We think that such domination of the morbidity with malignant neoplasms of residents in Lermontov is induced by ionizing radiation due to radon release from the earth surface and due to residence and staying in dwellings and public buildings being constructed over 1950-70s using the constructive materials with excessive contents of natural radionuclides, that is confirmed by the higher level of the female morbidity with the trachea, bronchus and lung cancer in Lermontov [2, 5].

In addition, in past, males have been subjected to direct radiation exposure when mining the uranium ore under underground conditions, especially over the first after-war years, when work conditions of miners were being specified by excessive level of the quartz containing dust, radon and its progeny [6]. Taking into account long latent period in case of the lung cancer incidence, these factors could result in the increased morbidity of the population with such pathology.

Nevertheless, in data of the state medical report, it is impossible to identify miners in common population of Lermontov under service, therefore in the course of continuing study, it is reasonable to develop the register with personal data.

Modelling with a CFD code the near-range dispersion of particles unexpectedly released from a nuclear power plant

[2] Análisis-DSC (Dynamic and Security Computations), Madrid, SPAIN

Abstract

An event in November 2007 in Ascó-1 nuclear power plant (Spain) originated the release of a significant amount of hot metallic particles through the discharge stack. Particles were dispersed and deposited in roofs and neighbouring areas within the NPP controlled area. However, the event was not detected until March 2008. More than 1,300 hot points with radioactive particles were found, 94% located inside the double fenced controlled area and 6% within the exclusion area; 5 particles were out of the exclusion area, across the river.

To provide additional insights on the potential consequences of the release, a computational fluid dynamics (CFD) code, Ansys-CFX-11, has been used to simulate the near-range atmospheric dispersion and deposition of the particles. The purpose of the analysis was to assess the distance travelled by particles of different sizes. A very detailed model of the site was built, taking into account the buildings and the terrain features including the river valley and the surrounding hills. The modelled domain was 3.2 x 5.2 km, with the atmospheric layer up to 4 km height. The atmospheric conditions recorded during different periods of time were classified into 37 representative categories.

In general, the distribution of the particles found was adequately reproduced. Particles larger than 100 microns could not travel beyond the double fence. Particles between 50 and 100 microns could have been deposited mainly within the exclusion area, with a small probability of travelling farther. Smaller particles could have travelled beyond, but also should have been deposited in the nearby area, while the majority of particles found are larger, thus indicating that the size of the released particles should be above 50 microns.

The detailed CFD simulation allowed answering relevant questions concerning the possibility of having an impacted region larger than the exclusion area.

Introduction

An incident classified as level 2 on the INES scale happened at the Ascó I nuclear power plant in Spain, consisting of the release of radioactive particles with activated corrosion product isotopes. This occurred due to the contamination of the fuel building ventilation system with water originating from the cleaning of the fuel transfer canal at the end of the refueling outage of the reactor, as a result of a combination of incorrect practices and noncompliance with the operating standards (CSN, 2009a).

The detection of the release and its subsequent notification took place over four months after the occurrence of the event, since it became evident not because of the available automatic radiological control systems but through a site radiological surveillance walkthrough. This was due mainly to the fact that these systems are designed to detect homogeneous radioactive emissions and not discrete particles such as those involved in the event. On March 14th 2008, hot particles were first detected in the containment hatch area. A further increase in radiological surveillance activities in the following days lead to discover several hot points on the roofs of the buildings adjacent to the NPP stack (see figure 1). On April 4th a report was released to the regulatory authority, the Nuclear Safety Council (CSN), which was followed by press releases and official statements to the public, as well as a wide campaign to check more than 2,700 persons through the whole body radiological counter, including workers and visitors. No person was found contaminated. A team of experts from the European Commission's General Directorate of Energy and Transport visited Ascó on April 29th and verified the radiological protection control methodology which confirmed the non-radiological significance of the event and endorsed the technology employed to guarantee the control measures from the operative, administrative and quality points of view.

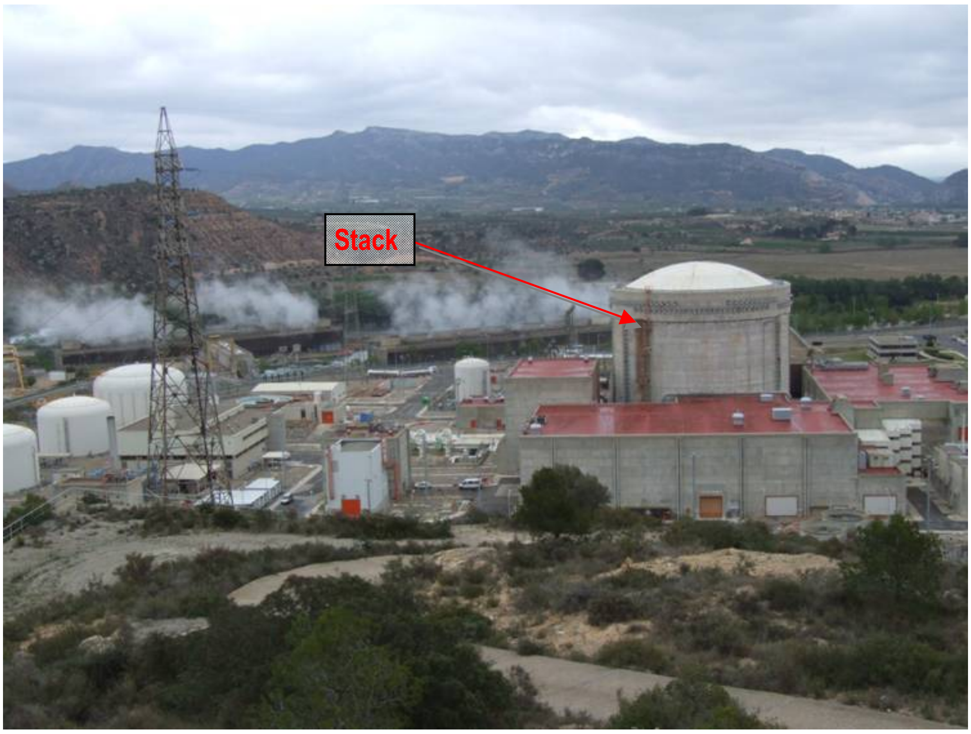

Fig. 1. Photograph of the Ascó I reactor building and the adjacent buildings of the nuclear power plant. The release of particles took place through the stack.

The event was investigated and the conclusion was that the release of hot particles to the atmosphere started on November 29th 2007, when the ventilation system was switched from filtered mode to normal mode (without filtration). As a consequence, particles were dragged out through the stack and then dispersed via the stack to the roofs of Unit I buildings.

An exhaustive active particle location programme was soon accomplished on the plant site, by the licensee in the area under its control and by the CSN in off-site areas, with more than 1,300 particles collected with a total activity of 409 MBq, subsequently calculated on November 26th 2007 (CSN, 2009b). As a comparison, the cleaning of the ventilation system allowed to recover a total of 37,6 GBq. 94% of the particles were located inside the double fenced controlled area and 6% within the exclusion area; 5 particles were out of the exclusion area, across the river (figure 2).

To provide additional insights on the potential consequences of the release, a computational fluid dynamics (CFD) code, Ansys-CFX-11, has been used to simulate the near-range atmospheric dispersion and deposition of the particles. The purpose of the analysis was to assess the distance travelled by particles of different sizes (and activities) and the probability that they have been deposited at a given location.

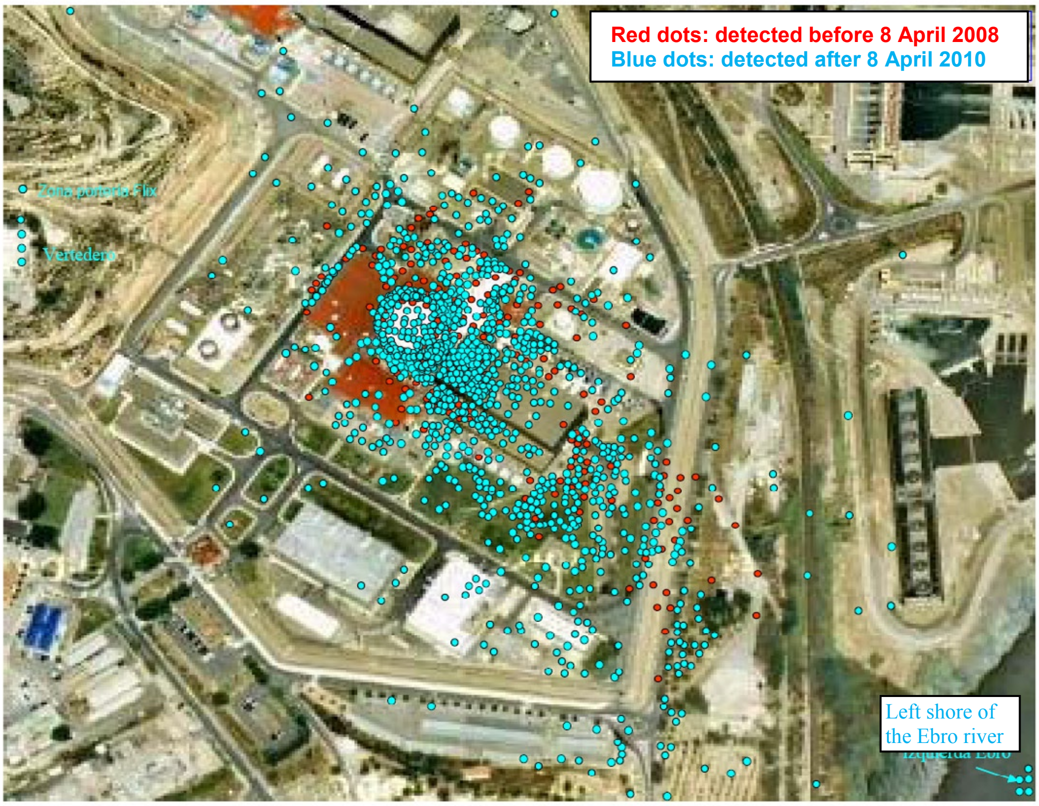

Fig. 2. Aerial view of Ascó I site showing the locations where hot particles were collected.

Material and methods

The modelled fluid flow presents two well differenced phases: a continuous phase of air mixed with steam and a dispersed phase, constituted by solid particles. Consideration of steam was necessary due to the presence of the forced and natural flow cooling towers.

Turbulent phenomena in the air flow have been included in the simulation by means of the SST model (Shear Stress Transport), widely used for industrial applications where limit layer effects in contact with surfaces are relevant. Therefore, the flow characterization is performed by solving the three equations of momentum for gases in x, y and z; the continuity or mass conservation equation; the energy conservation equation; the two equations of the turbulence model: for turbulent kinetic energy and frequency of turbulent structures; and the transport equations for steam. Also, the equations relative to particle transport which are solved by means of a lagrangian model coupled to the fluid flow model (one-way coupling).

A very detailed numerical model of the site was built, taking into account the buildings and the terrain features including the river valley and the surrounding hills. The modelled domain was 3.2 x 5.2 km, with the atmospheric layer up to 4 km height. The atmospheric conditions recorded during different periods of time were classified into 37 representative categories.

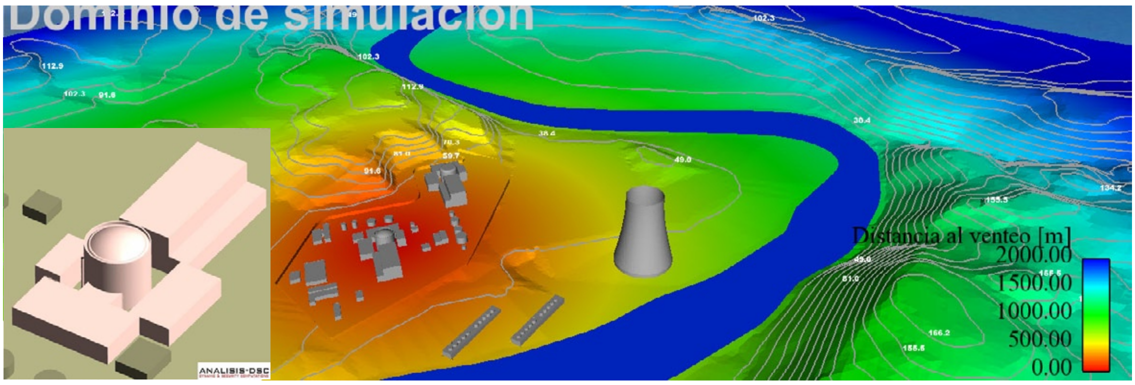

Fig. 3. Overall view of the geometric model of Ascó I site. On the left, a detail of the main buildings of the plant.

The steps followed in the study were the following:

1. Generation and adjustment of a 3-D detailed model for Ansys-CFX based on the terrain elevation (digital map of the area) and the dimensions of the buildings. The building geometries are less detailed for those that are farther from the release point. The general view of the geometric model can be seen in figure 3. The nodalization and mesh structure of the model is based in tetrahedrical finite volumes complemented by prismatic volumes near the surfaces. It is shown with some details in figure 4. Near the surfaces, the size of the cells is small enough as to adequately capture the behaviour in the interface.
2. Analysis of the meteorological data recorded at the site between 29 November 2007 and 31 January 2008. Data have been recorded at 10, 24.5 and 60 m above ground at 15 minutes intervals. The analysis of these data has lead to classify the different atmospheric conditions in a total of 37 categories as reasonably representative of the local meteorology during the period under study. There was a compromise between the need for realistic calculations and the computational resources needed for each simulation. In practical terms, the combination of these 37 categories, with adjusted frequencies, allowed to reasonably represent the atmospheric conditions in the following periods: 29/Nov/2007; from 29/Nov/2007

to 31/Dec/2007; from 29/Nov/2007 to 31/Jan/2008 (one day, one month and two months from the change in the ventilation system to non-filtered mode).

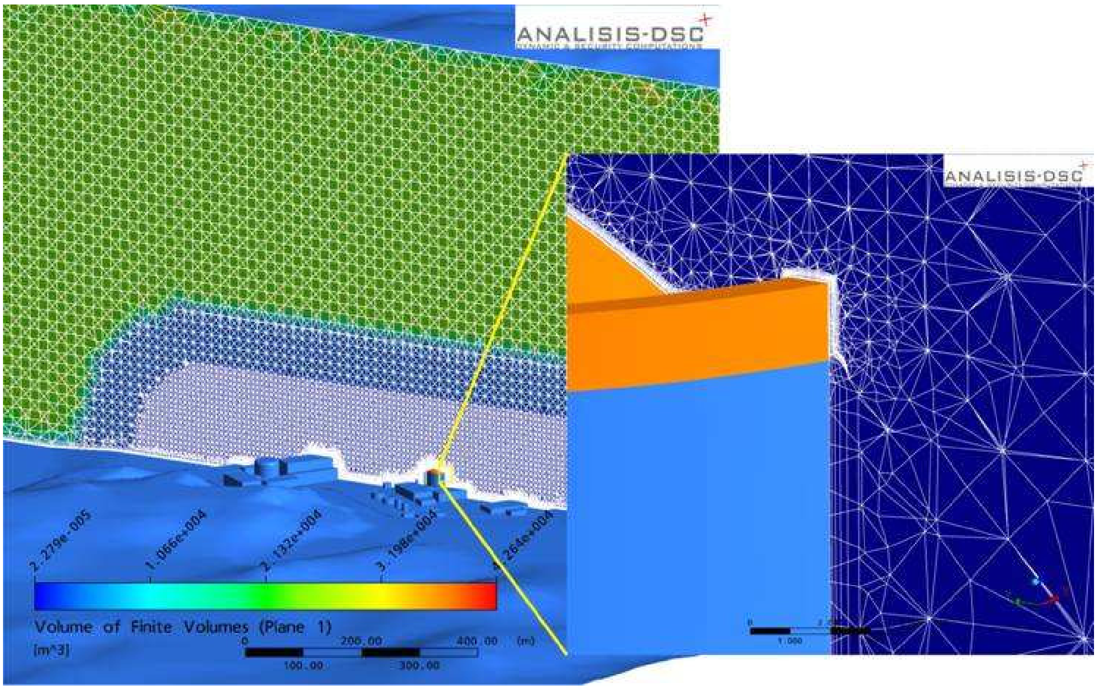

Fig. 4. Details of the nodalization of the atmosphere around the reactor building and in the mid-range distances along the site and up in the atmosphere.

3. Simulation of the 37 categories, with specific conditions of temperature gradient and atmospheric stability, relative humidity, wind speed and direction. The temperature gradient chosen was the typical for the atmospheric stability (Snell, 1994) and the most frequent temperature was chosen as representative for each category. Wind speed profiles with height were adjusted by considering a potential law dependent on the atmospheric stability (Hanna, 1982). The air flow released from the stack is 37 m^3/s with a temperature 20ºC. 3-D effects in the air flow around the site were very relevant, due to the irregular terrain features and the influence of the cooling towers.
4. Seven classes of particles were taken into account in the simulations: 1–25 μm; 25–50 μm; 50–75 μm; 75–100 μm; 100–150 μm; 150–250 μm; 1–250 μm. For bigger sizes, their behaviour is dominated by inertial forces and their distribution is similar. Larger particles could not leave the stack, as demonstrated with a preliminary study of balance of forces in the released flow. The particles density was taken as 7 g/cm^3, as it corresponds to metallic compounds from corrosion of the reactor primary cooling circuit.
5. Parametric study to get a probability of deposition of particles of different size in a given zone, taking into account the atmospheric dispersion. Combination of results for each of the 37 categories with their frequencies during each time period.

Results

The particle deposition map (fig. 2) is the result of the atmospheric dispersion and deposition of the particles released through the stack plus the later processes of resuspension and deposition by wind, transport by rain water runoff and other weathering factors which cannot be simulated in the model. It is therefore reasonable to see some differences with respect to the calculated deposition patterns. It is also necessary to remind that the collection of particles started in April 2008, while the release took place from 29 November 2007.

In order to give a useful representation of the deposition pattern, the number of simulated particles was 10,000 for each size range of 25 microns. To represent it, we have multiplied it by 100 so we have a number of 10^6 particles and the graphical representation displays the number of particles deposited (per m^2) per million particles released. The minimum representation limit is 1 particle per m^2. For the global case comprising 1–250 μm the number of particles assumed was 10^7.

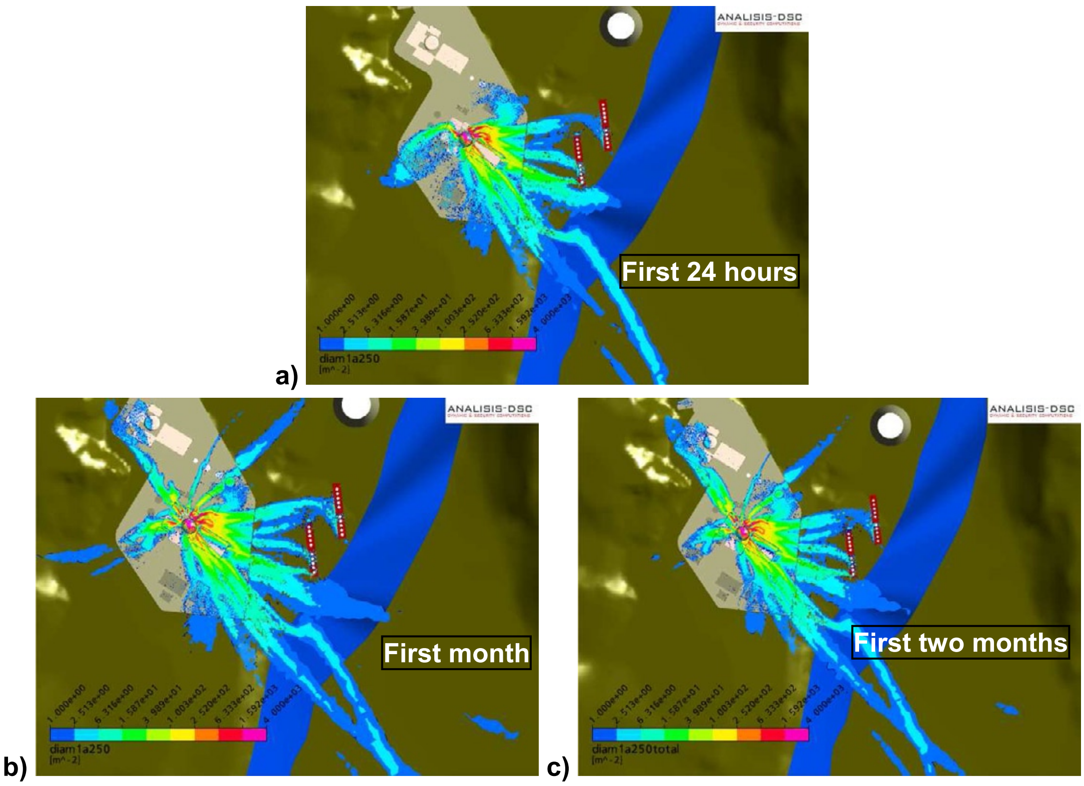

Fig. 5. Results of the simulated deposition of particles of diameters 1–250 μm considering the atmospheric conditions in three different time periods. The patterns represent the particle density per m^2 assuming a release of 10^7 particles.

There is a preferential deposition in the South East area, partly due to the higher frequency of winds in that direction, combined with the effect of the forced flow cooling towers which force humid air to go upwards and which cause some entrainment of particles in that direction. By comparing the three periods considered in the calculations, the conclusion is that a release during the first 24 hours (fig. 5-a) cannot explain alone the pattern of particles found. However, the deposition reached in the period from 29 November 2007 to 31 December 2007 (fig. 5-b) is very similar to the one if the period extended up to 31 January 2008 is considered (fig. 5-c). This result suggests that the release could have taken place most likely in the first month after the change of the ventilation system to normal mode.

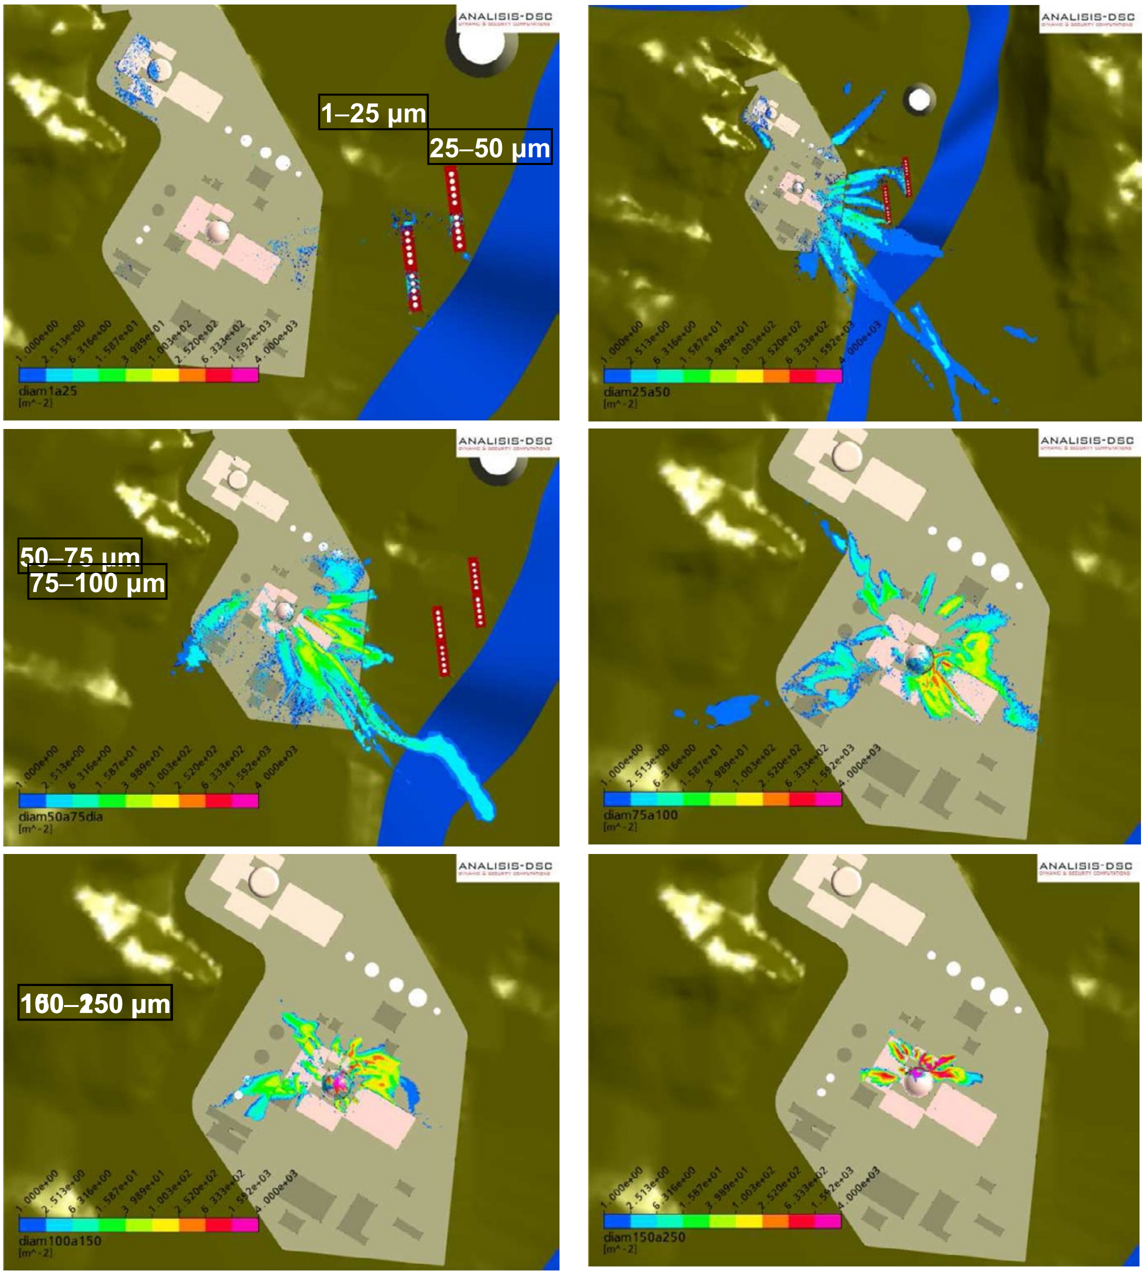

Fig. 6. Results of the simulated deposition of particles of different diameter ranges considering the weather conditions during the first month after the change of the ventilation system to normal mode (29/Nov/2007 to 31/Dec/2007). The patterns represent the particle density per m^2 assuming a release of 10^6 particles.

Fig. 6 displays the deposition patterns of particles of different size. Small particles (1–25 µm), of very low activity compared to the large ones, would be able to travel out of the calculation domain. They could also deposit, in small concentrations, around the stack and in other points of the site, with influence of the forced flow cooling towers.

However, in the radiological survey such small particles were not found, and therefore this result suggests that, if present, their fraction in the total should have been extremely low.

Particles of larger size (25–50 μm) show a distribution through a very large area, and their deposition density should be very small, with a likely deposition within the site, but also off-site. A significant fraction of such particles is leaving the calculation domain.

For particles with size between 50–75 μm, the larger fraction should be deposited within the site, although some of them could travel a bit out and cross the river. This could explain why 5 particles were found in that zone after a careful radiological survey. The radial-like deposition pattern seen in the figure is a reflection of the way in which the calculation has considered wind directions, with fixed angle in each category and a weighted combination of the results obtained.

When larger particles are considered, with sizes between 75–100 μm, they hardly seem able to leave the site, and they are deposited mainly along the dominant wind directions, towards E and SE as commented above.

Particles with size between 100–150 μm would be totally deposited within the plant fence, dominantly towards E and NE, because of the influence of the buildings in the local wind flow patterns. The majority of particles found did have sizes of this range, which could have been altered with time due to the particle "life" in the environment. In fact, many particles show a composition which is not purely metallic but associated with carbonates or silicates.

The biggest particles, with diameter larger than 150 μm, relatively very heavy and active, would deposit totally in short distances around the stack, many of them in the roofs of the reactor building and the surrounding buildings: auxiliary equipment building; fuel management and storage building; turbine building. Some of them would be trapped by the main wind flow and be able to go beyond the buildings, but certainly not far from the plant due to their high inertia. Later, resuspension or runoff phenomena could have transported them farther.

Discussion

This study had as starting point the distribution of the deposited particles, after about four months of weathering in the site. However, it has been affected by some uncertainties impossible to exclude; two of them were fundamental:

- Knowledge of the precise moments at which the release of particles took place.
- The particle size.

The study has tried to overcome these uncertainties by undertaking a wide parametric study covering a full range of particle sizes, from very small to the largest particles able to exit through the stack at the existing flow dynamic conditions, together with a variety of atmospheric conditions, 37 in total, which covered a high percentage of those existing during the likely emission periods.

Based on those considerations, the study has given valuable information with regard to the likely deposition pattern of particles of different sizes in different release periods, concluding that particles of all sizes could have been found within the inspected area where the hot particles were found. Particles larger than 100 μm could have not travel beyond the fenced area of the plant. A small fraction of particles sized between 50–75 μm could have leave the fenced area travelling towards the SE direction, where some particles were effectively found across the river. Small particles could in principle have travel far from the site, but they should also have deposited on site, and this was not the actual finding. Given their origin and the spread of particles found it is not very likely that these small particles were abundant in the release.

Conclusions

The main conclusion is about the usefulness of this study in order to better assess the radiological importance of the event. The great capability of CFD models to simulate very local effects –like the flow perturbation by the forced cooling towers, the buildings of the plant or the surrounding hills–, has proven essential to accurately interpret the behaviour of particles of different sizes. In summary, the detailed CFD simulations allowed answering relevant questions concerning the possibility of having an impacted region larger than the nuclear power plant exclusion area.

However, to give realistic results, these models need a significant effort in terms of modelling the site features, terrain elevation and geometry of the buildings and installations which could alter the overall wind flow. Also, current computational capacities in general do not allow simulating dynamic sequences with changing weather; therefore, we have chosen a representative set of "static" sequences and have weighted the results in order to obtain a realistic pattern of the likely deposition of the leaked particles.

In general these methods would be recommended only when the geometry and dispersion conditions of the site are very complex as well as in the case of particles whose dispersion is better simulated with lagrangian models.

Acknowledgements

We deeply acknowledge the support received from "Asociación Nuclear Ascó-Vandellós II", and their supply of data for the simulations.

Inspection Plan for the detection of contamination at a Nuclear Fuel Cycle facility

Pérez Fonseca, Agustín; Ortiz Trujillo, Diego
ENUSA Industrias Avanzadas, SPAIN

Introduction

A number of incidents related to the finding of contamination spots outside main operation buildings were detected at different nuclear sites in Spain over 2008. In response to these incidents, the CSN (Spanish Nuclear Regulatory Body) issued requirements demanding all the operators the execution of the site's comprehensive inspection plans in order to ensure that no contamination spots would be found out of control.

The ENUSA's Fuel Fabrication Plant at Juzbado is a nuclear fuel cycle facility whose specific features make it different to the rest of Spanish nuclear installations, provided that only Low Enriched Uranium (5% maximum) is handled as process material. Therefore, the inventory of isotopes consists only of U-isotopes and their daughters. These isotopes can be found in Nature in different amounts, depending on the geologic characteristics of the area, amongst others. Therefore, the natural background itself can contain spots of the contaminant, and must be taken into account for the preparation of the inspection plan adding complexity to its implementation. The criteria to distinguish background from non background values must be set (impacted and non impacted areas).

To implement the inspection plan at the Juzbado Plant, the MARSSIM methodology was chosen for the Scope & Characterization Surveys, following the Data Quality Objective (DQO) process. Derived Concentration Guideline Levels (DCGL) were not used: comparison between background values versus field values was used instead.

MARSSIM (Multi-Agency Radiation Survey and Site Investigation Manual) is a tool to conduct radiation surveys and investigation of contaminated sites. This method is used by different agencies and it is a reference for NRC, amongst others, being described on NUREG 1575.

Material and methods

Following the MARSSIM approach, there are six steps in the Radiation Survey Process:

a) Site Identification.
b) Historical Site Assessment.
c) Scoping Survey.
d) Characterization Survey.
e) Remedial Action Support Survey.

f) Final Status Survey.

As this is a facility that is not going to be decommissioned, only steps a) to d) will be performed.

To prepare the inspection plan, a review of all the activities that took place on site has been done. This, History Site Assessment (HSA using MARSSIM vocabulary), give us a map where contaminated material has been handled. The contaminated material has only been handled in the main building and radioactive liquid treatment facilities.

Fig 1. Map of Juzbado facility. Red spots indicate areas where contamination could be found.

After the review of the activities has been done, the other main conclusion at this point is that the only radioactive material handled was low enriched uranium, in the form of oxides (no UF_6).

With this information, we have a clear idea of what and where we have to found in order to prepare the characterization plan. No scoping survey will be done, we will try to perform only one characterization survey, using the regular periodic inspection that have been done in the facility as an scope.

The first part in the characterization survey is to classify the zones first in land areas or structures areas, because the types of surveys are different. After this, a risk based classification will be done. The areas with higher risk of contamination will be classified as class 1, and the areas with lower risk will be classified as class 3. To act in a conservative way, all the areas were considered as impacted areas, so all the areas must be surveyed.

The land areas we have in the facility according to the classification are included in the following map. The criteria used to classify each area is that areas where contaminated material was handled are classified as class 1, areas surrounding areas class 1 are class 2 and the rest is class 3.

Fig 2. Land areas. Green area is class 3 and blue areas area class 2.

The type of survey necessary to inspect each area was selected using the DQO (Data Quality Objective) process. These areas must be inspected by a scanning process and a simple measurement. For the scanning part, gamma measurement will be done, using portable equipment (INa monitor). For the single measurement a soil sample will be taken, and later alpha spectroscopy of the soil will be done, where ^{234}U and ^{238}U will be compared. For material with enriched uranium, the amount of ^{234}U is higher than what we can found in nature. To conclude if an area is contaminated or not, we compare the ratio ^{238}U:^{234}U (sample) vs ^{238}U:^{234}U (background). If the mean ^{238}U:^{234}U concentration in samples collected from a survey area is greater than the mean ratio from an equivalent number of samples randomly selected from the available background sample population + a substantial difference (S) of 2 times the full background sample population standard deviation determined, then decide enriched uranium contamination is present. Otherwise decide the uranium present is natural background. A summary of the process for class 1 areas is included on this table:

Table 1. Example of measures for the land areas, class 1.

Land Area	Scanning	Field Screening	Measurement/ Sampling
Class 1	Perform medium density (50%) gamma surface scans of all accessible surfaces in each Class 1 survey area.	Pause and investigate any locations with gamma radiation levels distinguishable from background. Mark investigative locations for potential judgmental sampling.	Use an statistics application to determine the sample size for each survey unit The input parameters, using the Wilcoxon Rank Sum (WRS) planning mode are: False Rejection Rate: 0.05% False Acceptance Rate: 0.05 or 0.10% Lower Bound of the Gray Region: 1.033 Specified Difference of True Means or Medians: 1.205 Estimated Standard Deviation: 0.086 NOTE: The WRS test mode is used for determining sample size. The non-parametric statistical test will be the Wilcoxon Mann-Whitney test.

Later, to analyze the data, Wilcoxon Mann-Whitney Test will be used, taking both sample and background data.

For the structures area, a map of the facility was taken, and every building or road was assumed to be a significant area. The criteria used to classify areas as class 1, 2 or 3 is the same as before. If contaminated material was handled, then the area is class 1. All areas surrounding class 1 are class 2. Once the area is classified, it splits on different cells, each one with a maximum surface, depending on the classification.

Table 2. Maximum surface allowed on every area.

Type of area	Maximum surface of the cell
Class 1	100 m2
Class 2	1000 m2
Class 3	No limit.

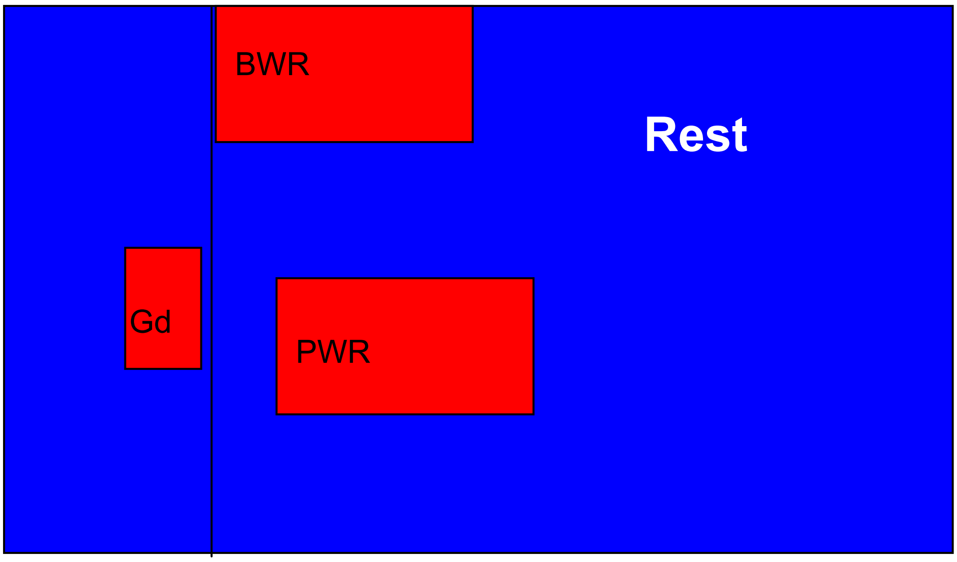

Fig 3. Example of survey plan on the roof. Areas around the stacks are red (class 1). The rest of areas are class 2 because they are near areas class 1.

The type of survey that will be performed on every area is also a scan or an static measurement, both with portable monitor able to measure alpha radiation. The measure will be done without any background subtraction, and will be compared to different background of different materials. If the mean cps (counts per second) in the survey area is higher than the mean of the cps from any equivalent number of background simple randomly selected from the available population + the equivalent value in cps of 0.04 Bq /cm^2, then it is determined there is contamination due to uranium. Otherwise, decide that area do not have contamination. In this step Wilcoxon Rank Sum Test will be used.

Fig 3. Device used to scan surfaces in order to find contamination spots.

Table 3. Example of measures for structures areas, class 1.

Structure Areas	Scanning	Field Screening	Measurement/ Sampling
Class 1	Perform high density scan (100%) in all the accesible surfaces	Pause and investigate any locations with radiation higher than background. Mark investigative locations for potencial judgmental sampling.	Use an statistic application to determine the sample size for each survey unit. The input parameters using WRS will be, for the surfaces used in background (concrete and asphalt): False Rejection Rate: 0.05% False Acceptance Rate: 0.05% Lower Bound of the Gray Region: (0.35 ó 0.44) Specified Difference of True Means or Medians: (1.41 y 1.50) Estimated Standard Deviation: (0.076 y 0.08) NOTA: The WRS will be used.

Conclusions

The MARSSIM methodology it is a powerful tool. It can be used for different projects, mainly decommission projects, but also for characterization purposes. For this reason the steps related to final status survey (that uses the data that support the decision for release of an area) is very well detailed in the NUREG 1575. On the other hand, characterization survey (or scoping survey) is not detailed as good as final status survey.

This plan intends to use all the steps of MARSSIM approach, for a characterization survey, using some of the analysis methods proposed for the final status survey.

With this plan, all the areas inside the fence of the facility will be scanned in order to prove that there is no contamination risk. The requisites asked by the regulator will also be fulfilled.

If contamination is detected over the limits specified in the regulations, will be cleared, explaining all the actions taken in the report that is going to be sent to the regulator.

Establishment of a special radiological surveillance programme at the “El Cabril” solid radioactive waste disposal facility

Ortiz, Teresa; Fuentes, Luis; Pinilla, José Luis
ENRESA, SPAIN

Abstract

Due to a requirement by the Nuclear Safety Council, the Spanish regulatory authority, a special radiological surveillance plan (SRSP) has been developed at the low and intermediate level Radioactive Waste Disposal Facility (El Cabril centre) in Spain. The objective of this plan, which covers outdoor areas on the site, is to identify and remediate possible contaminated areas, including exterior ground, walls, roofs or terraces, the walls of buildings, drains, channels, paths and roads.

The RSP has been developed in accordance with the MARSSIM methodology and includes an historical analysis of the facility and an initial radiological characterisation of the protected area.

Objective and scope

In response to a requirement by the Nuclear Safety Council, the Spanish Regulatory Authority, a special radiological surveillance programme (SRSP) has been developed at the Low and Intermediate Level Solid Radioactive Waste Disposal Facility (El Cabril), located in the province of Córdoba (Spain), covering outdoor areas of the protected zone of the Site, the aim being to identify and eliminate any possible contamination.

In accordance with the instructions given by the Nuclear Safety Council, the programme has addressed the following requirements:

– Analysis of practices that may have given rise to the presence of contamination at the Site.
– Special attention to the existence of points at which sludges are accumulated or concentrated.
– The entire surface area of the Site will be covered, with a more detailed and precise systematic approach being adopted for areas identified as presenting the highest risk of contamination.

The SRSP has been applied to the entire outdoor area of the protected zone of the Site. The study areas have included outdoor paved areas, walls, the roofing and/or terraces and walls of buildings, gardens, forested areas and external structures exposed to the weather, such as slabs, drains, channels, roads and paths, etc.

As regards the radiological surveillance of walls, it was decided that this would be carried out only if contamination were detected in areas in which the presence of contamination might be suspected.

The SRSP has been carried out in accordance with the MARSSIM methodology, including a historical analysis of the Facility and the initial radiological characterisation of its protected zone.

Development of the special radiological surveillance programme (SRSP)

The SRSP has been carried out by the Radiological Protection and Environmental Service of the El Cabril, with support from the ENRESA Radiological Protection Technical Unit and Safety Department. In addition, there has been support from an expert in spectrometry and instrumentation. Performance of the measures was undertaken by an external company, with a Senior Technician and two field measurement systems Operators.

The SRSP was performed between September 16th and October 8th 2009. The first task consisted of analysing the initial situation of the outdoor areas, as a basis for planning of the programme. As a result of this analysis, the protected zone was divided into Impacted and Non-Impacted Areas, these being defined as follows:

Non-impacted areas: those in which there has been no relation with radioactive materials during the operating lifetime of the Facility.

Impacted area: those in which there may have been a relation with radioactive materials as a result of the operating lifetime of the Facility. These are divided into three classes:

- Class 1: areas in which the existence of residual radioactivity is highly probable.
- Class 2: areas in which the existence of residual activity is a possibility.
- Class 3: areas in which the probability of residual activity is low.

The SRSP identified only the existence of class 2 and 3 Impacted Areas, no class 1 Impacted Areas were detected.

Definition of surveillance units (SU)

So–called Surveillance Units (SU) were defined for all the areas classified as being Impacted. These consisted of known surfaces of a specific area with a similar history and homogeneous radiological characteristics; in other words, the unit is constituted of the same material (concrete, natural terrain, gravel, etc.) and the spatial distribution of the contamination should be approximately homogeneous.

As regards size, the areas defined were larger or smaller depending on their radiological classification:

- SU's defined for outdoor areas (asphalt and concrete): 10 SU's between250 m^2 and 24,114 m^2.
- SU's defined for the vertical outdoor walls of buildings (concrete): 3 SU's of 500 m^2.
- SU's defined for the roofing of buildings (concrete, metallic sheeting and gravel): 6 SU's between 660 m^2 and 1,471 m^2.

Assessment of the radioactive background and identification of reference areas

In order to determine the radioactive background of the Site, Reference Background Areas (RBA) have been identified in non-impacted areas on the site. Given that the reference areas should have physical, chemical, biological and radiological characteristics similar to those of the areas in which the radiological surveillance is to be performed, a reference background area has been selected for each type of material in the areas to be characterised (asphalt, concrete, natural terrain and roofing gravel).

Thus, each SU has associated with it a non-impacted area known as the RBA that serves to establish the levels of investigation of the initial surveillance phase, on the basis of the radioactive background of the Site.

The measurements for characterisation of the RBA's were carried out using the same procedures and equipment as used for the Surveillance Units (SU's). In each RBA several scans were performed, each with a minimum of 30 data, and 30 stationary measurements were carried in different locations. In each RBA the average and typical deviation has been determined, this being used to determine the Background Estimator and Minimum Detectable Concentration for each measuring technique in each type of material.

Reference levels

In order to determine whether any point at the Facility presented a level of residual activity, different reference levels were established, these being classified as action levels (AL) and investigation levels (IL).

Action Levels: The action levels used are those established in the CRL for surface concentration on building surfaces (63FR222) and those for mass concentration in soils (64FR234). The levels of action for the key radionuclides Co-60 and Cs-137 are show in table 1.

Table 1. Action levels.

Type of surface	Action Level	
	Co-60	Cs-137
Permeable soil: earth, gravel, gardens	0.14 Bq/g	0.41 Bq/cm^2
Low permeability surfaces: concrete, asphalt	1.18 Bq/g	4.67 Bq/cm^2

Investigation Levels: For each SU the applicable investigation levels are determined taking into account: the applicable action level, the background in the RBA associated with the SU, the classification of the SU / (class 1, 2, 3) and the measurement method (scanning, static measurement or sample). The levels of investigation established are in table 2.

Table 2. Investigation levels.

SU Class	Scan	Static measurement or sampling
Class 1	> 10 NA	> 10 NA
Class 2	> NA	> NA
Class 3	> NA	> 0.5 NA

Once the investigation levels were defined, these were determined in the equipment measurement units. For the UCRM-II equipment, the investigation levels were determined in cpm, since this is the unit in which the results of the measurement are obtained.

Measuring methods used

The wastes arising from the operation and dismantling of Nuclear Power Plants constitute the largest part of the total waste stored at the El Cabril, in terms of volume and activity, this being represented to the largest extent by Co-60 and Cs-137. These are, therefore, the radionuclides to be characterised. However, if the spectrometric measurements provide evidence of the existence of other significant radionuclides, these will also be evaluated.

The measurement methods used have been as follows:

– Scanning with the UCRM-II equipment.
– Static measurement with the UCRM-II equipment.
– Static measurement with the ISOCS equipment.
– Sampling and laboratory analysis.

The scanning measurements with the UCRM-II equipment have been performed to detect potential areas of activity. Two types of scanning were performed: systematic scanning in accordance with a determined itinerary and specific scanning carried out in areas with the highest probability of presenting residual activity. At those points static measurements were performed for confirmation.

The Inspector 1000 has been used to locate areas with higher count rates in those areas in which investigation levels have been recorded in scanning.

The static measurements with ISOCS and the sampling have been performed to determine the average activity of the SU.

The number of measurements performed has been as follows:

– Scanning: 10% of the surface of SU’s of class 3, 50% for SU’s of class 2 and 100% for SU’s of class 1.
– Static measurements with UCMR-II: Whenever an investigation level has been detected in scanning.
– Static measurement with ISOCS: 5 measurements per SU (an initial point selected at random and the remainder in accordance with the pattern of the apexes of a W). Static measurements have also been performed using ISOCS at those points where a stationary investigation level has been confirmed with UCMR-II.
– Specific sampling in rainwater collection boxes and at rainwater pond discharge points. Samples have also been taken where the measuring equipment was inaccessible or in areas with high background levels.

Selection of measuring equipment

The detection and measuring equipment used in performance of the Special Surveillance Plan was as follows:

a) Radiological measurement field unit (UCMR-II)
The UCMR-II is a system that has been developed to cover radiometric requirements in the field, in scenarios with difficult access. It is a 2"x2" Ina detector connected to a CPU, both being incorporated on a transport carriage.
The equipment is made up of: a central processing unit; keyboard and LCD screen; data acquisition system; GPS unit; three-wheel transport carriage with metallic structure and collimating shielding.

b) ISOCS equipment (In Situ Object Counting System)
Is a system for the measurement of objects by spectrometry, made up of: coaxial germanium detector characterised by means of the Montecarlo modelling code; shielding assembly; Inspector 2000 MCA; ISOCS software and Genie-2000 data acquisition programme and three-wheel metallic structure transport carriage.

c) INSPECTOR 1000 equipment
Is a multi-channel analyser that allows for the measurement of dose and dose rate and for the acquisition and analysis of gamma spectra.
The equipment incorporates an internal Geiger-Müller detector for high dose rate measurement and a probe with a INa (Tl) scintillation detector. The equipment has been used in scan mode for the location of hot spots.

All the equipment used was calibrated "in situ" or had calibration certificates in accordance with the respective calibration procedures approved by ENRESA.

Analysis and evaluation of results

This section analyses and evaluates the results obtained in performing the SRSP for each of the Surveillance Units. In table 3 the main characteristics of the SU and the measurements carried out are shown.

Outdoor areas of the site. Paved areas

a) Building area yard (Zone 11)
<u>Surveillance Unit UV-A-VIG-11</u>
Asphalted section located between the Transitory Reception, General Services, Conditioning, Active Laboratory and Auxiliary Conditioning Buildings.

Scans were performed in one scan an Investigation Level was detected. This was verified by way of a one-off measurement and a sample was taken for analysis in the laboratory. The results of this analysis did not reveal any activity above the detection thresholds.

In the static measurements performed at random locations no activity was detected.

Specific sample of sediments from the rainwater collection box was taken. The results did not reveal any activity.

This area, which was initially classified as class 3, was reclassified as non-impacted.

Surveillance Unit UV-A-VIG-33

This belongs to unit UV-A-VIG-11 and was created as an intermediate unit between the class 3 UV-A-VIG-11 and UV-A-VIG-12, reclassified as class 1 after the initial measurements.

No investigation levels were recorded in gamma scans performed.

No activity was detected above the detection thresholds in statics measurements.

This Surveillance Unit, initially classified as class 2, was reclassified as class 3 since no activity was detected above the detection thresholds.

Table 3. Characteristics of SU and measurements performed.

Surveillance unit	Area (m^2)	Initial classification	Gamma scans			Number static measurements	Number samples
			Number	Area (m^2)	%		
UV-A-VIG-11	8,560	Class 3	21	874	10.2	5	2
UV-A-VIG-33	577	Class 2	6	305	53	5	-
UV-A-CON-12	945	Class 2	14	945	100	5	1
UV-A-VIA-17	24,114	Class 3	37	2,647	11	15 + 5	1
UV-A-PLA-18	1,930	Class 3	7	280	11	5	-
UV-A-PLA-19	1,930	Class 3	8	218	11	5	-
UV-K-VIG-26	1,114	Class 2	23	617	55	15 + 5	1
UV-K-VIG-27	1,965	Class 3	5	213	11	5	-
UV-K-VIG-28	513	Class 3	2	108	21	5	3
UV-K-VIA-31	2,852	Class 3	16	1,158	39	5	-
UV-K-VIA-32	250	Class 3	1	75	30	2 + 5	-
UV-C-01	1,270	Class 3	5	152	12	5	2
UV-C-02	660	Class 2	21	376	57	-	5
UV-C-03	1,100	Class 2				15 + 5	3 + 15
UV-C-04	1,471	Class 2	32	786	53	5	6 + 4

b) Parking area (Zone 12)

Surveillance Unit UV-A-CON-12

This is an asphalted area for the transitory parking of trucks carrying radioactive wastes.

In specific gamma scans 7 points above the Investigation Level were detected. 6 points above the Investigation Level were verified by static measurement. One point with a high Cs-137 count rate was confirmed by means of a specific measurement. In view of the results, this Surveillance Unit was reclassified as class 1, 100% of its surface area was investigated by gamma scanning.

In the static measurements at random locations, no activity was detected above the detection thresholds.

A sample was taken at the location with the high count rate. The result gave a value 10 times higher than the Action Level. This area was cleaned and a new soil sample was taken, the result was below the Action Level.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

c) Access road to North Platform and South Platform (Zone 17)
Surveillance Unit UV-A-VIA-17
Asphalted area corresponding to the access road to the radioactive waste Disposal Platforms zone.

In gamma scans performed 5 Investigation Levels were obtained. Static measurements were performed at these 5 locations, no activity was detected above the detection threshold.

No activity was detected above the detection thresholds in statics measurements at random locations.

Specific samples of sediments from the rainwater collection box were taken, no activity was detected.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

d) Temporary ISO container disposal facility to the south of the South Platform (Zone 18)
Surveillance Unit UV-A-PLA-18
This is an asphalted area located to the south of the South Platform where ISO containers with radioactive wastes from different incidents (Acerinox and others) are kept.

Any point above the Investigation Level was detected in gamma scans.

In static measurements at random locations, no activity above the detection thresholds was detected.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

e) Temporary ISO container disposal facility to the north of the South Platform (Zone 19)
Surveillance Unit UV-A-PLA-19
This is an asphalted area located to the north of the South Platform where ISO containers with radioactive wastes from different incidents (Acerinox and others) are kept.

No points above the Investigation Level were detected in gamma scans.

In static measurements at random locations, no activity above the detection thresholds was detected.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

f) Outdoor area to the west of the Modules and Technology Building (Zone 26)

Surveillance Unit UV-K-VIG-26

This is a concrete area located to the west of the Technology Building and the temporary radioactive waste storage Modules.

In gamma scans performed 15 Investigation Levels were detected. Static measurements were performed at these locations; no activity was detected above the detection threshold.

In static measurements no activity was detected above the detection thresholds.

Samples of sediments from the rainwater collection box were taken. The results for the sample showed background values.

This Surveillance Unit, initially classified as class 2, was reclassified as class 3.

g) Outdoor area to the east of the Modules and Technology Building (Zone 27)

Surveillance Unit UV-K-VIG-27

This is an outdoor concrete area located to the east of the Technology Building and the temporary radioactive waste storage Modules. It also includes the areas between the Modules.

In gamma scans performed, 21 Investigation Levels were detected. A checking was made and it was considered that these values were due to the influence of a high background resulting from the radioactive wastes contained in these Modules.

The static measurements showed that no activity was detected above the detection thresholds.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

h) Outdoor area to the east of the Technology Building and the east and south of the Modules (Zone 28)

Surveillance Unit UV-K-VIG-28

This is an area of earth located to the east and south of the temporary radioactive waste storage Modules.

In gamma scans performed 3 areas exceeding the Investigation Level were detected. Samples were taken and no activity was detected.

No activity was detected above the detection thresholds in static measurements.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

i) Access road to Cell 29 (Zone 30) and road between the Technology Building and Cell 29 (Zone 31)

Surveillance Unit UV-K-VIA-31

This is an asphalted area providing access to Cell 29.

A large number of alarms above the Investigation Level were registered, in gamma scans, due to natural radionuclides in the ground surrounding the road.

No activity was detected above the detection thresholds in static measurements.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

j) Band of ground between zones 11 and 13 (Zone 32)
Surveillance Unit UV-K-VIA-32
This is an area of land bounding Surveillance Units UV-A-CON-12, UV-A-VIG-11 and UV-A-VIA-17.

A single gamma scan was performed along the entire Surveillance Unit, 2 Investigation Levels were detected and confirmed by static measurements. Two samples were taken from these locations, no activity above the Detection Threshold was detected.

The measurement of the 5 random points was performed by sampling. The values obtained were those habitually found in the soils in the area.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

k) Outdoor areas in the zone surrounding the rainwater collection pools
The radiological surveillance of these areas was performed by taking samples and analysing sediments at the outlet from the buildings and platforms rainwater pools. The two samples gave values of Cs-137 similar to those of the soils in the area due to fallout.

Roofs of buildings

a) Roof of the Auxiliary Conditioning Building
Surveillance Unit UV-C-01
This is a concrete roof with a weatherproofing sheet and a final layer of gravel. It is a surface not considered to be affected by the discharge of gaseous effluents, for this reason was classified as the area in which it is located.

During scanning 2 investigation levels were registered, both confirmed by specific measurements.

The measurements performed at the 5 random points showed two points with values of CS-137 activity above the AMD/2 detection threshold, but below the actions levels. The specific samples taken at the two points did not show Cs-137 or Co-60 activity in either the coarse gravel fraction or the fraction of fine materials above the detection thresholds.

This Surveillance Unit, initially classified as class 3, was reclassified as a non-impacted area.

b) Roof of the Active Laboratory
Surveillance Unit UV-C-02
This is a concrete roof with a weatherproofing sheet and a final layer of gravel. It is a surface considered to be affected by the discharge of gaseous effluents.

During performance of the scans, 3 investigation levels were registered. The specific measurements performed did not confirm the alarms.

The measurements at the 5 random sampling points were performed by sampling due to difficulties in accessing the roof with the equipments. The results pointed to the no existence of residual activity above the detection thresholds.

This Surveillance Unit, initially classified as class 2, was reclassified as a class 3 area. However, it might be reclassified as a non-impacted area since no residual activity above the detection thresholds was detected in the random samples performed.

c) Roof of the Conditioning Building

This is considered to be affected by the discharge of gaseous effluents, for which reason it was initially classified as class 2.

Surveillance Unit UV-C-03

This includes the part of the rood of the Conditioning Building located to the west of the general ventilation duct. This is a concrete roof with a weatherproofing sheet and a final layer of gravel.

Systematic scanning was performed and 51 investigation levels were registered, both in the window for Cs-137 and Co-60, although expected due to the foreseeable influence of the contents of the Conditioning Building. A triangular mesh of 15 points, for specific samples, was designed additionally to the 5 points already established corresponding to the random ones.

In three of the statics measurements, activity above the action level was registered. These results show a more intense influence of the background which corresponds to the location of the containers shed. Samples were taken at these three points for laboratory analysis.

The analysis of the 15 specific samples and the three samples from random points reveals that in none of the 18 samples measured were Cs-137 or Co-60 activity values registered in excess of the detection thresholds.

This Surveillance Unit, initially classified as class 2, was reclassified as a class 3 area.

Surveillance Unit UV-C-04

This includes the part of the roof of the Conditioning Building located to the east of the general ventilation duct. This is a concrete roof with a weatherproofing sheet and a final layer of gravel.

The scans were performed in front of the stack emission points and the general ventilation duct, 8 investigation levels were detected. Of these 8 investigation levels, 6 were confirmed by specific measurements due to the confirmed influence of the interior of the building. Samples were taken at these six points for analysis.

The measurements at the random sampling points were performed using the ISOCS equipment but in four cases samples were taken due to the equipment was not operative.

The analysis of the results of the samples indicates that no Cs-137 or Co-60 activity was detected above the detection thresholds.

This Surveillance Unit, initially classified as class 2, was reclassified as a class 3 area.

d) Roofs of Modules and Technology Building
<u>Surveillance Units UV-C-05 and UV-C-06</u>
The radiological surveillance was not performed in these surveillance units, belonging to the roofs of the Temporary Storage Modules and Technology Building, respectively. In accordance with the initial analysis, the fact that these roofs are affected by the discharge of effluents constitutes a risk factor. However, since the Technology Building had not initiated its operation as of the date of performance of the programme, they were classified in the same class as the outdoor area in which they are located (class 3).
Consequently, in view of the results of the surveillance corresponding to the outdoor area, their reclassification as non-impacted might be assessed.

Vertical outer walls of buildings

The radiological surveillance of the surveillance units on walls (UV-P-01, UV-P-02 and UV-P-03) has not been carried out since no contamination was detected in the outdoor areas in which they are located.

Conclusions

– The methodology used in this SRSP is adequate for the purpose and will serve for the performance of later routine surveillance at the site of the El Cabril disposal facility.
– All the outdoor areas may be classified as non-impacted areas, with the exception of UV-A-VIG-33, which was reclassified as class 3.
– All the roofs of buildings were reclassified as class 3 areas. Nevertheless, they might be reclassified as non-impacted, since no residual activity above the detection thresholds was detected in the specific or random samples performed.
– All the vertical exterior walls of buildings might be reclassified as non-impacted or class 3 areas, since no contamination was detected in the outdoor areas in which they are located.

Monitoring of radionuclides in the vicinity of Czech nuclear power plants

Abstract

The monitoring in the surrounding environment of Czech nuclear power plants (NPPs) Dukovany and Temelin consists from routine determinations, performed by NPP's staff, and also extended, supervisory, sampling performed by research institutions. In our contribution several results of this monitoring are briefly discussed and summarized.

Introduction

At present, the most significant artificial sources of radiocarbon in the environment are effluents from nuclear power facilities, even though it is a minor contribution in comparison with its natural production. Nevertheless, radiocarbon makes a major contribution to the collective effective dose from all radionuclides released by nuclear power plants (NPP) with light-water pressurized reactors (LWPR) during normal operation (UNSCEAR, 2000). Although ^{3}H is not considered to be a particularly radiotoxic radionuclide and releases by commercial nuclear power plants have traditionally been well below regulatory limits, control and monitoring are important because of the sensitivity of the public to issues of radioactive material release and the potential of radiation exposure (Harris et al. 2008; Andersen 1995; Liu et al. 2003). The radionuclides ^{3}H and ^{14}C require special consideration because of their high mobility in the environment and the fundamental nature of hydrogen and carbon cycles in the biosphere (UNSCEAR 2000). Tritium produced by NPPs with LWPR can be released into the environment through waste discharge in either airborne or liquid forms (Kim & Han 1999; Harris et al. 2008). In general, normalized ^{3}H gaseous and liquid releases from LWPR are about 1.5 and 20 TBq GWyear^{-1}, respectively (Luykx & Frazel 1986). Tritium released to the atmosphere occurs in two forms: tritiated hydrogen (HT) and tritiated water vapour (HTO). HTO is subject to the same wet and dry deposition processes as other nuclides, but it can also diffuse into the soil pore space and the leaf stomates (Belot et al. 1979; Garland 1979). Tritium which is not returned to the atmosphere by evaporation moves through the soil primarily by the mass flow of liquid water (UNSCEAR 2000). The Czech Republic has two LWPR equipped NPPs, Temelin and Dukovany, with the installed power output 2x1000 MW and 4x440 MW, respectively. The monitoring in the surrounding environment of Czech nuclear power plants (NPPs) Dukovany and Temelin consists from routine determinations, performed by NPP's staff, and also extended sampling which is performed by several research institutions. Systematical monitoring of HTO in the air of NPPs surrounding was launched there by the National Institute of Radiation Protection in 2008. Systematic sampling of biota and agricultural products for ^{14}C activity monitoring was started in 2002 by Nuclear Physics Institute in the cooperation with National Institute of Radiation Protection (Svetlik et al. 2007, 2008). Environmental monitoring, performed by staff of NPPs, includes these determinations: gamma spectrometry, ^{90}Sr, ^{3}H (in surface and underground water), gross alpha and beta, and dose rate (ETE 2010, EDU 2010). Still other institutes are involved in the specialized monitoring of Czech NPPs surrounding, namely: Water Research Institute T.G.M. in Prague – HTO and ^{137}Cs in connected surface water (Hanslik et al. 2009a, b); Czech Technical University, Faculty of Nuclear Sciences and Physical Engineering, Department of Dosimetry – gamma spectrometry and dose rate in the NPPs vicinity (Thinova & Trojek 2009; Thinova & Kluson 2008).

Material and methods

As a part of project SÚJB 5/2008 "Monitoring and evaluation of nuclear power plants discharges containing tritium" tritium activity concentration in the air humidity was also determined. Air humidity samples were collected in surroundings of the two Czech nuclear power plants (Malatova & Hulka 2008). A sampling method using sorption of the air humidity on dried silica gel was developed. The method operates in two different time regimes utilizing both static (sampling period of about four weeks) and dynamic sampling applying Dwarf aerosol sampler for point sampling with duration of about 10 minutes (Fejgl et al. 2009). Tritiated water was recovered from silica gel by means of freeze-drying. Tritium activity concentrations were measured by low-background liquid scintillation spectrometers. Four outdoor HTO sampling campaigns at the vicinity of the Dukovany power plant and one outdoor sampling expedition to the vicinity of the Temelin power plant were performed during the years 2008 and 2009. During these sampling campaigns 112 air humidity samples were collected. Sampling around power plant Dukovany was emphasised because of elevated tritium activity concentration in cooling water (hundreds Bq per liter), therefore tritium could be discharged from the power plant not only via ventilation stack but also via cooling towers (Fejgl et al. 2009a). 10 sampling points for dynamic sampling and 17 sampling points for static samplings were laid out in distance between 100 and 900 meters from the cooling towers, see Fig. 1.

Monitoring of ^{14}C in surrounding of the Czech NPPs and in reference localities is performed utilizing biota samples, see fig 2. This type of monitoring is restricted on the part of vegetation period. Time interval of ^{14}C activity record depends on period of biomass cumulation in a given plant. ^{14}C activity in the sampling points can be locally influenced (lowered) by anthropogenic CO_2 emissions from fossil fuel combustion (traffic, heating of buildings). Fossil carbon (without significant ^{14}C amount) causes dilution of ^{14}C in carbon isotopic mixture (Suess effect). Local component of Suess effect can be observed namely in the vicinity of greater roads, cities, and other greater fossil CO_2 sources (Suess, 1955; Kuc & Zimoch 1998).

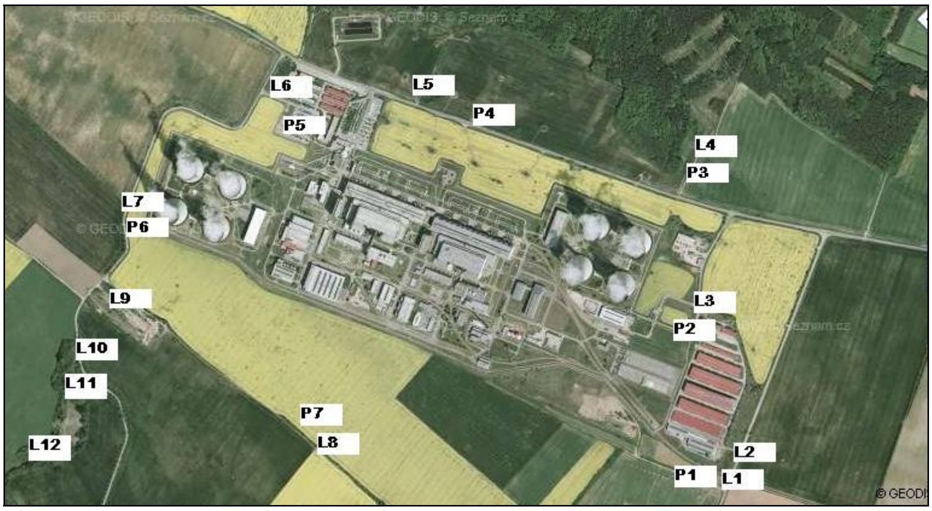

Fig. 1. Nearest sampling points around NPP Dukovany for HTO activity monitoring in air moisture. P – prompt sampling, L – long term period of sample cumulation.

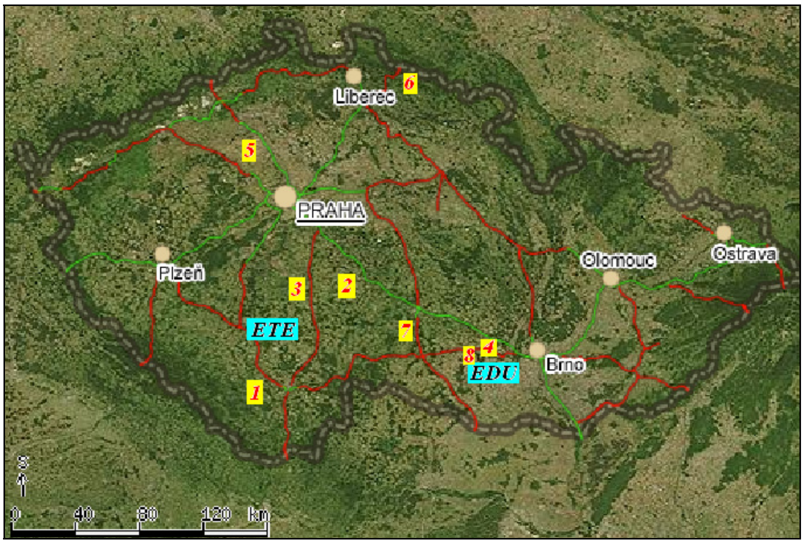

Fig. 2. ^{14}C sampling points in the area of the Czech Republic: NPP Dukovany – EDU; NPP Temelin – ETE; 1-8 reference sampling points in localities with smaller load of fossil fuel combustion.

Prevailing part of biota samples were leaves of deciduous trees, analogically to published studies performed in the vicinity of other NPPs. Leaves of *Sambucus nigra L.* (pipe tree) were preferred, because this tree is widespread in the Czech Republic, and it can be easy identified. Smaller part of samples collected were agricultural plants (spikes of wheat and barley). Dusty biota samples were washed by 10% HCl and distilled water, dried (105 ^{o}C) and homogenized. Washing by diluted HCl was suspended if presence of dust on sample surface was not evident. Dried samples were combusted and resulting CO_2 was purified. In the NPI AS CR a routine of sample processing based on benzene synthesis was followed (Gupta & Polach, 1985). ^{14}C activity was measured by liquid scintillation spectrometer Quantulus 1220 in 3 ml low-background Teflon vials. Total counting time was about 2000 minutes per sample. Benzene distributed by Sigma-Aldrich (spectrophotometric grade) was used as a blank sample. Calibration was performed using oxalic acid NIST (NBS) HOX II, SRM 4990-C (Schneider et al., 1995). Combined uncertainties include the individual uncertainties of measured sample, blank sample, calibration, quenching corrections, and uncertainty of the $\delta^{13}C$ value (Curie 1995). In the vicinity of NPPs Temelín and Dukovany several roads are situated and there also are some smaller cities and villages. The influence of local Suess effect could be estimated/quantified with difficulties, as data about local fuel combustion and density of traffic are absent. To compare ^{14}C activities in the NPPs surrounding with actual ^{14}C activity level in the environment two types of areas with different load of Suess effect were selected. It can be supposed that actual size of Suess effect influencing in NPPs surrounding will be in the interval demarked by the two types of reference areas (Svetlik et al. 2007). (A) Localities, in greater distances from fossil carbon sources, where only small local influence of Suess effect was supposed (Košetice, Kleť, Sudoměřice u Bechyně, Krokočín). (B) Localities where medium local Suess effect influence can be expected (bordering parts of Prague).

Staff of nuclear power plants Temelin and Dukovany is monitoring radionuclides in the NPPs vicinity following internal documents (programs of Environmental Monitoring in the Vicinity of NPPs Temelin and Dukovany). All gamma, alpha and liquid scintillation spectrometry measurements (^{90}Sr, HTO) of radionuclides were performed applying metrologically validated and calibrated instruments (Czech Metrology Institute - Inspectorate for Ionizing Radiation). Most of the utilized analytical methods are a subject of accreditation (Czech Accreditation Institute). The environmental monitoring of radionuclides includes these sample types: (1) Aerosols (13 sampling points in the distances from 2 to 26 km, flow rate about 40 m^3 per hour, one week exposition – determinations: gamma emitting radionuclides and ^{90}Sr), monitoring of ^{131}I for each NPP is also performed at distance from NPP Temelin 5 km (one point) and Dukovany, 6 points at distances 3-11 km (flow rate 4 m^3 per hour, one week of iodine cartridge exposition); (2) bulk atmospheric deposition (8 sampling points in distances from 2 to 11 km to NPP, sampling area 0.5 m^2, one month sampling period – determinations: gamma emitting radionuclides); (3) atmospheric precipitation (7 points, sampling period is one month, in distances from NPP Temelin and Dukovany from 1 to 11 km, respectively – determination HTO); (4) surface water in surrounding lakes (7 sampling points) and corresponding river profiles 10 of Vltava and Jihlava (one month sampling period – determinations: gross alpha and beta, gamma spectrometry, HTO), from each profile and sampling point also determination of ^{90}Sr is annually performed; (5) underground water, 25 boreholes in distances from NPPs Temelin and Dukovany from 1 to 3 km - determinations: gamma spectrometry, HTO); (6) drinking water (at least samples from 11 sampling points of tap and well water - determinations: gross alpha and beta, gamma spectrometry, HTO, ^{90}Sr); (7) milk (3 pieces of 3 litre samples in one month period (minimally) for gamma spectrometry measurement, subsequently are samples cumulated and ^{90}Sr determination is performed annually); (8) sediments and soils, annual quantity is about 16 sampling points (surface layers till 10 cm, fraction below 2 mm, gamma spectrometry measurement); (9) 12 agricultural and forest products (gamma spectrometry measurement) are processed annually.

Results

Basic statistical parameters of HTO monitoring in air humidity in the vicinity of Czech NPPs and background areas are reported in Table 1.

Table 1. Mean values of observed HTO activity concentration in air moisture and supporting data (prompt sampling/long term sample cumulation).

	NPP Dukovany	NPP Temelin	Background samples [c]
Median, Bq L^{-1} [a]	2.60 / 2.53	2.19 / 1.82	2.81
Number of values below significance level [b]	5 / 17	0 / 1	6
Number of outlying values	2 / 4	0 / 0	0
Number of observations	32 / 50	7 / 5	23

[a] Excluding outlying values in the case of NPP Dukovany.
[b] Decision threshold was calculated for 5% probability of the first kind error and was in the range 0.8 to 1.3 Bq L^{-1}.
[c] Background sampling was performed only for long term sample collection.

During period 2002 – 2005, 77 biota samples for ^{14}C analyses were collected in the vicinity of NPPs Dukovany (EDU) and Temelín (ETE). Likewise, 30 samples were collected in reference areas influenced with slight (A) and extended (B) local Suess effect. Basic statistical parameters of results (EDU, ETE, A, B) are reported in Table 2. Standard deviations of couples EDU-B, ETA-A, and ETE-B are equal on the base of F-tests performed (Fischer-Snedecor test). In the next step results from each type of area were compared utilizing t-test (student test, unpaired, probability of first kind of observation error 1%), see Table 3.

Table 2. Basic statistical parameters of biota samples collected in the vicinity of NPPs Dukovany (EDU), Temelín (ETE) and in reference localities with slight (A) and extended (B) local Suess effect. Sampling period 2002 – 2008. Activities are reported in ‰ of $\Delta^{14}C$ (Stuiver & Polach, 1977).

	EDU	ETE	Ref. localities A	Ref. localities B
Average	60.1	61.0	56.2	47.4
Median	58.3	60.4	56.2	45.7
Standard deviation (σ)	13.2	9.0	6.5	7.3
Variation	173	81	42.1	53.5
Number of observations	27	50	21	9
Observed maximum	95.9	84.4	67.9	58.7
Observed minimum	39.8	41.7	44.0	38.0

Table 3. Comparisons of activities of observed results from each type area (group of the data), values of T reported in table: T_o (observed) and T_c (critical); t-test, unpaired, probability of first kind of observation error 1%.

Couple compared	T_o	T_c	*t-test enclosures*
A-B	2.621	3.106	$T_o < T_c \Rightarrow$ *difference is not significant*
EDU-A	1.479	2.712	$T_o < T_c \Rightarrow$ *difference is not significant*
EDU-B	2.507	2.037	$\boldsymbol{T_o > T_c \Rightarrow}$ ***difference is significant***
ETE-A	2.336	2.651	$T_o < T_c \Rightarrow$ *difference is not significant*
ETE-B	3.913	2.668	$\boldsymbol{T_o > T_c \Rightarrow}$ ***difference is significant***
EDU-ETE	0.272	2,712	$T_o < T_c \Rightarrow$ *difference is not significant*

Discussion

HTO activity concentrations in the air humidity from background reference sites fall in the range from <1.2 up to 3.5 Bq/L. All the samples from NPP Temelín vicinity and most of the samples from the NPP Dukovany vicinity do not exceed the same range. In some of the samples significantly increased tritium activity concentrations were found. An increase was found in the samples from the sampling point L5 (10.57 ± 0.53 Bq L^{-1}, September 2008) for long-term sampling and P4 for instant sampling (11.37 ± 0.57 Bq L^{-1}, September 2008). Both these sampling points are placed near the wastewater pipe outfall; the increase can be explained by a local evaporation of the wastewater. Another increased activity concentration was found in the sample from September 2008 from the sampling point P7 for instant sampling (7.90 ± 0.62 Bq L^{-1}). This point is placed 100 meters to the south from the grounds of NPP Dukovany. It was raining during the sampling and the wind blew southwards. This increase is the only one which is explainable as a sorption of tritiated water evaporated from the cooling tower (Fejgl et al. 2009). Other increases were found in the samples from the dam Mohelno vicinity from September 2008 and September 2009 i.e. 13.28 ± 0.51 and 7.03 ± 1.08 Bq L^{-1}, respectively. Probable reason is the evaporation from the dam reservoir (tritium volume activity concentration ranges between tens and hundreds Bq per litre), see Fig. 3. Related increase was also observed in the sample collected near the Jihlava River (8.77 ± 0.91 Bq L^{-1}, September 2008).

Comparison of two air humidity sampling methods sorption on silica gel versus cold trap method (air flow-rate 30 L $hour^{-1}$, temperature -20 ^{o}C, sampling period a month) at the same place shows systematically augmented tritium activity concentrations in samples collected by sorption on silica gel. With respect to the fact that chemical laboratories of NRPI process highly tritiated water samples (up to 100 kBq L^{-1}), the cross-contamination seems to be the most probable reason of tritium activity concentration increase. An experiment with very low tritium activity water was performed off the premises. The water vapour was sorbed into silica gel, this was lyophilized and subsequently the tritium activity concentration in the sample was determined. The found value was 1.22 ± 0.59 Bq/l. This result confirms possibility of cross contamination during sample processing in the lab. Contamination of the dried silikagel just after it has been dried an before it is filled in the storage vessel seems most likely. Some precautions were applied in order to reduce cross-contamination risk. Processing time was shortened and the drying temperature was enhanced from 105 to 130 °C, the drying time was extended to 8 hours, what ensures extrusion of lasting humidity. For final evaluation of precautions it is necassary to get more data, therefore the monitoring of the samples from the background reference sites will continue.

Results of statistical comparison confirmed significantly greater ^{14}C activity level in surrounding biota from both NPPs in the comparison with reference area B with greater load from fossil fuel combustion (bordering parts of Prague). Nevertheless, if these tests were performed for probability of first kind of error 5% (a), significant differences were found also between reference localities A and B. The difference of ^{14}C activity level between biota from NPP Temelín vicinity and biota from reference area A (small local fossil fuel combustion) was found to be statistically significant also, see Table 2. In the point of view of local loads from fossil fuel combustion, it can be supposed that relevant reference ^{14}C activity level for NPPs surroundings with relatively frequented roads is allocated in the interval between reference areas A and B. Observed ^{14}C activity values for each type of locality are charged by relatively greater variations, namely in samples from NPPs surroundings, probably caused by local Suess effect from surrounding roads especially. Other reason of fluctuation can be given also by relatively short time interval of biomass cumulation in leaves of deciduous trees (about the first third of vegetation period). At this part of year activity of atmospheric $^{14}CO_2$ changes rather quickly (Levin & Kromer 2004; Levin et al. 1995, 2008, 2010; Molnár et al. 2007) and biomass of plants is cumulated in the dependence of the local microclimatic parameters (atmospheric precipitation, soil moisture, sunlight exposure). Local microclimatic differences can cause small time shift of atmospheric $^{14}CO_2$ intake period. Additional reason of ^{14}C activity variations in NPPs surroundings is given by relatively greater distances from NPPs stacks (below 9 km) in certain sample collection localities. Potentially influenced zones around NPPs can be probably found in the distance till 2 km, on the basis of ^{14}C dissipation model, (Rousel-Debet et al., 2006). Also the direct results of ^{14}C in biota monitoring performed in the vicinity of NPPs with boiling water reactors (BWR)[1] in Sweden confirm similar distances from stacks for maximal surplus of ^{14}C activity in biota (Stenström et al. 1996; Stenström et al. 1998).

On the basis of environmental monitoring performed by staff of NPPs Temelin and Dukovany during year 2009, there were observed activities of HTO enhanced above background level in surface water, see fig. 3. These activities are given by liquid releases of ^{3}H, which did not exceed authorized limits given by State Office for Nuclear Safety. In the case of NPP Dukovany surrounding, there were observed also several increased HTO activities in underground water, which did not exceed 60 Bq L^{-1}. Origin of such HTO is probably connected with cooling towers, which are evaporating water from Mohelno reservoir, see fig. 3. Analogically to previous years, during 2009, no activities exceeding reference activity values were observed in the environmental

[1] In the comparison with LWPR contain releases from BWR considerably greater percentage of $^{14}CO_2$, above 90% (Kunz 1995). This chemical form of released ^{14}C can be assimilated by plant photosynthesis and hence greater ^{14}C activity excess can be observed in the surrounding biota of NPPs with BWR.

surrounding of both NPPs (ETE 2010, EDU 2010). By direct field measurements or on the basis of laboratory determinations performed in laboratories of NPPs, the only radionuclides of artificial (possible artificial) origin measurable in the surrounding environment are ^{3}H and ^{137}Cs. Dominant source of ^{137}Cs in the environment of the Czech Republic was accident of Chernobyl NPP in 1986 and no increased activity level of this radionuclide (in the comparison with background values) was observed in the vicinity of both NPPs.

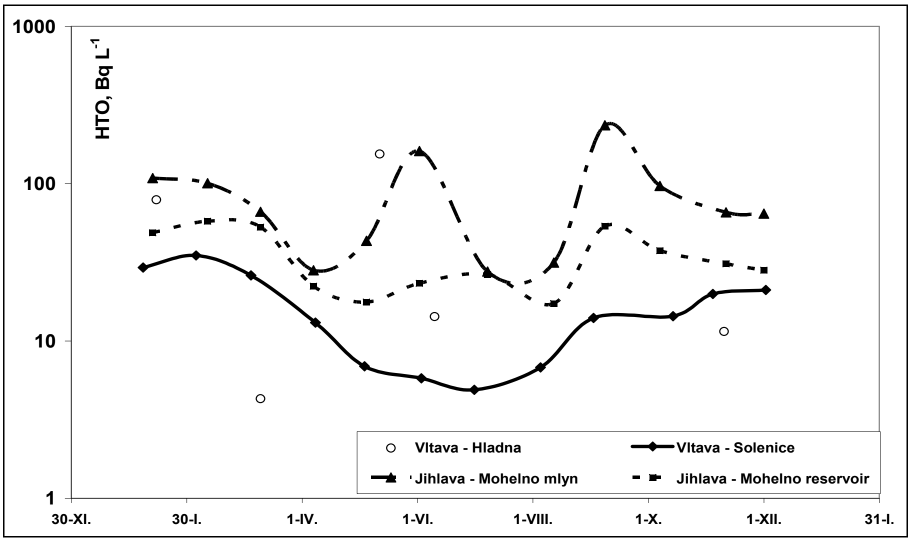

Fig. 3. Year 2009. Time course of HTO activity concentration in profiles Hladna (about 5 km downstairs from releasing channel of NPP Temelin in Korensko) and Solenice (below barrier of the great river reservoir Orlik, about 50 km downstairs from the releasing channel). Incrreased HTO activities in the profile Hladna can be observed only several days after discontinuous discharges from the NPP Temelin, in other cases are activities below 3 Bq L^{-1}. Liquid releases from NPP Dukovany are exhausted into Mohelno reservoir. River profile Jihlava-mlyn is about 1500 m downstairs from Mohelno reservoir barrier.

Conclusions

A brief summary of the monitoring performed by several institutions in the vicinity of NPPs Temelin and Dukovany was assembled. In the point of view of HTO monitoring in air moisture in the vicinity of NPP Dukovany, only several samples with significantly increased HTO activities were collected. Nevertheless, our sampling method based on silica gel sorption did not allow fine resolution and will be modified and validated. Results of ^{14}C activity monitoring, utilizing leaves of deciduous trees and agricultural products, in the surrounding of both NPPs highlights small probable surplus in the surrounding of NPP Temelin (about 5‰ Δ^{14}C). Enhancement of ^{14}C activity was not statistically significant in the vicinity of NPP Dukovany.

Enhanced HTO activities in rivers Vltava and Jihlava, where liquid releases are exhausted, have been observed by staff of NPPs within the frame of routine environmental monitoring. In the case of NPP Dukovany, HTO activities in the connected underground and well water have also been observed above actual environmental background, but deeply below limit of 100 Bq L^{-1}, given by Czech legislative. Significant, measurable, presence of other radionuclides originated from

NPPs has not been observed by monitoring performed by staff of nuclear power plants in the surrounding, although susceptible measuring methods were applied.

Abstract
Monitoring ^{14}C activity in the atmospheric CO_2 and in biological samples (fruits and vegetables) in the close vicinity of the NPPK was performed regularly since 2006 to estimate the possible influence of the plant on environmental ^{14}C levels and the possible contribution to the effective dose of local population through food chain.

Mean values of ^{14}C activity in atmospheric CO_2 in the years when the refuelling was not performed represent a barely visible increase in relation to the activities of ^{14}C in the atmosphere at the control point. Immediately after refuelling the atmospheric ^{14}C activity was increased for a short period of time. Spatial distributions of ^{14}C activities in biological samples show the dependence on distance and orientation. In all campaigns the highest activities were obtained at the same locations in the SW-NE direction that coincided with the most pronounced wind directions. Estimated contribution of ^{14}C released by NPPK to the natural dose is less than 1 μSv.

Introduction
^{14}C is formed in upper layers of the atmosphere in a reaction of neutrons from the cosmic rays and nitrogen atoms. All carbon isotopes take part in chemical reactions, hence ^{14}C is also oxidized into $^{14}CO_2$ and distributed uniformly throughout the atmosphere. Plants assimilate $^{14}CO_2$ through the photosynthesis process, and animals are fed by plants, thus the ^{14}C isotope is a part of the natural carbon cycle. In the past, the equilibrium between radioactive decay of ^{14}C and its production rate has been established, and the natural ^{14}C concentration, or better to say, specific activity of ^{14}C, in the Earth's atmosphere and biosphere is approximately constant and it equals 226 Bq/kg of carbon. Assuming atmospheric CO_2 concentration of 370 ppm, this equilibrium specific activity of ^{14}C in the atmosphere corresponds to 0.037 Bq/m^3 of air.

In the second half of the 20th century the natural ^{14}C distribution was disturbed by atmospheric bomb tests and in 1963 the atmospheric ^{14}C specific activity reached maximum of twice the natural activity. After the ban of atmospheric bomb tests the present-day atmospheric ^{14}C activity approaches the natural (non-disturbed) values.

^{14}C is produced also in nuclear power plants. The emitted $^{14}CO_2$ enters the carbon cycle, and through food chain it may contribute to the dose of the local population. The aim of this study was to determine distribution of ^{14}C in a close vicinity of the Nuclear Power Plant Krško (NPPK) in Slovenia close to the border with Croatia, and to estimate possible contribution of NPPK to the effective dose of local population through food chain.

Sampling and measurements

Atmospheric CO_2 was collected at two locations inside the NPPK area, marked as **A** and **B** in Figure 1, close to the release point of the plant ventilation system. Integral samples were collected since 2006 on a regular bimonthly basis by absorption of CO_2 in saturated NaOH solution. Na_2CO_3 thus produced was in the laboratory dissolved in HCl, and the obtained CO_2 was used for benzene synthesis. Benzene samples were measured by a liquid scintillation counter *Quantulus* (Horvatinčić et al. 2004).

Specific ^{14}C activity of biological samples (apples, corn, cereals, borecole, grass) was measured in immediate vicinity (locations **C**, **D**, **E**, **I**, **J**, **L** and **R**, 200 – 400 m from the NPPK release point), and in a wider environment (locations **F**, **G**, **H**, **K**, **M**, **N**, **O**, **P** and **Q**, about 1000 m) of NPPK (Fig. 1). As a control site, where no influence of the plant is expected, we have chosen village Dobova, about 10 km SE from NPPK. Two sampling campaigns have been performed each year since 2006, in June/July and in September/October. Samples were dried, carbonized (pyrolysis at 600°C), and combusted in a stream of oxygen. The obtained CO_2 was absorbed in a mixture of Carbosorb®E and Permafluor®E. ^{14}C activity was measured by the LSC *Quantulus 1220* (Horvatinčić et al, 2004; Krajcar Bronić et al, 2009).

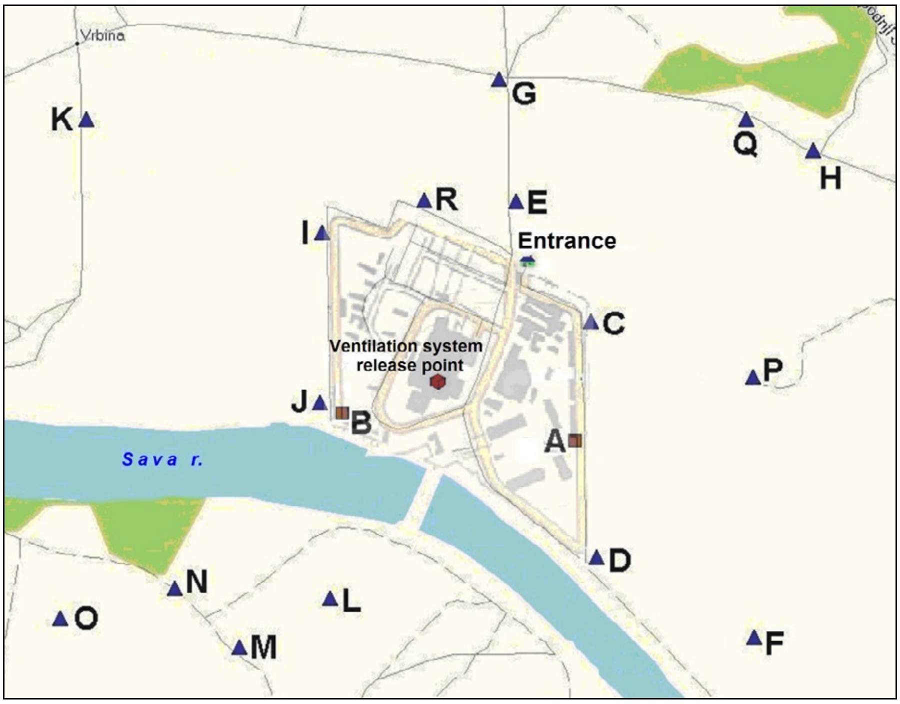

Fig. 1. Sampling locations in the vicinity of Nuclear Power Plant Krško. Locations A and B for atmospheric CO_2. Locations C – R for biological samples.

Results

The results are usually expressed as the relative specific activity $a^{14}C$, defined as the ratio of the specific activity of the sample and that of the atmosphere undisturbed by anthropogenic influence, in "percent of Modern Carbon", or pMC. Consequently, relative specific activity of 100 pMC corresponds to specific activity of 226 Bq/kgC or to the $^{14}CO_2$ activity concentration of 0.037 Bq/m^3 of air.

Activity in atmospheric $^{14}CO_2$

^{14}C activity concentrations in the atmosphere at two locations (**A**, **B**) inside the NPPK are shown in Figure 2. For comparison, a part of long-term atmospheric ^{14}C data in the city of Zagreb is shown (Krajcar Bronić et al, 2009), as well as the integrated monthly ^{14}C activities released through the plant ventilation system. Atmospheric ^{14}C activity at the location **B** is always slightly higher than that at the location **A**. This difference can be explained by the position of location **B** relative to the release point and the local prevailing wind direction SW – NE (Fig. 3), and is particularly evident in the refuelling outage periods and immediately thereafter. The half-life of the released ^{14}C in the atmosphere is estimated to app. 1.5 months. During the refuelling in October 2007 higher $a^{14}C$ values at the site **B** were observed (102 mBq/m^3) than during the refuelling in April 2009 (69 mBq/m^3) probably due to the of shorter sampling period (ten days in 2007 in comparison to three weeks in 2008), which coincided better to the highest ^{14}C release to the atmosphere.

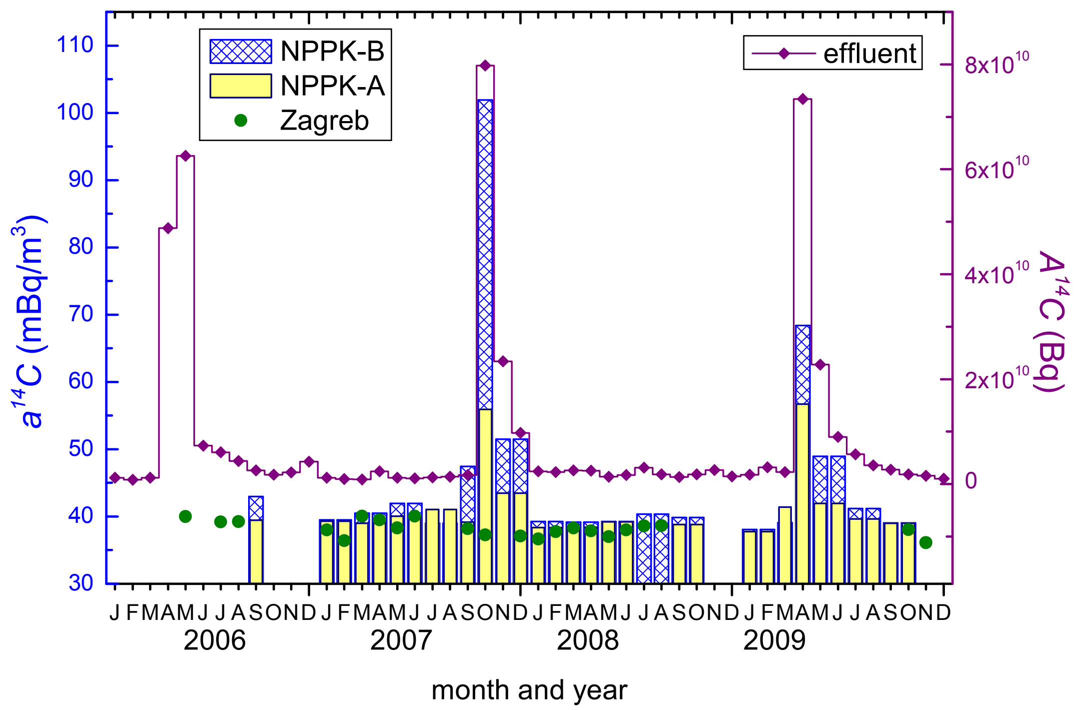

Fig. 2. ^{14}C activity concentration in atmospheric CO_2 at locations A and B and comparison with the results obtained in Zagreb (40 km E) (left ordinate). Monthly ^{14}C activity in effluent released through the plant ventilation system (right ordinate).

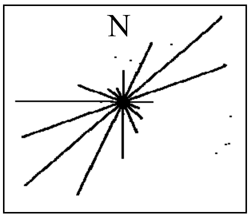

Fig. 3. Wind rose in the vicinity of NPPK, measured on a 10 m high column (according to the Environmental Agency of the Republic of Slovenia)

Mean values of $a^{14}C$ in atmospheric CO_2 in the years when the refuelling was performed (2007 and 2009) are 41.7 and 41.5 mBq/m^3 at the location **A**, and 47.9 and 44.2 mBq/m^3 at the location **B**. In 2008, when no refuelling was performed these values were 38.7 (location **A**) and 39.6 mBq/m^3 (location **B**). They represent a barely visible increase in relation to the activities of ^{14}C in the atmosphere measured in Zagreb (38.3 mBq/m^3 in 2007 and 37.8 mBq/m^3 in 2008), where the effect of reducing ^{14}C atmospheric activity is possible due to combustion of fossil fuels.

Activity in biological samples

In Figure 4. we present the spatial distributions of measured ^{14}C activities (expressed as specific activities in pMC) for all eight sampling campaigns, as well as the corresponding polar diagrams that show the dependence on distance and orientation. In polar diagrams we have separated closer locations **C**, **D**, **E**, **I**, **J**, **L** and **R** (inner circle) and farther locations **F**, **G**, **H**, **K**, **M**, **N**, **O**, **P** and **Q** (outer circle), and have also shown $a^{14}C$ values at the control point Dobova. Increased activities were observed in all sampling campaigns in SW – NE direction of most pronounced winds. As expected, higher activities of ^{14}C were measured in biological material which used CO_2 in the refuelling outage period which was performed during and immediately after the vegetation period. In 2006 and 2009 the power plant was refuelled in spring period, so the apples, having their vegetation period immediately afterwards, collected more active CO_2. Therefore, at all locations the highest ^{14}C activity was in July 2006 and June 2009, since both campaigns were performed after the refuelling in April of the corresponding year. At the other hand, in 2007 the refuelling was in autumn after the apples were harvested, and the mean ^{14}C activities in both sampling periods in 2007 (July and September) were similar to the activity measured at the control point Dobova (Table 1).

Based on predetermined spatial distribution of ^{14}C activities in biological samples around the plant, it is clear that important results could be obtained only within a few hundred meters distance from the plant (Breznik et al, 2008). This close distance is not very convenient for testing the dispersion model but enabled to detect higher activities in a shorter time interval.

Table 1. Mean values of $a^{14}C$ (pMC) in biological samples in all eight sampling campaigns. Inner circle – locations C, D, E, I, J, L and R. Outer circle – locations F, G, H, K, M, N, O, P and Q. * Measurements of samples from 9/2009 have not yet been completed.

09 / 2009	115.9 ± 11.4*	103.2 ± 2.3*	102.0 ± 1.4

Discussion

Equivalent annual dose E received by an average adult person by ingestion of food of specific ^{14}C activity $a^{14}C$ (Bq/kgC) can be estimated as

$$E = e \times a^{14}C \times m \times t$$

where t is a 1-year period (365 days), m is a mass of carbon ingested daily by food (0.3 kg, ICRP, 1996), $a^{14}C$ is measured ^{14}C specific activity (Bq/kg C), and e is the ingestion dose coefficient for ^{14}C, i.e., expected effective dose per unit ^{14}C activity, 5.8×10^{-10} Sv/Bq (ICRP, 1996).

It is difficult to realistically estimate a possible increase of the annual dose in case of ingestion of fruit grown in the vicinity of NPPK. As we have shown here, there are spatial and temporal variations in $a^{14}C$. It is also difficult to estimate the fraction of total ingested food that originates from the close vicinity of NPPK. It is reasonable to assume that the local products are dispersed in the general food supply system, and not all consumed by local population. The simplest and the most conservative model of ingestion takes "the most exposed adult person" who would consume only apples from the close environment of NPPK throughout the year. In that case, and for the year 2006 (highest mean ^{14}C activity) the increase of the total annual dose is about 0.1%. Since this the most conservative estimate is unrealistic and not probable, we propose the following more realistic although still rather conservative model. We suppose that: i) in the daily consume of 0.3 kg of carbon, one half comes from the fruits; ii) 6 months the fruits from the environment of NPPK are not available, and during this period one can ingest only the food which has $a^{14}C$ as it is at the control site; iii) during the other 6 months, ⅓ of the total ingested carbon comes from fruits from any point of the monitored area around the NPPK, and the rest ⅔ come from the control site. Therefore, this model is equivalent to the assumption of ingestion of the apples from the vicinity of the power plant during 1 month in a year, while during the rest of the year carbon comes from the wider area. Taking into account these assumptions, we can calculate the increase of the equivalent ^{14}C dose relative to the natural ^{14}C dose measured at the control point, as well as relative to the total natural dose in our country (1.22 mSv). The results for each year since 2006 are shown in Table 2.

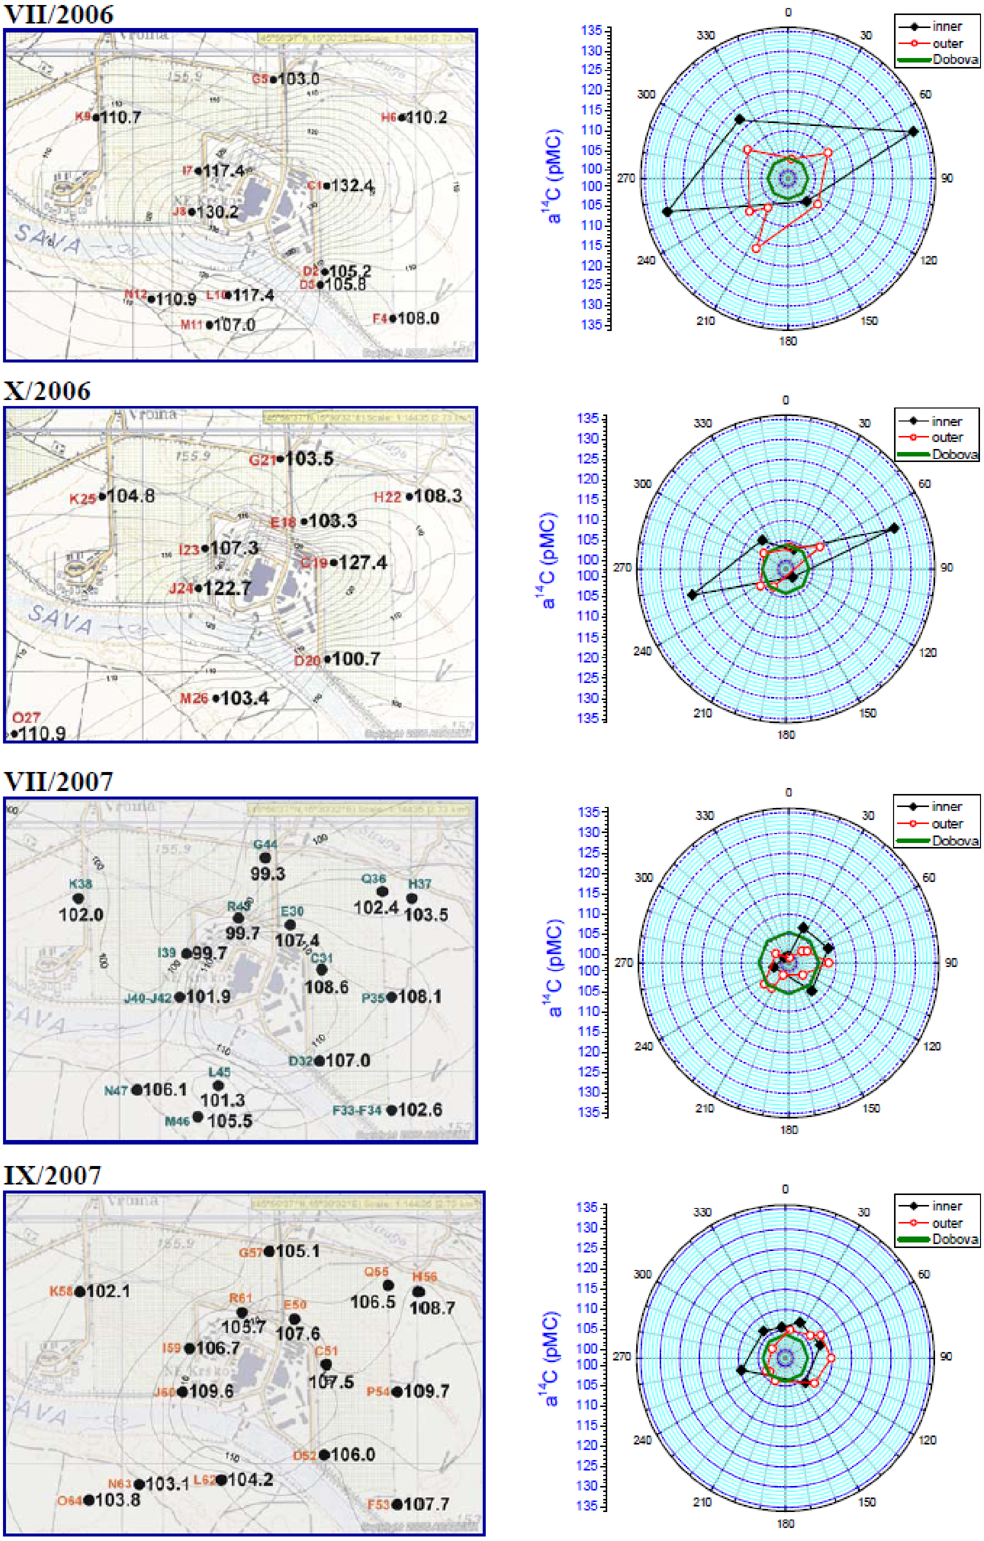

Figure 4. Spatial distribution and polar diagrams of relative specific ^{14}C activity (expressed in pMC).

Conclusion

Monitoring of $a^{14}C$ in biological samples in immediate vicinity and wider environment of the Nuclear Power Plant Krško in Slovenia resulted in spatial distribution of $a^{14}C$ that is clearly determined by the dominant wind directions (SW – NE) and influenced by the outflow of ^{14}C from the release point of the plant ventilation system. The difference to the natural present-day $a^{14}C$ is determined relative to the control site Dobova, about 10 km SE from NPPK. At most sites the difference ranges from 0 to several pMC, being the highest 29 pMC at site **J** in July 2006. However, these differences do not affect significantly the total annual dose due to natural radiation sources, according to our model of ingestion.

Uranium and long-lived decay products in water of the Mulde River

Abstract

The Mulde River is a left side tributary of the Elbe River and mainly situated in Saxony. The river system consists of the Freiberger Mulde River and Zwickauer Mulde River, which merge to form the Vereinigte Mulde River. The Zwickauer Mulde River drains the former uranium mining and milling areas in Saxony. This research project was established to quantify the long-term effect of the former uranium mining and milling activities by investigating the content of uranium and polonium of the water of the Mulde River. The specific uranium activity in samples from the Zwickauer Mulde River is still high compared with the natural background. The values measured in the water of the Vereinigte Mulde River are also elevated, but to a lesser extent due to the dilution effect caused by the merging with the Freiberger Mulde River. Furthermore, the level of contamination of the river water decreased by at least a factor of three as compared to the early 1990's. The specific activity of polonium shows no correlation with that of uranium and is generally much smaller.

Introduction

At the time of the Warsaw Pact, the former German Democratic Republic (GDR), was the third largest producer of uranium in the world and the most important supplier of uranium for the USSR. The Zwickauer Mulde River in Saxony and the Weiße Elster River in Thuringia are the most important river systems draining the uranium mining and milling dominated areas of the western Ore Mountains and its foreland, resulting in accordingly high heavy metal loads. Thus they are of particular interest for radiation protection and radioecology. Today this area is subject to a remediation project which, due to its large scale, can be characterized as pioneer work.

The Mulde River is a left side tributary of the Elbe River and mainly situated in Saxony. The river system consists of three main rivers: Zwickauer Mulde, Freiberger Mulde and Vereinigte Mulde. The Muldenberg Reservoir in the western Ore Mountains is deemed to be the source of the Zwickauer Mulde River. Four kilometers downstream of the dam, which is used as a drinking water reservoir, the river already receives contaminated water from the mine Schneckenstein. On its way through the Ore Mountains the river flows through the uranium mining area Aue and Bad Schlema. Downriver of Zwickau the Zwickauer Mulde River passes Crossen and its uranium ore processing plants and merges with the Freiberger Mulde River at river kilometer 162. The source of the Freiberger Mulde River is located in the Czech Republic, about 5 km from the German border on the ridge of the eastern Ore Mountains. It drains mining areas, however there is no uranium mining in its catchments area. The Vereinigte Mulde River, which is often simply called Mulde River, originates from the merging of the two frontal flows Freiberger Mulde and Zwickauer Mulde and disembogues into the Elbe River north of Dessau at river kilometer 124. At high water-levels the Mulde River is deemed to be the fastest flowing river in Central Europe. Due to its origin in a high-mineral and high-ore affected area it is the most significant reason for heavy metal entering into the Elbe River and thus into the North Sea.

This research project was established to quantify the long-term effect of the former uranium mining and milling activities by investigating the content of uranium and polonium of the water of the Mulde River. It is part of a work package dealing with transport and availability of uranium and its decay products in the Mulde floodplains, which in turn is part of a joint project on radionuclides in the environment and their transport to man via food chains, supported by the German Federal Ministry for Education and Research (BMBF).

Sampling and analysis

A total of 26 water-samples were collected in April, May and October 2008. 19 samples were collected along the course of the Zwickauer Mulde River and the Vereinigte Mulde River. Water from the Freiberger Mulde River, the headwaters of the Zwickauer Mulde River, a small influent of the Zwickauer Mulde River, and from the Leine River near Hanover, respectively, were used as reference samples. Figure 1 shows the Mulde system and the sampling locations.

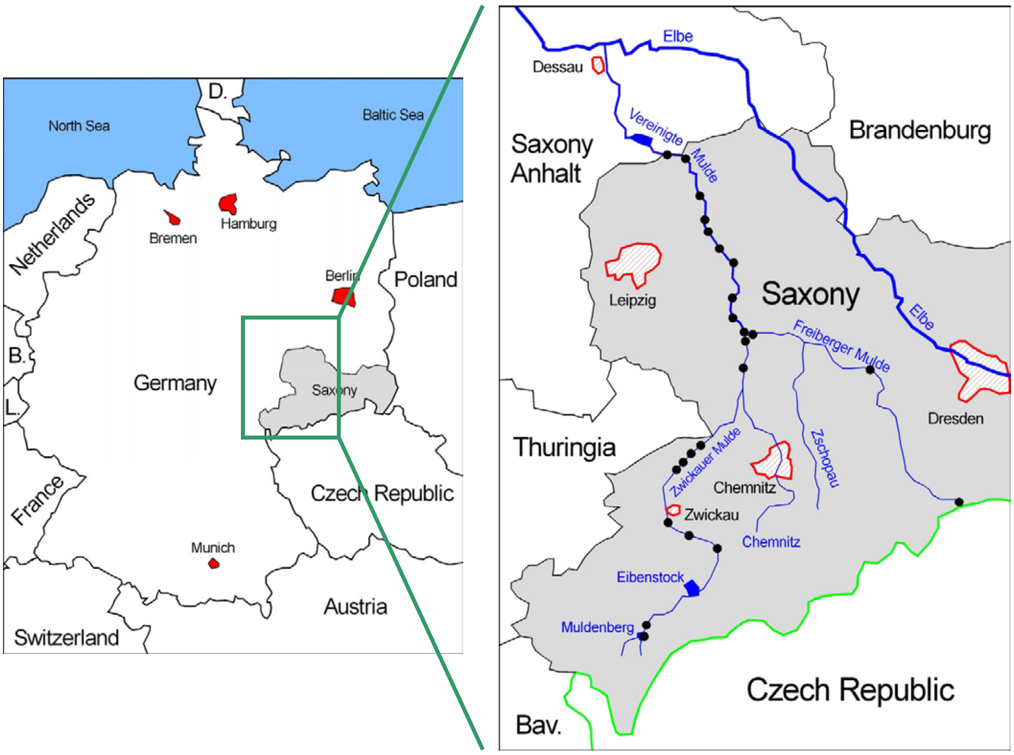

Fig. 1. The Mulde River system with the sampling locations.

Generally, four litres of water were collected at each sampling location. In four cases only two litres per sample were taken. The water was filtered on-site using folded filters of a pore size of 7 µm. Subsequently the samples were acidulated with nitric acid to a pH of 1.5 to 2 and stored on ice.

In the laboratory the samples were filtered through cellulose nitrate filters of a pore size of 0.45 µm. As a central step an enrichment of radionuclides via iron hydroxide-coprecipitation was performed. Following this polonium and uranium were separated by solid-phase chromatography using Pb-Resin and UTEVA from Eichrom, respectively. The polonium sample was obtained by means of autodeposition on nickel. The corresponding uranium sample was prepared using electrical deposition on stainless steel. Both samples were measured alpha-spectrometrically by a surface barrier detector. Figure 2 gives an overview of the analytical procedure.

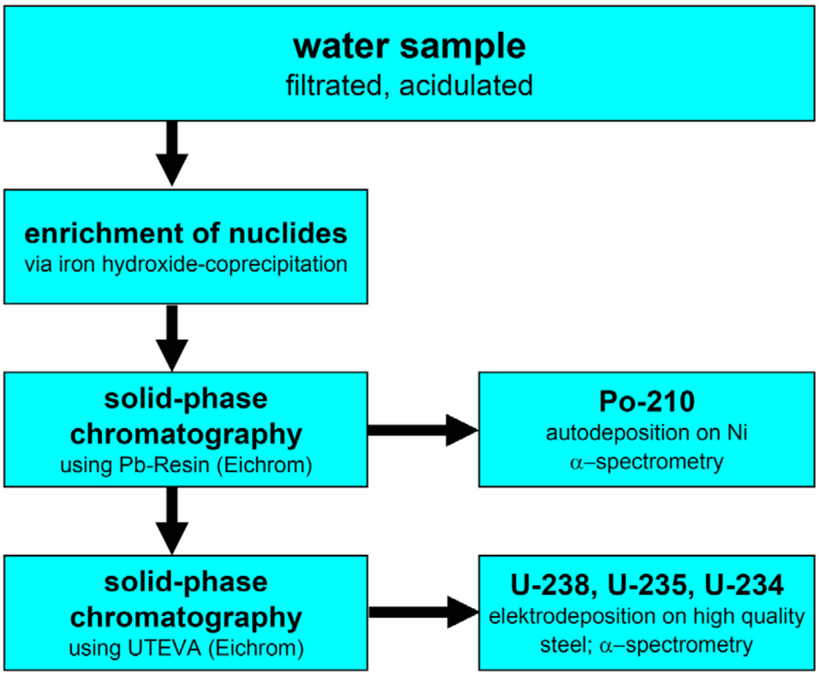

Fig. 2. Overview of the analytical procedure.

Results

Table 1 summarises the measured specific activities of uranium and polonium. The samples are numbered consecutively in flow direction, in which the two letters denote the origin of the sample ("FM“ = Freiberger Mulde River, "ZM“ = Zwickauer Mulde River, "VM“ = Vereinigte Mulde River).

Figure 3 shows the variation of the specific activities of uranium and polonium along the course of the Mulde River. Additionally, the arithmetic mean of five polonium blanks and the upper 1σ-interval are plotted. The blank value determination was performed for the overall procedure using ultra-pure water (18.2 MΩ*cm). Determination of five blanks results in an arithmetic mean of 1.75 mBq/kg with a 1σ-interval ranging from 0.26 mBq/kg to 3.24 mBq/kg. The determination of uranium blanks results in a value close to the detection limit.

Table 1. Specific activities (*a*) and related uncertainties (u(*a*)) for uranium and polonium in the water of the Mulde River; red values marked with "<“ lie below detection limit.

Discussion

Uranium

The measured values of the uranium isotopes (U-238, U-234 and U-235) exhibit the composition of natural uranium in almost all of the samples. This is in accordance with the expectation, as isotopic enrichment of uranium was no common practice in Germany.

The values can be divided roughly into three groups (see Fig. 3). The first group represents the reference values, which belong to non-affected areas with regard to uranium mining and milling activities. This includes the samples from the Freiberger Mulde River (FM1, FM2), from the small influent of the Zwickauer Mulde River (Bach) and the Leine River (Leine), as well as the samples ZM1 and ZM2 from the headwaters of the Zwickauer Mulde River. The first contaminated water from the mine Schneckenstein receives the River about 4 km downriver of the dam of the Muldenberg reservoir, which is regarded as the source of the river, and a few hundred meters downriver of the sampling location of ZM2 (see Fig. 4), respectively. The mean specific activity of uranium-238 for the reference samples is 6.2 mBq/kg, which represents a typical background value for unaffected surface water. The second group of values can be attributed to the Zwickauer Mulde River (ZM3 to VM1) – with a mean value of 75.5 mBq/kg for uranium-238. The third group consists of samples from the Vereinigte Mulde River (VM2 to VM10), showing a mean value of 31.5 mBq/kg. The VM1 sample was collected about 400 meters downriver of the rivers' confluence, more precisely, at the side, where the Zwickauer Mulde River flows in. It can be assumed that at this particular point no considerable mixing of the rivers has taken place.

Along the Zwickauer Mulde River significant variations of the uranium activities can be detected. Hence, Fig. 4 shows the variation of the specific activities of uranium-238 plotted against the river kilometers of the Zwickauer Mulde River extending to a point 15 km downstream of the confluence with the Freiberger Mulde River. Additionally, values from the years 1991 to 1993, determined by Beuge et al. [1], are depicted in order to allow a comparison. The numerical values are listed in Table 2. The determination of the uranium concentration by Beuge et al. [1] was performed employing total-reflection X-ray fluorescence analysis (TXRFA). The results are given as mass concentration in µg/L. The conversion to specific activity of uranium-238 in mBq/kg was performed assuming a density of 1 g/mL. Measurements of samples collected along the Freiberger Mulde River and the Vereinigte Mulde River yielded values, which rarely exceeded the detection limit of TXRFA at ~ 60 mBq/kg (5 µg/L). Thus, they are not considered here.

Table 2. Comparative values determined by Beuge et al. [1]; samling locations are specified by the corresponding river kilometers; uranium concentration is given as mass concentration (*β*) and as specific activity (*a*) of uranium-238, respectively.

sampling location	river kilometer	*β* (U) (µg/L)	*a* (U-238) (mBq/kg)
weir Hartenstein	55	27	335
short before Crossen	80	16	198
near Glauchau	94	23	285
near Sermuth	161	14	174

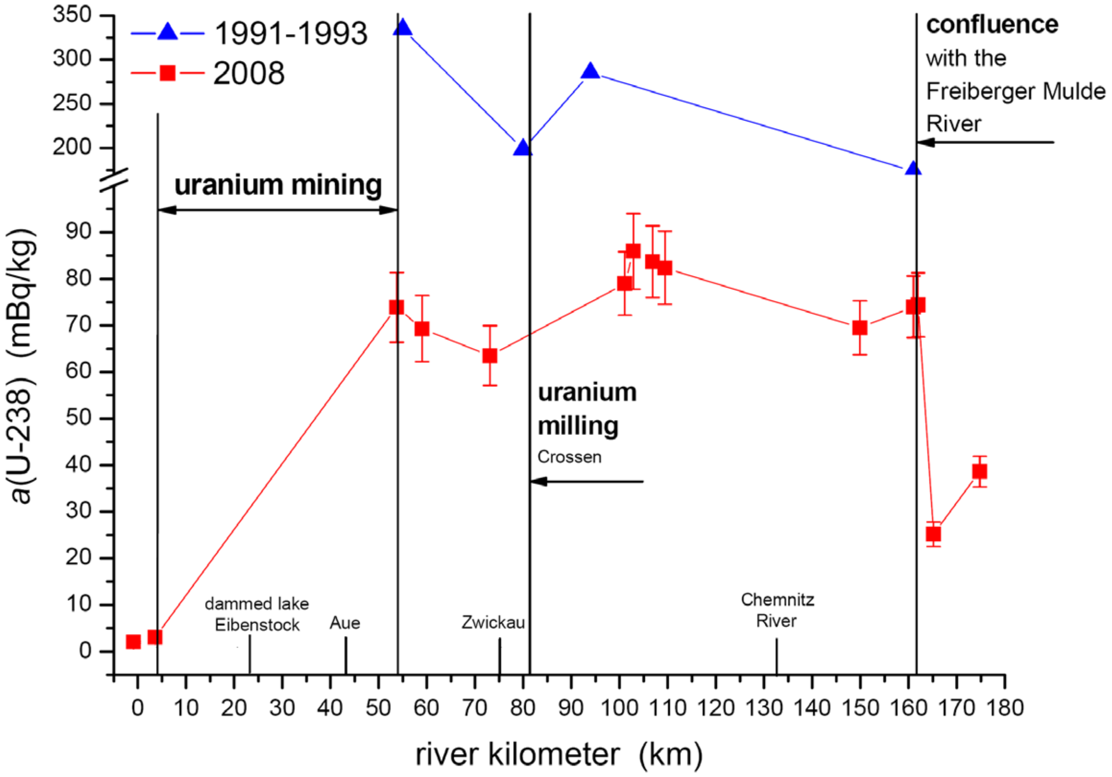

Fig. 4. Variation of the specific activities of uranium-238 in water of the Mulde River, plotted against the river kilometers; comparative values for the years 1991 to 1993 adapted from Beuge et al. [1]

As mentioned before, the first two samples taken from the source of the Zwickauer Mulde River represent the natural background of uranium. The next sample (ZM3) was collected at Hartenstein, where the river has already passed the uranium mining area around Aue and Bad Schlema. According to this position, the sample shows a high uranium activity. Following the course of the river to Zwickau (ZM5), the specific activities seem to decrease slightly. This effect can be explained by dilution with less contaminated water from tributaries. Downstream of Zwickau the specific activity of uranium in the water increases again. This increase results from the effluents of the uranium milling industry near Crossen. In the further course of the Zwickauer Mulde River, the activity remains approximately constant until the confluence with the Freiberger Mulde River. Due to measurement uncertainties, the values are in agreement with a slight decrease of the specific activity corresponding to dilution effects caused by tributaries, especially the Chemnitz River, largest tributary of the Zwickauer Mulde River. In contrast, the confluence of the Zwickauer Mulde River with the uncontaminated Freiberger Mulde River reveals a clear dilution effect, and correspondingly a significant decrease of the specific uranium activity.

The measurements from the early 1990's show the same characteristics, but at a much higher (activity) level. During the last twenty years, the contamination of the Mulde River decreased considerably, on average by a factor of 3.4. This effect decreases in the course of the Zwickauer Mulde River. At the upper reaches of the river, at Hartenstein, the difference between the values measured in 2008 (73.9 mBq/kg) and in the 1990's (335 mBq/kg) is considerably high, resulting in a decrease by a factor of 4.5. At Sermuth, which is located close to the confluence of the Freiberger Mulde River, the difference between the current value (74 mBq/kg) and the one from the 1990's (174 mBq/kg), yield a decrease by a factor of 2.3. This indicates that the decrease of the contamination mainly results from the decreasing emission of the uranium mining and milling industry and accordingly can be attributed to the remediation activities.

The specific uranium activity remains constant along the Vereingte Mulde River, showing an arithmetic mean of 31.5 mBq/kg. The variations of the first three measured values show a correlation between the side of the river on which these samples were taken and the confluence of the Zwickauer and Freiberger Mulde River. This has already been explained in the case of sample VM1. For the samples VM2 and VM3 an incomplete mixing of the water of the two rivers can be assumed as well. The sample VM2 was taken on the right-hand side in flow direction, and thus a stronger influence of the Freiberger Mulde River can be assumed. In contrast, the samples VM3 and VM1 were taken on the left-hand side, which causes a stronger influence of the Zwickauer Mulde River. At the same time the convergence towards the mean value shows the progressive mixing of the water. A decrease of the uranium activity along the Vereinigte Mulde River due to the dilution by smaller tributaries cannot be observed, because the influence of the tributaries decreases with enlarging of the river.

Polonium

The specific activities of polonium-210 are much lower than those of uranium. A large number of the measured values are well below 5 mBq/kg, and thus those data are relatively difficult to distinguish from the background. There is no apparent correlation with the specific activities of uranium. The low specific activities of polonium in the water can be explained by its very strong affinity to adsorption. Due to the strong adsorption to sediments the variations of the polonium activities are expected to change within a short distance. Only five samples exhibit specific activities above 5 mBq/kg. The samples ZM3 and ZM4 are the first two samples after the Zwickauer Mulde River passed the uranium mining region of the Ore Mountains. Consequently, the river water shows higher values for the polonium activities than the uncontaminated headwaters. The high activities of the other samples cannot be explained yet.

Radioecological relevance

The uranium and polonium concentrations found in river water are insignificant from the radioecologically point of view. The recommended value for uranium in drinking water given by the Federal Environment Agency (UBA) is < 10 µg/L [2]. This corresponds to a specific uranium-238 activity of 123.5 mBq/kg. None of the samples shows a uranium activity exceeding this value. In its recommendation from 2001 the EURATOM states 0.1 Bq/kg as maximum specific activity for polonium in drinking water [3]. Again, none of the analysed samples reaches such a high polonium activity.

Conclusions

During the last 20 years, the contamination of the Mulde River decreased by at least a factor of three. This effect mainly results from the decreasing emission of the uranium mining and milling industry and accordingly can be attributed to the remediation activities. On the other hand, an influence of the former uranium mining and milling activities can still be detected. The specific uranium activity in samples from the Zwickauer Mulde River is still high compared with the natural background. The values measured in the water of the Vereinigte Mulde River are also elevated, but to a lesser extent due to the dilution effect caused by the merging with the non-affected Freiberger Mulde River. The specific activity of polonium shows no correlation with that of uranium and is generally much smaller.

Abstract

^{129}I is a long-lived beta-emitting (E_{max} 154,4 keV) radioisotope of iodine. Its half-life is 15,7 million years. ^{129}I is produced mainly by human nuclear activities and especially it has been released to the environment from the spent nuclear fuel reprocessing plants. In the pre-nuclear era ^{129}I/^{127}I ratios in the environment were approximately 10^{-12}. Nowadays ^{129}I/^{127}I ratios have reached values from 10^{-10} to 10^{-4}.

In this study, activity concentrations of ^{129}I and its distribution into various chemical species (iodide I-, iodate IO3- and bound in organics) were analyzed from four lakes in Finland and from four different sea locations on the Gulf of Finland, the Bothnian Sea and the Bothnian Bay. ^{129}I was also analyzed from four rainwater samples.

After filtering the 0.3 l water samples, separation of various iodine species was done by anion exchange chromatography: $^{129}IO_3^-$ passes through an anion exchange resin bed in NO_3^- form while $^{129}I^-$ absorbs into the bed. $^{129}I^-$ is eluted from resin with NaClO. Finally samples were precipitated by $AgNO_3$ to form AgI and ^{129}I was measured by accelerator mass spectrometry (AMS). Stable iodine (^{127}I) was analyzed by inductively coupled plasma mass spectrometry (ICP-MS).

First results from a lake in the southern Finland and from sea water taken from the Finnish Bay in front of Helsinki show that levels of ^{129}I in lake water are around 1×10^9 atoms per litre while in sea water the levels are 4 – 5 times higher. ^{129}I occurs both in lake and sea water mainly in iodide form and the fraction of iodate form is only about 5%. The ^{129}I/^{127}I ratio is clearly elevated compared to natural levels, and are approximately the same in sea and in lake, 14×10^{-8} and 8×10^{-8}, respectively. These results are only preliminary and a better picture of the situation will be obtained after finalizing the project. The results obtained so far are, however, at the same level as obtained in Swedish studies at the same latitudes.

Monitoring and assessment of radioactivity in the Baltic Sea coordinated by HELCOM

Abstract

The Baltic Marine Environment Protection Commission (HELCOM) works to protect the marine environment of the Baltic Sea from all sources of pollution through intergovernmental co-operation between Denmark, Estonia, the European Community, Finland, Germany, Latvia, Lithuania, Poland, Russia and Sweden. Investigations of radioactivity in the Baltic Sea has been part of the HELCOM work since 1986 and carried out by the MORS project (Monitoring of Radioactive Substances) with participation from laboratories and institutes in the countries and organizations mentioned above including the IAEA.

The objective of the MORS project is to implement the Helsinki Convention on matters related to monitoring and assessment of radioactivity in the Baltic Sea. The Contracting Parties to the Convention carry out basic monitoring programmes and transfer the data to the HELCOM database. The monitoring is carried out according to guidelines which are revised annually. The guidelines give details on sampling locations, sample types covering seawater, sediment, fish, aquatic plants and benthic animals, and radionuclides to be determined in the samples. The guidelines furthermore specify the format for reporting the data to the database. High quality of the data is ensured through participation of the MORS laboratories in frequent group intercomparisons of analytical data from laboratory analyses as well as from evaluation

of the reported data at the annual meetings of the MORS group. Intercomparisons cover laboratory analyses of radioactivity in seawater, sediment and biota.

The data collected is summarized in indicator fact sheets that present results of radioactivity in seawater and fish from the Baltic Sea. More comprehensive assessments of radioactivity in the Baltic Sea are made by the group at larger intervals. The assessments include summaries of sources and inputs of radioactivity into the Baltic Sea, environmental levels and model-assisted estimates of radiation doses to man.

Results obtained in monitoring programmes and environmental studies carried out during more than 40 years in the sea areas surrounding the Finnish NPPs

Abstract

Environmental effects of thermal and radioactive discharges from the Loviisa and Olkiluoto NPPs in the recipient sea areas were assessed. The effects of cooling water on the temperatures in the sea were most obvious in winter. The formation of a permanent ice cover has been delayed, and the break-up of the ice has been advanced. The prolonging of the growing season has been the most significant biological effects of thermal pollution. At Loviisa, the thermal discharges have increased the production of organic matter in the discharge areas, which has led to more organic bottom deposits. The depletion of oxygen has caused remobilization of phosphorus from the bottom sediments, and contributed to deterioration of benthic macrofauna. Phytoplankton primary production has doubled in the area, and the thermal discharge has contributed to a stronger increase in the discharge area than in the intake area. The eutrophication of littoral vegetation has been the most obvious and unambiguous biological effect of the heated water in both areas.

Small amounts of local discharge nuclides were regularly detected in environmental samples taken from the discharge areas: tritium in seawater, and activation products in suspended particulate matter, bottom sediments and in indicator organisms. Discharge nuclides from the local nuclear power plants were almost exclusively detected at the lower trophic levels of the ecosystem. The concentrations of local discharge nuclides in the environmental samples have noticeably decreased in both areas in recent years. The radiation doses caused by the radioactive discharges to the population and to the biota were very low, practically insignificant. The effects of the thermal discharges were more significant, at least to the wildlife in the discharge areas of the cooling water, although the area of impact has been relatively small. The results show that the nutrient level and the exchange of water in the discharge area of a nuclear power plant are of crucial importance.

Introduction

During recent decades, thermal and radioactive discharges from nuclear power plants into the aquatic environment have become the subject of lively debate as an ecological concern. Recently, an increasing demand for facts has appeared in context with the Environmental Impact Assessment procedures that are being in progress for planned new nuclear power units in Finland. This paper is based on a thesis examined in University of Helsinki in September 2009 (Ilus 2009). The target of the thesis was to summarize the large quantity of results obtained in extensive monitoring programmes and studies carried out in recipient sea areas off the Finnish nuclear power plants at Loviisa and Olkiluoto during more than four decades.

Especially in the conditions specific for the northern Baltic Sea, where biota is poor and adapted to relatively low temperatures and to seasonal variation with a cold ice winter and a temperate summer, an increase in temperature may cause increased environmental stress to the organisms. Furthermore, owing to the brackish-water character of the Baltic Sea, many organisms live there near the limit of their physiological tolerance. On the other hand, the low salinity increases the uptake of certain radionuclides by many organisms in comparison with oceanic conditions.

The sea areas surrounding the Finnish nuclear power plants differ from each other in many respects (efficiency of water exchange, levels of nutrients and other water quality parameters, water salinity and consequent differences in species composition, abundance and vitality of biota). In addition, there are differences in the discharge quantities and discharge design of the power plants. In the thesis the environmental effects of the two power plants on the water recipients are compared and their relative significance is assessed.

There are four nuclear power plant units in Finland: two 488 MW_e units at Loviisa and two 840 MW_e units at Olkiluoto. The units at Loviisa were commissioned in 1977 and 1980, and those at Olkiluoto in 1978 and 1980. Environmental studies were initiated at Loviisa about ten years and at Olkiluoto six years before the start of operation of the power plants. Thus, 40-year-long time-series of results are available from the hydrographical, biological and radioecological studies carried out for monitoring the environmental effects of the thermal and radioactive discharges from the power plants in the recipient sea areas.

Brackish water from the Baltic Sea is used for cooling in the Finnish nuclear power plants, and both the thermal and liquid radioactive discharges are let out into the sea. Each of the power plants use cooling water at a rate of about 40–60 m^3s^{-1}, and the temperature rises in the condensers by about 10–13ºC. Loviisa NPP is located on the coast of the Gulf of Finland and Olkiluoto NPP on that of the Bothnian Sea. The state of the Gulf of Finland is clearly more eutrophic: the nutrient (total phosphorus and total nutrient) concentrations in the seawater are about 1½–2 times higher at Loviisa than at Olkiluoto, but the total phosphorus concentrations have still increased in both areas, even doubling at Loviisa between the early 1970s and 2000 (Fig. 1). The salinity is generally low in the brackish-water conditions of the northern Baltic Sea. However, the salinity of surface water is about 1‰ higher at Olkiluoto than at Loviisa (varying at the latter from near to 0‰ in early spring to 4–6‰ in late autumn). Thus, many marine and fresh-water organisms live in the Loviisa area close to their limit of existence, which makes the biota sensitive to any additional stress. The characteristics of the discharge areas of the two sites differ essentially from each other in many respects: the discharge area at Loviisa is a semi-enclosed bay in the inner archipelago, where the exchange of water is limited, whereas the discharge area at Olkiluoto is more open, and the exchange of water with the open Bothnian Sea is more effective.

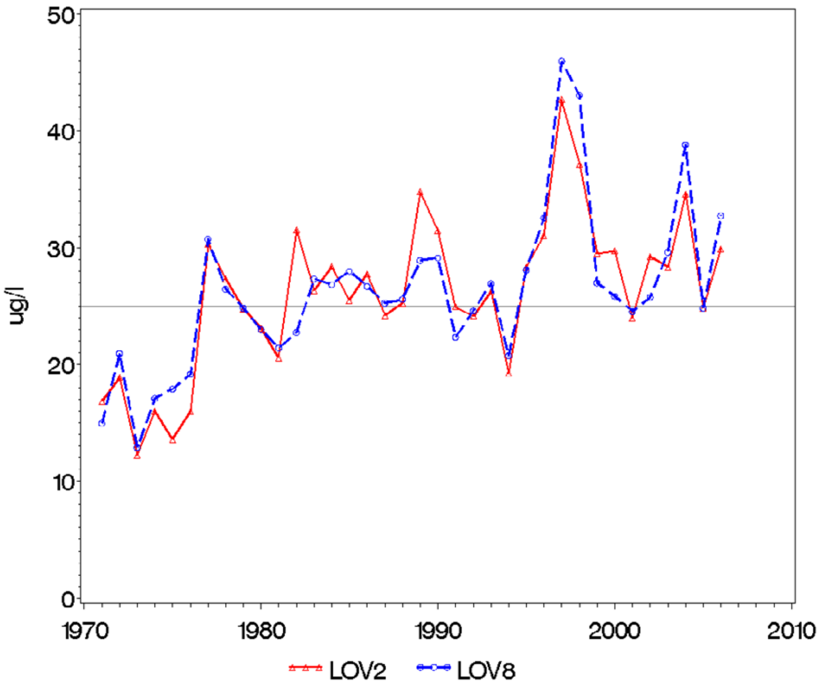

Fig. 1. Average total phosphorus concentrations (µgP l^{-1}) of surface water during the growing seasons (May–October) in the intake (Station 8) and discharge area of cooling water (Station 2) at Loviisa in 1971–2006.

Results and discussion

Environmental effects of cooling water

The effects of the cooling water on the temperatures in the sea were most obvious in winter, when the conditions also most fundamentally differed from those of the natural state. Thermal discharges have significantly affected the ice conditions in the vicinity of the power plants. The formation of a permanent ice cover in the discharge areas has been delayed in early winter. On the other hand, the break-up of the ice occurs earlier in springs so that the growing season has been prolonged at both ends. From the biological point of view, the prolonging of the growing season and the disturbance of the overwintering time, in conditions where the biota has adjusted to a distinct rest period in winter, have been the most significant biological effects of the thermal pollution. Aquatic organisms in the northern Baltic Sea are acclimatized to a distinct annual winter period. The shortening of the ice winter or a total lack of ice cover has led to a blurring of the limits between the growing season and the winter season.

Table 1. Change in mean surface water temperature of the growing season at eight sampling stations off Loviisa during 1976–2006. Station 8 is located in the intake area of cooling water and considered as a reference station.

During the growing season, the cooling water has raised the mean surface water temperatures at Loviisa by 4–5ºC at a distance of 0.4 km from the outlet and by 2.5–3ºC at a distance of 1–2 km in the discharge area, Hästholmsfjärden (Table 1). The rise in temperature has also been statistically significant at Station 4 in Vådholmsfjärden (distance 2.8 km) and at Station 1 in Klobbfjärden (distance 3.4 km), but not at Station 7 in Orrengrundsfjärden (distance 5.4 km).

A temperature rise generally increases the metabolic activity and growth rate of aquatic organisms. This means an increased production of organic matter, and thus, thermal pollution promotes the eutrophication process in eutrophied environments. The raised temperature also increases the rate of decomposition of organic matter in the receiving water bodies and leads to depletion of oxygen in deep water layers.

The hydrographical and biological results in the Loviisa area indicated a clearly higher level of eutrophy, which was based on the state of the whole Gulf of Finland. Thus, it was a challenge to distinguish the local effects of thermal discharges from the general eutrophication process of the Gulf of Finland.

During the past 40 years the soft-bottom macrofauna has steeply deteriorated at many sampling stations, at some to the point of almost complete extinction. A similar decline of the macrozoobenthos has been reported over the whole eastern Gulf of Finland. However, the local eutrophication process seems to have contributed into the decline of the bottom fauna in Hästholmsfjärden at Loviisa (Fig. 2). Thermal discharges have increased the production of organic matter, which again has led to more organic bottom deposits. Furthermore, these have increased the affinity of the isolated deeps for a depletion of oxygen, which has in turn caused a strong remobilization of phosphorus from the bottom sediments to the water phase.

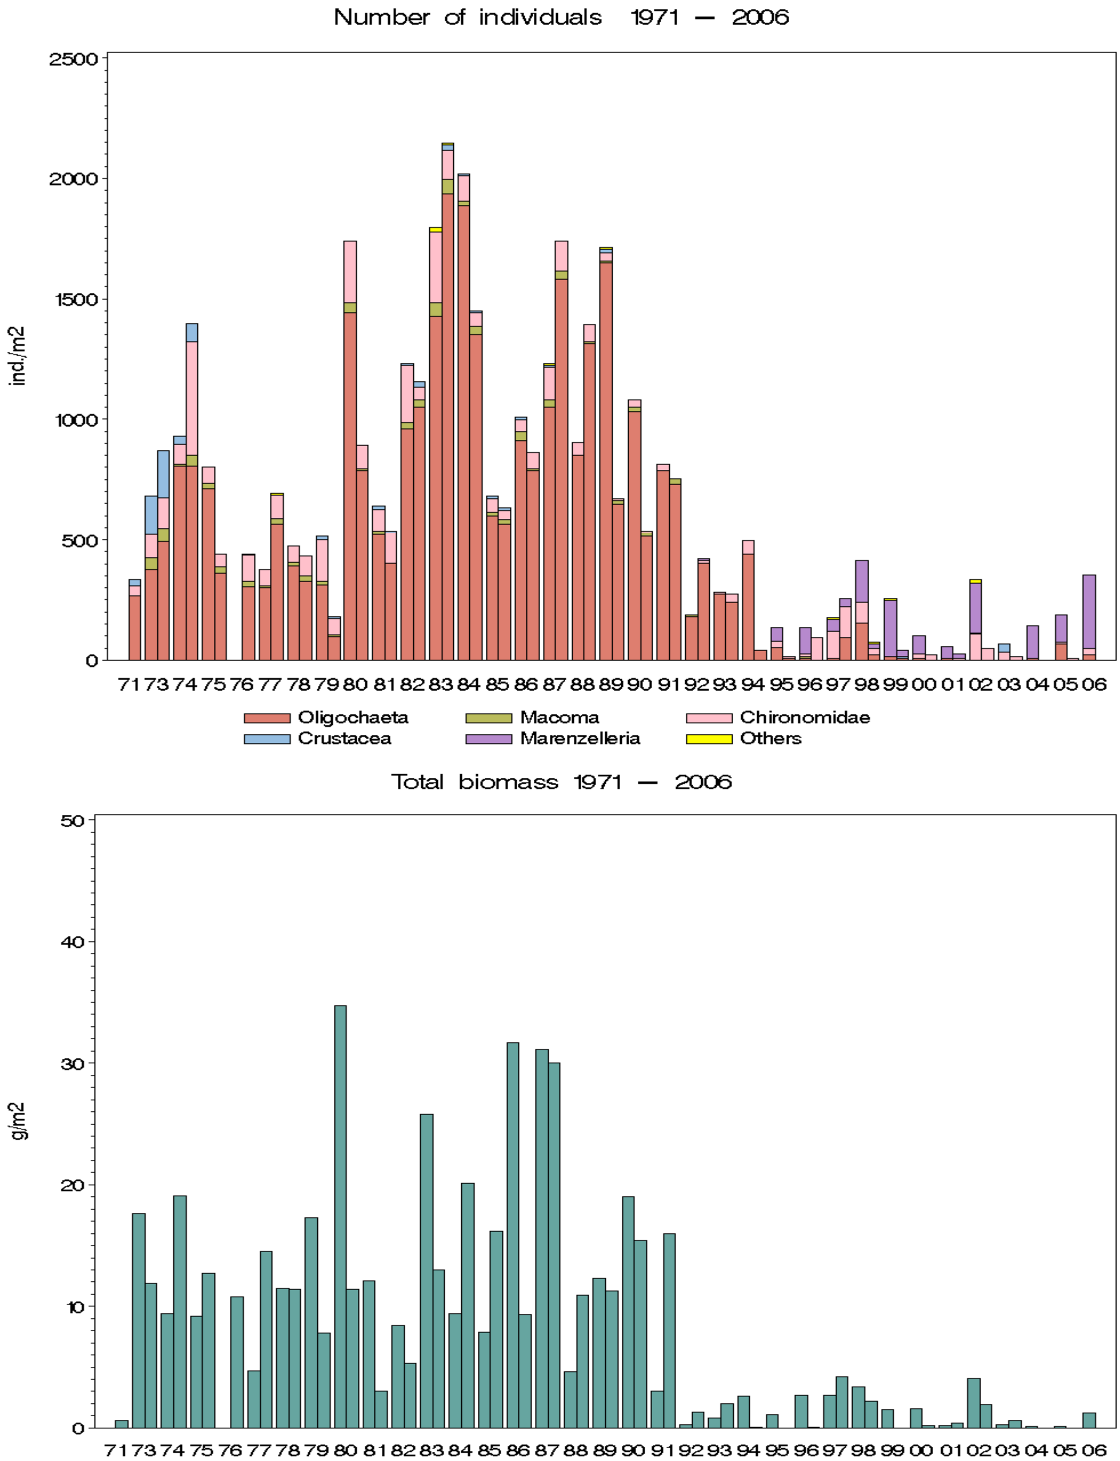

Fig. 2. Abundance of main species or taxonomic groups (ind. m^{-2}) and total biomass of macrozoobenthos (g m^{-2}) at a sampling station situated 0.4 km off the cooling water outlet at Loviisa.

Phytoplankton primary production and primary production capacity doubled in the whole area between the late 1960s and the late 1990s, but started to decrease a little at the beginning of this century. The focus of the production shifted from spring to mid-and late summer. The general rise in the level of primary production was mainly due to the increase in nutrient concentrations over the whole Gulf of Finland, but the thermal discharge contributed to a stronger increase of production in the discharge area compared to that in the intake area of the cooling water (Fig. 3).

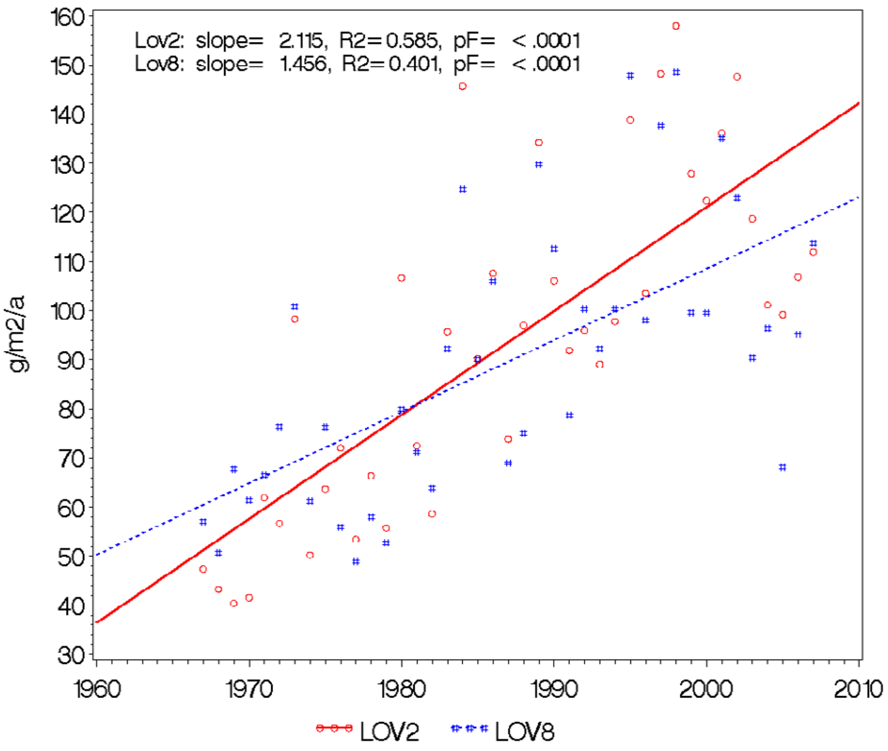

Fig. 3. The regression lines of annual primary production at the Loviisa 2 (discharge area) and Loviisa 8 (intake area) stations between 1967 and 2006.

The eutrophication of littoral vegetation in the discharge area has been the most obvious, unambiguous and significant biological effect of the heated water. Spiked water milfoil *Myriophyllum spicatum,* the pondweeds *Potamogeton perfoliatus* and *Potamogeton pectinatus* and the vigorous growths of numerous filamentous algae as their epiphytes have strongly increased in the vicinity of the cooling water outlet, where they have formed dense populations in the littoral zone in late summer (Fig. 4). However, the strongest increase of phytobenthos has extended only to a distance of about 1 km from the outlet, i.e., the changes in vegetation have been largest in those areas that remain ice-free in winter. A weaker eutrophication of littoral vegetation appeared in the whole area of Hästholmsfjärden Bay, but outside this area the phenomenon was slighter and observed only locally.

Fig. 4. Dense vegetation on the south coast of Hästholmsfjärden at Loviisa. (Photo by Anna Weckman).

At Olkiluoto, the studies focusing on the effects of warm water discharge were more concise. Similar trends to those noticed in the Loviisa area regarding to increasing eutrophication were also discernible at Olkiluoto, but to a clearly smaller extent; this was due to the clearly weaker level of background eutrophy and nutrient concentrations in the Bothnian Sea, and to the local hydrographical and biological factors prevailing in the Olkiluoto area. The level of primary production has also increased at Olkiluoto, but has remained at a clearly lower level than at Loviisa. In spite of the analogous changes observed in the macrozoobenthos, the benthic fauna has remained strong and diversified in the Olkiluoto area.

Environmental radioactivity

Radioactive discharges into the sea from the Finnish NPPs have been on average below 10% of the statutory limits. The discharged amounts of tritium were the most abundant, but those of other discharge nuclides were only a few percent of the limits, and still significantly decreased during recent years (during the last ten years to below 0.5%). Small amounts of local discharge nuclides were regularly detected in environmental samples taken from the discharge areas: tritium in seawater samples, and activation products, such as ^{60}Co, ^{58}Co, ^{54}Mn, ^{110m}Ag, ^{51}Cr, among others, in suspended particulate matter, bottom sediments and in several indicator organisms (e.g., periphyton and the bladder-wrack *Fucus vesiculosus*) that effectively accumulate radioactive substances from the medium.

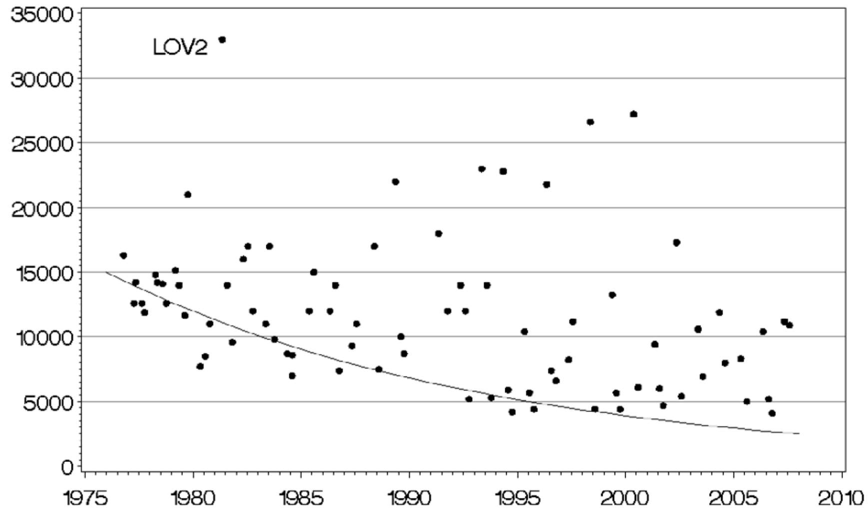

Fig. 5. Tritium concentrations in surface seawater (Bq m^{-3}) in Hästholmsfjärden (discharge area) at Loviisa in 1976–2007. The curve in the graph indicates the decay of weapons-tests tritium in Finnish coastal waters during the monitoring period.

The tritium discharges and the consequent detection frequency and concentrations of tritium in seawater were higher at Loviisa (Fig. 5), but the concentrations of the activation products were higher at Olkiluoto, where traces of local discharge nuclides were also observed over a clearly wider area, due to the better exchange of water than at Loviisa, where local discharge nuclides were detected outside the Hästholmsfjärden Bay only quite rarely and in small amounts. At the farthest, an insignificant trace amount (0.2 Bq kg^{-1} d.w.) of ^{60}Co originating from Olkiluoto was detected in *Fucus* at a distance of 137 km from the power plant (Fig. 6).

Discharge nuclides from the local nuclear power plants were almost exclusively detected at the lower trophic levels of the ecosystems (Fig. 7). Traces of local discharge nuclides were very seldom detected in fish, and even then only in very low quantities, but not at all in birds nor in the inner organs and reproductive products of fish and birds.

The best indicators for ^{60}Co were periphyton, the spiked water milfoil *Myriophyllum spicatum* and the bladder-wrack *Fucus vesiculosus*, whereas the intake of, e.g., Chernobyl-originated ^{137}Cs was highest in predatory fish, perch and pike. As a consequence of the reduced discharges, the concentrations of local discharge nuclides in the environment have decreased noticeably in recent years at both Loviisa and Olkiluoto (Fig. 8). Radioactive substances that originated from the Chernobyl accident and weapons-tests fallout (e.g. ^{137}Cs, ^{90}Sr, ^{239,240}Pu) were still being detected in the environmental samples; the concentrations of ^{137}Cs and natural radionuclides (e.g., ^{40}K, ^{7}Be) were in general higher than those of the local discharge nuclides.

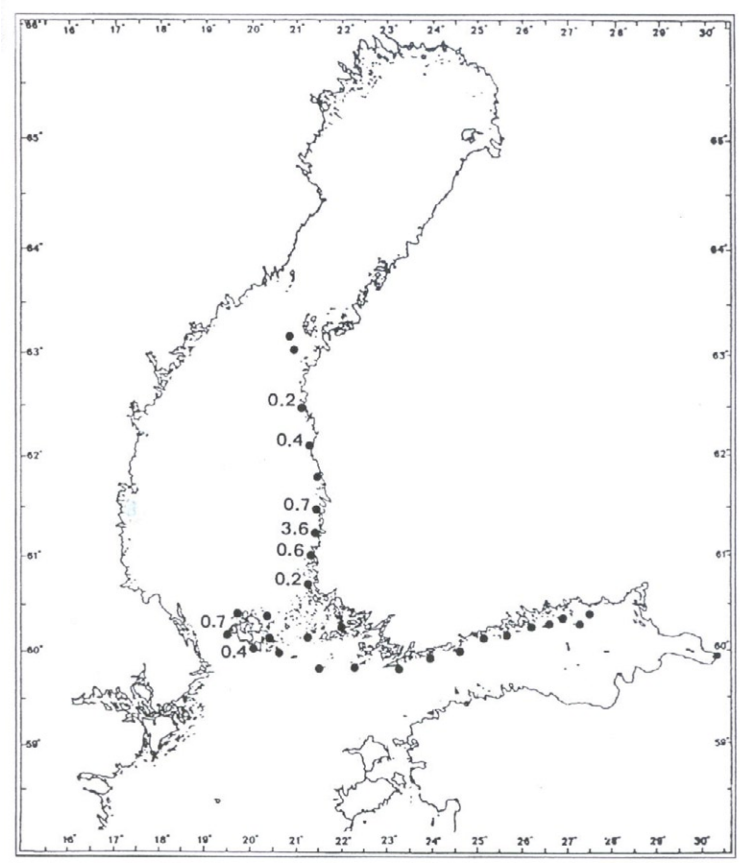

Fig. 6. Activity concentrations of ^{60}Co (Bq kg^{-1} d.w.) in *Fucus vesiculosus* collected from 29 sampling sites along the Finnish coast in 1995. A dot without a number means that the concentration was below the detection limit of 0.1 Bq kg^{-1} d.w.

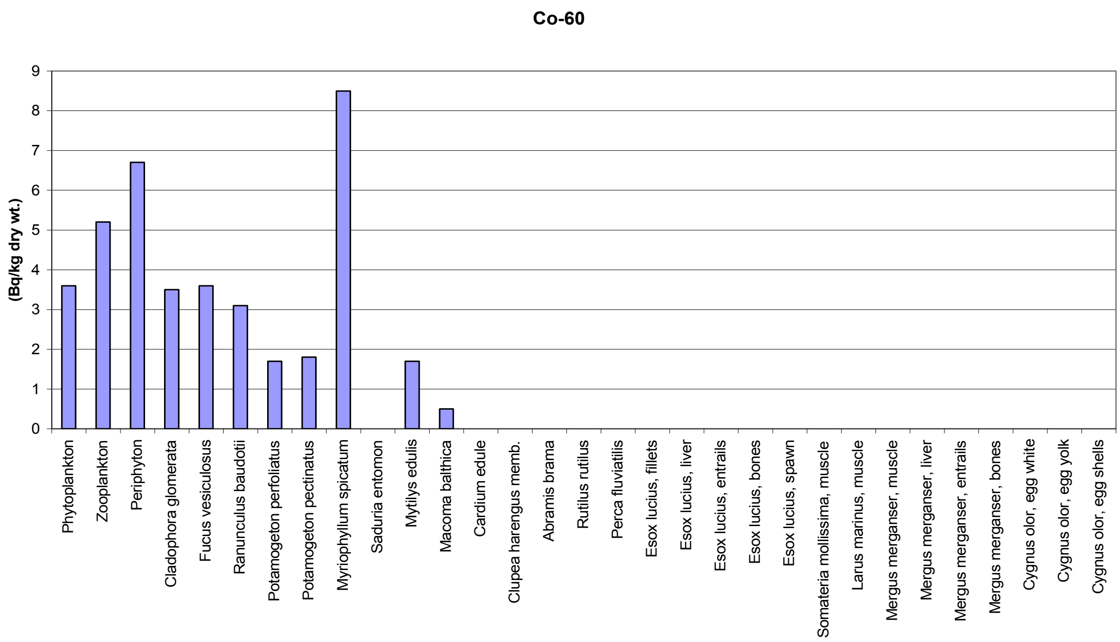

Fig. 7. ^{60}Co mean values (Bq kg^{-1} d.w.) in some indicator samples in the sea area off Olkiluoto in 2001.

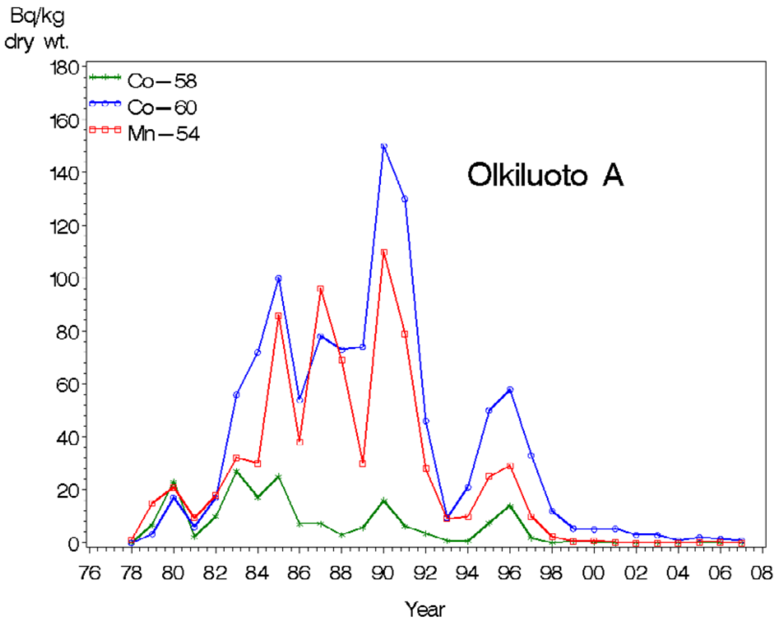

Fig. 8. Annual mean concentrations of ^{58}Co, ^{60}Co and ^{54}Mn in *Fucus vesiculosus* (Bq kg^{-1} d.w.) at a sampling site nearest to the cooling water outlet at Olkiluoto in 1987–2007.

The radiation doses to the public caused by discharges of radioactive substances from the Finnish nuclear power plants were small. The dose limit set for members of the public from the normal operation of Finnish nuclear power plants is 0.1 mSv a^{-1}. This is approximately 1/40 of the average radiation dose received by Finns from different sources during one year. During the whole operational history of the power plants, the effective dose commitments of the critical groups have been at their highest less than 4%, and during more recent years clearly below 1% of the set limit. In general, the minor doses of local origin to the critical groups have been due to liquid discharges of ^{60}Co and people's shore occupancy. The environmental risk caused by the ionizing contaminants discharged from the Loviisa and Olkiluoto power plants was negligible: the doses to organisms were far below the conservative screening level of 10 µGy h^{-1}.

Conclusions

Although the concentrations in environmental samples, and above all, the discharge data, are presented as seemingly large numbers, the radiation doses caused by them to the population and to biota are very low, practically insignificant. The effects of the thermal discharges have been more significant, at least to the wildlife in the discharge areas of the cooling water, although the area of impact has been relatively small. The results show that the nutrient level and the exchange of water in the discharge area of a nuclear power plant are of crucial importance.

Tritium level along Romanian Danube river sector

Varlam, Carmen; Stefanescu, Ioan; Vagner, Irina; Faurescu, Ionut; Faurescu, Denisa
National Institute for R&D for Cryogenics and Isotopic Technologies Rm. Valcea, ROMANIA

Abstract

Danube River is the eleventh longest river in the world, and is one of the important rivers from Europe. Tritium activity concentration from 12 locations distributed along Romanian Lower Danube River was determined by means of low level liquid scintillation counting. The three sampling campaigns were conducted between 2006 – 2007, on 975 km. The average concentration value registered for tritium activity for the studied area was around 15.4 TU, with higher values for Bechet and Seimeni locations. Special attention was accorded to Turnu Severin location, where tritium activity concentration from monthly Danube water was compared with monthly tritium concentration in precipitation. The behaviour of tritium concentration in the Danube water, at the begging of studied area, doesn't follow the behaviour of tritium concentration in precipitation, but the established values are far from any concern from radiological point of view.

Introduction

The Danube River Basin is the second largest river basin in Europe covering 801463 km^2 [ICPDR, 2005]. From its source in the Black Forest at height of 1000 m above sea level, to its three-armed delta on the Black Sea, the Danube flows through eights countries and drains a total of eighteen. Due to its geologic and geographic conditions the Danube River Basin can be divided into 3 main parts: Upper Danube Basin, Middle Danube Basin and Lower Danube Basin. 65% of Lower Danube Basin is the natural border between Romania and Bulgaria.

During the 80's the contribution of nuclear power to total primary energy supply as a percentage of fuel mix has increased significantly, from 9% in 1985 to 15% in 1995 [EC, 2000]. Nuclear power generates between 10% and 45% of electricity in the Danube Space countries. Nuclear electricity has been, on a variable cost basis, cheaper than other options, and consequently used in preference to coal, oil and gas. Two important nuclear objectives for both countries are situated in this region: Kozloduy NPP and Cernavoda NPP. Nuclear energy is considered by the two countries an option for the future development, so Romania already built a new CANDU type unit in Cernavoda, which has been operating since September 2007, and Bulgaria started negotiations for a new nuclear power plant in Belene.

The knowledge of tritium in the Romanian Lower Danube offers two important information: first in the environmental radioactivity monitoring program (Cernavoda is a CANDU type reactor, where tritium is the most important radioisotope evacuated in the environment) and second a primary estimation of river discharge signature for the end part of Danube by comparing the tritium level from precipitation and river water.

Material and methods

The Danube typology represents a harmonized system developed by the countries sharing the Danube River [ICPDR, 2005]. The most important factors used for this system are mean water slope, substratum composition, geomorphology and water temperature. Lower Danube Basin contains four ~~types of~~ sections: Iron Gates Danube, Western Pontic Danube, Eastern Wallachian Danube and Danube Delta.

Iron Gates Danube section (A, fig. 1) has an average width of about 750 m and runs in a canyon or through valley form. Dominant main channel has numerous rocks situated directly under the surface water. Sampling point chosen was Ieselnita (1, fig.1), location with easy access to the left side of the Danube. Next sampling point was from Cerna, Danube tributary, at Toplet location (2, fig. 1). Cerna is a small mountain river without industrial activity. The end of this section was Turnu Severin (3, fig.1) another sampling point.

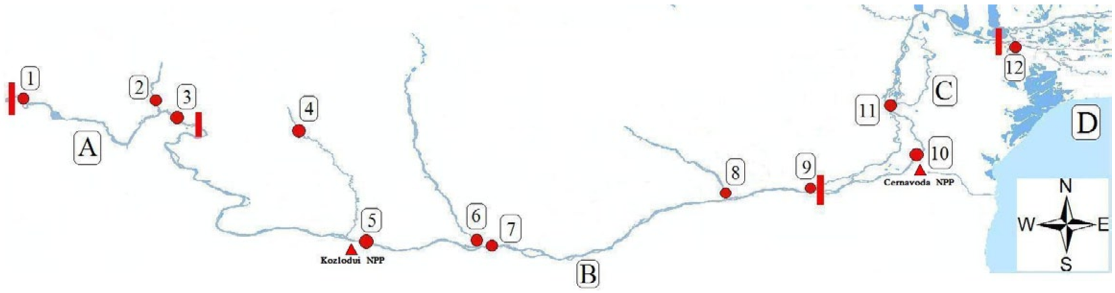

Fig. 1 Section type and sampling locations from Lower Danube Basin; A - Iron Gates Danube; B - Western Pontic Danube; C – Eastern Wallachian Danube; D – Danube Delta.

Western Pontic Danube section (B, fig.1) contain floodplain landscape with higher plains of terraced accumulation in a meander and plain floodplain valley. The Romanian bank is low and terraced with wide floodplains. The main channel has an average width of 830 m and mean depth of 8.5 m. The diversity of water bodies in this area close to the stream is large, but we focused on the main course and on few tributaries with important mining industry, Jiu river (4, fig.1), and chemical industry Olt river (6, fig. 1) and Arges river (8, fig.1). Bechet location (5, fig.1) from main course is important due to its location downstream ~~the~~ Kozloduy NPP. Another sampling point was Turnu Magurele (7, fig.1) which is located downstream to jonction to Olt river, approximately in the middle of this section. The end of this section is Chiciu-Silistra (9, fig.1) another important sampling point, before Danube splits in two branches: Old Danube and Borcea.

The Danube changes its watercourse northward in Eastern Wallachian Danube section (C, figure 1). There are two large isles, Balta Ialomitei and Balta Brailei, and many natural lakes. The main channel has an average width of 650 m, and a mean depth of 10.5m. The section is characterized by slow current velocities of 0.8 m/s. The first sampling point of this section was established in Seimeni (10, fig.1) downstream of

NPP Cernavoda discharge channel and the second in Giurgeni (11, fig.1), a point between the two isles were Danube has one main branch for a short distance.

The Danube Delta section (D, figure 1) is the Danube's youngest teritory. There are three main water channels: Chilia, Sulina and Sf. Gheorghe, with numerous canals and floating islands. This section is characterized by an average current velocity of 0.7 m/s. The shape of the delta is triangular, and at mean water levels, 60% of this area is covered by waters. The point from this section was only Tulcea (12, fig.1), due to difficult access to this part of the Danube.

Precipitation sampling was made on a monthly basis in a typical rain water collector [IAEA, 1989] in Drobeta Turnu Severin location and our Institute, starting with January 2007, and ending with October 2007. At the end of the month the container was shaken thoroughly and a sample of 1 liter was filled for shipment to the analytical laboratory. Special attention was given for collection and preservation of water sample [APHA-AWWA-WEF, 2005]. Type of section, water body, and sampling location are in the table 1.Water samples for tritium measurement were collected one meter from the left bank of Danube, 10 cm from the water surface, in glass bottle. pH, conductivity and temperature for water sample were measured in sampling location using portable apparatus WTV pH/cond 340i.

Table 1. Geographical coordinates of sampling locations.

Location number	Location name	Section type	Water body	Latitude	Longitude
1.	Ieselnita	A	Danube	44^{0}48'31''	21^{0}24'11''
2.	Toplet	A	Cerna	44^{0}47'58''	22^{0}23'26''
3.	Drobeta Turnu Severin	A	Danube	44^{0}40'2''	22^{0}32'51''
4.	Filiasi	B	Jiu	44^{0}34'8''	23^{0}27'19''
5.	Bechet	B	Danube	44^{0}44'56''	23^{0}57'14''
6.	Islaz	B	Olt	43^{0}44'38''	24^{0}46'46''
7.	Turnu Magurele	B	Danube	43^{0}42'45''	24^{0}53'25''
8.	Oltenita	B	Arges	44^{0}05'51''	26^{0}38'12''
9.	Chiciu/Silistra	B	Danube	44^{0}07'56''	27^{0}16'19''
10.	Seimeni	C	Danube	44^{0}23'31''	28^{0}03'28''
11.	Giurgeni	C	Danube	44^{0}45'2''	27^{0}52'17''
12.	Tulcea	D	Danube	45^{0}10'58''	28^{0}48'25''

As tritium is a soft beta emitter (5.72 keV mean energy), liquid scintillation is the most appropriate technique for its measurement. In this work, the low-background liquid scintillation spectrometer Quantulus 1220 (Wallac) has been used to determine tritium in water samples. The analytical method used to determine tritium in water samples was, briefly, the following: samples were filtered through slow depth filters; 250 ml of filtrate was distilled using ISO method [ISO, 1989]; 8 ml of distillate was mixed with 12 ml of scintillation cocktail OptiPhase Hisafe 3 in polyethylene vials; three background samples and tritium standards were simultaneously prepared. Samples, backgrounds and tritium standards were counted using Quantulus 1220 during

1000 min/samples. The tritium standards were internal standard capsules containing a tritium-labeled organic compound [fructose-1-^{3}H] provided by PerkinElmer. Tritium-free water (blank water) was deuterium-depleted water with a D/(D+H) value of 15 ppm (Varlam et al. 2009). The counting efficiency at the best factor of merit was between 24.84% and 25.02%, and the background between 0.714 ± 0.016 CPM (counts per minute) and 0.748 ± 0.017 CPM, following a minimum detectable activity of around 4 TU (confidence level of 2). The uncertainty due to the statistical nature of radioactive decay and background radiation was reported at 1σ.

Results and Discussion

The average fallout during the year 2007 in Romania was ~~with~~ 13.33% higher than the normal climatologic average (NRMA, 2007): for months of April, May, June and July it has been recorded a deficit in precipitation monthly average with an important negative deviation for April (75%), whereas for the month of October there was a significant excess in monthly average (124.9%).

Tritium concentration during the year 2007 at Turnu Severin location had a mean of 10.2 ± 2.1 TU (one Tritium Unit, TU, one tritium atom corresponds to 10^{18} hydrogen atom). The same value was recorded in our Institute, 10.7 ± 2.1 TU. We recorded a minimum tritium concentration of 4.6 ± 2.1 TU in January 2007 for Turnu Severin location (table 2) and a minimum tritium concentration of 6.1 ± 2.1 TU in February 2007 for our Institute. The maximum tritium concentration of 16.1 ± 2.1 TU was measured in July for Turnu Severin location, but we recorded for our Institute two months with the higher values of 17.2 ± 2.2 TU and 16.8 ± 2.2, May and August. Comparing published values for tritium in precipitation in Austria [Kralic et al., 2005] with measured values for the monitored locations we can conclude that annual tritium concentration average has had the same trend for the past years: 10.4 TU for 2000, 10.5 TU for 2001 and 10.46 TU for 2002. There are no other influences and tritium behaviour in precipitation has the same tendency to decrease in the environment.

Table 2. Tritium concentration during observation period of 2007 in Turnu Severin location and our Institute.

Period of sampling	Tritium concentration [TU] Turnu Severin	Tritium concentration [TU] Our Institute
January 2007	4.6+/-2.1	7+/-2.1
February 2007	7.3+/-2.1	6.1+/-2.1
March 2007	4.8+/-2.1	8.1+/-2.1
April 2007	8.9+/-2.1	12.7+/-2.2
May 2007	15.3+/-2.2	17.2+/-2.2
June 2007	12.7+/-2.2	8.8+/-2.1
July 2007	16.8+/-2.2	14.7+/-2.2
August 2007	15.9+/-2.2	16.8+/-2.2
September 2007	8.8+/-2.1	9.5+/-2.1
October 2007	7.2+/-2.1	6.8+/-2.1

A special behaviour regarding tritium concentration was recorded in the Danube water at Turnu Severin location, table 3. The average tritium concentration in the Danube water for this location was 13.7 ± 2.2 TU, higher than that of precipitation, without seasonal variation normally expected for surface water. The measured average for tritium concentration is far from any radioprotection concern (aprox. 1.6 Bq/l comparing with 100 Bq/l recommended by Council Directive 98/83/EC for drinking water), but is important for Danube River discharge signature at the beginning of Lower Danube Basin.

Table 3. Tritium concentration in Danube water and precipitation at Turnu Severin location.

Period of sampling	Tritium concentration [TU] Danube	Tritium concentration [TU] Precipitation
January 2007	11.5 +/- 2.2	4.6 +/- 2.1
February 2007	17 +/- 2.2	7.3 +/- 2.1
March 2007	13.7 +/- 2.2	4.8 +/- 2.1
April 2007	15.3 +/- 2.2	8.9 +/- 2.1
May 2007	14.8 +/- 2.2	15.3 +/- 2.2
June 2007	11.2 +/- 2.2	12.7 +/- 2.2
July 2007	16.3 +/- 2.2	16.8 +/- 2.2
August 2007	14.9 +/- 2.2	15.9 +/- 2.2
September 2007	10.6 +/- 2.2	8.8 +/- 2.1
October 2007	11.4 +/- 2.2	7.2 +/- 2.1

Tritium sampling campaigns were performed in August 2006, March 2007 and October 2007, table 4.

Table 4. Tritium concentration along Romanian Danube Sector for sampling campaign of August 2006, March 2007, and October 2007.

Location number	Location name	Water body	Tritium concentration August 2006 [TU]	Tritium concentration March 2007 [TU]	Tritium concentration October 2007 [TU]	Mean tritium concentration [TU]
1.	Ieselnita	Danube	17.6 +/- 2.2	7 +/- 2.1	15.7 +/- 2.2	13.4 +/- 2.2
2.	Toplet	Cerna	11.9 +/- 2.2	8.3 +/- 2.1	10.7 +/- 2.2	10.3 +/- 2,2
3.	Drobeta Turnu Severin	Danube	14.8 +/- 2.2	6.2 +/- 2.1	16.7 +/- 2.2	12.6 +/- 2,2
4.	Filiasi	Jiu	12.7+/- 2.2	9.3 +/- 2.1	10.5 +/- 2.2	10.8 +/- 2.2
5.	Bechet	Danube	27.9 +/- 2.3	29.2 +/- 2.3	24.7 +/- 2.3	27.3 +/- 2.3
6.	Islaz	Olt	11.6 +/- 2.2	6.8 +/- 2.1	13.2 +/- 2.2	10.5 +/- 2.2
7.	Turnu Magurele	Danube	12.8 +/- 2.2	8.9 +/-2.1	13.2 +/- 2.2	11.6 +/- 2.2
8.	Oltenita	Arges	12.2 +/- 2.2	11.6 +/- 2.2	11.8 +/- 2.2	11.9 +/- 2.2
9.	Chiciu/Silistra	Danube	9.7+/- 2.1	12.2 +/- 2.2	8.3 +/- 2.1	10.1 +/- 2.2
10.	Seimeni	Danube	32.4 +/- 2.3	33.5 +/- 2.3	28.7 +/- 2.3	31.5 +/- 2.3
11.	Giurgeni	Danube	15.9 +/- 2.2	7.4 +/- 2.1	7.2 +/- 2.1	10.2 +/- 2.2
12.	Tulcea	Danube	11.6 +/- 2.2	10.8 +/- 2.1	16.5 +/- 2.2	13 +/- 2.2

Two higher values than the tritium concentration average of 16.2 ± 2.2 TU were recorded for Bechet and Seimeni, 27.3 ± 2.2 TU and 31.5 ± 2.2 TU respectively. The two locations have nearby two different nuclear power plants, Kozloduy and Cernavoda, with important tritiated effluents discharged in the Danube. Tributaries had lower mean tritium concentration (between 10.3 ± 2.2 TU for Cerna River and 11.9 ± 2.2 TU for Arges River) than the tritium concentration average of the Danube. Tritium level in the Danube water is continuously decreasing from 20-25 TU in 1995 [Rank et al., 1999] to precipitation level, even if ~~the~~ nuclear objectives are in the monitored areas.

Conclusions

The tritium level in precipitation during the monitoring period was 10.2 ± 2.1 TU for Turnu Severin location. Tritium concentration in the Danube water in the same location had higher values than that of precipitation, the mean value calculated during the monitoring period being 13.7 ± 2.2 TU. This value is far from any concern from radiological point of view, but the behavior of tritium concentration during the cold months of the year (January, February) with values higher than 10 TU proves the influence of nuclear activity developed along the Danube. Tritium concentration average in the Danube water along the Lower Danube Basin was 16.2 ± 2.2 TU. Two higher values than the tritium concentration average were recorded for Bechet and Seimeni. The two locations have nearby important nuclear power plants. The highest mean tritium concentration measured during the three sampling campaigns for the Danube water was recorded in August 2006 with a value of 16.6 ± 2.2 TU. The lowest mean tritium concentration measured during the three sampling campaigns for the Danube water was recorded in March 2007 with a value of 13.8 ± 2.2 TU. Tributaries had lower values than tritium concentration average due to their different basins with strong groundwater components. Tritium level in the Danube water is continuously decreasing, from 596 TU in September 1966, to 12.6 TU in December 2005 (GNIR, Vienne Station). Environmental values recorded confirmed that precipitation is the primary source of tritium in the Danube water, in spite of the existence of the two important nuclear power plants in the monitored area, as previously mentioned.

Radioactivity monitoring of sediments in rivers in Serbia during the period 2005–2009

Eremic-Savkovic, Maja; Pantelic, Gordana; Vuletic, Vedrana; Tanaskovic, Irena; Javorina, Ljiljana
Serbian Institute of Occupational Health “Dr Dragomir Karajovic“, Belgrade, SERBIA

Abstract

In this paper we present radioactivity monitoring results of the sediments in Serbian rivers from 2005 through 2009. Sediment samples have been collected at eight sites on six Serbian rivers, usually during spring and autumn.

We have applied gamma spectrometry, gross alpha beta activity and radiochemical method of 90Sr separation as measurement methods.

Our results show that activity concentration of natural radionuclide in sediments (mean annual values in Bq/kg) is within the average values limits for the territory of Serbia. Activities of long living radionuclide of artificial origin have tendency of mild decrease as a result of dissolution, leaching and changes in river flow.

Introduction

Sediment is an essential dynamic component of aquatic systems due to the strong tendency towards bonding the tank of toxic and persistent compounds of anthropogenic origin. Sediment is composed of organic and mineral components. Organic component of the plant and animal material from the river and the watershed area and discharge of industrial waste water utilities. Mineral component contains erosive material from the surface of the entire river basin.

Sediment monitoring and assessment of its quality is usually conducted to determine the extent to which sediment tank and a secondary source contaminenata in surface waters. The aim of this monitoring was conducted in determining the status of the quality of sediment and its impact on the environment and human health through the study of various interactions in the sediment-water system.

Material and methods

Radioactivity control of sediment in the territory of Serbia is done in the following rivers:

– Danube river (sampling is done on Bezdan near the border with Hungary, in Belgrade and in Prahovo near Romania border)
– Sava (sampling is done at the Belgrade)
– Tisa (sampling is done at Kanjiza)

– Nisava (sampling is done near Pirot)
– Timok (sampling is done at Zaječar)
– Drina (sampling is done at Loznica)

Sediments of the Danube and Sava rivers were taken four times durnig the year, while sediments from other rivers were taken in the spring when water level is the highest and in the fall when water level is the lowest.

One by one kilogram of river sediment was taken by sampler and placed in to plastic containers. Sediment was dried at 105^0C to constant weight, sieved trough sieve and the fraction less than 250 µm is taken.

Gammaspectrometry is carried out on pure germanium detector manufactured by EG&G ″ORTEC″, which is connected with multichannel analyzer (8192 channels) produced by the same manufacturer and with adequate computer facilities. Energetic calibration, as well as calibration of detector efficiency is performed by means of Amersham radioactive standard (Debertin K. et al.1988, Pantelic G. et al. 1996)

The measurement of gross beta activity is carried out by alpha-beta proportional gas counter PIC-WPC-9550. The level of basic radiation is 0.4 imp/min. The size of planchet is 5cm. The performance of counter is 47% and is determined by ^{90}Sr standard.

Radiochemical method of ^{90}Sr separation is based on oxalate isolation of Ca and Sr, ignition to oxides and usage of aluminum as ^{90}Y carrier. The equilibrium is achieved in 18 days, and after that time ^{90}Y is isolated on Al $(OH)_3$ carrier (Brnovic 1972), which is then ignited to oxide that is subsequently measured by alpha-beta proportional gas counter

Results and discussion

Table 1 shows gross beta activity results with standard deviation. The scope of a monitoring program included gross beta activity measurements of river Danube at sites Bezdan and Belgrade as well as river Sava near Belgrade.

During the observation period 2005-2009 there was no significant variations of sediment measurement results of river Danube on both locations.

During the observation period 2005-2009 there was no significant variations of sediment measurement results of river Danube and river Sava obtained on a location near Belgrade.

Table 1. Gross alpha beta activity in sediments Danube and Sava river (mean annual values).

Year		2005	2006	2007	2008	2009
		Activity (Bq/kg)				
	Bezdan	708 ± 65	470 ± 140	658 ± 170	473 ± 92	573 ± 70
Danube	Belgrade	520 ± 140	508 ± 100	520 ± 180	503 ± 86	460 ± 220
Sava	Belgrade	480 ± 180	580 ± 140	590 ± 220	530 ± 120	487 ± 95

Table 2 illustrate the results of activity concentration of natural radionuclide in river sediments in Danube and Sava (mean annual values in Bq/kg with standard deviation).

Table 2. Activity concentration of natural radionuclide in river sediments Danube (Zemun) and Sava (Belgrade).

Year	River	^{40}K (Bq/kg)	^{232}Th (Bq/kg)	^{226}Ra (Bq/kg)	^{238}U (Bq/kg)	^{235}U (Bq/kg)	^{7}Be (Bq/kg)

The average natural radionuclide concentration with standard deviation for sediments in other Serbian rivers (Nisava, Timok, Tisa and Drina) in table 3 is shown.

Activities of natural radionuclides measured in all sediment samples are within the average values for the territory of Serbia. Activity concentration of cosmogenic radionuclide ^{7}Be is below the limit of detection.

Table 3. Activity concentration of natural radionuclide in river sediments Danube (Zemun) and Sava (Belgrade).

Year	River	^{40}K (Bq/kg)	^{232}Th (Bq/kg)	^{226}Ra (Bq/kg)	^{238}U (Bq/kg)	^{235}U (Bq/kg)	^{7}Be (Bq/kg)

The most important source of artificial radionuclides in the environment in Serbia is nuclear accident in Chernobyl Nuclear Power Plant. Results of gamma spectrometric measurement ^{137}Cs in sediments of Danube river in tree sites Bezdan, Belgrade and Prahovo shows descreasing during the period 2005-2009 (figure 1). Maximum activity 137Cs was mesured in 2009 in site Prahovo (figure 1).

The sediment was sampled in high water level season. At the actual sampling time, the river flooded the area outside banks, so the sampling of nearby soil has been performed as well.

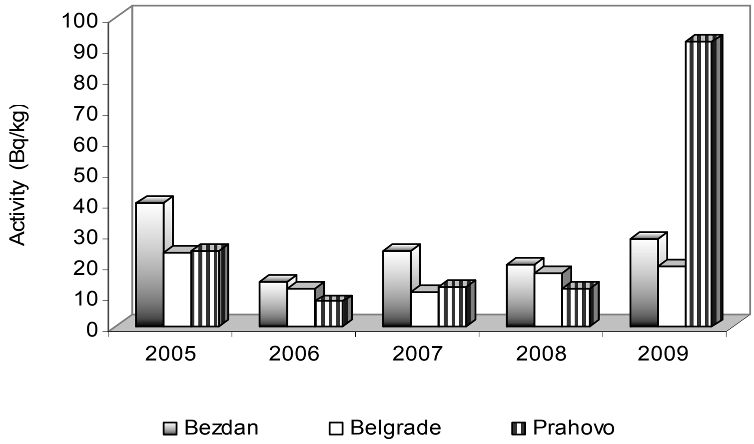

Fig. 1. ^{137}Cs activity concentration in sediment of Danube River (mean annual values).

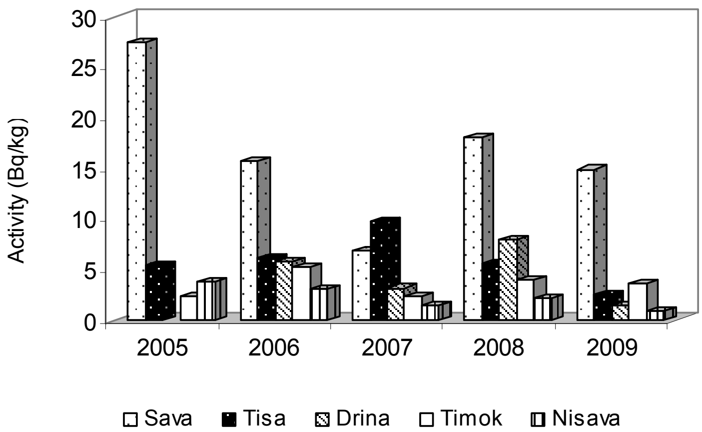

Fig. 2. ^{137}Cs activity concentration in sediments Sava, Drina, Tisa, Timok and Nisava (mean annual values).

Maximum activity of ^{137}Cs was in 2005. in Sava river sediment (figure 2).

Figure 3 shows 90Sr activity in Danube sediment during the period 2005-2009 at sites Bezdan and Belgrade. Average annual values in 2005 was 0.41Bq/kg at site Belgrade. Average annual values in 2007 was 0.12Bq/kg at site Bezdan. In 2009 90Sr activity in Danube sediment at site Prahovo was not measured.

During the period 2005-2009 90Sr activity was less then 1Bq/kg on all rivers at all sites and tends to decrease, as figure 4 illustrates.

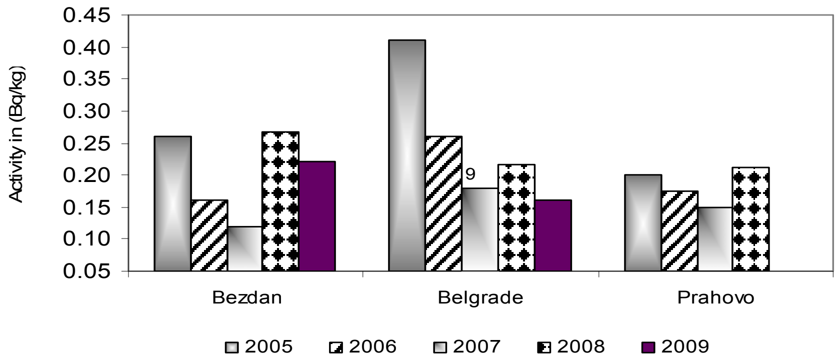

Fig. 3. ^{90}Sr activity concentration in sediments Danube river (mean annual values).

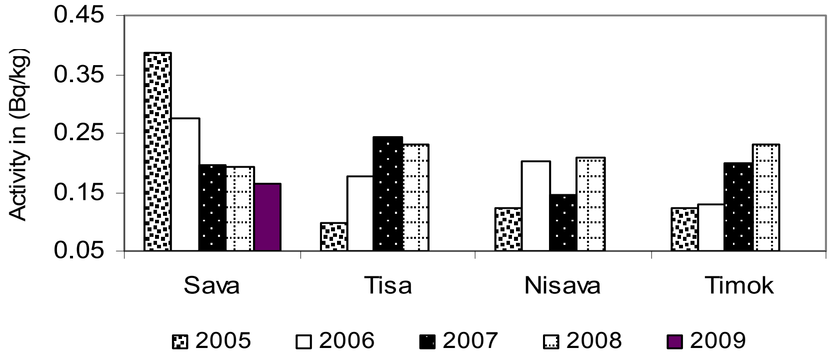

Fig.4. ^{90}Sr activity concentration in sediments Danube river (mean annual values).

Conclusions

By means of gamma spectrometry measurements of natural and artificial radionuclide as well as gross beta and ^{90}Sr activity in sediments of rivers in Serbia it is possible to assess the sediment quality and its impact on the environment. The results of the measurements conducted during the period 2005-2009 are within normal limits. Artificial radionuclide activity tends to decrease as a result of dissolution, leaching and river flow changes.

Radiation and tritium activity in the environment of the National Park Plitvice Lakes

Horvatinčić, Nada; Barešić, Jadranka; Krajcar Bronić, Ines; Obelić, Bogomil
Rudjer Bošković Institute, Department of experimental physics, CROATIA

Abstract

The disturbance of natural distribution of tritium (^{3}H) and radiocarbon (^{14}C) caused by thermonuclear weapon tests in the sixties of the last century made these isotopes very important tracers in environment. Their concentration can be also locally affected by fossil fuel combustion (decrease of ^{14}C) or by various nuclear facilities (increase of ^{14}C and ^{3}H). In our comprehensive study of the environment in the Plitvice Lakes National Park we measured ^{14}C in monthly samples of atmospheric CO_2 and ^{3}H in monthly precipitation in period 2003 – 2006. ^{14}C activity was also measured in the beech leaves and needles of spruce and abies collected as 1-year composite samples in the woods of the Plitvice Lakes area in 2005 and 2006. ^{14}C activity of monthly CO_2 samples vary between 101.5 and 109.6 percent of modern carbon (pMC) with slightly lower ^{14}C activities in winter months due to the influence of CO_2 from fossil fuel combustion. The values are similar to those measured in the city of Zagreb, which is a densely populated industrial center. The ^{14}C activities of tree leaves and needles are slightly higher than mean yearly atmospheric ^{14}C activities: the highest values have needles of abies (111 pMC, 110 pMC) and spruce (110 pMC, 109 pMC), followed by beech leaves (106 pMC, 105 pMC) and atmospheric CO_2 (104 pMC, 105 pMC). Higher ^{14}C activities of coniferous wood indicate that the collected needles represent an average of several years period while the ^{14}C of leaves of deciduous wood represent the mean ^{14}C from the growing period (spring-summer). ^{3}H activities of monthly precipitation showed seasonal fluctuations with maximum in summer (13 – 18 TU) and minimum in winter (0 – 5 TU), and are in good correlation with ^{3}H in the Zagreb precipitation. In conclusion, ^{14}C and ^{3}H in the atmosphere of the Plitvice Lakes area reflect the global trend of these isotopes in the atmosphere, and are at the same level as in highly populated area of Zagreb.

^{137}Cs concentrations in Saimaa ringed seals during 2003–2009

Ylipieti, Jarkko; Solatie, Dina
[1] STUK – Radiation and Nuclear Safety Authority, Research and Environmental Surveillance, Regional Laboratory in Northern Finland, Lähteentie 2, FIN-9600 Rovaniemi, FINLAND

Abstract

The Saimaa ringed seal (*Phoca hispida saimensis*) became isolated in Lake Saimaa at the end of the last ice age ca. 8000 years ago when the connection between Lake Saimaa and the Baltic Sea was broken. The Saimaa ringed seal is one of the very few seal species that live in inland waters. Due to climate change, however, the lack of an ice cover on the lake threatens to drastically decrease the seal population. The Saimaa ringed seal is an endangered species, with an estimated population of 260 seals, and it is protected by law.

As top predators in the aquatic food chain, fish-eating seals are vulnerable to the accumulation of contaminants. Seals are also important indicator species, which provide information about the current state of the environment. The aim of this study was to provide baseline data on radionuclide ^{137}Cs concentrations in Saimaa ringed seals. Altogether 54 seals were collected in Lake Saimaa by the Metsähallitus Natural Heritage Services between the years 2003 and 2009. The seals had died of natural causes or accidentally by drowning. The seals were sampled under the supervision of the Finnish Food Safety Authority EVIRA. Concentrations of ^{137}Cs were analysed in muscle, liver, kidney, bone, spleen and pancreas by the Radiation and Nuclear Safety Authority -STUK in Finland.

The mean radionuclide ^{137}Cs concentrations in muscle, liver and kidney, bone, spleen and pancreas were 76.2, 65.3, 63.5, 75.4, 90.0 and 83.3 Bq/kg f.w., respectively. The highest ^{137}Cs concentration, 180 Bq/kg f.w., was measured in 2004 and the lowest, 28.8 Bq/kg f.w., in 2009 in muscle tissue. The results indicate that the ^{137}Cs concentrations in Saimaa ringed seals decreased consistently not only in muscle, but also in liver and kidney, during the study period. A similar trend was found in the correlation between seal weight and the ^{137}Cs concentrations, which indicates high accumulation of ^{137}Cs in this species.

Introduction

The seals (*Phocida*) belong to high trophic level feeders that bioaccumulate many contaminants to a considerable extent. As top predators in the aquatic food chain, fish-eating seals are exposed to the accumulation of contaminants. Seals are also important indicator species, which provide information about the current state of the environment.

From the radiation protection point of view, ^{137}Cs is the most significant anthropogenic radionuclide because of its 30-year half life and mobility in the environment and subsequent accumulation in food chains. The Chernobyl accident in Russia in 1986 deposited ^{137}Cs fallout over large areas of Europe (AMAP 1998; Hamilton, 2004), including Lake Saimaa (Ylipieti et al.2008). The content of ^{137}Cs varies clearly in different parts of Lake Saimaa, the amount of fallout in 1986 ranging between 3-6 kBq/m^2 (Saxen, 2001).

In this study the concentration of ^{137}Cs in Saimaa ringed seals were analysed. The seal samples were collected in Lake Saimaa, which is a 4 400 square kilometer large freshwater lake situated in South East Finland (Fig. 1.). Lake Saimaa is the largest lake in Finland. All 54 seals were collected by Metsähallitus from different sites in Lake Saimaa: Haukivesi, Orivesi, Puruvesi, Pihlajavesi and Saimaa between the years 2003 and 2009 (Fig. 2.). All the seals had died of natural causes or accidentally by drowning.

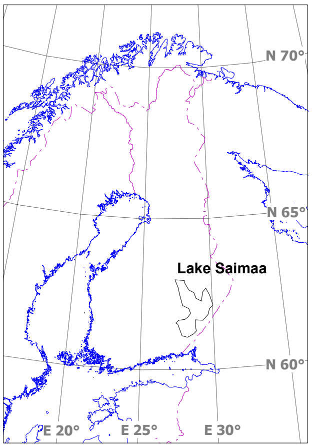

Fig.1. Location of Lake Saimaa.

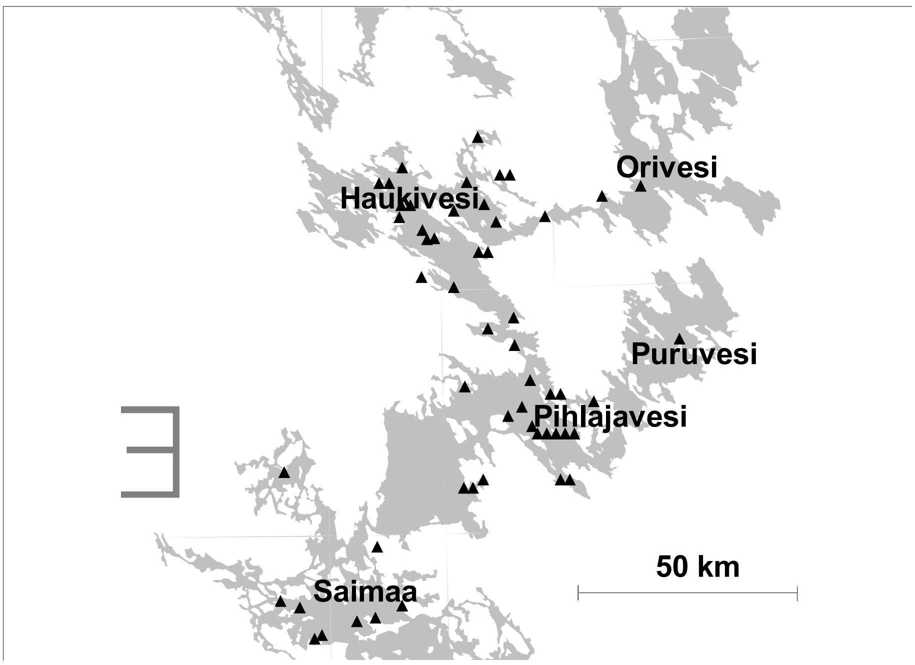

Fig. 2. Locations of the sampled seals.

Material and methods

The seals were divided into two groups according to their age. Adult seals (n = 35) were over one year old and pups (n = 19) under one year, most of the pups being only a few months old (Kokkonen, 2006). Preparation of the seals was carried out under the supervision of personnel from the Finnish Food Service Authority EVIRA. ^{137}Cs were analysed in muscle, liver, kidney, bone, spleen and pancreas by the STUK's Regional Laboratory in Northern Finland. A High-Purity Germanium (HPGe) detector with 30% relative effective was used in the analysis. The radioactivity concentration was determined using Gamma-99 software developed by STUK (Rantavaara et al., 1994).

Results

Muscle

^{137}Cs activity concentrations in muscle in adult and pup seals are presented in Table 1 and in the box plot in Fig. 3. Excluding 4 outlier points (2, 10, 11 and 23), the results show that the pups had almost similar ^{137}Cs concentrations in muscle than adult seals. In general, ^{137}Cs activity concentrations were below 100 Bq/kg f.w. Chernobyl-specific, short-lived ^{134}Cs was still detectable in small amounts in two muscle samples (0.23 and 0.38 Bg/kg f.w.). The correlations between ^{137}Cs concentrations and seal weight in adult seals are shown in Fig. 4.

Table 1. ^{137}Cs activity in muscle in adult and pups seals.

Descriptive Statistics

	N	Minimum	Maximum	Mean	Std. Deviation
adult_muscle	35	31,0	180	78,1	36,0
pup_muscle	19	28,8	154	72,7	30,4

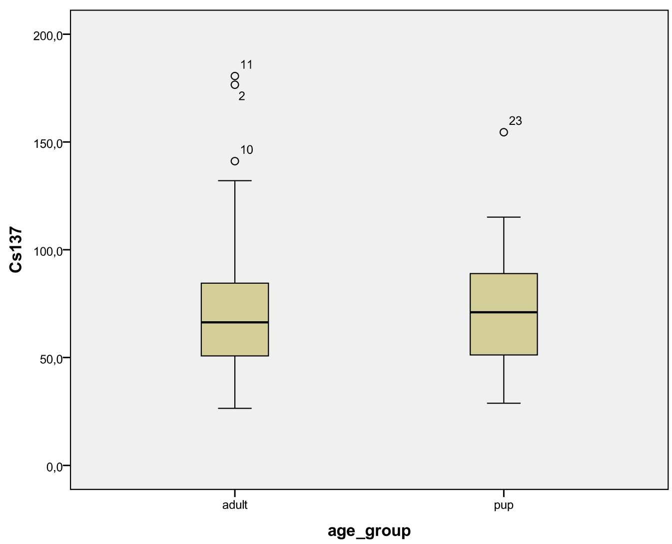

Fig. 3. ^{137}Cs concentrations in seal muscle in the two different age groups.

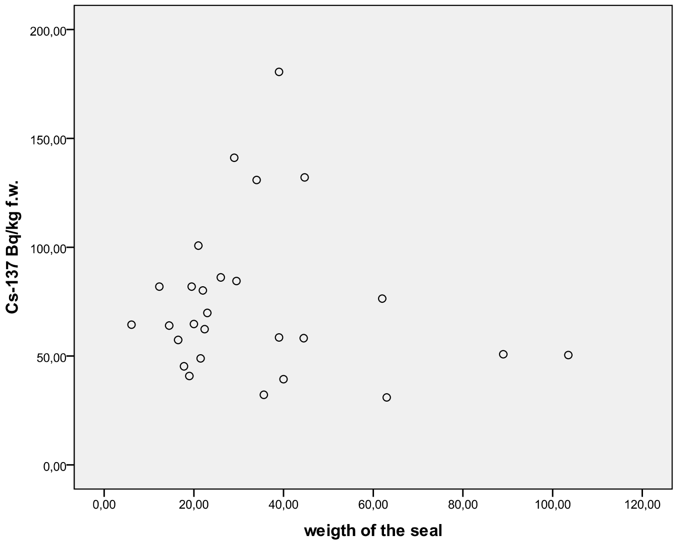

Fig. 4. Correlations between ^{137}Cs concentrations and seal weight in adult seals.

Liver

^{137}Cs activity concentrations in the liver samples were analysed in the same seals except for four adult seals and one pup seal. The results were at the same level and the same trend was observed as in the muscle samples Table 2. Pups were found to have almost similar ^{137}Cs activity concentrations than adults, as seen in Fig. 5.

Table 2. ^{137}Cs activity in seal liver in adult and pup seals.

Descriptive Statistics

	N	Minimum	Maximum	Mean	Std. Deviation
adult_liver	31	23,4	179	66,1	34,2
pup_liver	18	17,4	123	64,0	24,5

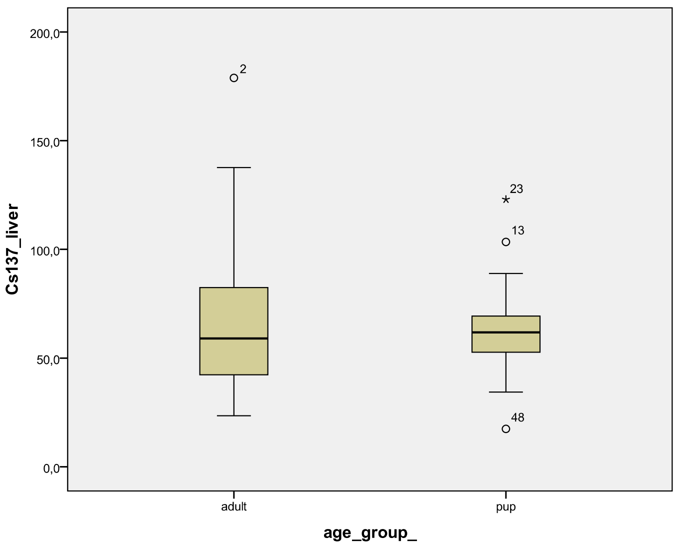

Fig. 5. ^{137}Cs concentrations in seal muscle in the two different age groups.

Kidney

^{137}Cs activity concentrations in the kidney samples are presented in Table 3. A small amount of Chernobyl-specific radionuclide ^{134}Cs was still detected in one kidney sample (4.6 Bq/kg f.w.).

Table 3. ^{137}Cs activity in adult and pup seal kidney.

Descriptive Statistics

	N	Minimum	Maximum	Mean	Std. Deviation
adult_kidney	31	21,0	167	60,1	31,9
pup_kidney	18	30,2	147	69,2	27,7

Bone, spleen and pancreas

Some bone, spleen and pancreas were also analysed. The results are presented in Table 4. ^{137}Cs concentrations in the spleen were at the same level in both adult and pups seals.

Table 4. ^{137}Cs activity in bone, spleen and pancreas in adult and pup seals.

Descriptive Statistics

	N	Minimum	Maximum	Mean	Std. Deviation
adult_bone	4	25.9	92.1	66.2	29.3

Geographical distribution of the ^{137}Cs in seal muscle in Lake Saimaa

The geographical distribution of ^{137}Cs in seals muscle is presented in Fig. 6. Red bars indicate the mean concentrations in adult seals and yellow the mean concentrations in pups during 2003-2009. The fallout situation in 1986 and the ^{137}Cs activity in seal muscle are combined in the same geographical context. Intensity of the gray shading indicates the magnitute of the fallout. (Arvela et al., 1990).

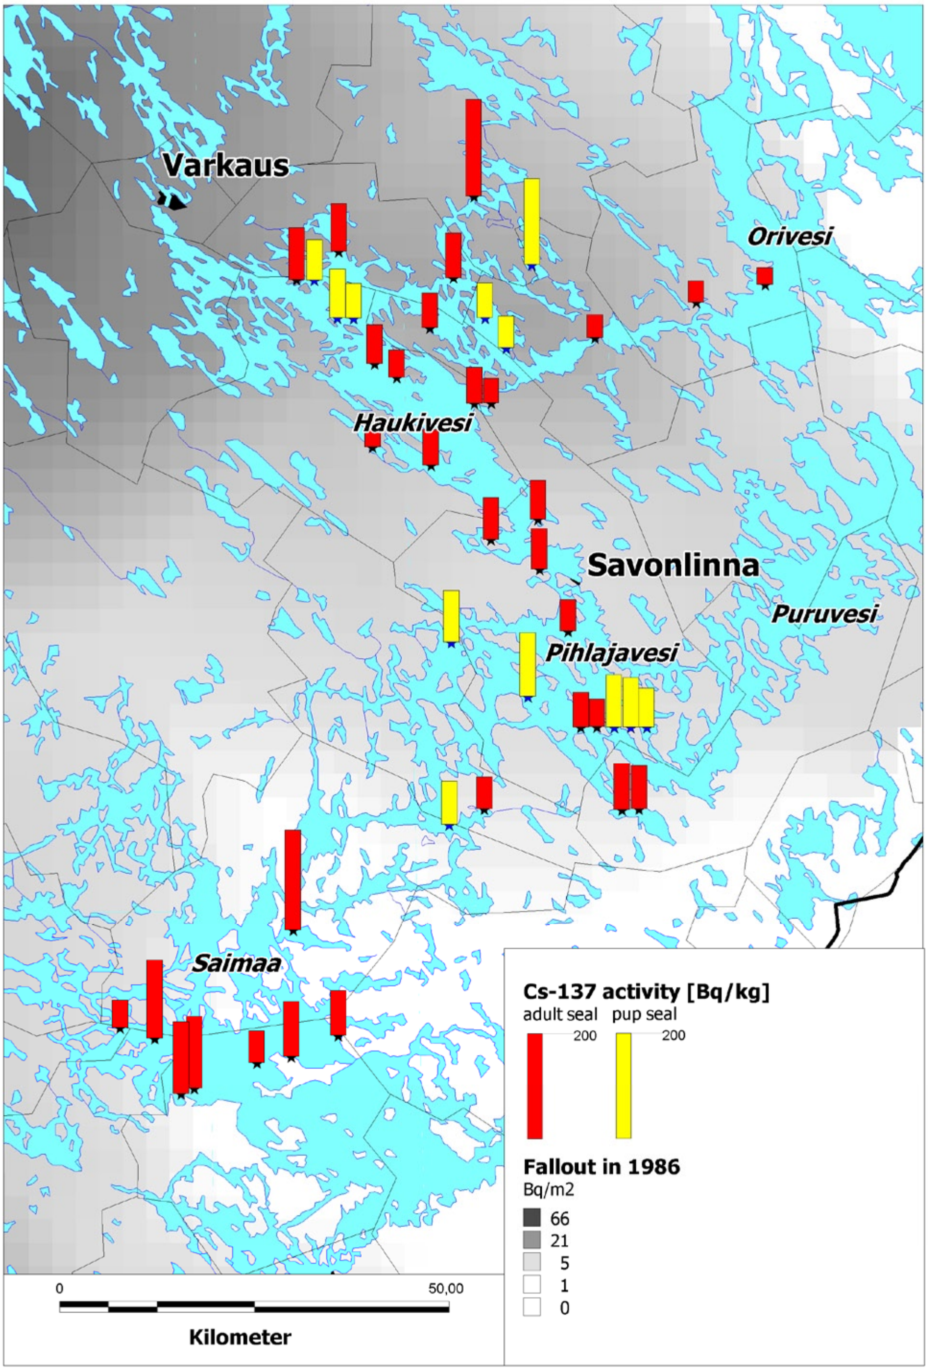

Fig. 6. ^{137}Cs activity in seal muscle and the level of Chernobyl fallout in 1986.

Changes in ^{137}Cs concentrations over time

Changes in the ^{137}Cs concentrations in time were observed in three tissues: muscle, liver and kidney (Fig. 7). One bar symbolizes the average minimum and maximum concentration per year. The ^{137}Cs concentrations in adults and pups were combined.

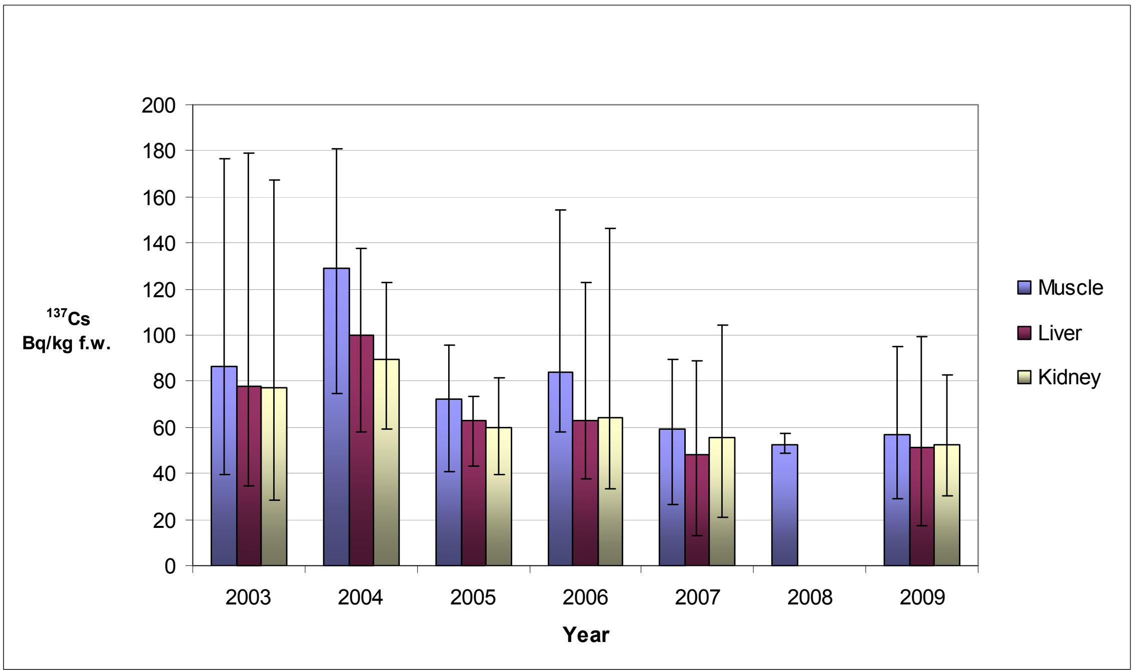

Fig. 7. ^{137}Cs concentrations in muscle, liver and kidney during 2003-2009.

Conclusions

Pups were found to have almost similar ^{137}Cs activity concentrations in their tissues (muscle, liver and kidney) than adult seals. No clear correlation was found between seal weight and ^{137}Cs activity in adults seals. This may be because the seals had been lying dead in the field for days or weeks before collection, with subsequent losses in their body weight. ^{137}Cs activity concentrations were found to decrease regularly over time in the tissues.

The highest ^{137}Cs concentration, 180 Bq/kg f.w., was found in muscle in adults seal. The mean concentration in muscle samples was 76.2 Bq/kg f.w, which is much higher than that in ringed seals from the Arctic Ocean, 0,21 Bq/kg f.w. (Carroll et al., 2002). This is due to the higher deposition from Chernobyl into Lake Saimaa than in the Arctic. The large variation in the ^{137}Cs contents is due to the uneven fallout from Chernobyl. A small amount of Chernobyl-specific radionuclide ^{134}Cs was detected in the same area where the fallout in 1986 was the highest, but the current ^{137}Cs activity concentration does not seem to correlate with the geographical distribution of the fallout in the southern part of the lake.

Radioactivity of ^{210}Po in oysters collected in Taiwan

Lee, Hsiu-wei; Wang, Jeng-Jong; Chang, Bor-Jing
Institute of Nuclear Energy Research, Atomic Energy Council No. 1000, Wunhua Road, Jiaan Village, Longtan Township, Taoyuan County 32546, TAIWAN, R.O.C.

Abstract

The Uranium-238 series decay product, polonium-210(^{210}Po), exists widely in the environment and is well known to be enriched in the tobacco, animal's viscera and suspension particles in surface sea-water. Oysters are cultivated in great quantity along the coast of Taiwan, and it is one of the most favorite foods for the Taiwanese. The oysters intake the suspension particles in surface sea-water, and the ^{210}Po is accumulated indirectly in them. It is necessary to evaluate the internal effective dose of ^{210}Po coming from the intake of oysters by Taiwanese. In this study, oysters around the coast of Taiwan were collected, dried, spiked with a ^{209}Po tracer for yield, and digested with concentrated HNO_3 and H_2O_2, and finally dissolved in 0.5 N HCl. The polonium was then spontaneously deposited onto a silver disc, and the activity of ^{210}Po was measured using an alpha spectrum analyzer equipped with a silicon barrier detector. Meanwhile, the internal effective dose of ^{210}Po coming from the intake of oysters by Taiwanese was evaluated.

Introduction

Natural environmental radioactivity arises mainly from primordial radionuclides, such as ^{40}K, and the radionuclides from the ^{232}Th and ^{238}U series. The major contribution to the radiation exposure received by mankind comes from natural sources. These include external sources such as cosmic rays and radiation from primordial radionuclides (^{238}U and ^{232}Th) and their decay products in the environment. Information on the levels of naturally occurring radionuclides is important as they also contribute a substantial fraction of the radiation dose to the natural ecosystems (Holtzam, 1966).

A large contribution to the radiation dose received by humans comes from the naturally occurring uranium series radionuclides accumulated in the body, namely alpha-emitting ^{210}Po (of physical half-life 138.4 days) and ^{210}Pb (precursor of ^{210}Po with physical half-life 22.2 years) (UNSCEAR, 1993). ^{210}Po is reported to account for up to 75% of the alpha-radiation dose in marine organisms (McDonald, Fowler, Heyraud, & Baxter, 1986) and up to 50% of the internal alpha-radiation dose in people (Holtzman, 1966). In 1988, a report of the United Nations Scientific Committee on the Effects of Atomic Radiation indicated that ^{210}Po is estimated to contribute about 7% of the total effective dose to man from ingested natural internal radiation (UNSCEAR, 1988). The polonium isotopes are amongst the most radiotoxic nuclides to human beings

(McDonald et al., 1986). The maximum permissible human body-burden for ingested ^{210}Po is only 1.1×10^3 Bq (CRC, 1982).

The main source of ^{210} Po in the environment is the gaseous ^{222} Rn, which escapes from the earth's crust into the atmosphere. The daughter products of ^{222} Rn are removed from the atmosphere with aerosol particles wet and dry deposition on the land surface and oceans (Skwarzec et al., 2001; Ladinskaya et al., 1973).

The main sources of ^{210}Po in the human body are food and cigarette smoke (Parfenov, 1974; Holtzman, 1978; UNSCEAR, 1982). Intake of ^{210}Po by food strongly depends on dietary habits. Polonium has an affinity for protein, enabling it to pass in significant quantities up the food chain. Thus, increased ^{210}Po burdens are found in people who consume high-protein diets of meat or fish and other seafood(Watson, 1985; Carvalho, 1995; Skwarzec, 1995). UNSCEAR (2000) quotes a worldwide average annual intake of 58 Bq of ^{210}Po in the diet. The value for annual ^{210}Po intake in the typical European diet is 40 Bq; however, this is based on data from only five countries (Italy, Poland, Romania, Russia and the UK).

The radioactivity of ^{210}Po had been measured in drinking and mineral water (Desideri et al., 2007a,b; Forte et al., 2007; Skwarzec et al., 2003, 2004; Vesterbacka, 2007)and cigarette but there are not much data for seafood , like oysters. The oyster is cultivated in great quantity along the coast of Taiwan, and it is one of the most favorite foods for the Taiwanese. The oysters intake the suspension particles in surface sea-water, and the ^{210}Po is accumulated indirectly in them.

The aim of the present study was to provide information on the levels of natural radionuclides ^{210}Po in samples of oysters products in different regions of Taiwan. The purpose of this work is to calculate the internal effective dose from ^{210}Po for the individual local public through oysters ingestion.

Experiment

Sampling and pretreatment

The samples of oysters sampling from 6 Taiwanese regions, as shown in Fig. 1, were purchased from traditional consumer markets.

The fresh oysters were dried at 110 ℃ for 24 hours in the oven. A weighted dry oyster sample was transferred into a beaker, then a known activity of ^{209}Po was spiked into the sample as a yield tracer. The oyster sample was digested with conc. HNO_3 and H_2O_2 solution. After the digested solution was evaporated to near dryness, the residue was then dissolved in 6 M HCl. The solution was filtered and the filtrate solution was then evaporated to near dryness. Finally, the residue was dissolved in 0.5 M HCl for deposited spontaneously. The process for the ^{210}Po analysis is shown in Fig. 2.

Spontaneous deposition

Polonium was spontaneously deposited onto a silver disk, from the 0.5 M hydrochloric solution in the presence of 1 g ascorbic acid (reduction of Fe^{3+}), at 90–95 ℃ in continuous for 4 hours. The spontaneous deposition plating apparatus for Po is shown in Fig3. The activities of ^{209}Po and ^{210}Po on the silver disk were measured by an alpha spectrometer equipped with semiconductor silicon detectors of surface barrier type. The counting efficiency of the silicon detectors for ^{209}Po and ^{210}Po was about 40%. The polonium yields from the analyzed oysters samples ranged from 50% to 65% for 80000 s counting time.

Results and discussion

Radionuclide activity concentration

The ^{210}Po activity concentrations for oysters sampling from 6 regions of Taiwan in our study are listed in Tables 1. The mean value of ^{210}Po activity concentrations for all oyster samples studied is 50.1 Bq kg^{-1} .The minimum activity concentration of ^{210}Po (16.9 Bq kg^{-1}) was found for sample in Dongshi region. And, the maximum activity concentration of ^{210}Po(193 Bq kg^{-1}) was found for sample in Penghu island region.

The annual production of oysters in Taiwan was about 30420 metric ton(Fisheries Agency,R.O.C. 2006,2007,2008), among which the production of oysters in Kinmen and Penghu islands regions were only 1.3%. The main 98.7% of oysters are produced around the Taiwan coastal areas. However, according to the study results in Table 1, the oysters coming from the Penghu islands and the Kimmen islands have the higher ^{210}Po activity concentrations.

Table 1. ^{210}Po activity Concentration(BgKg^{-1})in oysters.

Sample	^{210}Po Concentration(BgKg^{-1})
Wangkung	23.3 – 24.3
Dongshi	16.9 – 18.8
Pudai	28.8 – 31.5
Dangpenwan	27.6 – 29.5
Penghu islands	59.6 – 193.1
Kimmen islands	69.5 – 78.4
Mean	50.1

Dose assessment

The internal effective dose of Taiwanese via ingestion of ^{210}Po present in the oyster was calculated. Annual individual effective doses were calculated using the dose per unit ingestion conversion factors(ICRP-72, 1996) of 1.2 μSv Bq^{-1}for ^{210}Po in the body. Based on the ^{210}Po daily intake from oysters ingestion. The oysters consumption quantity was calculated by the average product of oysters in Taiwan from 2006 to 2008. The average product for three years of oysters in Taiwan was 30420 metric ton.

The internal dose of the ingestion for ^{210}Po in oyster for Taiwanese can be calculated by Eq. (1) :

$$D = K^{\cdot} \quad G^{\cdot} \quad C \tag{1}$$

where D is the effect dose via ingestion(Sv); K is the ingesting dose conversion factor of the ^{210}Po radionuclide(1.2 μSv Bq^{-1}) (ICRP-72, 1996); G is the oysters consumption per year; here is 1.32 kg y^{-1}, which is calculated from the annual production of oyster in Taiwan divided by population of Taiwanese; and C is the mean activity concentration of the ^{210}Po radionuclide(50.1 Bq kg^{-1}).

The annual ingestion (Bq y^{-1}) and the effective doses(mSv y^{-1}) of ^{210}Po in oyster for Taiwanese were estimated and listed in Table 2. The annual ingestion and effective dose of Taiwanese due to the ^{210}Po in oysters were found to be in the range from 22.3 to 254.9 Bq y^{-1} and 2.68×10^{-2} to 3.06×10^{-1} mSv y^{-1}, and the mean values of the annual ingestion and the effective dose for Taiwanese were 66.1 Bq y^{-1} and 7.94×10^{-2} mSv y^{-1}, respectively.

Taiwan Radiation Monitoring Center indicated that the annual effective dose for adults from natural background radiation in Taiwan is 1.62 mSv y^{-1}, including 0.90 mSv from external radiation exposure and 0.72 mSv y^{-1} from internal radiation exposure. The natural radiation dose level is only about 2/3 of the global average(2.4 mSv y^{-1}) quoted in the UNSCEAR 1993 Report. The mean annual effective dose of Taiwanese due to the ingestion of ^{210}Po in oysters was 7.94×10^{-2} mSv y^{-1}; which is 11.0 % of the ingestion dose(0.72 mSv y^{-1}) and 4.9 % of the total effective dose(1.62mSv y^{-1}) of the Taiwanese.

Table 2. Annual effective dose(mSv y^{-1}) of Taiwanese due to the ingestion of ^{210}Po in oyster.

Locations	Annual ingestion of ^{210}Po in oyster (Bg y^{-1})	Annual dose (mSv y^{-1})
Wangkung	30.8 – 32.1	3.69×10^{-2} – 3.85×10^{-2}
Dongshi	22.3 – 24.8	2.68×10^{-2} – 2.98×10^{-2}
Pudai	38.0 – 41.6	4.56×10^{-2} – 4.99×10^{-2}
Dangpenwan	36.4 – 38.9	4.37×10^{-2} – 4.67×10^{-2}
Penghu	78.7 – 254.9	9.44×10^{-2} – 3.06×10^{-1}
Kimmen	91.7 – 103.5	1.10×10^{-1} – 1.24×10^{-1}
Mean	66.1	7.94×10^{-2}

Conclusion

The ^{210}Po activity in the different Taiwan regions were determined. The results indicated that the oysters coming from Penghu island and Kinmen island regions contain higher concentrations of ^{210}Po in comparison with oysters from other regions, in spite of the oyster production of these two regions were just about 1.3 % of the total amount of Taiwanese oysters.

The mean annual ingestion and effective dose of Taiwanese due to the ingestion of ^{210}Po in oysters were 66.1 Bq y^{-1} and 7.94×10^{-2} mSv y^{-1}; which is 11.0 % of the ingestion dose(0.72 mSv y^{-1}) and 4.9 % of the total effective dose(1.6mSv y^{-1}) of the Taiwanese.

Natural alpha emitting radionuclides in bottled drinking water, mineral water and tap water

Benedik, Ljudmila; Jeran, Zvonka
Jožef Stefan Institute, Jamova 39, SI-1000 Ljubljana, SLOVENIA

Abstract

Quantitative information about the activity concentrations of critical alpha- emitting radionuclides in food and drink is important in the study of cumulative radiation effects on human health. In most countries there is an increasing tendency to replace tap water by consumption of commercial bottled natural and mineral water. Furthermore, various beverages as well as dietary supplements are also prepared from mineral water, not ordinary tap water. In this work tap water and bottled drinking and mineral water were collected in Slovenia and analysed in order to assess the radiation doses from ^{238}U, ^{234}U, ^{226}Ra and ^{210}Po. On the basis of radionuclide activity concentrations the internal radiation doses to individuals were assessed and are discussed together with the contribution of each particular radionuclide to the dose.

Introduction

In most European countries, there is an increasing tendency in population to replace tap water of satisfactory quality for human consumption with commercial bottled natural and mineral water. Moreover, various beverages are also prepared from mineral water, not ordinary tap water. Systematic studies on radiological characterisation of drinking water started after 1993, when the recommendations of the Guidelines for drinking water quality, issued by the World Health Organisation were published (WHO, 1993). These guidelines state that drinking water is safe from the radiological point of view if within the range of normal consumption (2 L per day), the annual dose rate originating from the presence of radioactive nuclides does not exceed 0.1 mSv. UNSCEAR reports (UNSCEAR, 1998, 2000) estimated that exposure to natural sources contributes more than 98 % of the radiation dose to the population (medical treatment is not taken into account). The main contribution to dose is largely due to the presence of naturally occurring radionuclides of both the uranium and thorium decay series. Due to their high radiotoxicity, the contributions of ^{210}Po and ^{228}Ra to the dose are more pronounced. The dose contributions of the radionuclides are in the order: ^{210}Po > ^{228}Ra > ^{210}Pb > ^{226}Ra > ^{234}U > ^{238}U > ^{224}Ra > ^{235}U. Increased concerns concerning the radiological quality of drinking water has led to an increased demand for real data assessment. The old drinking water regulation 980/778/EEC from 1980 (EC, 1980) in which neither radioactivity nor uranium were mentioned, were replaced by the European Directive 98/83/EC in 1998 (EC,1998). In this Directive, the reference dose level of committed annual effective dose due to drinking water consumption is 0.1 mSv. The Directive points out that the total indicative dose must be evaluated excluding tritium, ^{40}K, ^{14}C, radon and its decay products, but including all other radionuclides of the natural decay chains. The maximum values for radon and long-lived radon decay products such as ^{210}Pb and ^{210}Po are proposed in the European Commission Recommendation 2001/928/Euratom (EC, 2001). Uranium is covered by the Directive, although its contribution to the dose is minor due its small dose conversion factor. However, uranium is a toxic heavy metal and therefore has to be regulated and controlled. The WHO set the most stringent limitation of 2 µg/L in its 1998 report (WHO, 1998), but later (WHO, 2004) changed this limit to 15 µg/L; the USA (EPA, 2000) set the limit to 20 µg/L. Recently, Germany set the uranium limit of 2 µg/L for mineral water considered suitable for infants (Bundesgesetzblatt, 2006). Considering the importance of water for human consumption, its quality has to be assured and regularly controlled. The assessment of the radiological quality of natural or bottled drinking and mineral waters is also important in view of assessment and reduction of the radiation exposure of the population. For practical purposes, the recommended screening levels for drinking water below which no further actions are required are 0.1 Bq/L for gross alpha activity and 1 Bq/L for gross beta activity. If these values are exceeded, determination of particular radionuclides dissolved in drinking water needs to be performed. In 2004, the WHO published the third edition of its guidelines for drinking water (WHO, 2004) in which the recommended screening level for gross alpha activity was increased from 0.1 to 0.5 Bq/L. Due to the increasing tendency in the consumption behaviour of the population to replace surface tap water of sufficient quality for human consumption with commercial bottled drinking natural and mineral water, several studies to assess the radioactivity levels in bottled drinking and mineral water were performed around Europe. The report of Weknow (Weknow, 2005) gave a good overview of radioactivity levels found in drinking water across Europe, while data on drinking water quality in Slovenia are very scarce.

The experimental design of our study was to determine the activity concentrations of the alpha emitters ^{238}U, ^{234}U, ^{226}Ra and ^{210}Po in Slovenian bottled drinking and mineral water, as well as in tap water. The studied samples included bottled drinking and mineral water purchased in the period from October 2009 to March 2010, on the market in Ljubljana. All water samples originated from Slovenia. There are many companies in Slovenia producing natural drinking and mineral water from bedrock aquifers of different depths. Tap water was collected from chosen cities in Slovenia.

Materials and methods

For this study we analysed three of the most frequently sold mineral waters and eight bottled drinking waters “from the shelf”. We also analysed six tap waters (Fig.1). All reagents used in the analysis were of analytical grade. The tracer solutions (^{232}U, ^{209}Po, ^{133}Ba) used in the study were prepared from calibrated solutions purchased from Analytics, Inc. (Atlanta, GA, USA). The producer maintains traceability to NIST standards.

An alpha spectrometer (EG&G ORTEC) with a passivated implanted planar silicon (PIPS) semiconductor detector with an active area of 450 mm^2 and 28% efficiency for a 25 mm diameter disc was used for alpha-particle spectrometric measurements. The calibration of the detector was made with a standard radionuclide source, containing ^{238}U, ^{234}U, ^{239}Pu and ^{241}Am (code: 67978-121), obtained from Analytics, Inc. A coaxial HP Ge detector was used for measurements of the gamma emitting nuclide ^{133}Ba.

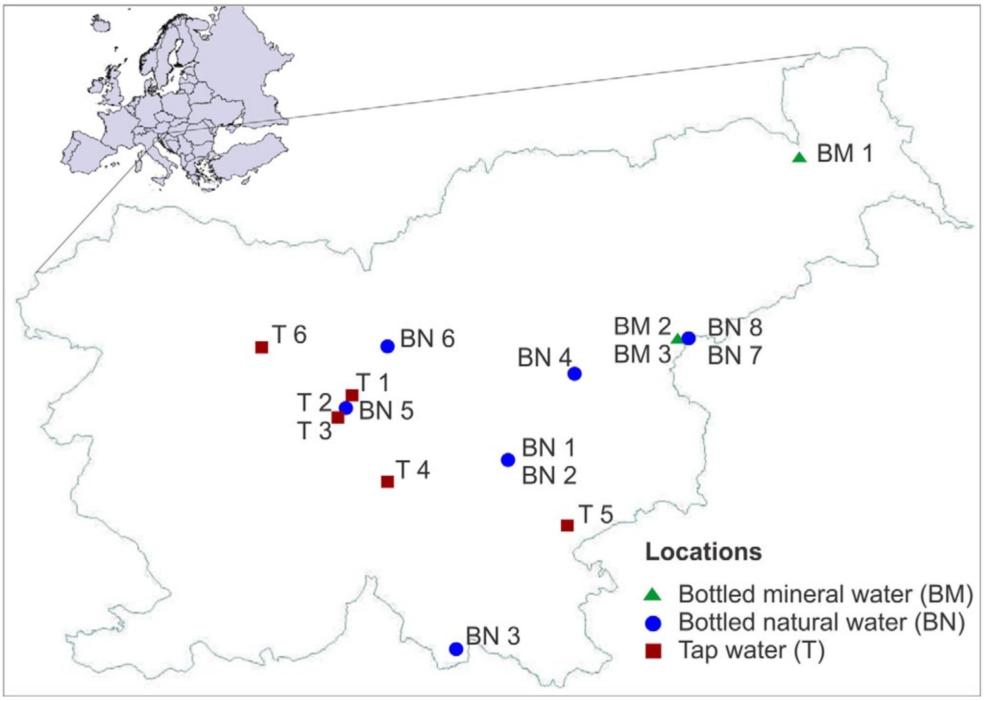

Fig. 1. Locations of tap water and bottling facilities of selected natural and mineral waters from Slovenia.

For determination of uranium radioisotopes a known amount of ^{232}U tracer (~ 0.5 Bq) was added to the water sample which was acidified with concentrated HNO_3 (3mL of acid per 1L of sample). Uranium was preconcentrated from the water samples by coprecipitation with iron(III) hydroxide at pH 9-10 using an ammonia solution. The precipitate was separated by centrifugation, washed with distilled water and dissolved in concentrated nitric acid. The solution was adjusted with distilled water to 3M HNO_3 and loaded onto a UTEVA column (Eichrom Industries Inc.) (Horwitz et al., 1993) pre-conditioned with 5 mL 3M HNO_3. The column was then washed with 3M HNO_3. Thorium radioisotopes were stripped from the column with 9M and 5M HCl. Uranium radioisotopes were eluted with 15 mL 1M HCl. The microcoprecipitation method with neodymium fluoride was used for thin source preparation in the alpha spectrometric determination (Hindman, 1983, Sill and Williams, 1981). The neodymium fluoride suspension was filtered through a 25 mm diameter 0.1 µm polypropylene filter. The dry filter was mounted on a stainless steel disc.

The analytical scheme for determination of ^{226}Ra was adapted from Lozano et al. (Lozano et al., 1997). The procedure is based on coprecipitation of $Pb(Ra)(Ba)SO_4$. The water sample was transferred to a glass beaker and acidified with concentrated H_2SO_4 (10 mL of sulphuric acid per 1L of sample). After addition of ^{133}Ba tracer together with Ba-carrier, the sample was stirred for approximately 30 min. With stirring, 30 mg Pb^{2+} was added in portions to allow good coprecipitation of radium and barium. After settling, the suspension was centrifuged and washed with distilled water. The $PbSO_4$ precipitate containing radium and barium was dissolved in 4 mL 0.1M EDTA, prepared in 0.5M NaOH. For ^{226}Ra determination 250 µg of 0.3 mg/mL Ba^{2+} solution was added together with 4 mL of saturated Na_2SO_4 solution. With stirring, 1:1

acetic acid solution was added until pH 4–5 was reached, thus precipitating $BaSO_4$, while Pb^{2+} ions remained in solution. Immediately after, 0.2 mL of a 0.125 mg/mL $BaSO_4$ suspension was added, acting as a seeding precipitate to obtain small particles. The suspension was allowed to settle for 30 min and filtered through a 25 mm 0.1μm polypropylene filter. The filter with $BaSO_4$ deposit was dried and mounted on a stainless steel disc and measured by γ–ray spectrometry for ^{133}Ba yield determination and by α–particle spectrometry for determination of ^{226}Ra.

For determination of ^{210}Po in water, ^{209}Po (~ 0.3 Bq) tracer was added to 9 L of water. After sample acidification with concentrated HCl (2 mL of acid per 1 L of sample), the radionuclides were coprecipitated with MnO_2. Precipitation of MnO_2 was achieved by adding $KMnO_4$ and $MnCl_2$ and adjusting the pH to 9 with ammonia solution. The precipitate was then dissolved with a mixture of HCl and H_2O_2, and adjusted with distilled water to pH 1. To prevent co-plating of other potentially interfering ions (Fe^{3+}, Mn^{6+}), 0.5 g of ascorbic acid was added. The spontaneous deposition of polonium on a 19 mm diameter silver disc was carried out at 90 °C for 4 hours. The Ag disc, covered on one side, was fixed in a holder and immersed in the solution (Benedik and Vreček, 2001). Polonium radioisotopes were then measured by alpha spectrometry.

Based on the results of activity concentrations of the four alpha emitters in drinking water presented in Table 1, the internal doses (committed effective dose) for an adult were estimated using an annual consumption rate of 730 L/year accoording to the WHO Guidelines for Drinking Water Quality (2004) and the dose coefficients of the relevant radionuclides from the “International Basic Safety Standards for Protection against Ionizing Radiation and for Safety of Radiation Sources” (IAEA, 1996).

Results and discussion

In Table 1 the results of the activity levels of ^{238}U, ^{234}U, ^{226}Ra and ^{210}Po in three different groups of drinking water, natural and mineral bottled water and tap water, are given. As seen the activity concentrations of uranium in the water samples analysed ranged from 1.1–57 mBq/L and 2.8–173 mBq/L for ^{238}U and ^{234}U, respectively. These values, except for the mineral water BM2 (57 and 173 mBq/L for ^{238}U and ^{234}U, respectively) were relatively low, comparable with some literature data from Italy (Jia and Torri, 2007) and well below the limit values (98/83/EC, 2004, WHO,2004). The lowest absolute values were found in tap waters; however, somewhat elevated levels were measured in three bottled natural waters originating from the east (BN1, BN2) and south (BN3) of the country.

^{226}Ra (Table 1) was in the range between 0.14–31.7 mBq/L and like uranium, can be regarded as low and comparable with data reported for Europe (Weknow, 2005). The highest absolute level of 32 mBq/L was found in a bottled natural water (BN1) which also had an elevated uranium level. Elevated activity concentrations higher than 10 mBq/L were found in two mineral (BM2, BM3) and two bottled natural waters (BN7, BN8) coming from the same region in the eastern part of the country (Fig.1), known for its thermal and mineral springs and spas. With the exception of one sample (T4), tap water had low levels of ^{226}Ra in a narrow range between 0.3-and 1.4 mBq/L.

Table 1. Radionuclide activity concentrations (mBq/L) in natural and mineral bottled water and tap water collected in Slovenia.

Sample	Type of sample	U-238	U-234	Ra-226	Po-210
BN1	**Natural water**	**28 ± 3**	**71± 8**	**32 ± 4**	1,1 ± 0,4
BN2		18 ± 1	57 ± 6	11 ± 1	2,1 ± 0,3
BN3		13 ± 2	15 ± 2	1,7 ± 0,2	0,9 ± 0,2
BN4		2,2 ± 0,5	3,5 ± 0,7	2,3 ± 0,3	0,43 ± 0,12
BN5		8,3 ± 1,1	12 ± 1	0,14 ± 0,05	2,0 ± 0,4
BN6		2,9 ± 0,5	13 ± 2	6,8 ± 0,8	1,2 ±0,3
BN7		5,1 ± 0,6	14 ± 2	16 ± 2	0,24 ± 0,07
BN8		4,2 ± 0,6	8,7 ± 1,2	15 ± 2	0,6 ± 0,2
BM1	Mineral water	1,1 ± 0,2	2,8 ± 0,5	2,4 ± 0,3	0,39 ± 0,11
BM2		**57 ± 9**	**173 ± 28**	12 ± 2	1,0 ± 0,3
BM3		5,2 ± 1,8	12 ± 2	17 ± 2	0,6 ± 0,1
T1	Tap water	7,2 ± 0,7	8,5 ± 0,8	1,0 ± 0,2	0,25 ± 0,06
T2		4,8 ± 0,9	6,9 ± 1,1	0,47 ± 0,10	1,0 ± 0,2
T3		6,7 ± 1,1	11 ± 2	1,3 ± 0,1	0,77 ± 0,16
T4		8,2 ± 2,8	8,8 ± 2,9	15 ± 2	1,1 ± 0,2
T5		7,0 ± 0,9	11 ± 1	1,4 ± 0,1	1,8 ± 0,4
T6		1,1 ± 0,3	3,0 ± 0,5	0,30 ± 0,03	0,67 ± 0,19

Among the alpha emitters analysed ^{210}Po has the lowest activity concentrations in the range between 0.24-2.1 mBq/L in all three groups of drinking water.

In Fig.2 the results of the calculated total effective doses (μSv/a) for adults drinking different types of water are presented. It is seen that doses are on average very low, in the range of 1-11 (μSv/a) and only by drinking for a whole year one mineral (BM2) or one natural bottled water (BN1) would the person obtain a dose higher than 10 μSv/a, which still represents only one tenth of the recommended reference dose level (RDL) of 0.1 mSv from 1 year´s consumption of drinking water (EC 1998).

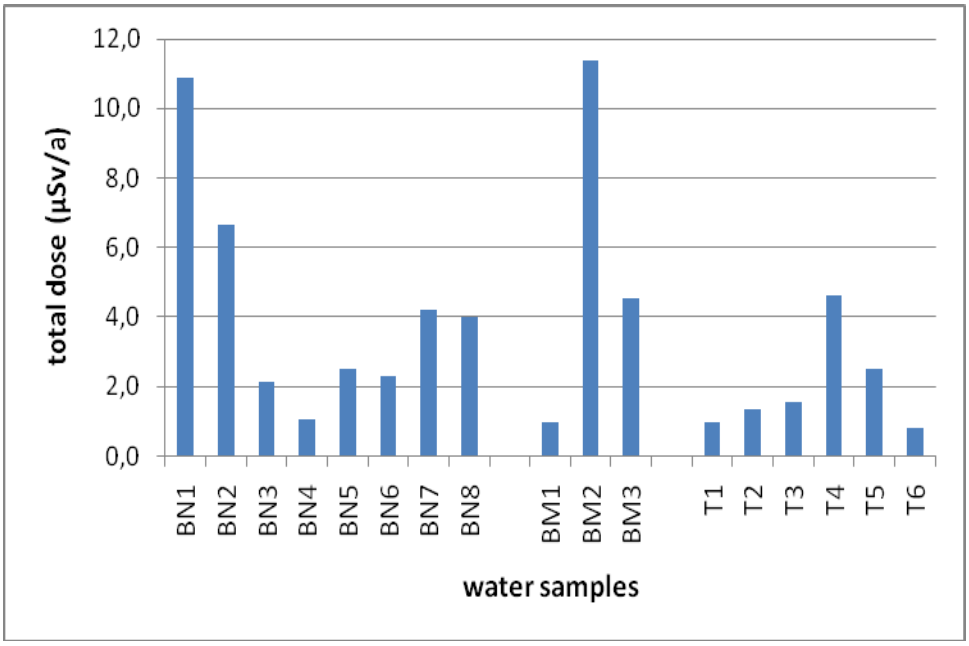

Fig. 2. Total internal dose (µSv/a) to adult member of the public due to drinking different types of water.

The contribution of each analysed radionuclide to the annual total internal dose varies among different types of water samples, but on average in natural bottled waters the contributions were in the order ^{226}Ra (mean: 46 ± 28%) > ^{210}Po (27 ± 22%) > ^{234}U (19 ±8%) >^{238}U (8 ± 6%) (Fig.3). In mineral water the order was similar (Fig.3). Only in the mineral water BM2 did ^{234}U contribute more than 54%, followed by ^{226}Ra (22 %), ^{238}U (16%) and ^{210}Po (8%). In tap water ^{210}Po (mean: 48 ± 23%) was the main radionuclide contributing to total dose due to its high dose conversion factor.

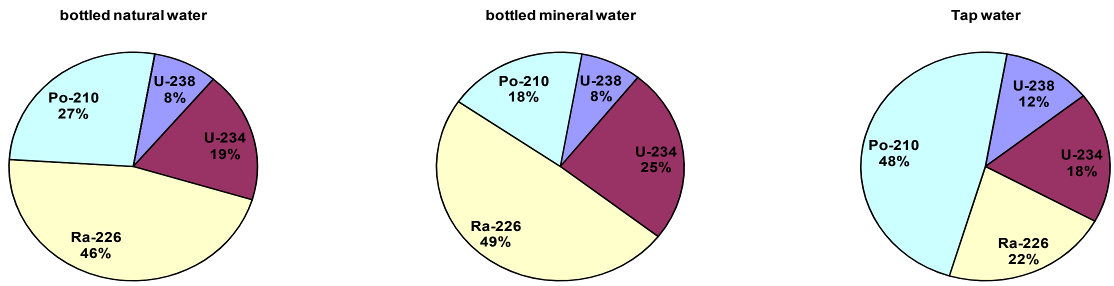

Fig. 3. The average contribution (%) of alpha radionuclides to internal commited effective doses to adult members of the public drinking different types of water.

Conclusions

The present study was a pilot study where only four selected alpha emitters were analysed in different drinking waters from Slovenia. From the survey it is evident that the activity concentrations, with the exception of one mineral and two natural drinking waters, were very low also leading to low calculated internal doses which constitute only a few percent of the recommended reference dose level (RDL) of 0.1 mSv. However, beside the analysed radionuclides there are also some other radio isotopes, namely the long- lived radon decay products ^{210}Pb and ^{228}Ra, which both have high dose conversion factors and should be determined and included in dose estimations in the future.

Radiation protection of the public and the environment: long-term, large-scale radioecological monitoring by spruce needles

Seidel, Claudia[1]; Gruber, Valeria[1]; Maringer, Franz Josef[2]

[1] University of Natural Resources and Applied Life Science, Low-Level Counting Laboratory Arsenal, AUSTRIA

[2] BEV – Federal Office of Metrology and Surveying, AUSTRIA

Abstract

In a two years radioecological study spruce needle samples of the Austrian Bioindicator Grid collected between 1984 and 2008 were analysed retrospectively by low-level gamma-ray spectrometry to investigate the geographical and temporal distribution of radionuclides in spruce needles of the last 25 years. Main focus was the development of the radioactive contamination before and after the Chernobyl fallout 1986. Overall more than 750 spruce needle samples of selected locations – well distributed among the area of Upper Austria – were analysed for different natural and anthropogenic radionuclides: Cs-137, K-40, Pb-210, Ra-226, Ra-228, U-238. Additionally soil samples were taken at selected sites to estimate transfer factors to describe the transfer of radionuclides from soil to spruce needles. On the basis of the measured Cs-137 activity concentrations in the spruce needles and soil samples estimations are carried out, how to use the Bioindicator spruce needles for environmental radioactivity monitoring. Hence the detection limits for additional Cs-137 deposits (Bq/m^2) in spruce needles samples are estimated at various locations. Furthermore the results have been integrated into an existing environmental surveillance programme in Upper Austria.

Slovenian experience with inconsistencies in the global contamination monitoring results

Cindro, Michel; Vokal Nemec, Barbara; Križman, Milko
Slovenian Nuclear Safety Administration, SLOVENIA

Abstract

Introduction Monitoring of the global radioactive contamination due to atmospheric nuclear bomb tests (1951-1980) and the Chernobyl accident (1986) has been carried out in Slovenia since the early sixties. The primary purpose of the monitoring programme is to provide a basis for calculating the exposure of the population due to radioactive contaminants. Secondarily, due to the very long measuring period, it is possible to observe and understand the trends of radionuclide concentrations in different media. Above all, two long-lived fission radionuclides, ^{137}Cs and ^{90}Sr, have been followed in the atmosphere, water, soil and in drinking water as well as in foodstuffs and feeding stuffs. In addition to that, river water contamination with ^{131}I due to medical use was also monitored. In all samples, other natural gamma emitters are also measured, as well as ^{3}H in surface water, drinking water and precipitation.

The measurement programme was for years roughly equally divided between two technical support organisations, each organisation always measuring the same type of samples, with few samples duplicated for checking purposes. With the changes in legislation and public procurements, this system had to be changed. As a consequence, the continuity is broken since 2005. The monitoring programme is still divided into 2 roughly equivalent parts, with organisations switching between those parts practically every year.

Both organisations are authorised for performing monitoring by the Slovenian Nuclear Safety Administration. The Slovenian legislation has set the accreditation according to ISO/IEC 17025 standard, used by testing and calibration laboratories, as one of the conditions for this. If we take this into account, the change of monitoring operator should not present a problem and all results should be consistent. Nevertheless, the SNSA have noticed some irregularities in long term trends.

Material and methods

Programmes for monitoring of levels of radioactivity in the environment as a consequence of global contamination due to nuclear bomb tests and the Chernobyl accident have been continuously carried out since the 1960s. In addition to the data on levels of radioactive contamination of the environment, the SNSA has also gathered data from the Krško NPP, the Žirovski Vrh Mine, the Low and Intermediate Level

Waste Depository and the Reactor Centre at Brinje. Beside regular monitoring programmes, the SNSA orders individual studies of particularly interesting aspects of contamination in the environment. All data from regular programmes and most of the data gathered in individual studies carried out since 1961 have been entered into a single database at the SNSA, named ROKO (the name derives from Slovenian Radioactivity in the Environment).

ROKO is a relational database with a simple user interface, intended for use of the SNSA staff and the whole community (http://www.radioaktivnost.si/ROKO/roko.php). We used data from the database to examine trends and to find inconsistencies in monitoring results that have arisen from changes of sampling locations, different calibrations, possible different sampling procedures or simply unexplained discrepancies.

In Slovenia, there are few organization that are authorised by the SNSA to perform environmental monitoring. The two most important ones are "Jožef Stefan" Institute (IJS) and Institute for occupational safety (ZVD). These two are accredited for measuring radioactivity in all environmental samples and perform yearly monitoring programmes for the SNSA and all nuclear facilities.

Results and discussion

Concentrations in air

Radionuclide concentration in air was historically measured by ZVD at Golovec, a small hill in the suburb of Ljubljana. The sampling point was situated in the forest environment, with higher ^{137}Cs content in upper layer of soil and consequently resuspension of particles with higher activity concentration of ^{137}Cs. In 2006, as well as in 2008 and 2009, IJS measured air in Podgorica, on flat alluvial ground with lower content of ^{137}Cs. The 2007 measurements were made by ZVD at Polje, situated also on the flat area of the Ljubljana basin. ^{137}Cs was measured in monthly samples and averaged over the whole year (
Figure 1). Values measured in Podgorica are systematically lower than the other measurements.

Although these 3 locations are geographically close (few kilometres around Ljubljana), their properties regarding environmental radioactivity are very different, making them unsuitable for following long term concentration trends.

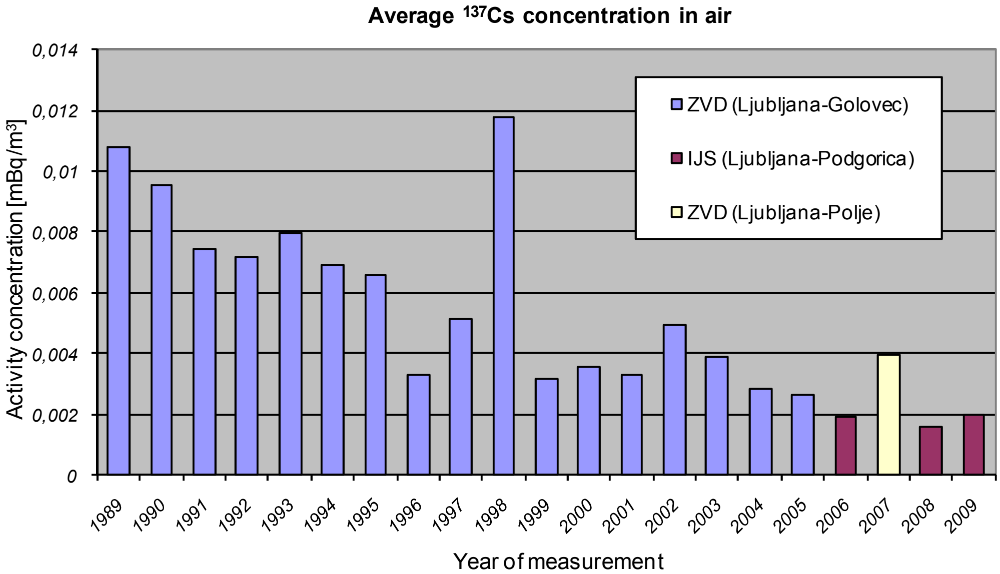

Figure 1. Average concentration of ^{137}Cs in air. Elevated values in 1998 are due to the accidental smelt of a ^{137}Cs source in Algeciras, Spain.

The activity concentration of ^{7}Be in air is also interesting. Values, measured by IJS, are obviously higher. Possible reasons for that could be in the difference between locations. Golovec is windswept and elevated, situated in a forest, Ljubljana-Podgorica is flat for several kilometres with no trees so there is no filtration, as shown on Figure 2. The measurements in Polje can not yet be evaluated, since there are not enough data till now.

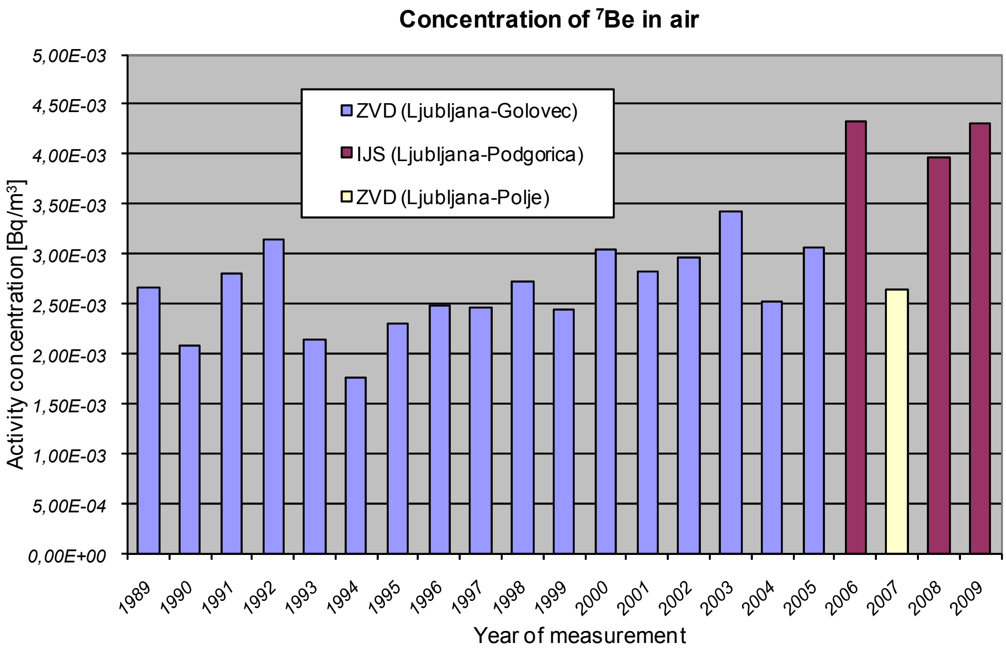

Figure 2. Average concentration of ^{7}Be in air. Measurements in Ljubljana (Podgorica) yield higher values.

Concentrations in soil

The long-term sampling place for radionuclide concentration measurement in soil was chosen in the 1960s at a big co-operative farm in Barje near Ljubljana (location name Ljubljana), with the intention to follow ^{137}Cs and ^{90}Sr along the food-chain. The laboratory that performed soil sampling in 2006 changed the sampling point to Podgorica. As a consequence, clayey soil sampled for four decades was substituted by washed-off alluvial soil with poor ^{137}Cs content. The measurements (Figure 3) show lower values for both years when soils was sampled in Podgorica (2006 and 2008), and the value for 2007, sampled again in Barje, is consistent with past measurements. In 2009, the measurements were again done in Barje, but this time by the laboratory that previously used the Podgorica location. The results are consistent with measurements done at the same location in the past, so we can assume that both laboratories have comparable sampling procedures and the past discrepancies were only due to different soil characteristics.

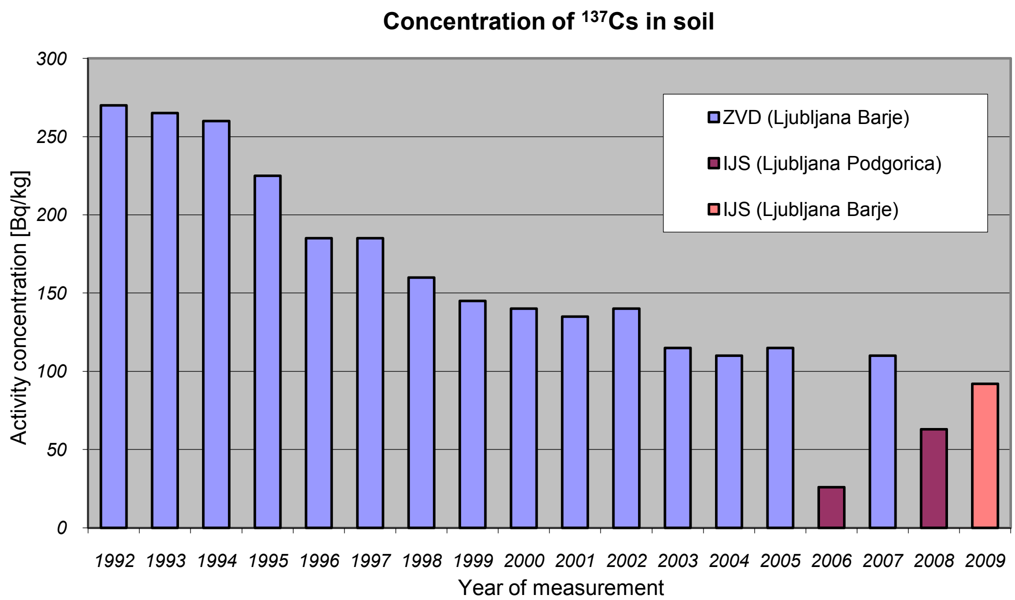

Figure 3. Activity concentration of ^{137}Cs in soil. Measurements done on different soil show different ^{137}Cs content.

However, such discontinuities in sampling and measurement may also lead to faulty analyses and evaluations. In 2006, the concentration of ^{137}Cs in soil was generalized for the whole country, and the evaluator omitted any comment on discontinuity of sampling history. As a consequence, the dose to the population calculated from this result was vastly underestimated.

Concentrations in river water

In the last decade, the content of ^{3}H in the Sava river showed average yearly concentrations between 1,3 and 1,6 kBq/m^3, while in the last 2 years the averages dropped to around 0,8 kBq/m^3. Up till the year 2008, the measurements were performed by IJS, department for environmental sciences, the first 9 months of 2008 were analysed by Austrian Research Centre Seibersdorf, and the last 3 months as well as 2009 by IJS again. (Figure 4).

The elevated values in the years before 2008 are explained by the laboratory to be a consequence of faulty calibration of the equipment (roughly 20%), which was later rectified, yet the results since are still not within the expected values. As a comparison, we used data collected by ARC Seibersdorf in rivers in Austria as well as data from Slovenia measured by IJS. The concentrations of ^{3}H in all these examples are consistently in the 1,1-1,4 kBq/m^3 range. ^{3}H concentrations measured in precipitation in these cases are slightly higher but also of the same range, so the low values measured in the Sava river at Krško are not expected and can not be easily explained.

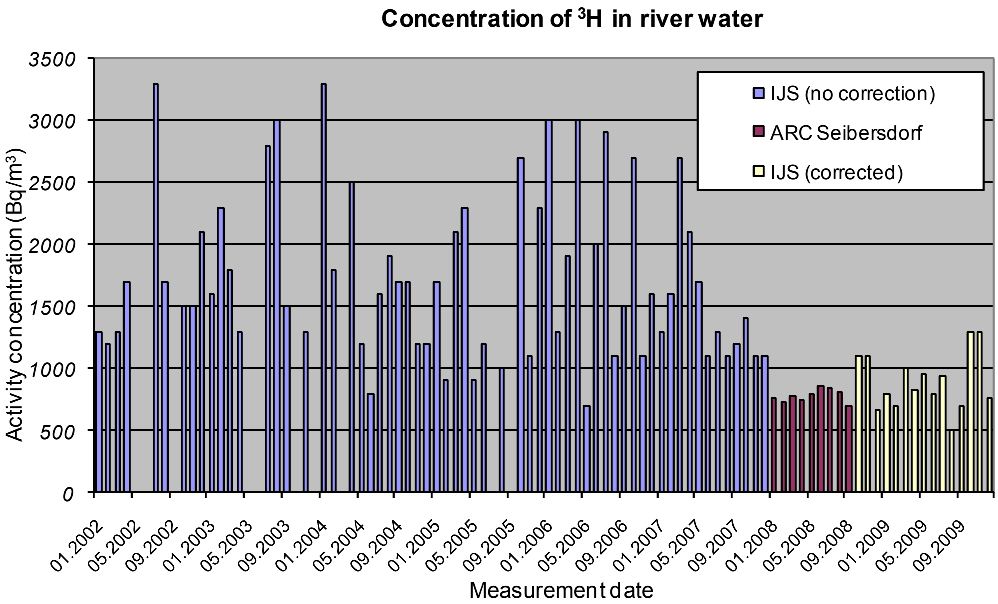

Figure 4. Activity concentration of ^{3}H in river water. Recent measurements show significantly lower values.

In 2008, the SNSA has started a campaign of independent monitoring programs designed to confirm results obtained thrugh the operational monitoring of emissions and immissionsthat is performed by nuclear facilities. Each year, a number of selected samples are simultaneously measured by an authorised organisation that is not involved in the operational monitoring of those samples. The sampling process is allways witnessed by the SNSA staff.

Among the samples checked in 2009 were grab samples of unfiltered Sava river water. It was measured by IJS in the scope of the operational monitoring program and checked independently by the ZVD laboratory. Measurements of concentrations of some radionuclides in samples simultaneously taken at Krško and Brežice are shown in Table 1.

Table 1. Measurements of grab Sava river water samples.

	^{210}Pb (Bq/m^3)	^{131}I (Bq/m^3)	^{40}K (Bq/m^3)
IJS	<2 to <6	8	120
ZVD	14 to 35	26	43

The values differ by up to a decade in worst cases, although the sampling was done simultaneously. Through the analysis of the SNSA photo archive, we were able to pinpoint the possible reason for these discrepancies in different sampling metodology. It is worth mentioning that results from simultaneously taken sediment samples show acceptable agreement. Since sediments are much easier to uniformly sample then unfiltered river water, it only strengthens the premise that sampling procedures must be re-examined and possibly prescribed by the authority in order to obtain relevant and comparable results.

Concentrations in deposition

In the scope of the yearly environmental monitoring programmes, the SNSA has organized simple intercomparison measurements for radioactive deposition due to precipitation at the sampling point Ljubljana. The measurements show that ZVD has consistently measured order of magnitude higher concentrations for ^{137}Cs then IJS (Figure 5). Even though the measured values are very low, thus higher variability is expected, the sampling and measuring procedures should be re-evaluated by both organisation to find the cause of this discrepancy.

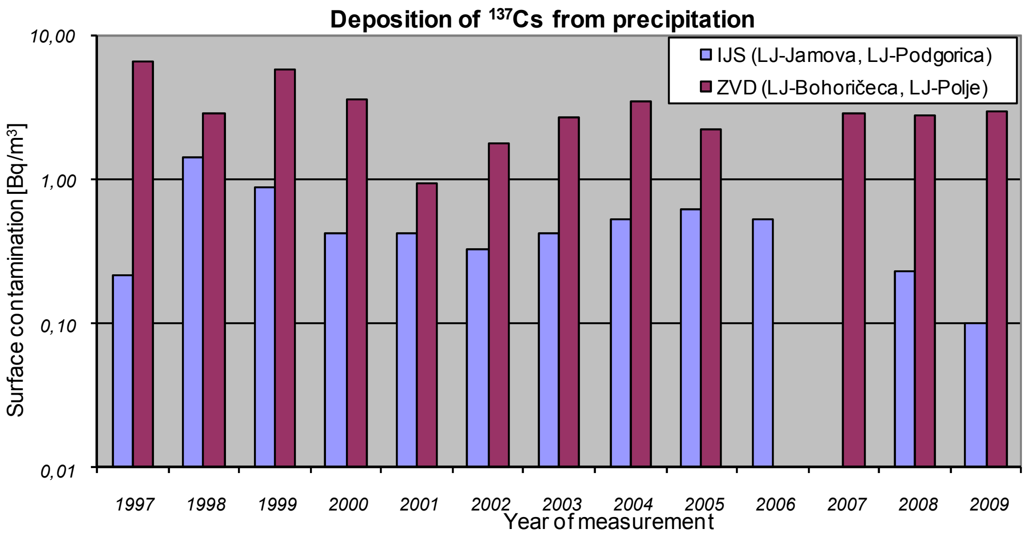

Figure 5. Activity concentration of ^{137}Cs in precipitation. Measurements done by ZVD show consistently higher values then IJS. There were no intercomparisons in 2006 and 2007.

Conclusions

The examples that are presented in this paper are only a fraction of the overall scope of the results of environmental monitoring, not to mention operational monitorings of different nuclear facilities. It is important to stress that there was no intention to qualify measurements as “right” or “wrong”. In most described cases it would even be impossible, since measurements are done at different locations. The intention was to discuss different influences on monitoring results.

Measurements of concentration of nuclides in air and soil show that location change leads to difficulties in data evaluation. Measurements of concentrations in water and precipitation, on the other hand, show discrepancies that may be due to transport, different sampling and preparation procedures or some, for now, unexplained reason. It is important to observe that the differences between measurements (50% and more) are much larger than the uncertainties (with the exception of precipitation, in the 10% range).

It is very important, that the contractors continuously analyse and evaluate measured results and compare them to expected values and historical trends. Whenever they find an inconsistency, it is imperative to try to find the reasons for it before reporting the measurements to the consignee.

It would be advantageous for the community if there would be more communication and cooperation between different organizations carrying out monitoring programmes. Due to the nature of the tendering process, it is possible that different organizations switch monitoring programmes from year to year. Especially in that case, it is important that the organizations share their experience and information so the continuity of measurement is preserved.

One of the more important facts that the contractors need to keep in mind is that the Slovenian data can not differ significantly from data of other, geographically similar regions or countries, so this can be used as one of the filters for data when it is needed.

ROKO database, maintained by the SNSA, can be one of the tools for all support organizations for evaluation and comparison of data. It is very important to carefully check all data before entering them into the database, since it is much harder to find mistakes later. Having in mind the number of measurements performed each year through and the number of values (roughly 10000) that are yearly entered into the database, it is a very demanding task.

All organizations performing environmental monitoring of radioactivity in Slovenia are accredited according to ISO17025 standard. This is an important step towards ensuring the uniformity of measurements, but it turns out that there are even more elements that influence results that are not included in the accreditation process.

Problems connected to measuring a valid Peak-to-valley ratio in field gamma spectrometry

Östlund, Karl; Samuelsson, Christer
Lund University, Medical Radiation Physics, SWEDEN

Abstract

During in-situ gamma spectrometry, the ratio between count rates of the full-energy peak and the count rates of an energy region just below the peak, can be used as an indicator of depth of the source below ground level. The peak-to-valley ratio decreases with increasing depth of the source due to forward scattered Compton photons producing counts in the valley. The concept Peak-to-valley ratio used for environmental radioactivity measurements, is connected to a lot of difficulties regarding equipment and measurement geometry. There is great need to keep the ratio as free from disturbance as possible, this because the ratio is always suffering from bad statistics. Tests how changes in measurement geometry changes the ratio in laboratory environment was performed to better understand what to be accounted for in a normal measurement situation. Tests of how dead time might influence the ptv-ratio was conducted with good results for two specific preamplifier types, the resistor feedback and the transistor reset type. The transistor reset preamplifier was showing stability of the ratio for the different settings of the electronics and preserving the ratio to a constant value.

Interception of wet deposition of radiocaesium and radiostrontium by *Brássica napus*

Rosén, Klas; Bengtsson, B. Stefan
SWEDEN

Abstract
In this study we examined the effects of ^{134}Cs and ^{85}Sr in the form of wet deposition on spring oilseed rape (*Brássica napus* L. 'Joplin'). Simulated rainfall containing the radioisotopes ^{134}Cs and ^{85}Sr was applied to the crop on six different occasions during the season. The interception fraction was found to be positively correlated to the leaf area index, with an *r*-value of 0.75 for ^{134}Cs and 0.77 for ^{85}Sr and to crop biomass, with an *r*-value of 0.80 for ^{134}Cs and 0.77 for ^{85}Sr.

Introduction
It is important to investigate the direct uptake of ^{134}Cs and ^{85}Sr during the first year after wet deposition, when the rate of translocation of these radioisotopes to edible plant parts is high compared with the rate of transfer from soil to plant (Madoz-Escande *et al.*, 2004).

The level of radionuclide capture, or interception, by plant parts is dependent on climate conditions, physico-chemical form of the radionuclides, plant morphology and biomass density (Vandecasteele *et al.*, 2001; Rosén & Eriksson, 2008). The proportion of precipitation that can be hold by the plant declines over time, but after the maximum water retention capacity is reached, the concentration of radioactive particles may continue to increase due to accumulation depending on their physico-chemical properties (Kinnersley *et al.*, 1997). The time from deposition to harvest also has an effect on the total uptake of radio isotopes in plants. This effect, referred to as 'field losses' has been described by Chadwick and Chamberlain (1970).

In the present study, wet deposition of ^{134}Cs and ^{85}Sr were applied to spring oilseed rape at different growth stages in order to study interception of ^{134}Cs and ^{85}Sr of different development stages of the crop and of plant growth. The crop used was spring oilseed rape (*Brássica napus* L.) and the contaminating isotopes that were used, ^{134}Cs and ^{85}Sr, were deposited using simulated rainfall. The study was conducted in the field, on agricultural land under normal cultivation treatments. Biomass samples were dried and activity measured by HPGe detector.

Materials and methods

Cultivation of rape

Spring oilseed rape (*Brássica napus* L. 'Joplin') was cultivated on a clay soil (situated at Vipängen, Uppsala, Sweden), with fertilizer supplied at sowing. The field trial consisted of 81 plots (1 m × 1 m) and radionuclides were applied of six plant growth steps.

Rain simulation

A rain simulator was constructed at the Department of Soil and Environment based on a drip infiltrometer described by Joel and Messing (2001). The water drops hit the crop at a 90° angle and an intensity of 41.6 mm h^{-1}. The target amount of precipitation was 1 mm m^{-2}. The precipitation consisted of water that was purified and deionised before each deposition event. The appropriate volume of stock solution was added to obtain the desired concentration of radionuclides (20 kBq m^{-2}) for both isotopes. The actual content of the radionuclides in the precipitation was measured using an HPGe detector (GMX-13200) after application to the plants.

Radioisotopes

The radioisotopes used were supplied by Canberra Solution AB on 20 May 2009: ^{85}Sr in the form of strontium chlorine in a 0.5 M HCl solution at a volume of 2 mL and an concentration of 1.84 MBq g^{-1}; and ^{134}Cs in a 0.1 M HCl solution at a volume of 1 mL and an concentration of 4.991 MBq g^{-1}.

Wet deposition and measurements

The deposition time was equivalent to application of 1 mm of precipitation to the crops. Each plot had three replicates for each treatment and these plots were randomised and plant materials were taken on six different plant growth stages. The plant materials were weighed, dried, re-weighed and milled before measurement of radioactivity. Measurements were made using three HPGe detectors that had an efficiency of 14.2% (GMX-13200), 31.3% (GMX-33210) and 20.5% (GEM-20200) at 1.33 MeV ^{60}Co. The leaf area index (LAI) was measured on the day of sampling using a LAI 2000 device (LI-COR, Nebraska, USA). Statistical analyses were performed using the statistical computer programme Minitab 15.1.30.0 (Minitab Inc.).

Interception fraction of ^{134}Cs and ^{85}Sr

The percentage of radionuclides intercepted after a wet deposition event was determined by calculating the interception fraction (*f*) as the ratio between the activity in the dry weight biomass of plants directly after deposition had occurred (A_i, Bq m^{-2}) and the total amount of activity deposited (A_t, Bq m^{-2}) and multiplying by 100 to get percentage. Modified after Proehl (2009):

$$f = \frac{A_i}{A_t} \times 100 \qquad (1)$$

Results

Leaf area index and biomass

The leaf area index increased with growth of the spring oilseed rape up to a maximum at flowering stage and then decreased until harvest. Plant biomass of the spring rape reached its maximum at the stage at development of fruit and then declined until the senescence stage.

Interception fraction of ^{134}Cs and ^{85}Sr

Interception fraction of ^{134}Cs and ^{85}Sr was calculated for samples taken on the next day after deposition, or two days after in the case of growth stage leaf development (first leaf unfold) due to weather conditions (Table 1). The interception fractions of ^{134}Cs and ^{85}Sr were not statistically different (paired *t*-test *p*-value of 0.132). The interception fraction of ^{134}Cs and ^{85}Sr increased over time in line with growth of the spring oilseed rape. The interception fraction was positively correlated to the leaf area index of the spring oilseed rape (Fig. 1) and as well to crop biomass (Fig. 2).

Table 1. Interception fraction of ^{134}Cs and ^{85}Sr deposition for spring rape (mean ± S.D.)

Growth stage	Biomass (g dry wt. m^{-2})	LAI*	Total amount deposited (A_t)		Interception on spring rape *f* ** (A_i)			
			^{134}Cs (kBq m^{-2})	^{85}Sr (kBq m^{-2})	^{134}Cs (kBq m^{-2})	^{85}Sr (kBq m^{-2})	^{134}Cs (%)	^{85}Sr (%)
Leaf development (first leaf unfold)	5	0.0	16.2 ± 0.13	14.8 ± 0.1	0.1 ± 0.02	0.1 ± 0.008	0.3	0.5
Leaf development (5 leaves unfold)	42	1.8	19.2 ± 4.29	17.7 ± 3.9	0.4 ± 0.07	0.4 ± 0.099	2.0	2.5
Full flowering	354	4.1	17.0 ± 0.24	16.7 ± 0.2	2.8 ± 1.93	2.7 ± 1.821	16.3	16.2
Development of fruit	667	4.1	17.3 ± 0.78	16.1 ± 0.7	4.5 ± 0.22	4.7 ± 0.531	17.6	29.4
Beginning of ripening	892	2.8	16.9 ± 0.32	15.3 ± 0.3	4.5 ± 0.18	4.7 ± 0.521	26.6	30.5
Senescence	648	1.7	16.5 ± 0.06	15.1 ± 0.1	1.7 ± 0.20	2.1 ± 0.140	10.4	13.8

***leaf area index and **interception fraction**

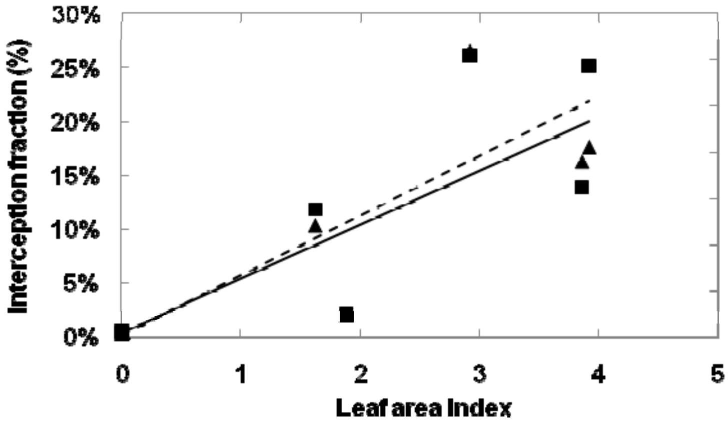

Fig. 1. Relationship between interception fraction and leaf area index of spring oilseed rape plants during the growing season. Mean values shown for ^{134}Cs (▲), ^{85}Sr (■), linear function of interception fraction for ^{134}Cs (—) and linear function of interception fraction for ^{85}Sr (– –).

The interception fraction was positively correlated to the leaf area index of the spring oilseed rape, with high interception of radioisotopes at high values of leaf area index. The data were fitted with a correlation coefficient had an *r*-value of 0.75 for ^{134}Cs and 0.77 for ^{85}Sr (Fig. 1). Plotting the interception fraction against biomass density (expressed as kg m^{-2}) showed that interception values reached highest at high density of the biomass. The correlation coefficient had an *r*-value of 0.77 for ^{134}Cs and 0.80 for ^{85}Sr (Fig. 2).

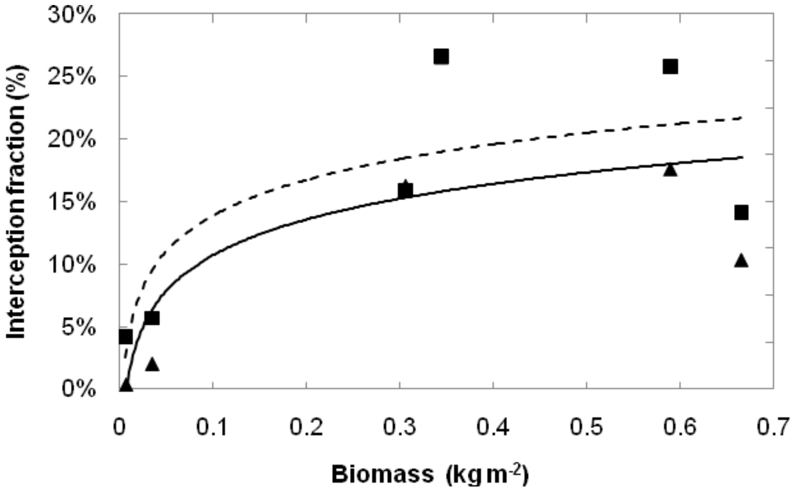

Fig. 2. Relationship between the interception fraction and dry biomass density (kg m^{-2}) of spring oilseed rape during the growing season. Mean values shown for ^{134}Cs (▲),^{85}Sr (■), logarithmic function of interception fraction for ^{134}Cs (–) and logarithmic function of interception fraction for ^{85}Sr (−−).

Discussion

The interception fraction, which was positively correlated to the leaf area index, followed the same pattern, increasing to a maximum value and then decreasing during ripening of the crop (Table 1, cf. columns LAI and *f*). A similar relationship between interception fraction and LAI, and between interception fraction and biomass, has also been observed for wet deposition on spring wheat (Vandecasteele *et al.*, 2001).

A higher value of interception fraction was observed for ^{85}Sr in the stage of development of fruit than for ^{134}Cs and as well in beginning of ripening. This can probably be explained by different physico-chemical form of ^{134}Cs and ^{85}Sr or the physiology of the epidermis. The interception fraction by spring oilseed rape was lower when compared to a study performed by Vandecasteele *et al.* (2001) of interception fraction by spring wheat. In the study the interception fraction was up to 84 % for ^{137}Cs and 88 % for ^{90}Sr.

Conclusions

This paper presents the results from the first year of a three-year study. The overall aim is to examine the effects of wet deposition of radioisotopes in ‘real’ conditions on oilseed crops and the levels of concentration of caesium and strontium in the crop during the season.

These preliminary results showed a positive correlation between the interception fraction for caesium and strontium radioisotopes and the biomass and leaf area index of the spring oilseed rape. There was also found that ^{134}Cs intercepted to a maximum level of 26.6 % and ^{85}Sr of 30.5 % both at growing stage beginning of ripening.

Variation of dietary intake of radioactive cesium after the Chernobyl fallout in Finland

Kostiainen, Eila; Outola, Iisa; Huikari, Jussi; Solatie, Dina
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

The deposition of radiocesium after the Chernobyl accident in 1986 was unevenly distributed in Finland. The variation of ingestion doses was studied in three areas, in central Finland with the ^{137}Cs deposition 50–80 kBq m^{-2} and in southern and northern parts of the country where the deposition was 1–5 kBq m^{-2}.

Estimates of dietary intake of radiocesium were made for years 1987, 1997 and 2007 by using the foodstuffs monitoring data and statistics of food consumption. The annual internal radiation doses in the three areas ranged in 1987 from 0.04 mSv a^{-1} to 0.38 mSv a^{-1} and decreased then ranging in 2007 from 0.006 to 0.09 mSv a^{-1}. The peak values of radiocesium in agricultural products were found in 1986–87 and the contents of ^{137}Cs decreased rapidly thereafter. The contribution of wild products to ^{137}Cs intake in 1987 varied from 32 to 56 percent. Due to the faster decline of ^{137}Cs in agricultural products the contribution of wild products to the intake increased, and in 2007 their contribution was 77–97 percent of the ingestion dose. Currently the variation in consumption and origin of the wild foodstuffs are the main contributors to the dose variation in Finland.

The ingestion doses calculated via data on foodstuffs were comparable to those received from the whole-body measurements or using data on mixed-diet measurements.

Introduction

The accident at the Chernobyl nuclear power plant in 1986 gave rise to an unevenly distributed ^{137}Cs deposition in Finland. In consequence, contamination of foodstuffs varied considerably in various parts of the country. In northern Finland, elevated ^{137}Cs contents in foodstuffs were found in reindeer meat and a slight increase also in freshwater fish and wild berries and mushrooms, but hardly any change in agricultural products. In central Finland with high ^{137}Cs deposition, higher levels of radiocesium were measured in all foodstuffs, especially in freshwater fish after the deposition. The variation of radiocesium levels in agricultural products produced in different parts of Finland was largest during the first years after the accident but later on the ^{137}Cs contents of agricultural products have been rather low and do not differ significantly in various parts of the country. In this work variation of ingestion dose due to radiocesium was assessed in 1987 and after that in ten year intervals, 1997 and 2007. The ingestion dose depends not only on the contamination level in the area but also on the consumption rates of different types of foodstuffs and the proportion of local foodstuffs in the diet.

Ingestion dose can be estimated by calculating the intakes of radiocesium through various dietary components, when information on the consumption rates and activity concentrations is available. Another way is to analyse whole representative mixed-diet samples instead of the main components of diet. Analysing mixed-diets gives the intake where the food consumption and processing are already included. Disadvantage of this method is that it gives no information on the contributions of different components to the intake. The third way is to estimate internal radiation dose by measuring the body content of ^{137}Cs in people with whole-body counters. In this work the results of these three different methods are compared.

Material and methods

The three studied areas, Helsinki, Tampere and Rovaniemi are situated in southern, central and northern parts of Finland (Fig. 1). The ^{137}Cs deposition in Tampere region after the Chernobyl accident varied from 50 to 80 kBq m^{-2}, and in Helsinki and Rovaniemi regions it was less than 5 kBq m^{-2}. The map (Fig.1), based on mobile radioactivity measurements of STUK, shows the distribution of ^{137}Cs deposition in Finland (Arvela et al. 1990). The foodstuffs data originates from the nationwide monitoring data of years 1987, 1997 and 2007 (Rantavaara 1991, Mustonen 1999, 2008, Rissanen 1997, Kostiainen 2007, 2008, Ylipieti 2007, 2008).

The ingredients of the diet included in the study were: vegetables, potato, fruit and berries, cereals, egg, meat (pork, beef, poultry, mutton), milk, fish, reindeer and game meat, wild berries and mushrooms. For the years 1997 and 2007 also data of the preceding and following years were used, if sufficient data for the years in question was not available. The production of vegetables and cereal grains is low in northern Finland, and therefore in our calculations we used ^{137}Cs concentrations of these products originating from the main production areas. The main local products of diet in Finland are freshwater fish and forest products: various game, moose, wild berries and mushrooms. For game the activity contents of moose were used, because moose meat covers over 70 percent of the game meat annually consumed. All the reindeer meat consumed in Finland originates from the reindeer herding area in northern Finland.

The food consumption data for 1987 is mostly based on the balance sheets for food commodities (Rantavaara 1987, 1991).The consumption data for 1997 and 2007 originates from national Findiet surveys (Finravinto 1997, Paturi et al 2008) and the information on consumption of domestic vegetables and cereals (Penttilä 2000). The national Findiet surveys are based on the results of the 48-hour dietary recall data. The same food consumption rates were used for all the areas. Dietary habits and food choices vary in different parts of the country, and also by gender and age. The consumption rates used in this study are averages for the Finnish adult population, 25- to 64-year-old men and women. The same consumption rates of wild berries and mushrooms were used for all the years in spite of possible variation during the years (Markkula 1997). The statistics of game bags were used for reindeer and game consumption (Saarni et al 2005, Annual Game Bag Statistics 2008). The fish consumption data for 1997 and 2007 originates from statistics of Finnish Game and Fisheries Research Institute and data for 1987 is based on statistics of fish catches.

In calculations of effective doses the average ^{137}Cs concentrations of foodstuffs for each year were used, and the delays in consumption were not taken into account although cereals, potato, root vegetables, cabbages, fruit, berries and mushrooms are harvested in autumn, and consumed until the next harvest. The delays in cereal consumption are even longer. Also the effect of food processing on the intake was neglected. It was assumed that all the foodstuffs consumed were domestic. The consumption of e.g. domestic fruit comprises only a minor part of fruit consumption, and the consumption rate for fruit includes only the domestic fruit.

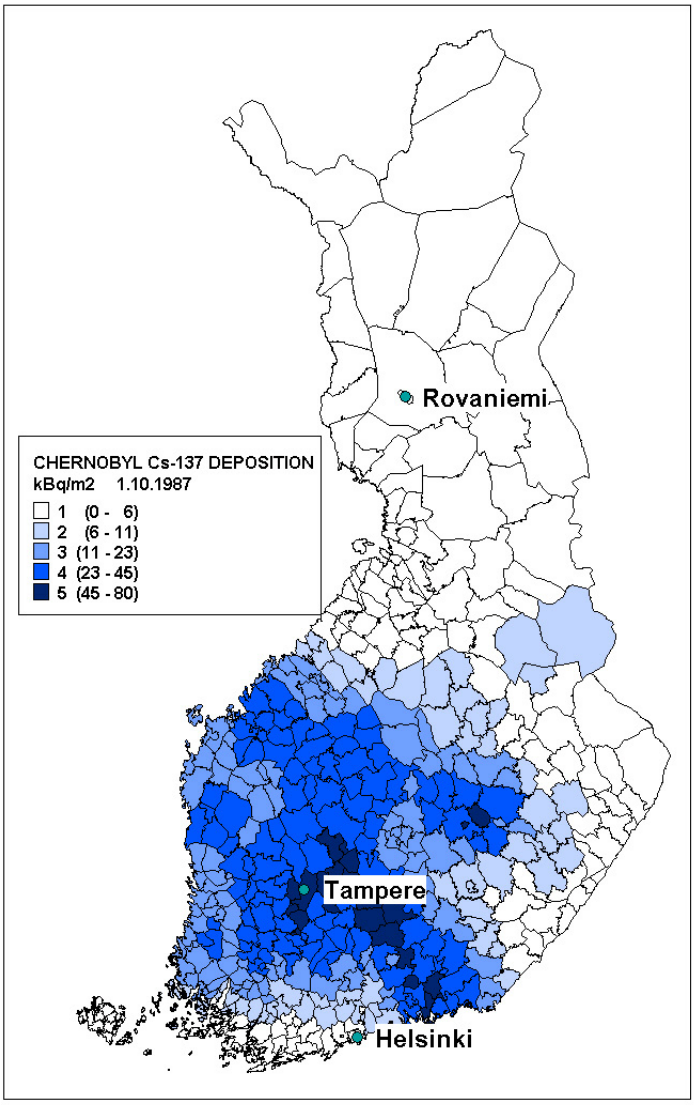

Fig. 1. Distribution of ^{137}Cs deposition kBq m^{-2} in Finland, reference date October 1, 1987. Study sites: Helsinki, Rovaniemi and Tampere.

Results and discussion

The consumption rates of foodstuffs are given in Table 1. The consumption rates for 1987 are higher than those for the years 1997 and 2007 due to differences of the methods used in collecting the dietary data. In the consumption of wild foodstuffs, especially of wild berries and mushrooms, there is a lot of variation from season to season caused by the availability of the natural products, which depends on the weather conditions. The mean consumption of mushrooms varies between 0.5 to 2 kg a^{-1}.

Table 1. Annual mean consumption of foodstuffs (kg/year) for Finnish adult population in 1987, 1997 and 2007.

Foodstuff	1987	1997	2007
Milk & milk products	262	157	145
Eggs	11.0	6.9	5.8
Beef	16.4	8.4	7.8
Pork	19.0	12.0	9.5
Poultry	4.0	6.0	10.0
Mutton	0.2	0.3	0.3
Wheat	44.2	33.8	29.6
Rye	19.0	22.3	19.0

Wild mushrooms	1.3	1.5	1.5
Drinking water	730	730	730

The average ^{137}Cs concentrations for the areas used in dose calculations are given in Table 2. The sampling density and the sampling sites remained not the same during the years for all foodstuffs. This increases variation in ^{137}Cs concentrations, and the data in Table 2 shows the level of ^{137}Cs contents of foodstuffs in each area based on sample measurements.

The concentrations of ^{137}Cs in agricultural products were highest in 1986-87 and have decreased since then rapidly. Since 1997 the average ^{137}Cs contents of the agricultural products in all the areas were less than 5 Bq kg-1, whereas those of natural products were remarkably higher, ranging up to some hundreds of becquerels per kilogram. The dose conversion factors used were those reported by ICRP (1996).

Table 2. Average ^{137}Cs concentrations of foodstuffs (Bq kg^{-1}) in Helsinki, Rovaniemi and Tampere areas in 1987, 1997 and 2007.

Foodstuff	Helsinki			Rovaniemi			Tampere		
	1987	1997	2007	1987	1997	2007	1987	1997	2007

Drinking water	0.66	0.038	0.021	0.0005	0.0005	0.0003	0.190	0.011	0.005

The annual internal radiation doses for the areas ranged in 1987 from 0.04 to 0.38 mSv a^{-1} and decreased then ranging in 2007 from 0.006 to 0.090 mSv a^{-1} (Fig. 2.).

The contribution of wild products (reindeer, game, fish, berries, mushrooms) to the total internal dose in 1987 was 32 percent in Helsinki area, 56 percent in Rovaniemi and 49 percent in Tampere. By 2007, the contribution of natural products to the dose increased to 77 percent in Rovaniemi, 84 in Helsinki and 97 percent in Tampere. Natural products in the diet only account about 5 percent of the total consumption but their relative contribution to the dose is larger depending on the time after the deposition. In 1987, the contribution of drinking water to the dose in Helsinki area was 6 percent, and decreased by 2007 to 2 percent. In Rovaniemi and Tampere the doses received via drinking water were less than 0.5 percent of the ingestion doses. The raw water in Helsinki is surface water, in Tampere both surface and ground water, and in Rovaniemi all the raw water is ground water which is well protected against fallout radioactivity (Mustonen 2000).

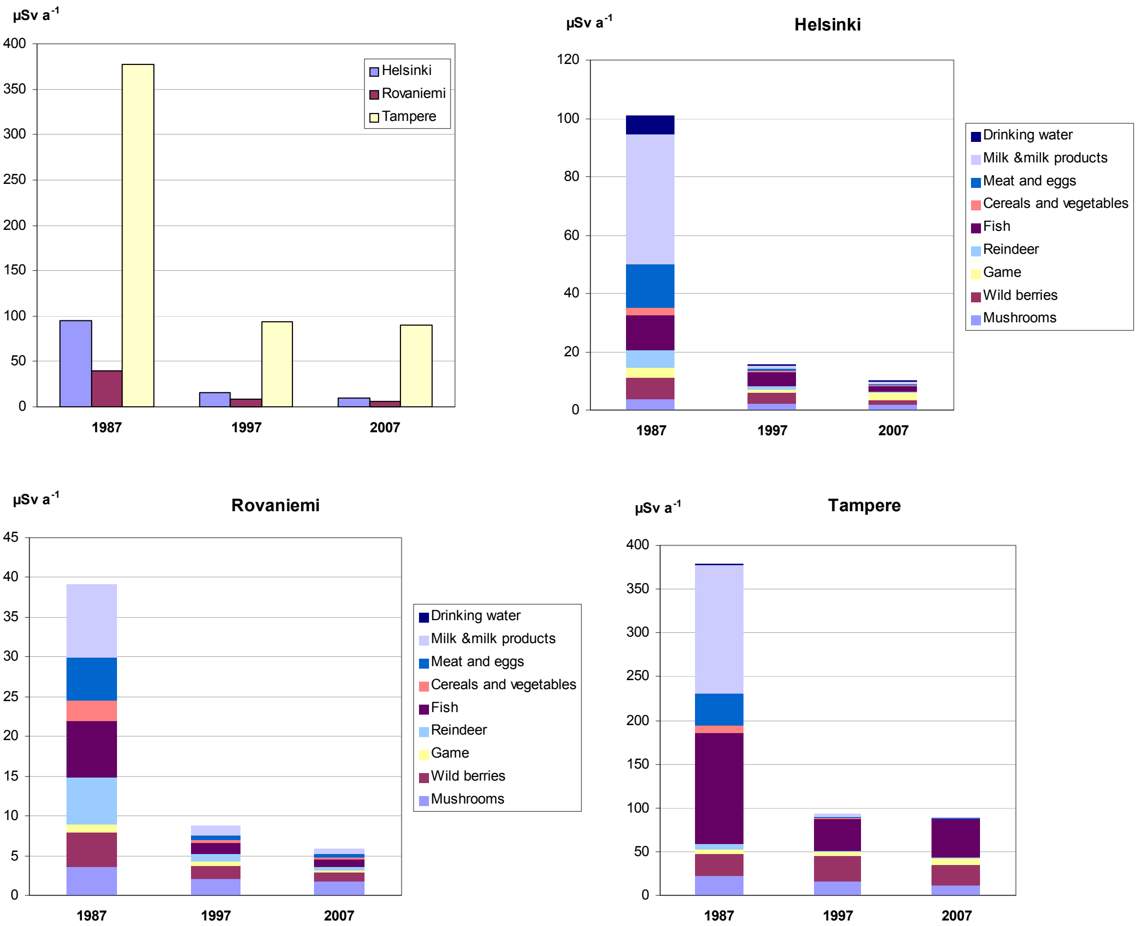

Fig. 2. Annual internal doses μSv a^{-1} in Helsinki, Rovaniemi and Tampere regions and the distribution of the doses by foodstuff groups in 1987, 1997 and 2007.

Discussion

The differences in the radiation doses in the three studied areas reflect the ^{137}Cs deposition levels in the areas. The ^{137}Cs deposition in Tampere region was more than ten times higher than in Helsinki or Rovaniemi, and this same ratio was seen in the internal doses calculated by using the foodstuffs monitoring data from these areas. The same consumption rates were used in all the areas although it is known there are some differences in consumption rates of northern and southern parts of the country. For example, the consumption of vegetables, fruit and poultry is lower in the northern parts of Finland compared to the central or southern parts of the country (Helakorpi 2002). Also the consumption of cereals and wild berries is highest in northern Finland. The total consumption of foodstuffs for 1987 was about 50 percent higher than that for 2007 due to different origin of consumption data in different years. If consumption data of 2007 were to be used for all the years, the dose due to the agricultural products in 1987 would decrease about 50 percent, but the dose from natural products would remain almost the same.

The average annual doses from ingestion of ^{137}Cs in Finland have been assessed to be about 0.15 mSv a^{-1} in 1987 and about 0.03 mSv a^{-1} in 1997 (Rantavaara 2008). The results of this study indicate that the average doses received by people living in the most contaminated area were about three times higher in 1987.

The surveillance program on environmental radioactivity run by STUK since 1999 includes regular monitoring of mixed diet samples in Helsinki, Tampere and Rovaniemi (Mustonen 2000, 2008). This monitoring program typifies the food prepared in institutional kitchens, and the level of radioactivity it contains. The deficiencies in this program are minor amounts of natural products included in the diets of institutional kitchens and the contingency of the diet as it is based only on two sampling days. The annual ingestion doses calculated via these mixed diet samples were 6.8–7.6 µSv a^{-1} in 1999 and 3.1–6.7 µSv a^{-1} in 2007. In 1996 the mixed-diet sample meals were studied by analysing the diets of six weeks, in which case elevated ^{137}Cs concentrations were seen in the meals that included wild products. (Rantavaara 2002). The annual dose calculated from the results of this six week study was 8.7 µSv a^{-1} in 1996 in Helsinki area.

The internal annual doses calculated via the results of whole-body measurements were 0.074 mSv in 1987, 0.011 in 1997 and 0.008 in 2007 in Helsinki area. The doses calculated via mixed-diet in Helsinki were lower, about 60 percent of the doses received via the whole-body measurements. This difference may reflect the absence of wild products in the meals of institutional kitchens. The whole-body measurements for a group of people living in central Finland near Tampere area were 0.42, 0.12 and 0.09 mSv a^{-1} in 1987, 1997 and 2007, respectively. The people in this group consume a lot of natural products like freshwater fish, wild berries, mushrooms and moose meat. The doses calculated from the whole-body measurements are at the same level as the doses calculated via foodstuffs for Tampere area with average consumption rates of natural foodstuffs. We have assumed in our calculations that all the food consumed is produced in the area, although in practice food products are distributed all over the country and only natural products are consumed locally.

Table 3. Internal doses received by the three different methods.

Site	Internal dose, mSv a^{-1}, in 1987; 1997; 2007		
	Foodstuffs data	**Mixed diet data**	**Whole-body measurements data**
Helsinki	0.10; 0.016;0.010	–[1]; 0.009[2]; 0.005	0.074; 0.011; 0.008
Rovaniemi	0.039; 0.009; 0.0060	–; –; 0.003	-
Tampere	0.38; 0.093; 0.090	–; –; 0.007	0.42; 0.20; 0.09 [3]

[1] No data; [2] Data of 1996; [3] Data from group of people that consume natural products in large quantities

The results of this study were calculated assuming average consumption habits. However, consumption of natural products that contributes most to the ingestion dose in later years after the deposition varies greatly from one individual to another. Among the critical group that consume natural products in large quantities, the doses can be more than tenfold compared with the average consumer.

The internal doses assessed here do not include the dose increase due to ^{134}Cs, which was in 1987 about 40 percent. By 1997, the dose from ^{134}Cs decreased being less than two percent compared to the dose from ^{137}Cs.

Conclusions

The different ways to assess internal doses due to ^{137}Cs in foodstuffs give similar results. When calculating the doses via foodstuffs, the consumption data used affects greatly the results. However, it gives information on the dose distribution by different foodstuff groups which is not extracted from diet measurements or whole-body measurements.

Investigation of ^{137}Cs redistribution within urban ecosystem

Seleznev, Andrian A.; Yarmoshenko, Ilia V.; Ekidin, Alexey A.
Institute of Industrial Ecology, Ural Branch of Russian Academy of Sciences Ekaterinburg, RUSSIA

Abstract

Contamination of puddle sediments by ^{137}Cs within the urban ecosystem is studied. The investigation is made on the example of Ekaterinburg city, Middle Ural region of Russia. Contamination density of ^{137}Cs in the region due to fallouts after atmospheric testing of nuclear weapons and nuclear accidents is assessed about 5.1 kBq/m^2, it associates with maximum activity concentration of the upper 15 cm layer bellow 30 Bq/kg. Results of the survey indicate a mean value of ^{137}Cs concentration in puddle sediments of 70 Bq/kg, with a maximum value of 540 Bq/kg. It is estimated that horizontal migration has led to about fourfold concentration of ^{137}Cs in puddle sediment.

Introduction

During the period of atmospheric testing of nuclear weapons and accidents at nuclear facilities the primary attention of researchers was drawn to study radionuclide redistribution patterns in natural ecosystems. The urban ecosystem was not considered as the main object of the research. The aim of the study is to obtain data on levels of accumulation and redistribution of ^{137}Cs in the city.

The basic hypothesis for the study was the significant redistribution of ^{137}Cs in the urban environment. Local surface depressed zones where rain water and sediment accumulate in puddles are considered as such deposits. ^{137}Cs precipitates at the puddle catchments area, which include surrounding soil and ground and roofs of buildings. Radiocaesium is supposed to reach the puddles along with horizontal migration, in soluble (precipitations) and insoluble form (particles of soil and other material such as silt, peat, decomposed plants, domestic and construction wastes on which ^{137}Cs has adsorbed). In the urban environment routine measures such as cleaning the territory, grass mowing, garbage disposal, land fill, planting and uprooting, adjusting the channels and drainage channels contribute to ^{137}Cs redistribution as well.

Measurements of activity concentration of ^{137}Cs at puddle sediments were conducted in Ekaterinburg city, Russia. ^{137}Cs contaminated the urban ecosystem under study due to the global fallout after atmospheric nuclear weapon's testing and the Chernobyl accident. The study includes the analysis of archive data on ^{137}Cs contamination in Ural region, sampling of puddle sediments in Ekaterinburg city, direct measurements of ^{137}Cs activity concentrations in the samples and data analysis.

Material and methods

Appropriate depressed zones in the city were selected by visual inspection. Samples were taken at the depressed zones that seemed as the eldest and relatively undisturbed for past years. The samples were taken from the upper 5-cm layer, with a sample mass of about 1.5 kg of dry weight. During the sampling process, domestic wastes and grass were removed. Information on location and site-specific description and photo documentation of puddle and environment were performed. The position of the sampling areas was assigned according to its address and was marked on the city map. The sampling of puddle sediments was carried out during the field study seasons 2007-2009 in 240 locations in 15 districts of the city.

The samples were air-dried under the indoor temperature in the laboratory during one month at least. Dried samples were milled and homogenized. ^{137}Cs activity concentrations were measured using stationary gamma-spectrometer equipped with NaI(Tl) scintillation detector (crystal size 63 x 63 mm.). Counting time was 3 hours providing detection limit 5 Bq/kg.

Results and Discussion

Available archive data on ^{137}Cs contamination were considered as follows:

- results of direct measurements of ^{137}Cs concentration in fallout by The Federal Service for Hydrometeorology and Environmental Monitoring over the period 1994-2006 presented in the annual reports,
- results of grass contamination measurements over the period 1966-1987 obtained from reports of local agricultural service.

In addition levels of annual deposition of ^{137}Cs produced in atmospheric nuclear testing over the period 1945-1985 in the northern hemisphere summarized by UNSCEAR (UNSCEAR, 2000) were used.

Analysis of these data allowed reconstructing the ^{137}Cs contamination in Middle Ural region retrospectively. According to this reconstruction:

- total deposition density of ^{137}Cs in soils reaches 5.1 kBq/m^2 in 2007 with regard to decay;
- over the 20 years after the Chernobyl accident, the ^{137}Cs activity has increased approximately by 1 kBq/m^2;
- the values of the ^{137}Cs concentration in the 15-cm undisturbed ground in 2007 in dependence on the year of surface formation were modelled under conditions of absence of horizontal migration and suggested median rate of vertical migration <0.5 cm/year (Schuller, 1997; Arapis, Karandinos, 2004);
- the Chernobyl accident contributed up to 30% to the ^{137}Cs activity concentration in the 15-cm undisturbed ground of Middle Ural region. While the ^{137}Cs vertical migration rate <0.5 cm/year, the 15-cm layer accumulates more than 70% of total nuclide activity in 2007. The ground surface, which has been formed in the years just before the Chernobyl accident and undisturbed later, are contaminated by ^{137}Cs in the range of 20-30 Bq/kg, the landscape formed in the period of intensive nuclear weapon testing (1950s and 1960s) possesses higher ^{137}Cs concentrations,

up to 50-60 Bq/kg. The estimates of contamination obtained by modelling are in agreement with the results of numerous measurements of the upper ground horizon in Ekaterinburg city. ^{137}Cs surface contamination level of soils below 30 Bq/kg is typical for the city. That level corresponds to the ground formation in period 1970-2000, which is most likely according to direct observations as well.

Fig. 1 presents distribution of ^{137}Cs activity concentrations in samples of puddle sediments obtained for Ekaterinburg city. The arithmetic mean of ^{137}Cs concentration is 70 Bq/kg, the maximum value of the ^{137}Cs concentration is 540 Bq/kg and the minimum value is below the detection limit. The geometric mean of the ^{137}Cs concentration is 57 Bq/kg. The concentration of ^{137}Cs exceeds 100 Bq/kg in about 15 % of samples. According to chi-square test, ^{137}Cs concentrations distribution deviates from lognormal ($\chi 2=34.80$, df=7, $p<0.01$).

The heterogeneity of data on ^{137}Cs concentrations was supposed to be associated with features of spatial distribution of contamination. Results of gamma spectrometry measurements of ^{137}Cs concentration in puddle sediments by the city districts are presented in Table 1.

Process of puddle formation is considered to be similar to forming large water reservoir. Under gravitation transport of water the solid particles are scavenged and transferred to surface depressed zone forming the puddle sediments. ^{137}Cs concentration in the puddle sediment is supposed to consist of the concentration transferred with solid particles from the surface ground (on which the adsorption in the catchments area surface during the water accumulation in puddle took place) and concentration of water-soluble fraction of ^{137}Cs in atmospheric precipitation.

The typical activity concentration in the ground's upper layer, C_{soil}, for the case under consideration is about 20 Bq/kg, it corresponds to the forming of the catchment area in 1987. The ^{137}Cs activity concentration of puddle sediments, $C_{sed.}$, is the sum of water-soluble activity concentration of atmospheric precipitation, C_{water}, and the activity concentration transferring into the puddle with solid particles from the ground surface, $C_{soil.}$ C_{water} is calculated as

$$C_{water} = I \cdot k \cdot \frac{S}{m}, \qquad (1)$$

where I is the ^{137}Cs total activity of atmospheric precipitation estimated as $I \approx 1000$ Bq/m^2 for period 20 years after the Chernobyl accident; k is the factor of collection of ^{137}Cs activity within puddle; S is the catchment area, m^2; m is the puddle sediment mass, kg. m/S is estimated as 2 kg/m^2 for the typical puddle existing for 20 years, i.e. a typical puddle catchment area is about 200 m^2 and puddle sediment mass is about 400 kg. Then $C_{sed.}$ is calculated as follows:

$$C_{sed.} = I \cdot k \cdot \frac{S}{m} + C_{soil}, \qquad (2)$$

Accepting $C_{sed.}=70$ Bq/kg and solving equation (2) relative to k we obtain a value $k=0.1$. Thus about 10% of the ^{137}Cs activity of precipitations are transferred to the puddle in water soluble phase. Water transfer forms about 70% of activity concentration in puddle sediments.

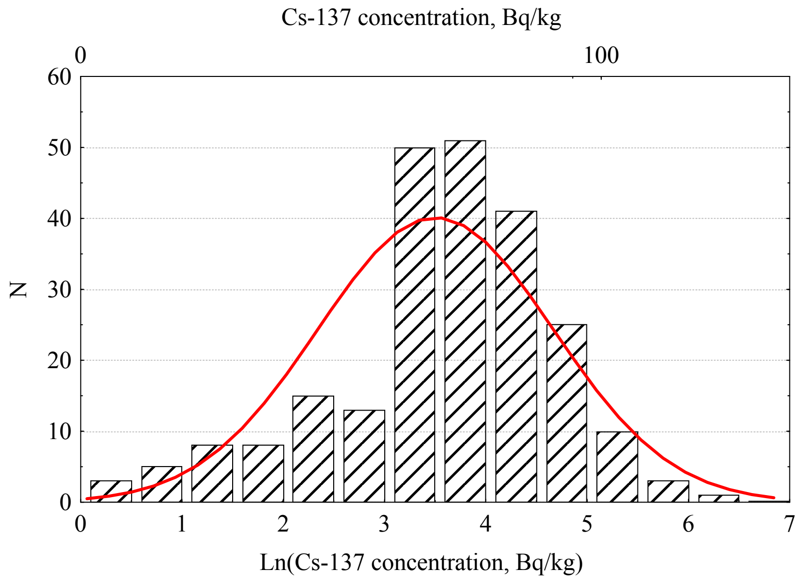

Fig. 1. Distribution of ^{137}Cs activity concentrations in samples of puddle sediments obtained for Ekaterinburg city.

Table 1. Arithmetic, geometric mean and portion of samples with ^{137}Cs concentration >100 Bq/kg by districts of Ekaterinburg city. Results based on gamma spectrometry measurements in samples of puddle sediments.

District	Arithmetic mean of ^{137}Cs concentration, Bq/kg	Geometric mean ^{137}Cs, concentration, Bq/kg	Portion of samples with ^{137}Cs concentration >100Bq/kg
West	63	30	0.16
Centre	59	41	0.19
North	58	40	0.14
North East Suburb	67	42	0.19
East Suburb	29	16	0.05
South	44	35	0.05
South West Suburb	64	36	0.22

Conclusions

The hypothesis that puddle sediments in local depressed zones of the urban landscape are the final deposits of ^{137}Cs has been proved. ^{137}Cs contamination levels in puddle sediments are relatively high in comparison with contamination of surrounding soils. The activity concentration of ^{137}Cs in 14 % of the samples exceeds 100 Bq/kg, with a maximum activity concentration of 540 Bq/kg. Such activity concentrations are comparable with the activity found in bottom sediments of water reservoirs of nuclear facilities in the region and lakes of the East Ural Radioactive Trace (Trapeznikov, 2007).

Characteristics of the urban environment and ground management can provide suitable conditions for local migration and concentration of radioactive contamination. The observed local surface migration of ^{137}Cs has led to an approximately fourfold concentration in puddle sediments in comparison with typical activity concentrations in surrounding soils. The study of ^{137}Cs migration in the urban environment should take into account the influence of anthropogenic processes on radionuclide redistribution.

Puddle sediments are supposed to be prospective object of environmental monitoring in the urban ecosystem. During such monitoring ^{137}Cs can be applied as a marker of puddle's age. Obtained characteristics of ^{137}Cs redistribution in the urban environment can be used in investigation of environmental pollution by other metals similar by their properties.

The research has been made under the financial support of RFBR, project: 10-05-96011.

Radioactivity in the environmental samples around the Cernavoda NPP

Popoaca, Simona; Bucur, Cristina; Simionov, Vasile
SNN – Cernavoda NPP, ROMANIA

Abstract

The Cernavoda Nuclear Power Plant is dedicated to produce electrical & thermal power in a safe and efficient manner for at least 30 years, from nuclear power using CANDU technology.

The factors presented below ensure that the public health and environment are adequately protected:

- source control;
- effluent control;
- effluent monitoring;
- environmental monitoring.

The Environmental Radioactivity Monitoring Program around Cernavoda NPP is designed to meet the following objectives under normal NPP operating conditions:

- to measure the radionuclide concentrations in environmental media;
- to provide an independent assessment of the effectiveness of the source control, effluent control and monitoring based on measurements in environment;
- to validate the models and parameters used in the calculation of the derived emission limits;
- to provide data to aid in the development and evaluation of models and methodologies which adequately describe the movement of the radionuclides through the environment.

The Environmental Control Laboratory of the Cernavoda Nuclear Power Plant, located in Cernavoda town, is equipped with modern analyzing systems to determine the natural and artificial radionuclide content in the following environmental samples from an area with 30 km radius around the NPP:

- airborne particles, iodine, aqueous vapours and deposition from air;
- surface water, deep ground water, infiltration water, drinking water;
- soil and grass;
- sediment and fish;
- milk, eggs and meat (chicken, pork and beef);
- vegetables, grain, corn and fruits.

The results of the monitoring program are annually compared with the results of The Preoperational Environmental Monitoring Program performed between 1984 and 1994. There were no environmental radioactivity modifications around the Cernavoda NPP comparing to the period before the NPP operation.

Introduction

The site of the first Romanian Nuclear Power Plant comprising five 700 MWe units was chosen in the Dobrogea area, near the Cernavoda - a town of approximately 20,000 inhabitants. The choice was based on the following main reasons: the Danube river-Black Sea Channel that represents an important source of cooling water, as it provides an easy access route for the heavy and beyond standard equipment, and the low seismicity of the region as compared to other regions of the country.

Cernavoda Nuclear Power Plant is dedicated to produce electrical and thermal energy in a safe and efficient manner for at least 30 years, using CANDU (Canadian Deuterium Uranium) nuclear technology.

Among the activities to be performed during the operational phase of Cernavoda NPP, the following factors are identified which ensure that the public health and the environment are adequately protected: a) source control; b) effluent control; c) effluent monitoring; d) environmental monitoring.

The purpose of the environmental monitoring program is to provide reliable and accurate data, which comprise statistically valid data sets per nuclide/ environmental media combination on an annual basis.

The monitoring program is designed to meet the following objectives under normal nuclear power plant operating conditions:

- to measure the radionuclide concentrations in environmental media;
- to provide an independent assessment of the effectiveness of the source control, effluent control and monitoring based on measurements in environment;
- to validate the models and parameters used in the calculation of the derived emission limits;
- to provide data to aid in the development and evaluation of models and methodologies which adequately describe the movement of the radionuclides through the environment.

Material and methods

The Environmental Control Laboratory of the Cernavoda Nuclear Power Plant, located in Cernavoda town, at 1.8 km far from the plant, is performing the Environmental Radioactivity Monitoring Program for Cernavoda NPP.

Indicator locations are outside the plant perimeter, and are established depending on emission type, critical groups and pathways used for DEL (Derived Emission Limit) calculation. In addition to these locations, a network of TLD locations was established around the plant beyond the exclusion zone.

Measurements of ambient background are conducted beyond the influence of station emissions. For emissions to air and direct exposure pathway (external irradiation and inhalation) one background location is provided. For water and sediment samples, one background location each is fixed.

The background levels were determined before of first operation of Unit 1 of the Cernavoda NPP, through the Preoperational Environmental Monitoring Program in period 1984 – 1996; all present results are compared to these levels to assess the influence of power plant operation on environment and public health.

The following environmental samples are included in the actual monitoring program, from an area with 30 km radius around the NPP:

- airborne particles, iodine, aqueous vapours and deposition from air;
- surface water, deep ground water, infiltration water, drinking water;
- soil and grass;
- sediment and fish;
- milk, eggs and meat (chicken, pork and beef);
- vegetables, grain, corn and fruits.

The frequency of monitoring or sampling is related to the mean lifetime of the nuclide in a pathway. In the same time for air monitoring, the frequency was established as a function of plant emissions (percentage of DEL/weeks).

Table 1. Determination of monitoring frequency.

Nuclide	Half life ($T_{1/2}$)	Environmental media	Mean residence time	Mean life time	Monitoring frequency
Tritium	12.3 years	air	minutes	minutes	continuous
		vegetables-fruits	3 months	3 months	quarterly
		milk	5 days	5 days	weekly
		water	1 day	1 day	daily

Airborne water vapours are collected by drawing air through molecular sieve. Sampling is continuous with an integration period of one month, during which 4 – 6 m^3 of air are passed through the collector. The absorbed water is removed from the sieve by heating at 350ºC. Water samples are prepared by distillation, free water from food samples (milk, fish, vegetables, fruits) is extracted by azeotropic distillation in toluene.

Tritium activity concentration is determined by liquid scintillation counting on sample prepared by mixing extracted water with a scintillation cocktail.

Table 2. Sample measurements: measurement device used and counting time for tritium.

Nr. Crt.	Sample type	Measurement device	Radionuclide assessed	Counting time
1.	Aqueous vapours in air	20 ml PE vial	Tritium	400 min
2.	Water – individual and bulked sample			
3.	Milk – individual			
4.	Deposition – bulked sample			
5.	Fish, meat, vegetable, fruit, grain			
6.	Soil and sediment			

The frequency of analysis is determined by the following elements:

(1) the minimum required sensitivity;
(2) the analytical sensitivity of the method;
(3) the number of results per nuclide/pathway combination per year required to generate a statistical valid data set;
(4) significance of plant radioactive effluent emissions.

The minimum required detectable specific activity should be such as to detect radionuclides present in the environment as a result of Cernavoda NPP's operations. The Minimum required specific activity was calculated for each specific radionuclide and environmental media with *the following relation:*

$$MDA = \frac{D_a}{C \times DCF}$$

where: MDA = Minimum Detectable Activity; D_a = Maximum additional annual whole body dose above background due to Cernavoda NPP' operations; C = Annual Intake Rate for analyzed media; DCF = Dose Conversion Factor.

Table 3. Measurement system for tritium.

	Type	• 1220 Quantulus Ultra Low Level
	Calibration procedure	• Internal departmental calibration procedures
	Maintenance procedure	• Maintenance and service contract
	Standards used	• Unquenched H-3, C-14 and background standards for energy calibration and weekly QA verification
		• Quenched H-3 and C-14 sets of standards for annually efficiency calibration

Results

Forteen years of experience in CANDU operation at Cernavoda NPP have shown that tritium is the most significant radionuclide released in gaseous and liquid effluents, mostly as tritiated water, which represents more than 80% of the total radioactivity released. For this reason the environmental monitoring program is heavily weighted toward measurement of tritium.

Air from the radiological area is conducted, after filtration, to the evacuation stack where it is measured for radioactive particulates, gases and tritium water vapours. The total radioactive gaseous effluent emissions are weekly compared with the administrative limits, which are below the approved DELs. An indicator air monitoring station for critical group (Cernavoda inhabitants) is located at 1.8 km (NV) far from the Cernavoda NPP, in the Cernavoda town (ADI-08) and the background station is located at about 30 km (N) far from the NPP (straight line) in Topalu village (ADB-01). Results of tritium measurements (Bq/m^3) in the water vapour samples from the two locations, in period 2006 – 2008, are represented in the Figure 1.

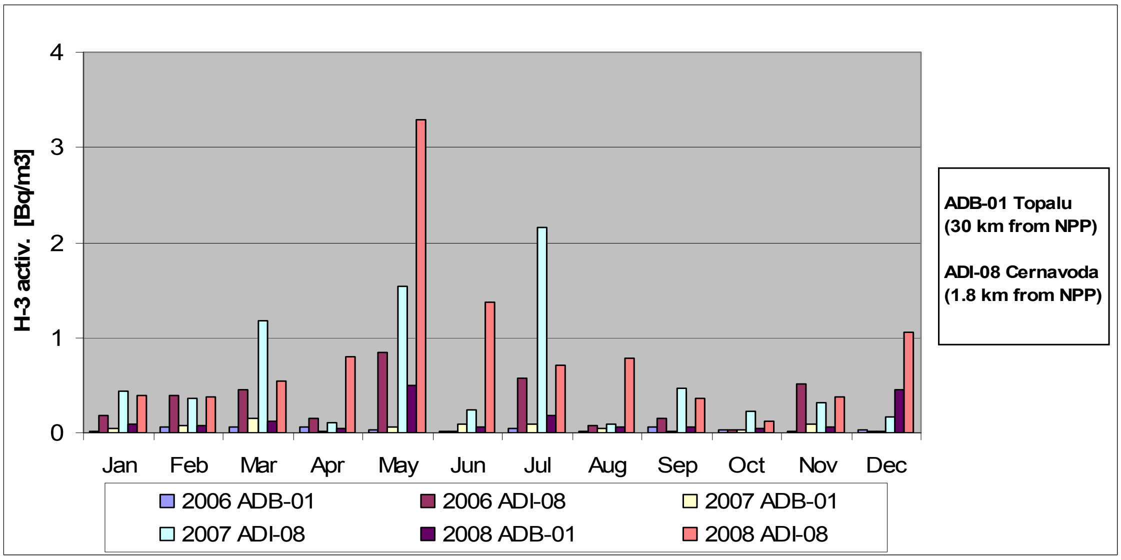

Figure 1. Tritium concentration activities in air, between 2006 and 2008, around Cernavoda NPP (2 monitoring stations situated at about 1.8 km and 30 km far from NPP).

Drinking water for the Cernavoda town is coming from the Danube River and after the specific treatments is distributed through the drinking water system. Samples are from the laboratory tap (AII-03, 1.8 km NV). Drinking water for Saligny is supply from underground water and samples are from a drilled well (SSS-03, 5 km SE). Results of tritium measurements (Bq/l) in the drinking water samples, in period 2007 – 2009, are represented in the Figure 2; the legal limit (100 Bq/l) is also represented.

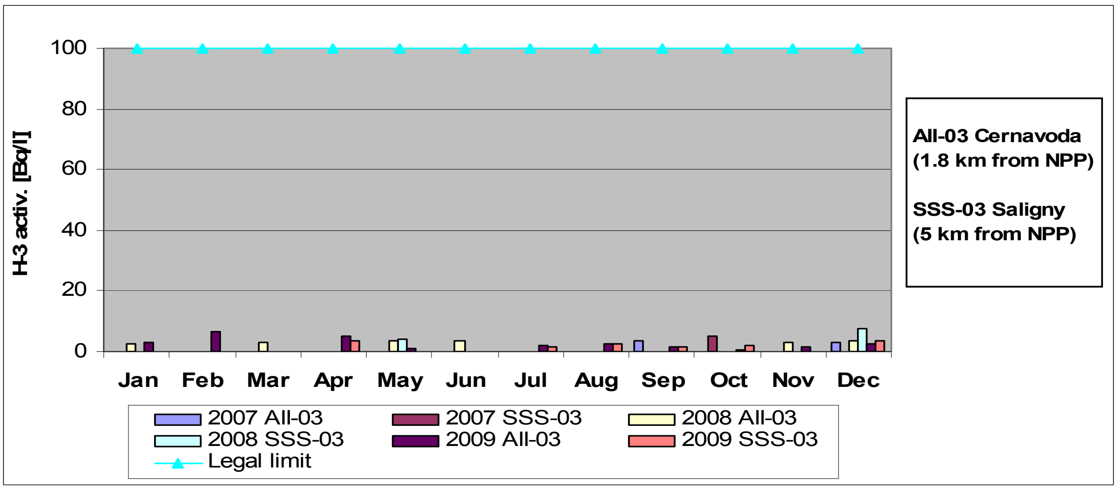

Figure 2. Tritium concentration activities in drinking water, between 2007 and 2009, around Cernavoda NPP (2 locations situated at about 1.8 km and 5 km far from NPP).

All food samples are cultivated, grown or produced in the monitoring area and representative for the local diet. Milk samples are provided by a dairy farm located in Seimeni village (AII-02), at about 8 km (NNE) far from the plant. Results of tritium measurements (Bq/l) in the milk samples, in period 2006 – 2008, and the mean value over this period are represented in the Figure 3.

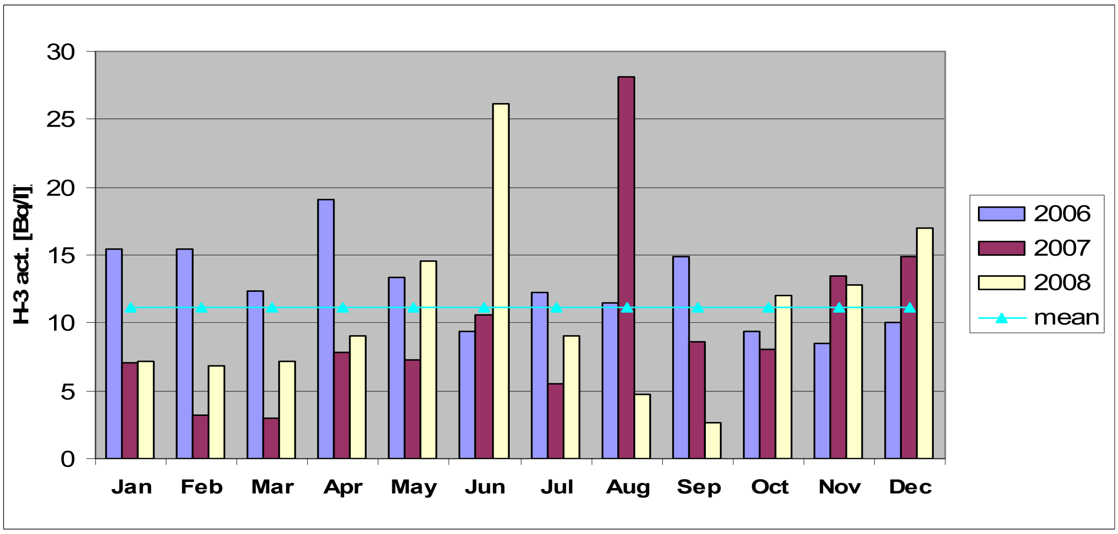

Figure 3. Tritium concentration activities in milk, between 2006 and 2008, around Cernavoda NPP.

Fish samples are analysed from Danube River – Cernavoda Harbour (indicator location LII-09, downstream of confluence of evacuation canal with Danube River) and Danube-Black Sea Channel – Cernavoda Harbour Lock (reference location LII-05, upstream of evacuation way) – for liquid emissions in the environment, and 3 pounds: Domneasca (AII-01, 8 km NNE), Baciu (SSS-14, 17 km SV) and Faclia (SSS-15, 8 km SE) – for gaseous emissions in the environment; the last two locations have been introduced in the monitoring program since 2008. Results of tritium measurements (Bq/kg) in the fish samples, in period 2006 – 2008, are represented in the Figure 4.

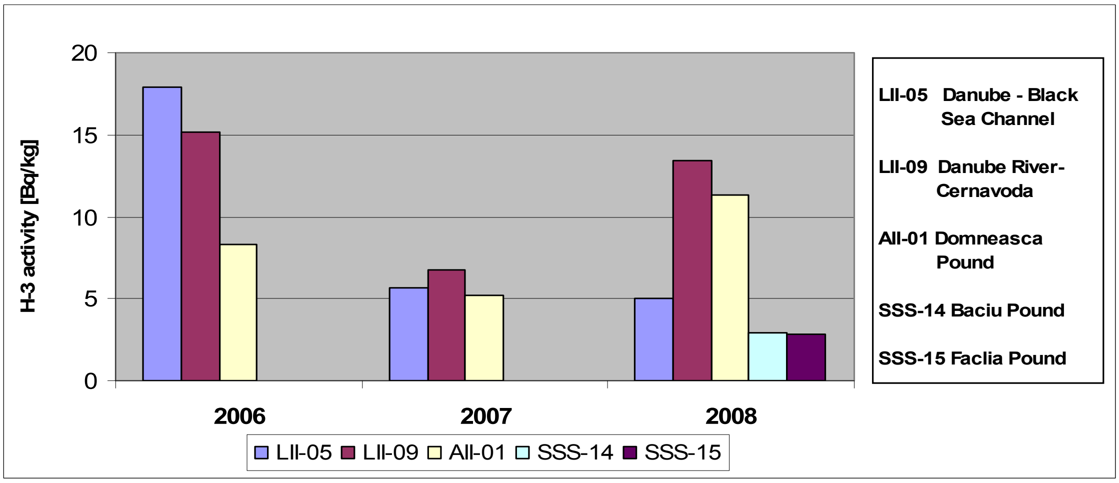

Figure 4. Tritium activity concentration in fish samples from the Cernavoda NPP monitoring area, between 2006 and 2008.

Discussion

Results of tritium measurements in water vapour samples, in period 2006 – 2008, for 2 locations (represented in the Figure 1), are relatively low. For the indicator location – Cernavoda town (ADI-08) results are situated between 0.010 and 3.290 Bq/m^3 (mean value: 0.580 Bq/m^3) and for background station – Topalu village (ADB-01) results are from 0.010 to 0.050 Bq/m^3 (mean value: 0.080 Bq/m^3).

Tritium activity concentrations in drinking water sample, represented in Figure 2, are very low comparing with legal limit of 100 Bq/m^3. Most of the results are situated below MDA (2.4 Bq/l).

In milk samples, tritium activity concentrations (monthly mean values of weekly sample measurements) in period 2006 – 2008 (represented in Figure 3) are situated between 2.7 and 28.2 Bq/l. Annual mean values of the monthly averages are the following: for 2006 – 12.6 Bq/l, for 2007 – 9.8 Bq/l, for 2008 – 10.8 Bq/l. The mean value for entire studied period is 11.1 Bq/l.

For fish samples, it can be notice that tritium activity concentrations in free water, in the studied period (represented in Figure 4), are lower in the pound water than in the flowing water. The mean value for period 2006 – 2008, for flowing water is 10.7 Bq/kg and the mean value for the same period in pond water is 6.1 Bq/kg.

Conclusions

The results of the monitoring program are annually compared with the results of The Preoperational Environmental Monitoring Program performed between 1984 and 1996. There were no environmental radioactivity modifications around the Cernavoda NPP comparing to the period before the NPP operation.

In generally, measurements shown that the radiation levels in the external area of a nuclear power plant are around 0.01 mSv per year, comparing with the annual effective dose due to natural radiation sources of 2.4 mSv – the major component coming from the radon (Rn-222, $T_{1/2}$ = 3.8 days) – about 1.3 mSv.

Radionuclides activity concentration in soil in Serbia

Pantelić, Gordana[1]; Eremić Savković, Maja[1]; Vitorović, Gordana[2]; Vuletić, Vedrana[1]; Tanasković, Irena[1]; Javorina, Ljiljana[1]

Abstract
The soil is the basic environment of migration of radionuclides into plants, where from they reach the people and animals through food. The type of soil affects the distribution of radionuclides in the soil itself and their transfer into plants, respectively. Systematic testing of radioactivity of soils in the Serbia is performed after the Chernobyl accident. The periods of sampling were spring and autumn every year. According to collected data, the activity of natural radionuclides was very equal on all locations every year as it was expected because of long half lives of natural radionuclides. High standard deviation and big difference between minimal and maximal ^{137}Cs activity concentrations suggested typical artificial pollutant. The activity of long-living radionuclide ^{137}Cs is constantly decreasing in the upper layers of uncultivated soil, but because of its long half-life it will remain in ecosystem for a long time.

Introduction
The primary reason for being concerned about radioactive contamination of the environment is that it results in exposure of humans. External irradiation from radionuclides naturally present in the environment or released from man-made practice or events is usually an important component of the exposure. Most of the food consumed by human beings is grown on land. Contamination of land can occur either from deposition of material originally introduced to atmosphere, or from waste products discharged directly placed in or on the ground, from which they are eventually mobilized by groundwater or erosion.

Soil consists of mineral and organic matter, water, and air arranged in a complicated physicochemical system that provides the mechanical foothold for plants in addition to supplying their nutritive requirements. The type of soil affects the distribution of radionuclides in the soil itself and their transfer into plants, respectively.

Radionuclides deposited on land may enter human food chain in the following ways:

– by direct deposition onto the leaves or exposed parts of plants that are eaten by humans or other animals,

– by persistence in layers of soil from which they are taken up into growing plants through their roots,
– by resuspension as dust from the soil or from other exposed surfaces,
– by being washed of the surface or from deeper ground layers into water sources that are used ultimately for drinking or for irrigation, or as media from which fish or other food are drawn.

The global source of radionuclide contamination in our country is the fallout due to previous nuclear testing and Chernobyl accident, and, in the recent time, after the NATO aggression, depleted uranium content in the environmental samples.

The three naturally occuring radioactive series and ^{40}K contribute for most of the naural terrestrial radoactivity. Aditionally ^{137}Cs is the most important radionuclides which contribute to human exposure after nuclear testing and Chernobyl accident.

Material and methods

Systemic testing of radioactivity of soils is performed on 10 locations in the Serbia (Belgrade- 3 sites, Lazrevac, Obrenovac, Novi Sad, Subotica, Niš, Zaječar, Zlatibor), twice a year during the 20 years period after the Chernobyl accident according to methods defined by regulations (Pantelić et al., 2006).

Additionally to that program undisturbed grassland soils were sampled in 33 different sites in Serbia during 2006-2008. Several sites are located in a mountainous area in the west and central of Serbia (Zlatibor, Kopaonik), several sites in a flat northern Serbia (Vojvodina) and several sites in the south Serbia. In each site 5 cm thick sample layers were separately collected. The periods of sampling were spring and autumn.

The soil samples were purified from plants and rocks. Each sample was dried in an oven at 105°C-110°C to constant weight during 24-48 h. The dry soil was crushed and sieved (0.5 mm). The resulting sample was weighed and transferred into a Marinelli beaker. Natural and artificial radionuclides concentrations were measured using a high-resolution gamma ray spectrometer (HPGe detector - 30 % efficiency at 1332 keV). Time of measurement was at least 20000 s.

The radionuclide activity of uranium and thorium series and ^{40}K, as well as the artificial radionuclide ^{137}Cs was determined.

Results and discussion

The radionuclide activity of natural uranium and thorium series, and natural radionuclide ^{40}K was determined in all soil samples. Among fission products, only ^{137}Cs was measured, while other radionuclides were below detection limit.
The results of measurements are presented in tables 1-4.

Minimum, maximum and average radionuclide concentration measured in 2005 in different regions in Serbia in table 1 is showed. Natural radioactivity in Vojvodina and west and central part of Serbia is very similar, while this activity in south part of Serbia is little bit higher. These results are the same as previos obtained results (during 1987-2004) for the same sites in Serbia because of long half lives of natural radionuclides (Eremić-Savković et al., 2002; Pantelic et al., 2000; Pantelić et al., 2006).

The similar results for natural radionuclide concentration were obtained during 2006-2008 (table 2-4). Maximum activity concentratin for all natural radionuclide is twice time higher then minimum concentration for the same radionuclide at the same region, but calculated standard deviation is less then 30 % for almost all natural radionuclides.

Table 3. Radionuclide activity concentration in the soil in the west and central part of Serbia.

	^{40}K (Bq/kg)	^{137}Cs (Bq/kg)	^{232}Th (Bq/kg)	^{226}Ra (Bq/kg)	^{238}U (Bq/kg)	^{235}U (Bq/kg)
Minimum	162	6.3	7.4	11	9.4	0.5
Average	440 ± 170	69 ± 73	35 ± 19	36 ± 15	45 ±22	1.7 ± 0.7
maximum	586	197	60	55	117	2.6

Table 4. Radionuclide activity concentration in the south part of Serbia

	^{40}K (Bq/kg)	^{137}Cs (Bq/kg)	^{232}Th (Bq/kg)	^{226}Ra (Bq/kg)	^{238}U (Bq/kg)	^{235}U (Bq/kg)
Minimum	368	1.4	28	28	24	1.3
Average	512 ± 83	21 ±11	43 ± 16	46 ± 12	74 ± 44	2.5 ± 1.0
maximum	603	31	70	67	146	4.4

Radionuclide ^{137}Cs was present in all soil samples. High standard deviation and big difference between minimal and maximal activity concentrations of cesium suggested typical artificial pollutant. Given that its half-life is 30 years, it is distributed deeply into soil by washing out, and it will remain in ecosystem for a long time. Extremely high ^{137}Cs concentrations were recorded in the uncultivated soil in the west part of Serbia, that could be explained by first precipitations following immediately the Chernobyl accident. The activity of long-living radionuclide ^{137}Cs is constantly decreasing in the upper layers of uncultivated soil comparing with mesurement before 2006 (Pantelić et al., 2006).

Conclusions

Three years of monitoring the content of natural radionuclides as well as radionuclides of artificial origin in soil samples in the Republic of Serbia indicated that there was no deviations in the natural activity from the average values for the same types of soil samples obtained before 2006. High standard deviation and big difference between minimal and maximal ^{137}Cs activity concentrations suggested typical artificial pollutant. The activity of long-living radionuclide ^{137}Cs is constantly decreasing in the upper layers of uncultivated soil, which is the result of cesium breakdown and its transport into lower layers.

Abstract
Presented results are the part of the project financed by Ministry of Science and Technological Development, Republic of Serbia. As the main influences come from uranium, thorium and potassium we measured their concentrations in soil by radiometric techniques. Further we calculate external doses as well as effective doses for particular organs and specified tissues using Monte Carlo code. In this paper only the results for external dose equivalent at 1 m from the surface are presented. Two depths of the soil are taken into consideration, infinite and 15 cm. The results are given for the territory of Bela Crkva and Vrsac in Vojvodina district, Serbia.

Introduction
The most widely spread radionuclides of natural origin come from uranium and thorium series as well as from potassium (UNSCEAR 2000). Those natural occurring radionuclides are internal or external sources of radiation depending on the position to the organisms. In this survey just radiation originating from the internal exposure is taken into consideration, which arises from intake of terrestrial radionuclides by inhalation and ingestion.

Recently, few researches were carried out on territory of Republic of Serbia in order to determine concentrations of natural occurring radionuclides in surface soil (Bikit et al. 2005; Dragovic et al. 2006). In this study, in addition to measuring concentrations of natural radionuclides in the territory of Bela Crkva and Vršac, the goal was the estimation of effective dose from inhalation and ingestion. The region of interest is located in a northern-east part of Serbia, in the province of Vojvodina. It is mainly oriented to the agriculture, but it is potentially interesting for tourism. Therefore it is important to determine the impact of internal exposure to natural radionuclides (uranium, thorium and potassium). In Figure 1 the location under investigation is shown on the map of Vojvodina.

Eighty soil samples were taken from the area of Bela Crkva and Vršac to evaluate concentration of these natural radioactive sources. The concentrations of radionuclides in the samples were measured by radiometric methods. Based on those measurements the activities of uranium, thorium and potassium were calculated. Using Monte Carlo simulation the conversion factors were determined in order to estimate the contribution of above-mentioned radionuclides to the effective dose from ingestion and inhalation.

This study was supported by Ministry of Science and Technological Development of Republic of Serbia. The purpose of the project was determining concentration of natural radionuclides in the soil samples and evaluating the radiation doses, received by people living in the area under investigation, resulting from the inhalation and ingestion. The outputs of the project were radiometric maps, which showed the level of the exposure from the radioactive sources.

Fig. 1. Map of Vojvodina district.

Material and methods

Sampling and radioactivity measurements

For the purpose of this research, eighty soil samples were taken from 13 uncultivated locations in the same geographic area in the vicinity of Bela Crkva and Vršac. They were collected at a depth of (0-5) cm, and each sample weighed 0.5 kg. Geographical coordinates of sampling positions were determined using a GPS tracker. All the samples were air dried, homogenized and sieved to grain size of less than 0.60 mm. They were prepared and placed in cylindrical gas-tight containers with the same geometry as to sample container used for efficiency calibration. The samples were kept for at least three weeks before the measurement to reach secular equilibrium between thorium and radium and their decay products.

Further, gamma-spectrometric measurements were performed with high purity, low energy germanium semiconductor detector (HPGe), manufactured by ORTEC, accompanying electronic equipment and ORTEC software for spectra evaluation. Relative efficiency of HPGe is 28 % and the energy resolution achieved in the measurements is 2 keV, both at the 1.33 MeV reference transition of ^{60}Co. Calculated minimum detectable concentration (MDC) is 1.1 Bq/kg for ^{238}U, 1.3 Bq/kg for ^{232}Th and 2.4 Bq/kg for ^{40}K. The counting geometry is identical for all radionuclides. The expanded uncertainty of determined radionuclide concentration is 15 % (k = 2) in each case. Detectable energy range of used instrument is up to 2 MeV. Instrument calibration was performed using reference sources:

1) NBL 103 (USAEC), content of U: 0,05 %
2) NBL 107, 0,1 % Th
3) K in form of potassium-chloride
4) Certified mix source, Amersham, 1988 (^{55}Fe, ^{60}Co, ^{137}Cs, ^{226}Ra and ^{241}Am).

Monte Carlo simulation

In dose estimation, it is assumed that natural uranium contains three isotopes: 99,284 % ^{238}U +0,711 % ^{235}U + 0,0058 % ^{234}U, while other isotopes of uranium neglected.

In order to determine the conversion factors which are needed for calculation of the effective dose due to exposure to radionuclides entered by inhalation or ingestion, Monte Carlo method is used. Firstly, the dose rate conversion factor (absorbed dose rate in air per unit activity per unit of soil mass, nGy/h per Bq/kg) was estimated. For simulation the inscattered and scattered radiation is taken into account.

The main assumption of the problem starts from the polynomial expansion matrix, which solves the transport problem of radionuclides in the soil and between soil and air. Given the gamma lines of radionuclides of interest, the problem of relatively narrow energy range from 1 keV to 2.75 MeV was resolving.

It is assumed that the ground is infinite medium for photon scattering and radionuclides are uniformly distributed over the surface from which the soil samples were taken. Characteristics of soil and cross-sections for photons are taken from existing database.

The code for simulation is written in FORTRAN 77. The simulation is done in 2π geometry, which was only reasonable solution due to the assumption of indefinite soil thickness. The same density of soil is taken for all the samples, ρ = 2.6 kg/m^3, which brought additional errors in calculation, but not greater than 2%. The “detector” is 1 m above the soil and is simulated by a square surface with side of 2 m, located in the center of the square slab which represents the soil.

The mechanisms of interaction of photons with matter taken into account were the photoelectric effect, Compton scattering and pair production. Keeping in mind the characteristics of natural radionuclides and its interaction with soil, a cut off the energy range from 50 keV to 2.6 MeV was introduced. This is the reasonable cut off, as the highest important gamma energy of natural radionuclide is 2614 keV and because photons even below 50 keV contribute a negligible amount to the dose rate. (Clouvas, A. et al 2000)

In order to determine effective dose, voxel phantom was used in Monte Carlo simulation. It enabled solving transport problem of radionuclides entering human body through the respiratory and digestive tract. The effective dose coefficients obtained by Monte Carlo method are expressed in units of Sv/Bq. Effective doses from inhalation and ingestion were determined by multiplying the activities and obtained conversion factors.

Results

The activity concentrations of ^{238}U and ^{232}Th varied from (3.24-57.02) Bq/kg and from (3.4–90.42) Bq/kg, respectively. ^{40}K was found in higher concentration, it ranges from (84.78–3114.8) Bq/kg. In some samples it was not possible to determine the radionuclide concentration, because it was lower than the minimum detectable concentration. The mean concentration is 25.23 Bq/kg, 39.03 Bq/kg and 873.69 Bq/kg for ^{238}U, ^{232}Th and ^{40}K, respectively.

The concentrations of ^{238}U, ^{232}Th and ^{40}K analyzed in this research and those reported by UNSCEAR (B) (2000) are presented in Table 1. It is shown that activity concentration of ^{238}U agrees with one in other countries, and concentration of ^{232}Th is a bit out of worldwide activity range. In the case of ^{40}K, the mean activity concentration is much higher that the worldwide average value (400 Bq/kg). It may be explained by either the use of fertilizers or the soil type. (Colmenero Sujo et al. 2004)

The mean concentrations in soil samples from Serbia and Montenegro are 597.96 Bq/kg, 35.697 Bq/kg and 42.12 Bq/kg for ^{40}K, ^{238}U and ^{232}Th, respectively (Dragovic et al. 2006). When the obtained results from are study are compared with these values, it is obvious that concentrations of ^{238}U and ^{232}Th are lower, but measured concentration of ^{40}K is higher in our study.

Table 1. The comparison of activity concentration ranges of natural radionuclides in soil samples from the present study with the values obtained in other studies conducted worldwide.

Concentration (Bq/kg)	^{40}K	^{238}U	^{232}Th	Reference
Croatia	140-710	83-180	12-65	UNSCEAR, 2000

Poland	110-970	5 -120	4 -77	Jagielak et al., 1992
Median value	140-850	16-110	11-64	UNSCEAR, 2000
Bela Crkva and Vršac	84.78-3114.8	3.24-57.02	3.4-90.42	Present study

Furthermore, the effective dose was calculated using the determined activity concentrations of ^{238}U, ^{232}Th and ^{40}K and the conversion factors, which the output of Monte Carlo simulation were. The annual effective dose from inhalation of ^{238}U ranges from (58 - 1100) µSv, the effective dose of ^{232}Th varies from (39 - 1040) mSv and the effective dose of ^{40}K varies from (0.53 – 19.5) µSv. On the other hand, the annual effective dose received by ingestion of ^{238}U ranges from (0.01 – 0.2) µSv, the effective dose of ^{232}Th varies from (1.25 – 33.3) µSv and the effective dose of ^{40}K varies from (0.21 – 7.8) µSv.

Using adequate software and based on the GPS coordinate of a taken soil sample, the distribution maps of the activity concentration were generated. The maps are shown in Figures 2-4. It is important to emphasize that distribution of effective dose due to ingestion and inhalation has the same distribution, just the corresponding values are different.

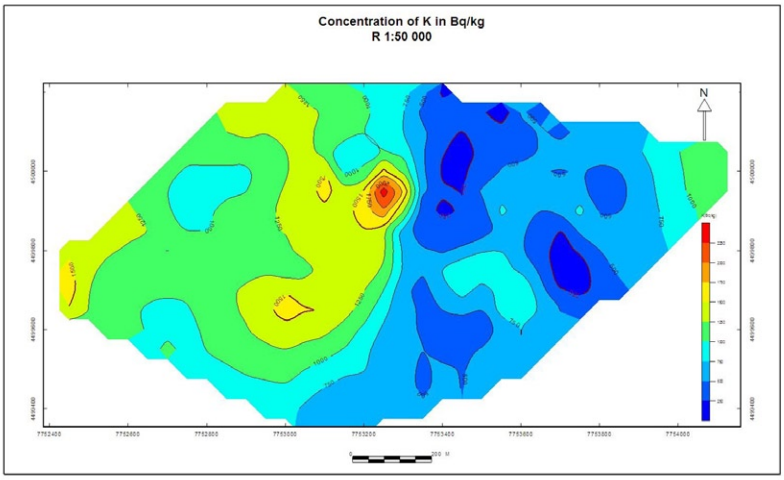

Figure 1. Activity concentration of ^{40}K in the area of Bela Crkva and Vršac.

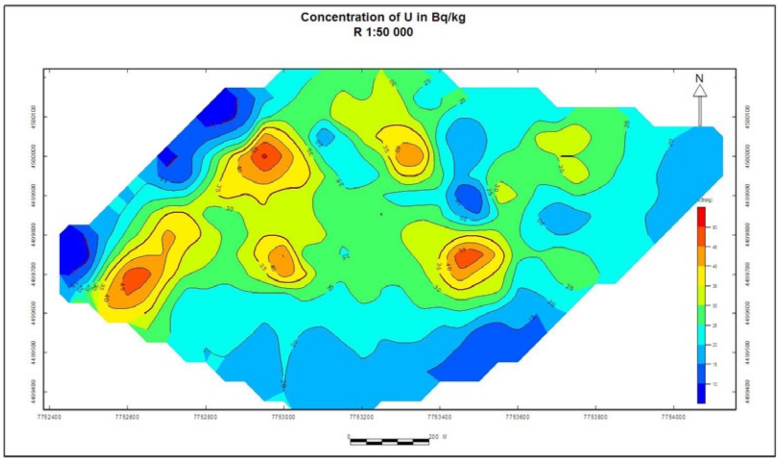

Figure 2. Activity concentration of ^{238}U in the area of Bela Crkva and Vršac.

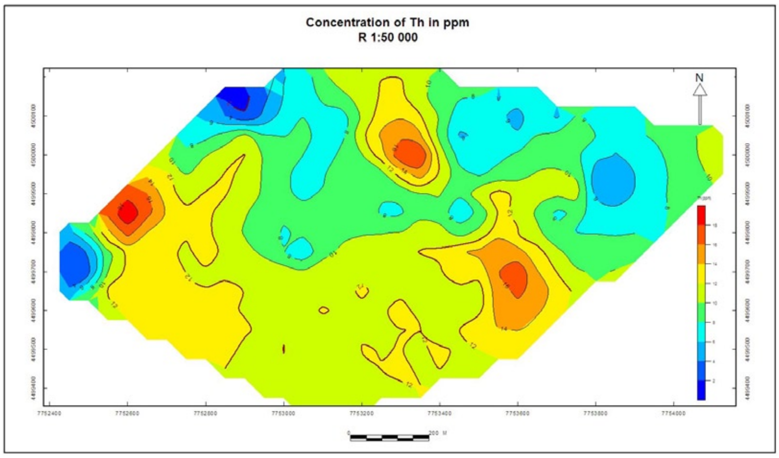

Figure 3. Concentration of ^{232}Th in the area of Bela Crkva and Vršac.

Discussion

There are two main processes that contribute to internal exposure, the general term used to describe exposures that involve the intake of radionuclides into the body. The two processes are inhalation of contaminated air and ingestion of contaminated foodstuffs. (UNSCEAR 2000) As it is already mentioned, the aim of this research was to determine annual effective dose from inhalation and ingestion of long-lived radionuclides.

Table 2. Annual effective dose from ingestion of terrestrial radionuclides.

Ingestion	Average (UNSCEAR 2000)	Bela Crkva and Vršac (Present study)
^{40}K	0.17	0.004
U and Th series	0.12	0.017
Total ingestion exposure	0.29	0.021

Since ^{238}U and ^{232}Th are alpha-emitters, when they are ingested or inhaled, they contribute significantly to the radiation dose that people receive. (Colmenero Sujo et al. 2004) Whereas potassium is beta-emitter, its impact is less significant. These facts agree with the output of this research. In Table 2 the obtained effective doses are compared with values reported by UNSCEAR. It is shown that effective dose from ingestion of ^{40}K (4 μSv) is lower than the average value (170 μSv). Obtained annual effective dose from ingestion of ^{238}U and ^{232}Th (17 μSv) is lower than the average value (120 μSv). The total effective dose from inhalation is higher than average value given in UNSCEAR report.

Conclusions

This paper presents the radioactivity concentrations of ^{238}U, ^{232}Th and ^{40}K for 80 soil samples collected in the area of Bela Crkva and Vršac. According to the obtained results, it is shown that activity concentration of ^{40}K exceeds worldwide average value. Further investigation should be done in order to give an explanation, but it can be assumed that using fertilizers could contribute to higher potassium concentration. Concentrations of ^{238}U and ^{232}Th are similar to the reference values provided by UNSCEAR.

Effective dose, an indicator of the stochastic effect of radiation, has been widely used in dose evaluation in the environment. In this research the effective dose from inhalation and ingestion of natural radionuclides is estimated. It is proven that effective dose from ingestion is pretty lower than average values. As regards inhalation, effective dose exceeds average value.

Further research will include using risk assessment.

Interpretation of radionuclide concentrations near the detection limit for dose calculations

Črnič, Boštjan; Korun, Matjaž; Zorko, Benjamin
Jožef Stefan Institute, Jamova cesta 39, Ljubljana, SLOVENIA

Abstract
As with many other environmental pollutants, the concentration distribution of various radioactive substances in the environment can be measured. The influence of radioactive releases into the environment, based on these measurements, can then be used in assessments of the radiation doses, so determining the implied risks to the population.

The outcome of a measurement of the activity concentration can be described as a result that is below the decision threshold, a result that has an uncertainty too large to be reported or a definite measurement outcome. In the first case the analyte does not appear in the list of the results, in the second case it appears as an upper limit and in the third case as a measurement result including its uncertainty. A method for consistently treating these three kinds of measurement outcomes is presented.

When the measurement data are used for dose assessments, averaging may be introduced in order to reduce the amount of input data. It has been shown that in order to reduce the systematic influences occurring when calculating averages from sets of data, where measurement outcomes below the decision threshold or measurement results with an unacceptably high relative uncertainty are frequent, the maximal acceptable relative uncertainty should be set as high as possible. Because of the different characteristics of the analytes, however, it is advantageous to use analyte-dependent maximal acceptable relative uncertainties.

Introduction
Radiological environmental-monitoring programs are carried out in order to survey the radioactivity in the natural and living environment. The purpose of the survey is to assess the impact of the radioactivity on the population, which is performed by evaluating the doses. The radiological impact of nuclear installations in normal operations is commonly considered to have two aspects: the annual dose to a member of the critical group, and the collective dose. This annual dose is compared to the respective regulatory dose limit. To perform the comparison it is useful to know the uncertainty of the dose, which includes the uncertainties associated with the measurement results. Therefore, for a realistic evaluation all the relevant pathways have

to be controlled and the concentrations of the most radiotoxic isotopes have to be measured.

It is important to assess the doses in accordance with the directions of the regulatory bodies and the recommendations of international organisations. If possible, the doses are calculated from the concentrations of materials from the environment. However, doses from discharges in normal operation can accumulate over many years and at distances where the radionuclides are diluted below the detection limit. Therefore, mathematical models and statistical approaches have to be used to evaluate the doses, including the projected doses, correctly.

If the concentrations of the radionuclei of interest are below the detection limit of the measurement methods used, the measurement outcomes may be described as measurement results or concentrations below the decision threshold. Alternatively, some of the radionuclei may be identified in the sample, but the concentrations may be too low to be evaluated quantitatively. In this case the relative uncertainty of the measurement result may approach or even exceed 100%. To treat these results a maximum relative uncertainty is introduced for results reported. The measurement results having a larger relative uncertainty are quoted as a concentration below an upper limit, which is given as the measurement result, increased by its uncertainty, multiplied by a coverage factor, which is determined by the interval of confidence. To arrive at a reliable dose estimate these incomplete data have to be included in the evaluation. However, neither the decision thresholds nor the upper limits are properties of the sample and therefore do not describe the state of the nature but the properties of the measurement process. Therefore, the doses assessed must not depend on them.

It is the aim of this contribution to present a method for how to treat the experimental data in such a way that the assessed doses themselves depend on the sample properties and the uncertainties of the doses on the properties of the analytical process. How to carry out the analytical process in order to minimize the systematic influences arising from converting the measurement results into upper limits is described. This method is used in the evaluation of doses in the program of the off-site radiological monitoring of the NPP Krško (Glavič-Cindo 2006, Glavič-Cindo 2007, Črnič 2008, Črnič 2009, Zorko 2010).

Material and methods

The analytical process

The samples that are collected in the annual programs of the radiological survey are usually taken fortnightly, monthly or quarterly. The yearly averages, which are used in the dose assessment, are obtained by averaging the measurement results. Most of the samples, collected in the environment, are measured using gamma-ray spectrometry. For such samples, gamma-ray spectrometry is the method of choice, because of its sensitivity, selectivity and price. Since gamma-ray spectrometry is a multi-nuclide method, the result of a gamma-ray spectrometric measurement is a list of radionuclides identified in the sample and their concentrations.

Within the sample-analysis procedure several operations are made, where the peak count rates or activities are corrected for contributions that do not originate in the material sampled. These operations are a background subtraction, the correction for a blank and the interference corrections. If the signal from the sampled material is not present or much smaller than the uncertainty of the contribution, which is subtracted, a positive or a negative result is equally probable. In the first case a type-1 error occurs, which occurs in the report as a measurement result with a large relative uncertainty. In most cases this is quoted in the form of an upper limit. Such results are indistinguishable from the results corresponding to samples with a concentration above the decision threshold (critical limit) but having a relative uncertainty exceeding the maximal. It follows that type-1 errors may occur frequently in the measurement outcomes for radionuclei, which are present in the spectrometer background. These are long-lived, naturally occurring radionuclei with their decay products and Cs-137.

If the result of the subtraction is negative, the peak or the radionucleus is deleted from the list of peaks or the radionuclides present in the material sampled (Canberra Industries, 1998). It follows that by the repeated measurements of samples containing a negligible concentration of a radionucleus, one half of the measurements will result in a positive identification. This fraction may be even larger for multi-gamma emitters, if the criterion for the detection allows identification by the recognition of just one of several peaks. For a multi-gamma-ray emitter the activity is calculated as an average over the activities obtained from attributed peaks only, which may result in a considerable systematic influence. The peaks with a negative area are excluded from further analysis and the average calculated corresponds only to the peaks with positive net areas. In the extreme case it may happen that the uncertainty of the average shrinks to a value that results in the average having a relative uncertainty smaller than the maximal. In this case an erroneous result is reported. To decrease the probability of such errors the laboratories maintain maximal relative uncertainties that are much smaller than 100%.

Presentation of the measurement results

Often the measurement results referring to a specific medium are presented in tables. The measurement results of periodically collected samples of the same medium are presented as records, describing the concentrations of radionuclei at a given sampling time. The measurement outcome can appear in one of three forms:

- as a measurement result: $a \pm u(a)$, where $u(a)$ denotes the uncertainty of the activity concentration a,
- as an upper limit: $< q(a)$, where $q(a)$ denotes the decision threshold or the sum of the measurement result and its uncertainty multiplied by the coverage factor
- as an empty space (blank), which implies that the radionucleus was not detected in the sample.

To calculate the yearly averages the three types of entry content have to be converted to the measurement results and their uncertainties. It should be noted that the averaging must not be performed with weights, depending on the uncertainties, in order not to introduce systematic influences into the average.

The uncertainty of the average can be evaluated as the *a-priori* uncertainty, which is given by the uncertainties of the individual measurement results, or as the *a-posteriori* uncertainty, which is given by the spread of the measurement results around the average. Here, care should be taken not to interpret the expected time variations, e.g., seasonal variations, as deviations from an average, which is assumed to represent a concentration characteristic for the time interval of the averaging. Usually, as the uncertainty of the average, the larger of the *a-priori* and *a-posteriori* uncertainties is used.

Often, the uncertainties are quoted with a coverage factor of unity, defining the interval with a confidence level of 68%. On the other hand, the upper limits are normally calculated for a confidence interval of 95% (ISO 2005). For the one-tailed probability distribution this corresponds to a coverage factor of 1.65 (Hurtgen, 2000). Since the upper values, like the uncertainties, describe the analytical process, they should be treated on the same basis. Therefore, when upper limits are converted to measurement results they are transformed into uncertainties calculated with a coverage factor of unity.

The transformation, which is used for converting the three forms of data in a format that is appropriate for use in the averaging, is the following:

$$\begin{aligned} &a \pm u(a) \Rightarrow a \pm u(a) \\ &< q(a) \Rightarrow 0 \pm q(a)/1.65 \\ &[blank] \Rightarrow 0 \pm 0 \end{aligned} \qquad (1)$$

It can be observed from the Eqs. (1) that the upper limits are transformed to measurement uncertainties. Consequently, the upper limits do not influence the average itself, but its uncertainty.

When performing this transformation, a systematic influence is introduced since all the measurement results having a relative uncertainty exceeding the maximal are replaced by zeros. This effect partially compensates for the effect of false identifications.

If in the spectrum analysis just one peak is used for the calculation of an activity concentration of a radionuclide, and if this peak occurs in the spectrometer background, the probability density distribution for reporting the result $a \pm u(a)$ when the radionucleus is not present in the sample is

$$p(a) = \frac{1}{2u(a)\sqrt{2\pi}} e^{-\frac{a^2}{2u(a)^2}} \qquad (2)$$

giving an average reported activity concentration of $u(a)(\sqrt{2/\pi} \pm \sqrt{1-2/\pi})$ (Korun, 2010). It follows that the relative uncertainty of the average of the wrongly reported activity concentrations, is $\sqrt{\pi/2-1} = 0.76$. Then, in the measurement reports such results are quoted as $< u(a)\sqrt{2/\pi}(1+1.65\sqrt{\pi/2-1}) \approx 1.8u(a)$ and interpreted in the average as $0 \pm 1.8u(a)/1.65$. It follows then that type-1 errors arising from the background subtraction, interference corrections and corrections for blank for the radionuclides that are determined from one spectral peak are, in the averages, properly taken into account with a maximal relative uncertainty of 76%.

It should be noted that the approach described does not comply with the European Commission recommendation on the information on discharges from nuclear installations (Commission recommendation 2004/2/Euratom). Here, the measurement outcomes below the decision threshold should be substituted by one half of the decision threshold. Only in the case of repeated measurement outcomes below the decision threshold should zeros be assumed to be true values. In our approach the concentration of the radionuclides is reported correctly from the point of view of the analytical process, since the measurement uncertainty is used for determining the measurement outcome.

Results and discussion

In this section, examples are given in order to illustrate the influence of the maximal relative uncertainty for various types of gamma-ray emitters on the average activity concentration and consequently on the assessed doses.

Let us present the influence of the maximal relative uncertainty on the average over the measurement data, transformed to a form shown in Eqs. (1). In the second row in Table 1 are the hypothetical measurement results, evenly distributed over the interval from 0.7 to 2.7. Since the uncertainties near the decision threshold are dominated by the statistical uncertainty, the measurement uncertainty is a slowly varying function of the measurement result (Weise 2006). Therefore, uncertainties independent of the measurement result are assumed. In these conditions, the *a-priori* uncertainty exceeds the *a-posteriori* uncertainty, and therefore only the *a-priori* uncertainty of the average is presented. For each maximal relative uncertainty in the first row the measurement results, as presented in the measurement report, are given, and in the second row these data are transformed by Eqs. (1) into the form appropriate for averaging. It can be observed that the average value reproduces the average of the measurement results better if the upper limits are calculated for results having a high relative uncertainty, i.e., by using a high maximal relative uncertainty. As it was shown in the previous section, the upper limits for the results with a relative uncertainty exceeding 76% should be quoted. It should also be noted that the difference between the average over the measurement results and the average of the transformed data is covered by the uncertainty in all the maximal relative uncertainties used, but the systematic effect amounts to a factor of 4 when a maximum relative uncertainty of 80% instead of 40% is used.

Table 1. Comparison between the average over the measurement results (in arbitrary units) and the averages over the measurement data transformed to a form that is appropriate for averaging.

For gamma-ray emitters radiating photons at a number of different energies in the identification process, the so-called "abundance limit" parameter is used (Canberra, 1998). This parameter defines for a gamma-ray emitter the minimum ratio of the sum over the emission probabilities for gamma rays identified in the spectrum versus the sum of all the probabilities for the emission of gamma rays for this emitter. It is advantageous to use as many gamma-ray peaks as possible in the activity calculation since interference corrections can then be performed and the average becomes less susceptible to a possible wrong-peak-area evaluation. If the spectrum of a multi-gamma-ray emitter appears in the spectrometer background, it is expected that 50% of the peaks will be identified, providing the concentration of the emitter is well below the decision threshold. With an abundance limit of 50% it is expected that such a radionucleus will be identified in approximately one half of the measurements.

To illustrate the influence of the maximal relative uncertainty on the average a hypothetical example is presented, describing the case of an emitter radiating at several energies with approximately equal probabilities. The case of a multi-gamma-ray emitter radiating at an energy with a much larger probability than at other energies is similar to the case of a radionucleus radiating at a single energy, which was considered in the previous paragraph. The emitter is present in the spectrometer background and radiates at three energies with such probabilities that the uncertainties of the activity concentrations calculated from the areas of the peaks at the three energies are equal. A nucleus, which resembles this example, is U-238, which is in equilibrium with its daughter Th-234 and with U-235 in the natural isotopic ratio. Then, the activity concentrations calculated from the 63-keV, 93-keV and 186-keV peaks have approximately equal uncertainties. The value of the abundance limit parameter of 50% implies that the emitter is identified if any two of the three peaks are identified. Thus, the probability for a false identification is 50%. The average activity concentrations are $u(a)[\sqrt{2/\pi} \pm \sqrt{(1-2/\pi)/2}]$ in the case of two identified peaks (38% of measurements) or $u(a)[\sqrt{2/\pi} \pm \sqrt{(1-2/\pi)/3}]$ in the case of three identified peaks (12% of measurements). The corresponding relative measurement uncertainties are 54% and 44%. To avoid reporting these false results for radionuclei resembling this example, the maximal relative uncertainty should be decreased to below 44%.

Alternatively, increasing the value of the abundance limit parameter can prevent the reporting of false results. A value of 0.7 decreases the probability for reporting false results to 12%, but this is accompanied by an increased probability of type-2 errors.

To present the influence of the abundance limit and maximal relative uncertainty on the frequency of various kinds of measurement outcomes if the activity concentration is near the decision threshold, let us consider again the case of a gamma-ray emitter radiating at three energies. It is assumed that the sample contains an activity concentration that equals its uncertainty if the activity concentration is determined from just one of the three gamma-ray peaks. Since the emitter radiates at three energies, in one measurement three determinations are made and the relative uncertainty of the average activity concentration is $1/\sqrt{3}$. From the probability-density distribution it follows that the probability of the occurrence of type-2 errors is 0.041, the probability for reporting an upper limit is 0.625 (with a maximal relative uncertainty of 80%) and the probability for reporting a positive measurement result is 0.334.

Table 2 presents the probabilities for the type-2 errors and the probabilities for reporting the upper limits if the abundance limits of 50% or 70% were used in the analysis. In the first case the emitter is detected if two of the three peaks in the spectrum are recognized. In the second case the emitter is recognized only in the case when all three peaks are recognized in the spectrum. The probabilities are given for a maximal relative uncertainty of 80% and 44%.

Table 2. Probabilities for type-2 errors and reporting the upper limits for the case of a gamma-ray emitter radiating at three energies with a concentration corresponding to the statistical uncertainty of one peak area.

Abundance limit	Probability of Type-2 errors	Maximal relative uncertainty	
		80%	44%
50%	0.025	0.15	0.64
70%	0.31	0.14	0.43

It can be observed that at a high abundance limit an unacceptably high probability for measurement outcomes resulting in type-2 errors occurs. These errors occur since the emitter is identified only if all three peaks are identified. At the abundance limit of 50%, at the maximal relative uncertainty of 80%, the minority of measurement outcomes are reported as an upper limit, whereas at the maximal relative uncertainty of 44% the majority is reported in this form. In Table 3 the average over the measurement outcomes resulting in reporting activity concentrations are presented as well as the averages over all the measurement outcomes. In this average activity the concentrations corresponding to type-2 errors and the upper limits are taken into account as zeros.

It can be observed that the systematic influences covered by the uncertainties are smaller at the abundance limit of 50%. At the maximal relative of 44% these influences are larger, since here most of the results are reported as upper limits. It can also be observed that the systematic influences are smaller when a higher maximal relative uncertainty is used.

Table 3. Average activity concentrations reported and average activity concentrations, calculated over measurement results (in arbitrary units). Here type-2 errors and upper limits have been taken onto account as zeros.

Abundance limit	Maximal relative uncertainty			
	80%		44%	
	Average reported activity concentration	Average over all results	Average reported activity concentration	Average over all results
50%	1.17 ± 0.59	0.97 ± 0.64	1.56 ± 0.59	0.52 ± 0.92
70%	1.23 ± 0.58	0.68 ± 0.47	1.54 ± 0.58	0.40 ± 0.58

Conclusions

It can be concluded that systematic influences originating from transforming the measurement outcomes to a form that is appropriate for averaging can introduce substantial systematic influences into the averages, if results near the detection limit are abundant. To minimize the systematic effects on the average the maximal relative uncertainty, quoted in the reports, has to be optimised. This optimisation has to take into account two conflicting requirements: minimizing the probability of reporting the wrong results and minimizing the systematic influences on the average. Whereas according to the first requirement the maximal relative uncertainty should be set low, the second requirement demands a high relative uncertainty. The smallest systematic influence on the average can be achieved by using a maximal relative uncertainty, which is nuclide dependent. When the measurement outcome is dominated by the information extracted from a single determination, a relative uncertainty of 76% should be used. On the other hand, when the measurement outcome information from more determinations contributes, the maximal relative uncertainty should be set to a smaller value.

If the averages are used in dose assessments, great care should be taken in order to minimize the systematic influences on the calculated doses. Since doses should be assessed realistically, they must be free of impacts originating in the analytical process as well as in the way the measurement results are presented.

Abstract

Nuclear and radiological installations are subjected to the regulatory control throughout their life. A preoperational monitoring program must be designed to assess the background radioactivity level in the area impacted by any future nuclear or radiological activity and shall cover at least one year before the installation will start to be operated. The paper presents the analytical techniques that were developed, optimized and applied during such an environmental monitoring program which addressed the impact area of a pilot tritium removal facility. Since the radionuclide of concern was tritium, a difficult to measure radionuclide, various methods were applied to extract and purify the water from air, vegetation and food products, which are presented in the paper. Due to the low background tritium measurement method applied, a seasonal variability was exhibited as concerns the tritium in air concentration, which confirms the natural origin of tritium background.

Radioecological studies in the Barents Sea (results of expedition in 2007–2009)

Abstract
The results of radioecological investigations carried out within the framework of the Russian-Finnish high-latitude expeditions in 2007-2009 are presented.

Introduction
Since 1991, the Murmansk Marine Biological Institute of the Kola science center of RAS (MMBI KSC RAS) has carried out comprehensive investigations of radioactivity of Arctic and Subarctic marine ecosystems, which are based on extensive documentary, geographic, and taxonomic materials. Interest in this region stemmed from the availability of potential regional and local sources of radionuclide emission: atomic fleet bases, nuclear test sites on the Novaya Zemlya Archipelago, and radioactive waste burial sites on the shelf.

MMBI KSC RAS implements annual scientific expeditions to the Barents Sea. In 2007 and 2009, a scientist from Radiation and Nuclear Safety Authority (STUK) joined MMBI expeditions. The objective of collaboration was to study contemporary distribution of radioactive contaminants, anthropogenic and natural (NORMs) radionuclides in the Barents Sea ecosystem.

Material and methods
The expeditions were carried out with MMBI's research vessel RV Dalnie Zelentsy. The vessel is equipped to carry out extensive marine research for wide field of disciplines. The area and the route of the last three expeditions (2007-2009) covered parts of the Barents Sea which included standard section No. 6 (Kola Section) in the Central Barents Sea and the Franz Josef Land area. The focus of the studies in 2007-2008 was primarily on the Eastern Barents Sea, when sections along the northeastern border of the Sea, the area near the Novaya Zemlya western coast, and section via the trenches in the southeast of the Sea were investigated. In 2009, the focus was on the Western Barents Sea, when investigations along standard sections No. 3 and No. 19 and in the Svalbard/Spitsbergen area were carried out (Fig 1).

Sampling of seawater, bottom sediments, and living organisms was carried out during the expedition. Bottom sediments were sampled by Van-Veen grab where the top layer (0-3 cm) was collected. Cesium isotopes' pre-concentration from 100-litres of sampled water was performed by the cellulose-inorganic sorbent «Anfezh» on board the vessel. The samples' analysis was carried out jointly at the laboratories in Murmansk (Russia) and Rovaniemi (Finland). The samples were prepared before measurements. The activity concentrations of ^{137}Cs, ^{40}K, ^{226}Ra, ^{228}Th were measured with low-background gamma-spectrometer. The content of ^{238}Pu, ^{239,240}Pu, and ^{210}Po isotopes was determined by alpha-spectrometric method and the content of ^{90}Sr was determined by beta-radiometric method after the corresponding radiochemical preparation of the samples.

Results

Research results of the previous years show very low levels of anthropogenic radionuclides/radioactivity in all components of the Barents Sea ecosystem. The average ^{137}Cs content in seawater was about 2 Bq/m^3, and of ^{90}Sr − 5 Bq/m^3 (Fig. 2). The specific activity of ^{137}Cs and ^{90}Sr in bottom sediments varied within the range of 1−8 and 0.2−4 Bq/kg of dry weight respectively (Fig. 3). However, there are some regional differences in radioactivity concentrations. Higher concentrations of radioactivity were found, in bottom sediments and in sea water, in western parts of Barents Sea where Atlantic waters are more dominant. In proportion, areas where Arctic waters are more dominant show clear reduction in radioactivity concentrations. In addition, in bottom sediments increase in radioactivity concentrations were also observed in straights and deep trenches of the Barents Sea were excess radioactivity has accumulated in a sedimentation process (Fig. 2 and 3).The ^{238}Pu concentrations in bottom sediment along the standard section No. 6 were 0.02-0.04 Bq/kg and ^{239}Pu concentrations 0.4-1.3 Bq/kg, respectively. Thus the ^{238}Pu/^{239}Pu ratio in the sediment samples was 0.03-0.04 indicating that the Plutonium is of the global fallout origin relating to atmospheric nuclear weapon testing. In addition to water and sediment samples some samples of Barents Sea fauna were also measured. The ^{137}Cs concentrations in the main commercial fish species were about 0.2 Bq/kg of wet weight. This is very low compared to ^{137}Cs concentrations of tens of Bq/kg in fresh water fish in Northern Scandinavia (AMAP, 2009). The radioactivity in the Barents Sea nowadays is primarily determined by the presence of natural radionuclides (NORMs) (Table 1).

Conclusions

As a whole, according to the contemporary levels of radioactive contamination, almost the entire Barents Sea may be considered as an area very minor affects of human activity. The local influence of anthropogenic factor was observed mainly in water areas affected by economic activity in bays and inlets of the Barents Sea. Although the radioactivity of the marine environment is generally decreased, it is important to carry out regular monitoring especially in the regions where the potential risk of radioactive pollution is high.

Abstract

The transport of radionuclides through terrestrial environments is determined by a multiplicity of processes with time-scales ranging from a few minutes to many years. The importance of understanding and predicting the radionuclide migration from soils to vegetation arises from its potential radiological impact: slow migration has as result an increase availability of radionuclides for root uptake and gives rise to external doses for a long time.

The transfer factors (TF) for natural uranium isotopes (^{234}U and ^{238}U) and ^{226}Ra were obtained in vegetation samples growing in granitic soils around disused uranium mine located in the Ciudanovita region in the West of Romania. Affected and non-affected areas of the mine presented large differences in the activity concentrations of radionuclides of the uranium series. We also determined transfer factors for several stable elements (essential and non-essential). A set of statistical tests were applied to validate the data.

Introduction

It is important to understand the behaviour of natural radionuclides in the environment (distribution pathways, mobility, transfers, etc.) because the information can be used as a natural analogue for the long-term behaviour of materials and processes in developing and testing models, and in obtaining the associated parameter values appropriate for radiological performance assessments [4]. After the exploitation of the mineral, the uranium mine enters a phase of inactivity until its restoration. During both these phases, large amounts of materials, more or less rich in radionuclides, are exposed to environmental agents. In the phase of inactivity, the uranium mine can be regarded as a very appropriate natural laboratory to investigate the mobilization of natural radionuclides by means of their distribution in different compartments (soil, vegetation, water, sediment, etc.), as well as the transfer between them. The soil-to-plant transfer factor is one of the important parameters widely used to estimate the internal radiation dose from radionuclides through food ingestion. In general, transfer factors show a large degree of variation dependent upon several factors such as soil type, species of plants and other environmental conditions. Due to a predicted long-term transfer of radionuclides in the environment, an understanding knowledge of the geochemical and ecological cycles is also needed as they relate to the behaviour of radionuclides. In addition, the distribution of radionuclides in plant components is beneficial in understanding the dynamics of radionuclides in an agricultural field. Because non-edible parts of agricultural plants are returned to the soil, they may again be utilized in the soil-plant pathway. As a case study, in this work has been considered the uranium waste dump reservoir from the mining perimeter of Ciudanovița.

Material and methods

The environmental samples like soil and vegetation was collected from the dump of the waste rock of the mine EM Banat, Oravita, Caras-Severin county, in order to evaluate soil to plant radionuclide transfer factors (TF). The definition of TF proposed by the IUR [5] has been used:

$$TF = \frac{concentrationofradionuclideinplant(Bqkg^{-1}drycropmass)}{concentrationofradionuclideinsoil(Bqkg^{-1}drysoilmas\sin theupper20cm)}$$

The vegetation samples at each point were collected from the surface at which the soil sample had to be removed. In all cases, only the aerial fraction was sampled. About 100 g of a representative fraction was obtained by homogenization after drying and chopping. The samples were carefully washed in the laboratory in order to remove all the adhered soil particles. Materials for sampling and pre-treatment of the samples were always cleaned before initiating each procedure in order to avoid cross contamination. Twenty-five sampling campaigns soil and vegetation were performed during a one-year period (2007-2008) in order to take the variability in meteorological conditions into account. The total uranium concentration and the isotopic composition from vegetation and soils samples collected at the same sampling site, were determined by high resolution ICPMS Element 2 after separation and preconcentration of uranium. Content of ^{226}Ra, ^{234}U and ^{238}U from the solid waste and vegetation samples were determined by means of the spectrometric gamma measurement chain HPGe-Oxford, with 40% efficiency. Processing of experimental data was performed using STATISTICA 6.0 software which used methods Quadrat Surface and spleen, with a confidence coefficient set to introduce the experimental values of 95%.

Results

STATISTICA 6.0 has enabled the distribution of transfer factors for ^{226}Ra, ^{234}U and ^{238}U, depending on the concentrations of both radionuclides in soil and vegetation in 25 point of prelevation. These distributions are show in the graphs in Fig. 1-2-3. Radium is the last member of the alkaline earth metals, a group of metals whose lighter members (Ca and Mg) play a very important role in plant growth and nutrition. The TF values show a very wide variability for ^{226}Ra. Results have been obtained for radium in grass with a TF mean value of 4.705, and a range between 0.07-9.34. The statistical analysis of the results indicates that the TF mean values in grass corresponding to the ^{234}U are 0,17, and a range between 0.03-0,17, and the TF mean values for ^{238}U are 0,355 and a range between 0,05-0,66. It was established correlations: the concentration of ^{226}Ra (soil) - the concentration of ^{226}Ra (grass) -TF (relationship 1) and the concentration of ^{238}U (soil) - the concentration of ^{238}U (grass) -TF (relationship 2), which are plotted in Figures 1 and 3.

$$\text{TF } ^{226}\text{Ra} = 61,635+2,0345x-20,434y+0,0181x^2-0,3817xy+1,8685y^2 \quad (1)$$

where: x= the concentration of ^{226}Ra in soil [Bq/kg] and y= concentration of ^{226}Ra in grass [Bq/kg]

$$\text{TF } ^{238}\text{U}_{nat} = 36,9526+1,0011x-11,5731y+0,0088x^2-0,1876xy+1,0083y^2 \quad (2)$$

where: x= the concentration of ^{238}U in soil [Bq/kg] and y= concentration of ^{238}U in grass [Bq/kg].

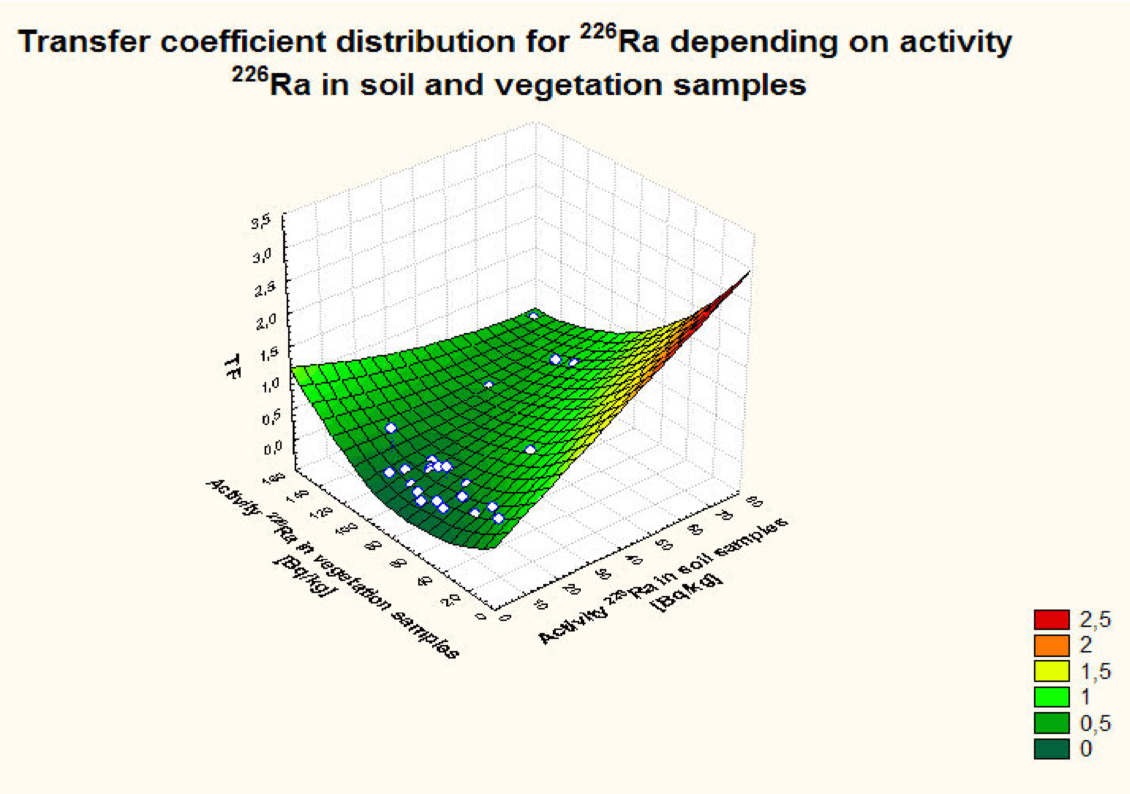

Fig. 1. Distribution of the TF values for ^{226}Ra corresponding of the activity concentrations of ^{226}Ra in soil and grass.

The TF corresponding to ^{226}Ra can be considered, at a 95% confidence level, higher (by two orders of magnitude) than uranium isotopes studied. The excess of ^{226}Ra in vegetation versus ^{234}U and ^{238}U must be explained by the higher absorption of radium. From the comparison between the TF values corresponding to the two elements studied (uranium, and radium), we conclude that the uptake for radium is higher than for the other once element. The fact that uranium is both actinides may explain their more analogous chemical behaviour, whereas this argument cannot be extended to radium which is an alkaline-earth.

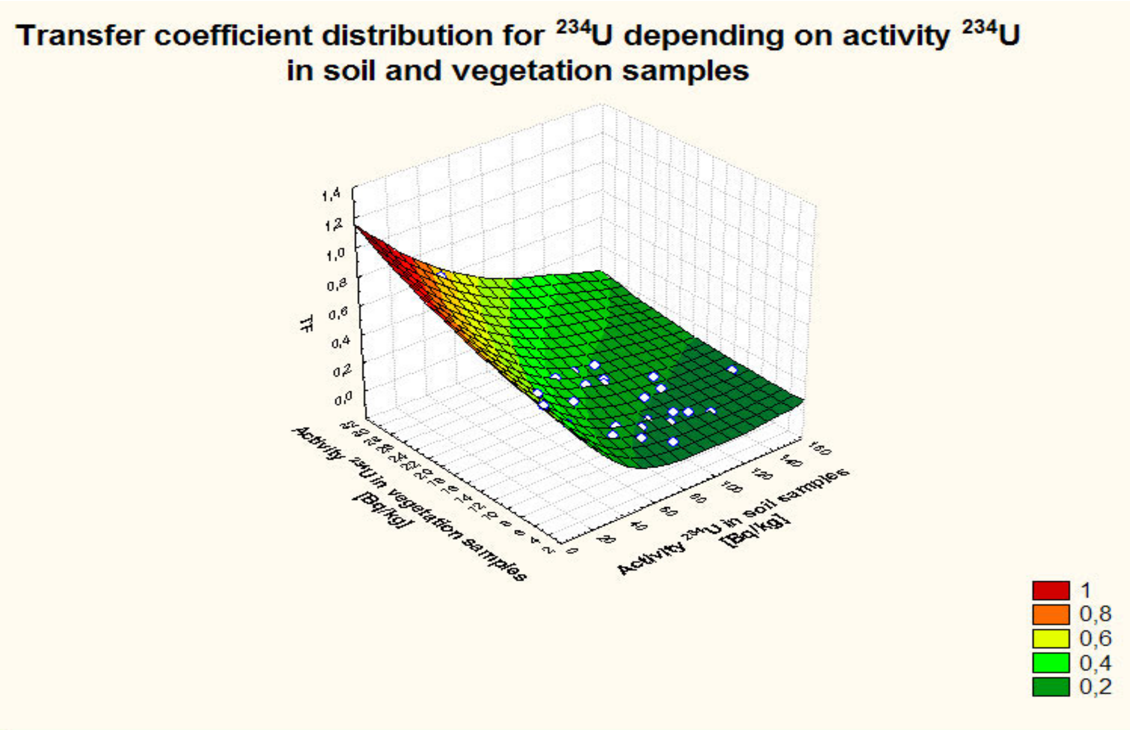

Fig. 2. Distribution of the TF values for ^{235}U corresponding of the activity concentrations of ^{235}U in soil and grass.

This general result is in agreement with other afirmation that TF values for elements in oxidation state +II are almost always greater than for those elements in oxidation state +IV. The results obtained for the soil samples show that the $^{234}U/^{238}U$ atom ratios in all soil samples, are clearly higher than the natural $^{234}U/^{238}U$ atom ratios, 5,54019E-05. Higher $^{234}U/^{238}U$ ratios in soil were observed at 100 and 200m from uranium dump, decreasing with further distance from the uranium tailing dump. When aquatic systems are in contact with minerals, selective leaching processes lead to preferential dissolution and transport of ^{234}U, resulting in enhancement of $^{234}U/^{238}U$ ratio. The reason underlying the enhancement of the ratio is attributed, as a major cause, to a "recoil induced vulnerability to leaching". The mechanism is view as a creation of defects in the crystal lattice when the parent nuclide (^{238}U) recoils during emission of an alpha particle, thus the daughter nuclide (^{234}U) is in a microenvironment that is more susceptible to chemical attack than the parent [1]. Electron stripping during the decay process such that ^{234}U is more likely to be in more soluble U(VI) state, facilitating the solution of this isotope by a surface etching process [2]. In the vegetation samples collected up to 200 m from the uranium tailing dump, half of the samples analysed presented an enhancement of the ratio $^{234}U/^{238}U$ ratio being always higher in grass than in Tussilago farfara. The mobility of uranium in plant tissues is limited, as it tends to adsorb on cell wall materials; therefore, concentrations are typically higher in tissues found lower on the plant and are highest on the root surfaces [3].

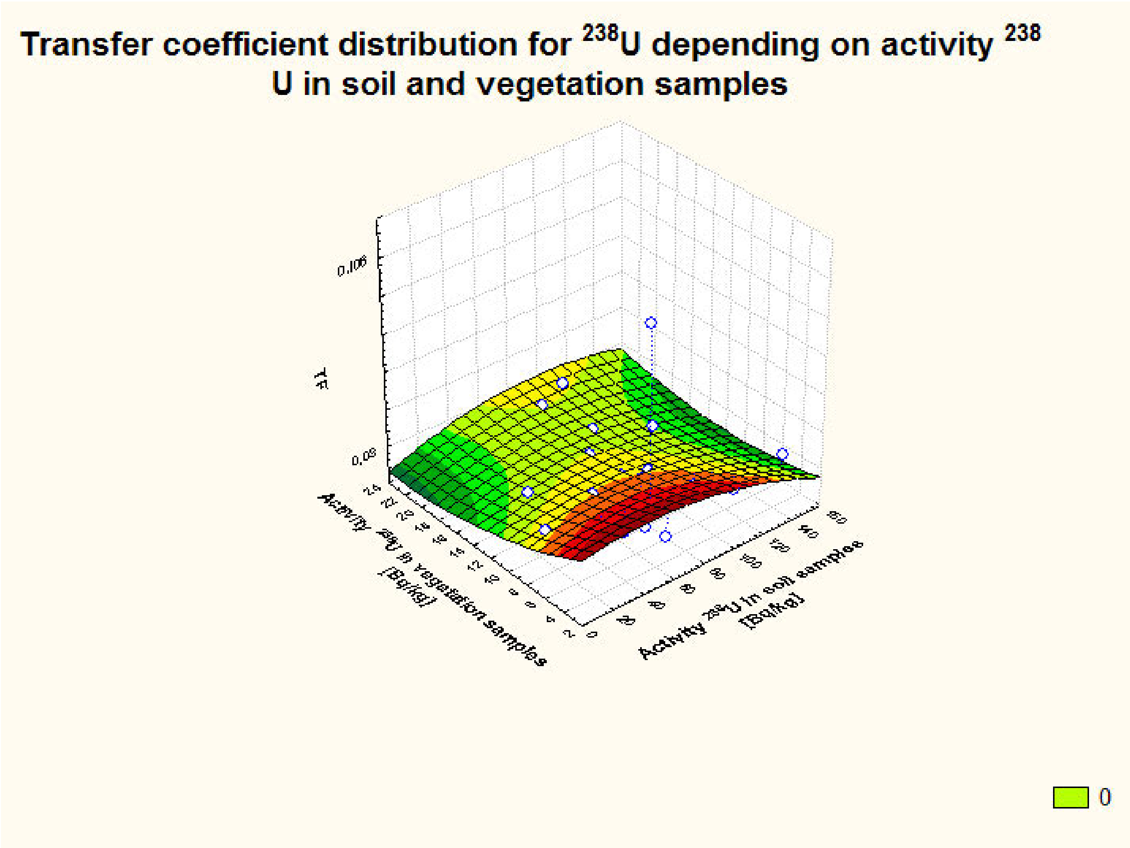

Fig. 3. Distribution of the TF values for ^{238}U corresponding of the activity concentrations of ^{238}U in soil and grass.

In fig.4 is shown correlations between ^{234}U/^{238}U ratios in grass and Tussilago farfara and in soil where the plants were grown.

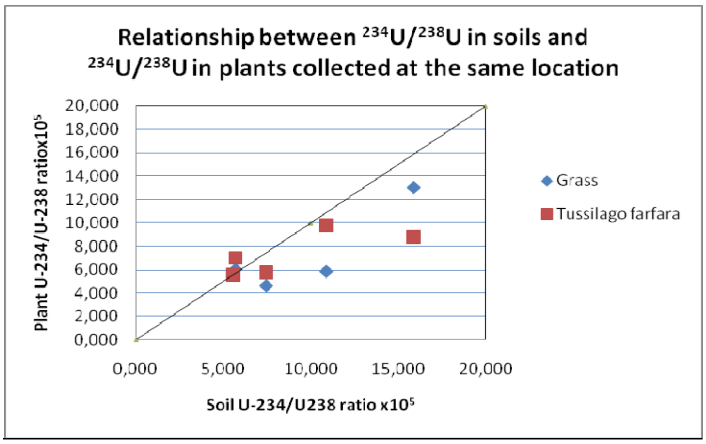

Fig.4. Relationship between ^{234}U/^{238}U ratios in soils and ^{234}U/^{238}U ratios in plants collected at the same location.

Although these plants were grown and harvested simultaneously, we can see that both ^{234}U and ^{238}U were more easily transferred from soil to roots of grass as compared as compared to transfer of these radionuclides from soil to roots Tussilago farfara.

Plant radionuclide concentrations are not so often linearly related to soil radionuclide concentrations. Nonlinearity can complicate the measurement of bioavailability, because each plant and soil combination may have a unique curvilinear relationship. The study of temporal variations of ^{234}U and ^{238}U in plant showed that short-term dynamics of radionuclide plant concentrations are rather significant and species-specific.

Conclusions

Transfer factors (TF) for different natural radionuclides (^{226}Ra, ^{234}U and ^{238}U) have been presented for grass samples in an area where a disused uranium mine is located.

The radium uptake is greater than for uranium by about some orders of magnitude. These differences have been attributed to the different solubilities of the elements with oxidation state +II. The Ra-transfer factor depends the plant part concerned, climate conditions, and the physicochemical form of radium. Radium has a high affinity for the regular exchange sites of the soil.

HYDRUS-computer simulation of radionuclide migration in groundwater due to clearance of low-level waste from decommissioning

Merk, Rainer
BfS Federal Office for Radiation Protection, D-38201 Salzgitter, GERMANY

Abstract
Bulk amounts of cleared building rubble mainly arise due to decommissioning of nuclear power plants. Depending on the type of clearance, weakly contaminated rubble can be released to be deposited in landfills. Leaching of radionuclides is caused by infiltrating rainwater and may lead to migration of radionuclides through the landfill and the vadose zone into the aquifer where the contaminated seepage is mixed with groundwater. If contaminated groundwater is used for irrigation or direct consumption, the food chain may be affected (water pathway). Clearance levels for radionuclides have to be calculated in such a way that the water pathway is considered and the effective dose for an individual of the public is at most of the order of 10 micro Sievert per year. In the wake of availability of inexpensive and fast computers, the leaching of radionuclides, their transport through the various zones of rubble and soil and eventually the contamination of groundwater can be computed by means of sophisticated mathematical models. The software package HYDRUS constitutes an internationally established standard in contaminant transport modeling. We apply HYDRUS to problems of nuclide transport and water dynamics in landfills, the vadose zone and the aquifer.

Introduction
Most of the building rubble from decommissioning of nuclear power plants has low radioactivity and can be released for disposal in landfills, provided the activity concentration (in Bq/g) of the material per radionuclide is below the respective clearance level. In Germany, clearance levels are part of the radiation protection ordinance. Following progress in science and technology and adapting to changing conditions concerning, among others, new requirements of new waste legislation, they are continuously updated.

An important radionuclide pathway in the case of low level material contained in landfills is the so-called water pathway. The assumption is that radionuclides contained e.g. in concrete rubble are carried away by rainwater. Radionuclides may migrate through the landfill and the unsaturated vadose zone beneath the landfill. The contamination may also reach the aquifer and eventually the drinking water and the food chain.

As new approach to estimate groundwater activities resulting from disposal of concrete rubble, the radionuclide transport in the landfill, the vadose zone and the aquifer was calculated in one dimension by means of the computer program HYDRUS (Simunek et al. 1998). With HYDRUS, water transport, leachability of radionuclids and radionuclide migration through the porous structures of rubble, soil and the matrix of the aquifer was simulated numerically. The main equations used within HYDRUS are the Richards equation (water transport) and the convection-diffusion equation (CDE, for the nuclide transport). The computer program HYDRUS represents an internationally established standard tool in the area of groundwater hydrology and contaminant modeling.

With the Richards equation considered here, wetting, drying and the water movement through porous material is adequately described also for non-saturated water contents and precipitation can be varied according to the annual seasons. Physical effects for radionuclide migration considered in our model include the advective transport of radionuclides, their sorption to the background matrix (e.g. rubble or soil), diffusion and dispersion. Also, the radioactive decay is considered as a sink term in the transport equation. Altogether, the HYDRUS code allows for calculation of groundwater activity values. The results are compared with values from the IAEA model of the water pathway suggested for exemption and clearance (IAEA Safety Reports Series No. 44, cf. (IAEA 2005)).

Material and methods

Water transport model

The fundamental physical basis used for the water transport is Darcy's equation. It desribes fluid flow through porous media. It is known that soil and the aquifer are best described as porous matrix. The same is assumed for rubble in a landfill.

Usually, Darcy's equation for the water velocity is written as (v: Darcy velocity, K: hydraulic conductivity, h: hydraulic head, l: spatial coordinate, ψ: pressure head, cf. the monograph by Freeze and Cherry (1979) for all details on groundwater hydrology)

$$v = -K(\psi)\frac{dh}{d\ell}$$

In Hubbert's analysis of the fluid potential, the relationship between different pressures within a system of fluid, air and porous medium is expressed in terms of manometer heads and written as $h = z + \psi$, where z (elevation head) measures the vertical distance to the reference point z=0 (datum) and ψ represents the suction effects of the porous material. It is thus the total gradient of both elevation and suction that drives the water flow through a porous medium.

The equation for v was established around 1856 by French engineer Henry Darcy following his engineering work related to water supply. Nowadays, it can be derived from the more general Navier-Stokes equations in case of water flowing through a porous matrix. This is the basic situation in a saturated aquifer. However, physics becomes more involved once the pore space is only partially saturated, which is the case in the vadose zone and within a landfill consisting of rubble. Besides ψ, the moisture content θ (0 ≤ θ ≤ n, with n: porosity) becomes an important characteristic of the system.

In unsaturated material, K and θ may be related to ψ. The most commonly used empirical relationship between these quantities for soil material is named after M. van Genuchten and Y. Mualem as van Genuchten-Mualem model (VGM). In principle, this model leads to S-shaped wetting and drying curves saying that conductivity is increasing as moisture content is approaching saturation. The curves have to be inserted into the respective water transport equations with the consequence that a considerable degree of complexity is added to the theory. Furthermore, the main experimental problem is to determine the curve parameters for a given soil type. For example, for concrete rubble, these parameters are usually unknown and hence the water dynamics cannot easily be predicted.

For unsaturated media, the Darcy equation can be coupled with the equation of continuity to yield what is known as the Richards equation (Lorenzo Richards, 1931):

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x}[K(\frac{\partial \psi}{\partial x} + 1)]$$

In most of the models of the vadose zone, the Richards equation is the starting point for a mathematical analysis of the fluid flow. It can be assumed to hold for concrete rubble as well, at least as long as a sufficient amount of fine-grained material is present.

While hydraulic parameters of the VGM are tabulated for many soil types, available data for rubble is sparse. It is not clear, for example, whether data for coarse-grained sand is sufficient to describe wetting and drying dynamics in a landfill. Therefore, the hydraulic properties of concrete rubble are presently determined by Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) in collaboration with the Technical University Braunschweig as part of a consultant contract with the German Federal Office for Radiation Protection (BfS). A preliminary set of values was calculated from multistep-outflow experiments by means of inverse modeling.

Radionuclide transport model

Radionuclide transport in water is described by the convection diffusion equation (CDE). In the HYDRUS model, the CDE approach was adopted for radionuclide transport in water flowing through the porous media of concrete rubble, unsaturated soil (vadose zone) and saturated aquifer (Freeze and Cherry (1979). For undisturbed soils, the validity of the CDE approach was demonstrated by Bossew and Kirchner (2004)). The CDE is basically a differential equation expression of mass conservation,

$$\frac{\partial(nC + \rho_b \overline{C})}{\partial t} + \overline{v}\frac{\partial}{\partial x}nC = \frac{\partial}{\partial x}D\frac{\partial}{\partial x}nC - \lambda\rho_b\overline{C} - \lambda nC$$

(C: radionuclide concentration in water, $\overline{C}$: sorbed nuclide concentration, D: dispersion coefficient, λ: decay constant, ρ_b: solid material density).

The dispersion coefficient includes both the effects of diffusion and of hydrodynamic dispersion caused by the porous material structure. Initially sharp and narrow concentration profiles are thus smeared out after travelling through the porous material, resulting in lowered local concentrations.

Sorption is described by a linear relationship between C and $\overline{C}$, which is known as K_d model

$$\overline{C} = K_d C .$$

The CDE can be reduced to an equation for the dissolved fraction C only. However, migration of the dissolved fraction is retarded: high values of K_d therefore result in slowly progressing contamination fronts.

Modeling the water pathway with HYDRUS-1D

In the HYDRUS numerical code, all of the equations described above are implemented. These differential equations are coupled and usually cannot be solved analytically. HYDRUS attempts a numerical solution of both Richards equation and CDE by applying finite difference and finite elements methods. HYDRUS was validated by BfS against known solutions of the CDE under simplified conditions. The HYDRUS output proved to be in excellent agreement with the known solution. In addition, various test runs were performed before modeling started. For example, in a numerical scheme it can be important to control the (finite) timestep and the resolution of the numerical spatial grid.

We have applied the one-dimensional version of the code to a model situation as depicted in Fig. 1. The landfill is located on top of vadose zone and aquifer, and rain is assumed to infiltrate the landfill. Radionuclides migrate in vertical direction and enter the aquifer where the seepage is diluted by incoming groundwater.

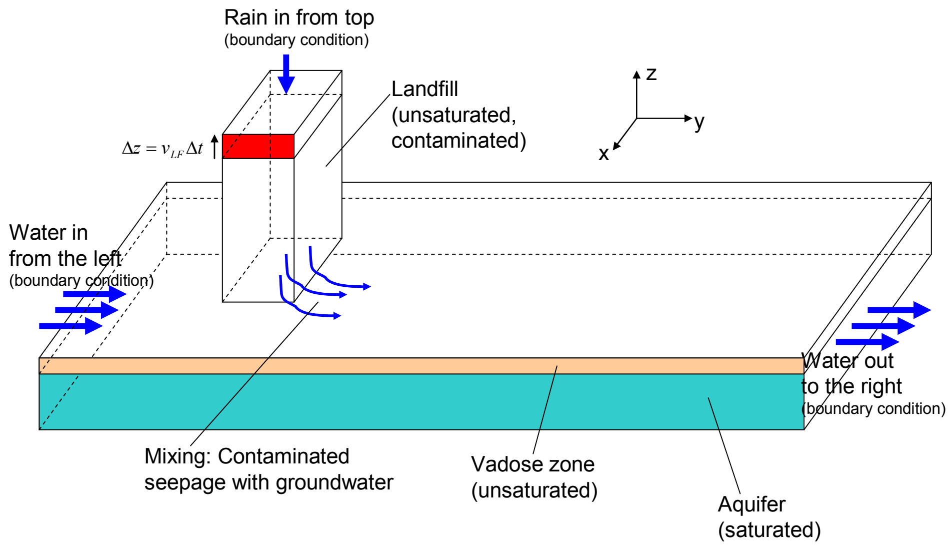

Fig. 1. 3D-Illustration of the model situation used. Modeling is performed by combining two 1D-Hydrus computer runs, one for the landfill and vadose zone and another one for the aquifer.

Two one-dimensional computer runs are necessary in the model situation described in Fig. 1, the first one comprising landfill and vadose zone. Dilution with groundwater is performed analytically and the result is inserted into a second simulation for the aquifer.

The IAEA (SR 44) water pathway model

The IAEA modeling approach is a straightforward analytical method to obtain generic activity levels of contaminated groundwater and was inspired by the RESRAD family of computer codes (Yu et al. 2007). In the IAEA Safety Reports Series No. 44 (IAEA 2005), the water pathway is part of a set of exposure scenarios. Altogether, the exposure scenarios serve to calculate so-called activity concentration (AC) values (in Bq/g). The IAEA suggests to use AC values for exemption and clearance.

The IAEA model is not designed to solve differential equations, rather, it is based on simple estimates and conservative assumptions. It applies the concept of K_d and retardation and directly results in radionuclide concentrations in the seepage and groundwater. Since it does not solve differential equations, the time evolution of the contamination is impossible to follow, which is certainly one of the major drawbacks of this model. Furthermore, dispersion remains unconsidered and the dynamics of the water flow is neglected.

Basically, the model starts with a contaminated zone containing a radionuclide of 1 Bq/g specific activity. It is assumed that the entire inventory of radionuclides is carried away by rainwater at a leach rate of

$$L = \frac{I}{\theta^{cz} z^{cz} R^{cz}} \quad .$$

In this equation, I stands for the infiltration rate, θ^{cz} stands for the volumetric water content of the contaminated zone, z^{cz} is the thickness of the contaminated zone and R^{cz} is the retardation factor. R^{cz} is largely determined by K_d . Note that the volumetric water content is taken to be a constant, since full water dynamics cannot be modelled with the IAEA model.

The radionuclide concentration in the seepage can be calculated according to the formula

$$C^s = \frac{McL}{IA^{cz}}$$

(M: total mass of contaminated material, c: specific activity of the radionuclide in the contaminated material, A^{cz} is the surface area of the contaminated zone). The explanation of these formulae is in the end straightforward application of proportionalities.

An unsaturated zone is assumed in the model. For this zone, a delay time t_i is inserted into the law for radioactive decay, which considers the time needed to traverse the unsaturated zone. There is no further impact from the assumption of an unsaturated zone. This is a considerable simplification and, in principle could only be justified retrospectively, after a detailed model of the vadose zone has been calculated. The delay time is calculated on the basis of proportionalities from infiltration rate, thickness of the unsaturated zone, retardation factor, saturation ratio and porosity of the unsaturated zone.

In the end, the radionuclide concentration in the well water is calculated from the radionuclide concentration in the seepage by

$$c^w = \frac{IA^{cz}}{U^{gw} + IA^{cz}} C^s e^{-\lambda t_i} .$$

Here, U^{gw} is the volume of groundwater per unit of time. The first term in the last equation represents dilution by groundwater. There is no detailed modeling of the aquifer and obviously, the well has to be assumed conservatively as being located very close to the landfill.

Results

In the HYDRUS-modeling approach, two one-dimensional HYDRUS computer runs are combined to calculate the groundwater contamination at a distance of 500 m from the landfill. The first run is for the downward directed water and radionuclide transport through the landfill and the vadose zone.

We have used hydrological data from standard hydrology literature to model in a preferably realistic rather than overly conservative manner (see, for example, the monographs by Freeze and Cherry (1979) and Heath (1988)). Hydraulic data for the vadose zone and the aquifer is provided by HYDRUS (Simunek et al. 1998) within the VGM framework. Respective VGM data for the landfill was determined experimentally by GRS. In the HYDRUS model, an annual precipitation typical for Northern European climate conditions was assumed. An initial activity of 1 Bq/g was taken for the radionuclides contained in the rubble.

Usually, we apply K_d values that are the conclusion of a literature survey within a study performed by a technical consultant of the German Ministry of Environment, Nature Conservation and Reactor Safety (BMU) and published by Deckert et al. (1993). However, note that BfS is also involved in both experimental and theoretical derivation of K_d values. We plan to analyze possible differences in a future investigation. Furthermore, for a preliminary numerical study such as the one sketched here, it is sufficient and easier to analyze if the same K_d is used in all segments of the model.

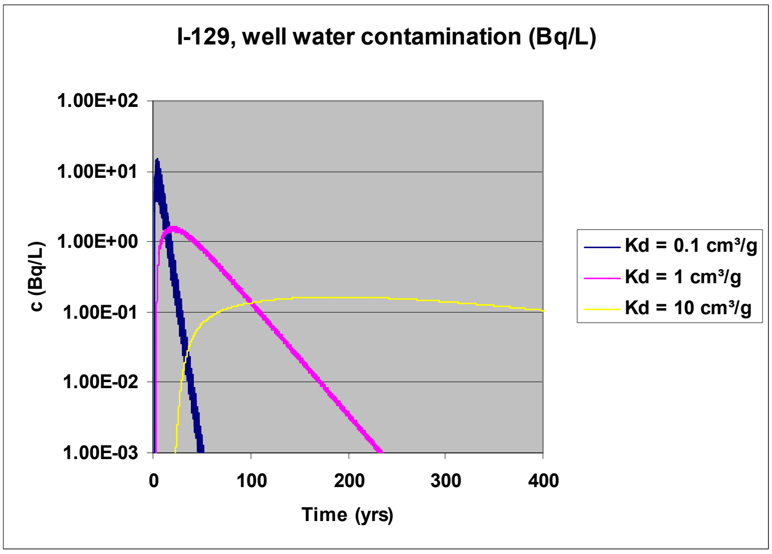

Fig. 2. I-129 well water contamination time scales (in years) for K_d = 0.1; 1; 10 cm³/g calculated with HYDRUS.

Fig. 2 shows HYDRUS-modeling results for I-129 (half-life 1.6×10^7 yrs). K_d was varied between 0.1 and 10 cm³/g, the baseline value being 1 cm³/g. The figure displays the evolution of I-129 groundwater contamination at a model well at a distance of 500 m from the landfill. Obviously, K_d controls the radionuclide transport dynamics to a large extent. Peak contamination levels span three orders of magnitude between around 0.1 and 10 Bq/l and the duration of contamination at the well varies considerably between about 50 yrs (K_d = 0.1 cm³/g) and more than 400 yrs (K_d = 10 cm³/g). Similarly, the arrival times at the well may vary depending on sorption. Although peak contamination levels can often be estimated from a given K_d , reliable contamination time spans are difficult to obtain without numerical analysis. Reasons for this are the dynamics of leaching and the dispersion effects along the path that tend to broaden the contamination peak structure.

In general, it was found that the IAEA modeling results are comparable to our HYDRUS results, provided free parameters are adjusted to ours. It is easier to study how the IAEA model *itself* performs if parameter values vary as little as possible between the models considered. Applying a simplified model can be useful whenever it is intended to get a rough idea of the course of data in a given context. The IAEA model can be programmed as a relatively short computer script and does not consume much computation time.

An example is shown in Fig. 3. Well-water contamination levels were calculated by means of our own computer scripts based on an IAEA model with parameters adjusted to the HYDRUS-model parameters.

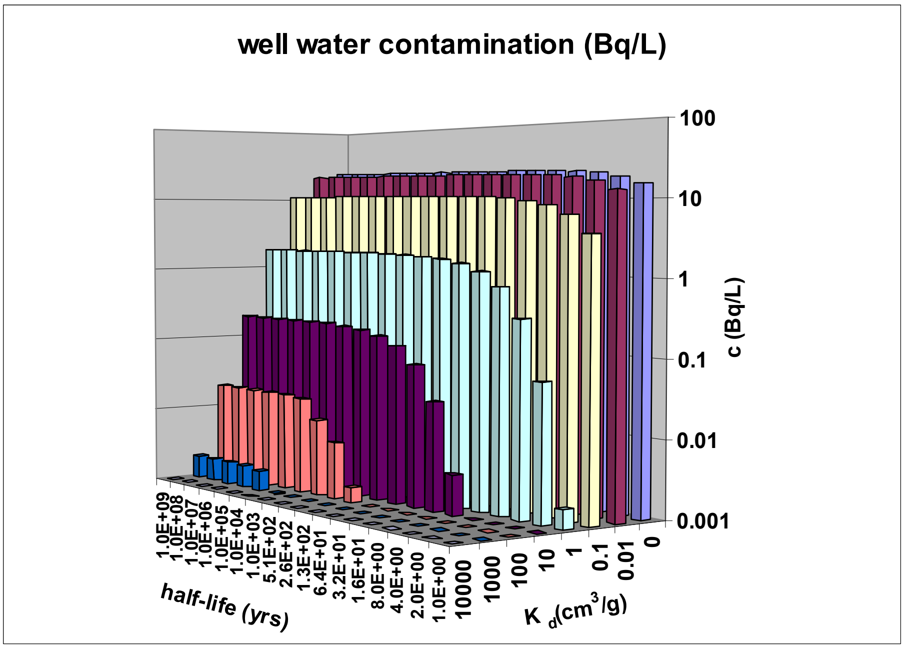

Fig. 3. The IAEA (SR 44)-modeling approach as applied to the parameter space spanned by K_d and half-life. The columns represent the calculated well water contamination values for a given pair of K_d and half-life. Other free parameters are chosen in accordance with the HYDRUS model (cf. text for details).

Due to computation time restrictions, general results are sometimes difficult to obtain by performing detailed HYDRUS simulations. For example, the plot depicted in Fig. 3 would require a total number of 272 HYDRUS-computer runs. On the other hand, if a site-specific study of great importance is needed, one should resort to a detailed computer simulation. The same holds if the transport process itself (e.g. the transport through a given segment of soil) is to be studied and compared with experimental data.

Conclusions

Well water activity levels (in Bq/l) resulting from leaching of radionuclides contained in concrete rubble were calculated by means of HYDRUS computer simulations. The computer program HYDRUS for one-dimensional water and nuclide transport through landfill, vadose zone and aquifer proved to be a robust and modern tool to assess groundwater activity values. Modeling results are similar to values obtained by applying the modeling strategy suggested by the IAEA in the publication (IAEA 2005). The simplified analytical IAEA model for the groundwater pathway appears to be well suited for general-purpose estimates, e.g. to derive generic clearance levels as indicators for a broad class of disposal situations.

In general, the calculation outcome largely depends on K_d . The determination of K_d values, however, was not part of our study so far. In the present approach, K_d is merely an input parameter and was not even varied along the radionuclide path. The same holds for the IAEA study. As the K_d concept appears to control the outcome of water pathway calculations to a large extent, the question may arise whether clearance level calculations based on a generic approach are trustworthy or not. If site-specific parameter values (e.g. K_d) are available by explicit measurement, detailed computer modeling is therefore to be preferred in site-specific clearance as far as the water pathway is concerned.

Abstract

Samples of Trinitite and soil from Trinity site were studied in the radioactivity measurements laboratory at the University of Bremen and at the authors' facilities in Anaheim (JCR) and Edgewater (WMK). Gamma spectroscopy was used to identify and quantify radionuclides in Trinitite and to perform a radiometric characterization of soil at the Trinity site. Additionally, a similar material ("atomsite") formed during a soviet test at the Semipalatinsk nuclear test site was investigated. Fission products (^{137}Cs, ^{155}Eu) together with activation products (^{60}Co, ^{133}Ba, ^{152}Eu, ^{154}Eu, ^{241}Am) and ^{239}Pu were identified. A literature search including some publicly available archive sources was conducted and our data compared to previously published results. Obtained data on Trinitite were also compared to literature data on atomsite formed during atmospheric nuclear tests in Algeria. Variability of radioactivity in Trinitite and relationship of distance from the ground zero and activation were discussed.

Introduction

Trinity

The terms Trinitite or atomsite are used for a fused glass-like material formed during the first nuclear test in the desert in White Sands Missile Range, New Mexico, USA, on July 16, 1945. Its colour is usually greyish-green, the top surface (facing the explosion) is smooth and typically more active than the bottom side, which is rougher and contains sand and small stones from the desert surface. The thickness of the Trinitite layer varies usually between 0.5 and 1 cm and the material contains plenty of air inclusions. Trinitite was cleared from the area by the Atomic Energy Commission in 1952, but visitors of the Trinity site can still find small pieces on the ground. Although it is illegal to remove Trinitite from the site now, specimens can be found for sale on the internet and from mineral dealers. The Ground Zero (GZ) of the Trinity test, which is a National Monument since 1965, lies within the military area and can be visited by the public twice a year, always in April and in October (WSMR, 2010).

The physical properties of the glass formed during the first nuclear explosion are described in LA-1126 report (Staritzky 1950). The glass covered an area of about 610 m diameter with a total estimated mass of $17 \cdot 10^5$ kg. A health physics survey more than 20 years after the Trinity test was made to determine the radiological risk for the public visiting the site (Fey 1967). In this study, monitoring of samples of Trinitite carried away from the site for gamma-exposure rates, measurement of surface exposure rate from individual Trinitite pieces and calculation of deposition of radioactivity in the body from ingested Trinitite were performed. In a later report (Hansen, Rodgers 1985), radiological conditions were evaluated for the Trinity site and the associated fallout zone. Here also qualitative data for activity concentrations of selected radioisotopes in the soil at GZ were given.

As for scientific literature easily accessible to the public, Atkatz & Bragg published a Trinitite NaI gamma spectrum in 1995 and from ^{137}Cs activity they calculated the explosive yield of the device. In a response to the paper, Schlauf et al. (1997) showed advantages of HPGe spectroscopy and identified other gamma emitters in Trinitite. Sixty years after the Trinity test, a comprehensive study of Trinitite radioactivity by means of alpha-, beta- and gamma- spectroscopy was published (Parekh et al., 2006). Among other findings, the authors used ^{152}Eu as a slow neutron flux monitor and conducted isotopic analyses of Pu in Trinitite samples. In a subsequent study (Semkov et al 2006) based on isotopic data, calculations and modeling, parameters characterizing the Trinity test were determined. Additionally, based on non-radioactive Trinitite properties, Hermes and Strickfaden (2005) devised a new theory on its formation during the explosion. The majority of the Trinitite layer was formed not on the ground, but by a rain of molten glass. After falling to the ground, the surface of Trinitite was further heated by the fireball and developed a smooth surface.

Fig. 1. A specimen of Trinitite. Left: top side. Middle: edge. Right: bottom side. Mass 3.170 g.

Semipalatinsk test site

The USSR conducted its first nuclear explosion at the Semipalatinsk test site in Kazakhstan on August 29, 1949. The Soviets coded it RDS-1 (the acronym is not well understood), while the American intelligence designated it Joe-1, after Joseph Stalin. The tested weapon was a plutonium bomb design similar to that in Trinity, detonated on a tower. The yield was estimated to 20 kt TNT.

Although not much information has been published about radioactivity at the Semipalatinsk test site, there is evidence that the first Russian explosion also created pieces of fused rock at GZ (Kruglov 2002, Hodge and Weinberger 2008). They are called Kharitonchiki in honour of one of the leading Russian nuclear weapons scientists, Yuly Khariton, but are more broadly referred to as atomsite. The authors are not aware of any clean-up involving removal of atomsite, as in the case of Trinity site.

Information on activity concentrations of radionuclides in the upper 2-3 cm of soil at the site of the RDS-1 test at the Semipalatinsk test site has been published by Yamamoto et al. (1996). A mainly in-situ gamma spectroscopic study was performed by Shebell & Hutter (1998).

Fig. 2. A specimen of atomsite from Semipalatinsk test site. Left: top side. Middle: edge. Right: bottom side. Mass: 2,545 g.

Algeria

France performed 4 atmospheric nuclear tests in the Algerian part of the Sahara desert between 1960 and 1961 at the Saharan Military Test Centre near Reggane. The first of the tests, conducted on February 13, 1960, was called Gerboise Bleue. The fission device was detonated on a 100 m tower with an estimated test yield of 40-80 kt. In 1999 the IAEA conducted a field expedition with the goal of evaluating residual activity due to the atmospheric nuclear tests (IAEA, 2005, Danesi et al. 2008). The atomsite from Gerboise Bleue test is described as black, vitreous and porous material, typically 100-1000 times more active than unmelted sand.

Material and methods

Trinitite[1] samples analyzed in the Radioactivity Measurements Laboratory, University of Bremen (Landesmessstelle für Radiaktivität, LMS) included 6 individual larger pieces of 1.4-3.8 g each (one of them in Figure 1), 3 plastic cylindrical containers filled with many small pieces (68, 50 and 14 g each) and 2 samples of powdered Trinitite (1.9 and 1.1 g). Additionally, a 103 g bulk sample of soil from the upper 5 cm of soil collected outside the inner fence, in the distance of approx. 100 m from GZ, was measured. The samples were analyzed by low-level low-background gamma

[1] Most of the Trinitite in the present study is from the Derik Bower collection. Based on personal communications with Ralph Pray (April 2006 to September 2009) and Derik Bower (January 2003 to October 2008), it is almost certain this material was collected by Ralph Pray in the summer of 1951. It would have been located on the south road leading to GZ, possibly between 150 and 220 m from GZ.

spectroscopy using a coaxial HPGe detector (Canberra Industries) of 50% rel. efficiency housed in a 10 cm Pb shielding with Cu, Cd and plastic lining, operated under Canberra Genie 2000 software. Efficiency calibration was performed for each individual sample separately based on its individual size, density and geometry relative to the detector using the Monte-Carlo based LabSOCS Genie 2000 calibration tool (Bronson 2003). Since some of the analyzed gamma emitters have complicated decay schemes (^{133}Ba, ^{152}Eu), the probability of detecting two photons emitted by the same decaying nucleus as one (a phenomenon known as cascade summing), is not negligible (up to 25%), therefore a cascade summing correction has been applied.

Spectra of another piece of Trinitite (#26) purchased from United Nuclear and a sample of atomsite from the Semipalatinsk test site (Figure 2) were obtained using the author's (JCR) Ortec LO-AX-51370/20 coaxial HPGe detector shielded by approximately 7cm Pb, lined with Cu and Sn foil within PVC and acrylic layers. Samples collected by the author (WMK) in October 2006 at Trinity site with known locations around GZ were measured using the author's (WMK) 5" Bicron NaI(Tl) well detector housed in 2 cm of Pb shileding with Cu foil grading. For the two later mentioned setups the efficiency calibration as described above was not achievable, therefore the resulting spectra were used for qualitative and comparative purposes only.

Results

Gamma spectroscopy of Trinitite enabled identification of several natural and artificial radionuclides, formed as a result of fission and activation or found as remains of nuclear fuel. A gamma spectrum of one of the samples is shown in Figure 3. Radionuclides are listed in Table 1 together with remarks on their origin. Some of the radionuclides (^{60}Co and ^{155}Eu, which were not reported in previous studies) were initially present in very high concentrations; therefore it is possible to detect them, even after more than 10 half-lives. Table 2 gives the specific activity of individual isotopes in Trinitite compared to literature values (Atkatz & Bragg 1995, Schlauf et al. 1997 and Parekh et al 2006).

Table 1. List of detected artificial gamma emitters artificial in Trinitite and their origin.

Isotope	Half-live (yr)	Origin
^{60}Co	5.3	Activation of ^{59}Co – from test tower steel and from soil
^{133}Ba	10.5	Activation of ^{132}Ba. Baratol - Ba $(NO_3)_2$ - was part of explosive lens system of the Gadget
^{137}Cs	30.0	Fission product (beta decay of ^{137}Xe and ^{137}I and also independently)
$^{152,\ 154}$Eu	13.3 / 8.8	Activation of stable isotopes ^{151,153}Eu in soil by slow neutrons
^{155}Eu	4.8	Fission product
^{239}Pu	24110	Principle isotope of nuclear fuel
^{241}Am	433	Mostly present as daughter product of ^{241}Pu (beta emitter), produced mainly from ^{239}Pu during the explosion via double-neutron capture. Based on ^{241}Am ingrowth activity of ^{241}Pu is possible to determine.

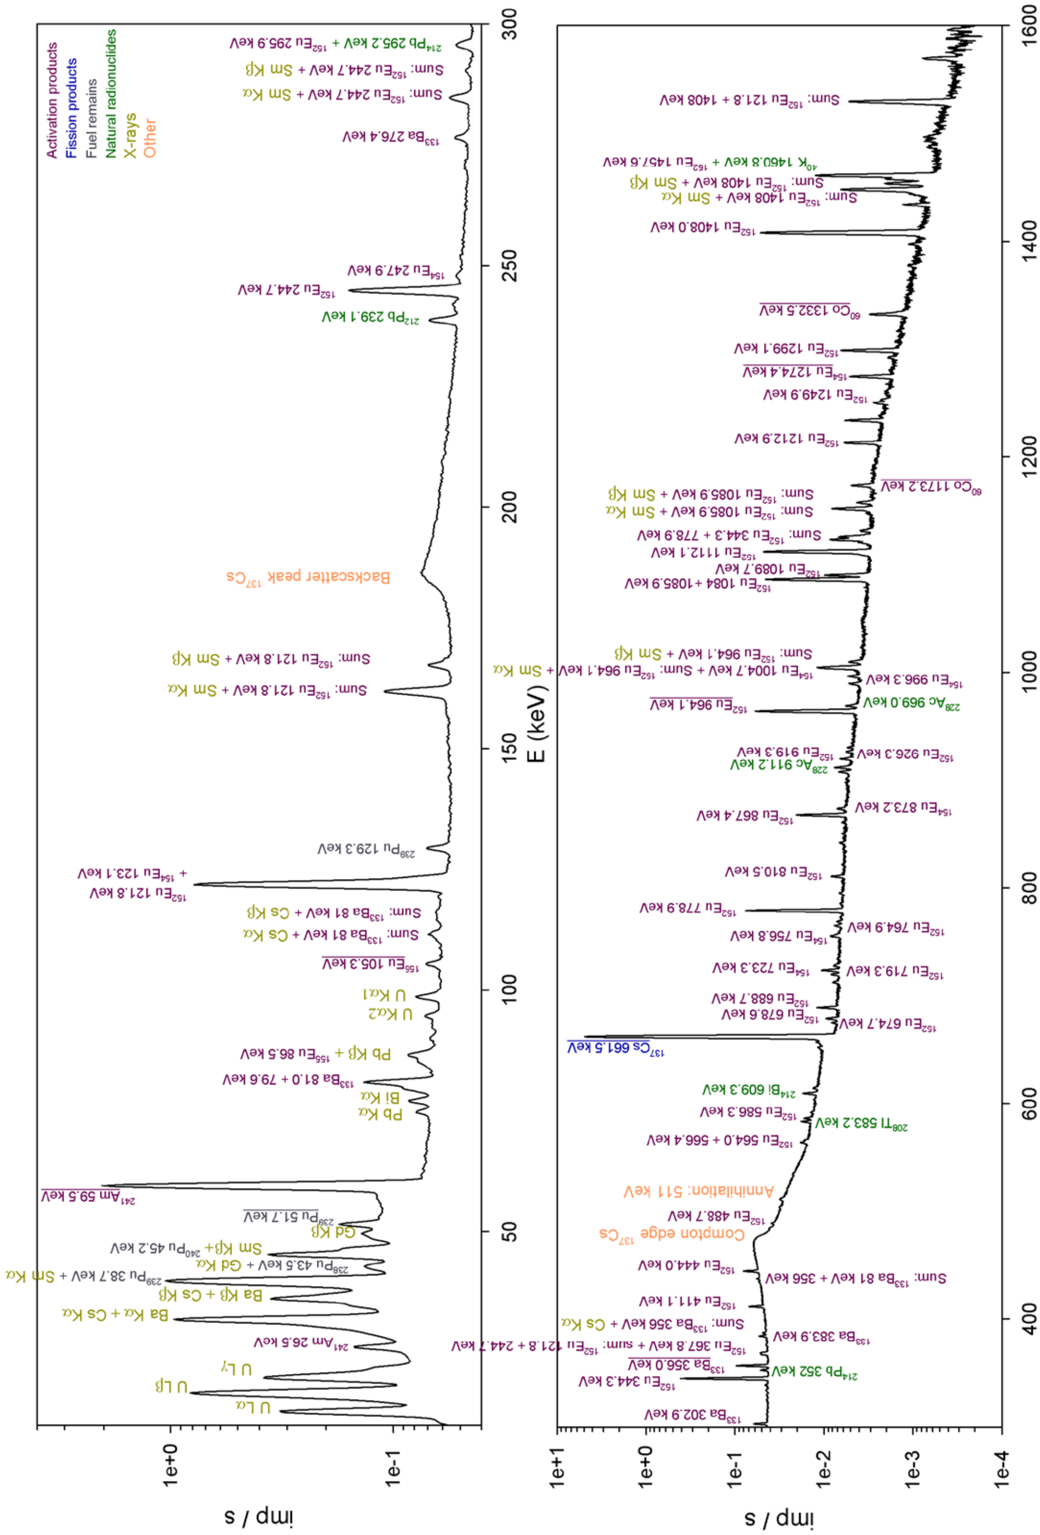

Fig. 3. A HP-Ge gamma spectrum of a sample of Trinitite measured in LMS (50.2 g, pieces of Trinitite in a plastic cylindrical container, height 20 mm, diameter 70 mm, live-time 423281 s).

Table 2. Table of comparison of activity concentrations (Bq/g, uncertainties 1σ) of artificial radionuclides detected in Trinitite and soil from nuclear test sites recalculated to the date of respective nuclear explosions (^{241}Am, which is ingrowing from ^{241}Pu, is reported to the date of analysis - in brackets).

Several values measured by LMS were below detection limit, mainly due to low sample mass and/or shorter measurement times.

The spectrum of radionuclides (with exception of ^{239}Pu) found in Trinity soil was similar to that of Trinitite. The absolute activities of $^{152,154}Eu$ and ^{60}Co, isotopes being formed by activation of elements present in soil itself, were present in the same order of magnitude as in Trinitite. The activity concentrations of ^{137}Cs, ^{133}Ba and ^{241}Am were 1-2 orders of magnitude lower in soil than in Trinitite (Table 2).

Discussion

Correlations

Correlation analysis was performed for the set of 11 Trinitite samples measured in LMS using Pearson test (normality was positively tested by Shapiro-Wilk test). Significant positive correlation was found for ^{152}Eu and ^{154}Eu (r=0.823;P=0.016). That is in agreement with similar origin of both isotopes (activation of stable Eu isotopes from soil). On the other hand, activation product ^{152}Eu and fission product ^{155}Eu are not correlated (r=0,305; P=0,557). ^{239}Pu and ^{241}Am, which is present as a decay product of ^{241}Pu (activation of fuel during the explosion), show strong positive correlation (r=0.967; P=0,000001). Activation product ^{133}Ba is positively correlated with ^{239}Pu (r=0,768; P=0,006) and ^{241}Am (r=0.785; P=0,004). Fission products ^{137}Cs and ^{155}Eu were significantly correlated with ^{239}Pu (r=0,827; P=0,0017 and r=0,836; P=0,038, respectively) and similarly with ^{241}Am. Positive correlation was also found for ^{137}Cs and ^{152}Eu (r=0,703; P=0,0159). ^{60}Co is not correlated to any other radioisotope.

Inhomogeneous distribution of radioactivity in Trinitite

The difference of activity at the top surface and the bottom surface of Trinitite is remarkable, mainly for beta activity. Measurements performed on 6 Trinitite specimens collected by WMK in 2006 using a 2" pancake tube inside a plastic bag to stop alpha radiation showed the top/bottom surface ratios ranging between 2.6 and 22.9 (with exception of one sample of unusual appearance showing ratio <1). Gamma measurements do not show such a pronounced difference due to higher penetrability of gamma radiation. A repeated measurement of one piece of Trinitite on a HPGe detector (LMS) top side up and top side down showed top/bottom ratios significantly increased for ^{137}Cs (1.24±0.05), ^{239}Pu (1.49±0.11) and ^{241}Am (1.25±0.08). Top/bottom ratios for ^{133}Ba and ^{152}Eu,however, were close to 1 (1.0±0.1 and 0.96±0.09, respectively).

Variability of radionuclides in Trinitite

While some variation in radionuclide activity (Table 2) can be attributed to sample size and normal variance, differences due to location are also expected and have been observed. Semkow et al (2006) found a power-law dependence between ^{152}Eu and slant range to the nuclear explosion center. Semkow calculated a least-squares exponent of -6.257 using 1946 data from 300 to 500 m (instruments closer to GZ were destroyed), whereas a spherical spread of neutrons would have resulted in an exponent of -2. Trinitite collected by the author (WMK) in October 2006 from 18 locations between 60 and 260 meters from GZ did, however, exhibit a power-law dependence with an exponent of -2.03 and least-squares correlation of R^2=0.777. The activity in counts-per-hour per gram at 1112 keV was found to be 68350 $s^{-2.03}$, where s is the slant range in meters to the top of the 30 m tower. The same specimens showed no significant relationship between ^{137}Cs activity (a fission product) and slant range using the 662 keV peak. It is not known how site clean-up activities may have affected the distances measured to GZ but evidence found during the 2006 survey suggests the specimens were probably within a meter of two of their original locations.

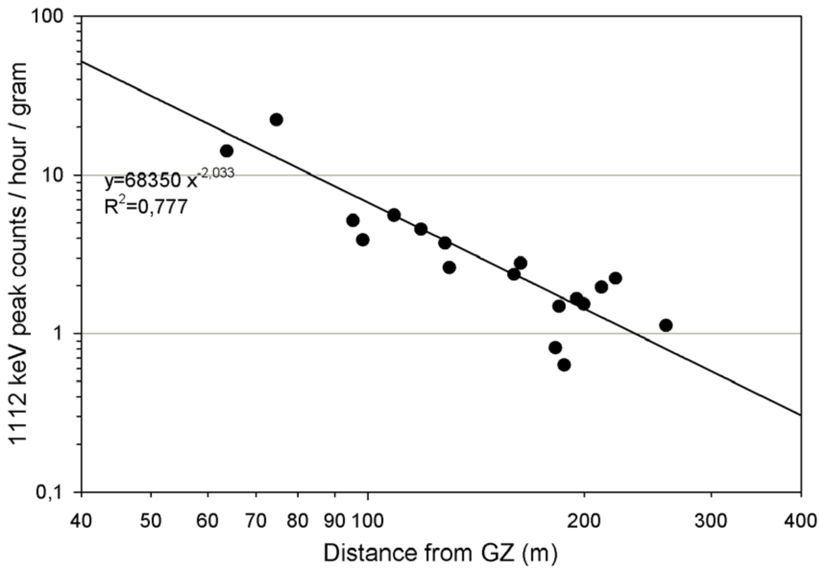

Fig. 4. ^{152}Eu activity vs distance from GZ in Trinitite samples collected in October 2006 by WMK measured with 5'' NaI(Tl) well detector.

Comparison of Trinitite to atomsite from Semipalatinsk

Gamma activity of a 2.545 g specimen of atomsite (Figure 2) from Semipalatinsk was compared to a typical 6.5 g specimen of Trinitite (gamma spectra in Figure 5). The net peak areas of radionuclides measured in both spectra were corrected by respective masses and decay corrected to the date of explosions (1945 and 1949, respectively). Atomsite from Semipalatinsk showed significantly higher activity than Trinitite. The activity ratios of Semipalatinsk/Trinity atomsite were: ^{137}Cs: 16.1±0.1, ^{152}Eu: 23.0±1.5, ^{241}Am (^{241}Pu): 3.4±0.1 and ^{239}Pu: 3.4±0.6. ^{154}Eu and ^{60}Co were under detection limits in Trinitite. ^{133}Ba was not detected in atomsite from Semipalatinsk. This is surprising due to the fact, that Baratol was also used in explosive lenses in the first Soviet nuclear test (Kruglov 2002).

Comparison of Trinitite to atomsite from Algeria

Literature values of a sample from Gerboise Bleue atomsite from Algeria (IAEA 2005 – sample No. ALG 4) described as black fragments of fused sand were compared to values of Trinitite measured by LMS (Table 2). Generally, the Algerian atomsite is more radioactive (activities recalculated to dates of explosions). ^{137}Cs value is about 1.5 times higher than median Trinitite values, ^{152}Eu 2 times higher, ^{154}Eu 4 times higher, ^{60}Co 3.5 times higher, ^{133}Ba 5 times higher. ^{155}Eu and ^{241}Am values are comparable for both Trinitite and atomsite from Algeria. Higher radioactivity in Algerian atomsite is likely due to the higher yield of the tested device.

Comparison of soil from Trinity to soil from Semipalatinsk test site

Soil data collected from the First Experimental site near the hypocenter where the first Soviet nuclear bomb was tested were published by Yamamoto et al (1996). They were compared to samples of soil from Trinity site. All activities were 1 or 2 orders of magnitude higher in soil from Semipalatinsk site than Trinity. The main difference was the absence of ^{133}Ba, as the activation product of stable Ba in baratol in Semipalatinsk site.

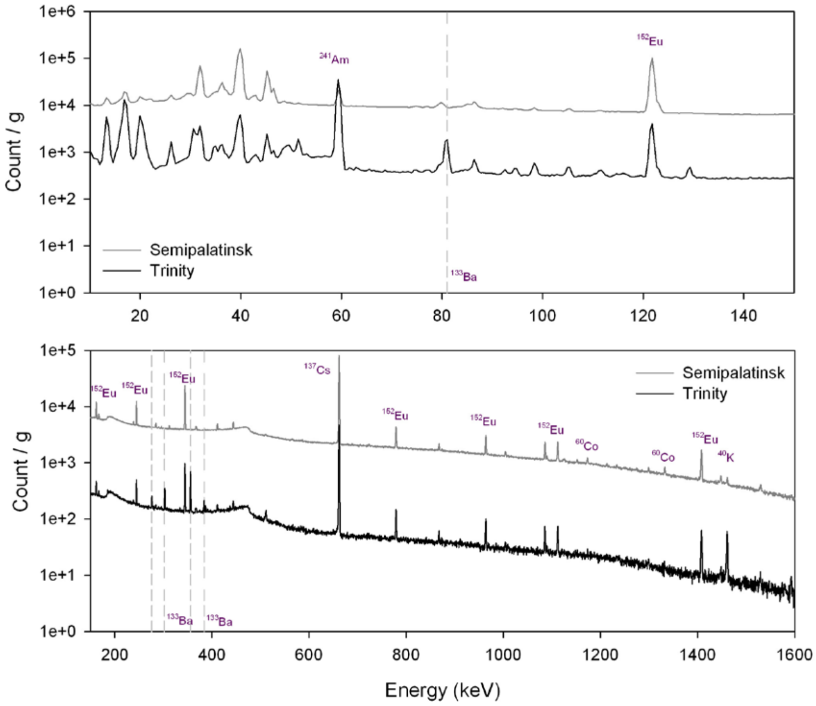

Fig. 5. 24 hour comparison spectra of atomsite from Semipalatinsk and Trinitite (sample #26) measured by Ortec LO-AX HPGe detector. Dashed lines indicate the main ^{133}Ba gamma lines in Trinitite and the lack of ^{133}Ba in the sample from Semipalatinsk.

Conclusions

Gamma spectroscopic studies of Trinitite, atomsite from Semipalatinsk and soil from Trinity was conducted. The experimental data were compared to literature data for Trinitite, atomsite from Algeria and soil from Semipalatinsk. ^{133}Ba (an activation product of Ba in explosive lenses) is present in Trinitite and atomsite from Algeria, but absent in atomsite and soil from Semipalatinsk. ^{155}Eu, a fission product, was found to be detectable in Trinitite after more than 13 half-lives. Correlations between radionuclides in Trinitite and the inhomogeneous distribution of radioactivity in Trinitite were discussed. Power-law dependence with an exponent close to -2 between ^{152}Eu and distance from GZ was found.

Acknowledgements

The authors are grateful to Robert E. Hermes for making it possible to study his specimen of atomsite from Semipalatinsk. Bernd Hettwig’s gamma spectroscopy consultations are greatly acknowledged.

External exposure of a representative individual at selected sites of the peaceful underground nuclear explosions in Russia

Ramzaev, Valery; Repin, Victor; Medvedev, Alexander; Khramtcov, Evgeny; Timofeeva, Maria; Mishin, Arkady
Institute of Radiation Hygiene, St-Petersburg, RUSSIA

Abstract

During the period 2001–2009, eight field expeditions have been conducted to seven selected sites of the peaceful underground nuclear explosions, which were performed in the European and Asian parts of Russia in the last century. Those are: "Crystal" and "Kraton-3" (Yakutia); "Dnepr" (Murmansk region); "Angara" and "Quartz" (Khanti-Mansiysk region); "Globus-1" (Ivanovo region); "Taiga" (Perm region). Evaluation of current doses from the man-made source to a representative individual was one of the main aims of the radiological investigations at the areas. This paper summarizes the key experimental data that are relevant to estimation of external doses.

External doses from the man-made γ-ray emitting radionuclides to a human were calculated using data of *in situ* measurements and results of laboratory radiometric analyses. Realistic estimations of the location factors were used for model calculations of the doses. The estimated effective doses included contribution from global fallout and Chernobyl debris. It is demonstrated that for some UNE sites the dose of interest may exceed a negligible limit of 10 μSv y^{-1}. At the same time, for all these sites the current doses are far below a value of 300 μSv y^{-1}, which is the threshold for application of countermeasures, accordingly to the Russian legislation.

Introduction

Practical implementation of underground nuclear explosion (UNE) technologies in a framework of the National Program "Nuclear Explosions for the National Economy" (Program №7), which had been carried out in the USSR throughout the period 1965–1988 (Ministry of the Russian... 1996), resulted in appearance of a number of sites contaminated by the long-lived man-made radionuclides (Logachev 2001, 2005; Norduke 2000; Yablokov 2003). The majority of the industrial UNE (81 from a total of 124) were conducted in the Russian Federation at the areas located beyond the boundaries of conventional nuclear test sites. The most pronounced contamination of the territory was reported for the UNE Kraton-3 (with ^{137}Cs, ^{90}Sr, plutonium) and Globus-1 (^{137}Cs, ^{90}Sr), where accidental releases of the radioactivity had occurred, and for the UNE Crystal (^{137}Cs, ^{90}Sr, plutonium, ^{60}Co) and Taiga (^{3}H, ^{137}Cs, ^{90}Sr, plutonium, ^{241}Am, ^{60}Co) polluted as a result of the planned technological conditions

(Gedeonov et al. 2002a, 2002b; Logachev 2001, 2005; Lurie 2002; Miretsky et al. 1997). Presently, general public has unlimited access to the sites, and therefore some additional exposure from these man-made sources of the ionizing radiation to a human might be expected.

This paper is devoted to evaluation of the current external γ-ray dose to a representative individual with respect of the four above mentioned sites of UNE. Three different sites (Dnepr, Quartz-3 and Angara), which did not have significant contamination by the long-lived γ-ray emitting radionuclides from the local sources, are taken for comparison.

Material and methods

Table 1 summarises locations and some technological characteristics of the explosions considered. Additional technical details on the UNEs, including geological conditions, may be found in Logachev (2001), Norduke (2000), and Ramzaev et al. (2007, 2009a, 2010b). The sites of selected UNEs are located at forested areas within the moderate or cool climatic zones. Examples are given in Fig. 1 and 2. All selected explosions were carried out in the closest proximity of rivers.

Table 1. Locations and some technological characteristics of selected UNEs (in chronological order). The geographic coordinates have been recorded during our expeditions to the UNE sites; other data are given accordingly to Logachev (2001).

Name of UNE	Year of detonation	Region, geographic coordinates	Depth, m	Power equivalent, kt of TNT	Purpuse
Taiga	1971	Perm region 61.3° N, 56.6° E	127	3×15 (45)	Constructing of a canal
Globus-1	1971	Ivanovo region 57.5° N, 42.6° E	610	2.3	Deep seismic sounding of the Earth's crust
Dnepr-1	1972	Murmansk region 67.8° N, 33.6° E	131	2.1	The breakage of ore
Crystal	1974	The Republic of Sakha (Yakutia) 66.5° N 112.5° E	98	1.7	Constructing of a reservuar dam
Kraton-3	1978	The Republic of Sakha (Yakutia) 65.9° N, 112.3° E	577	22	Deep seismic sounding of the Earth's crust
Angara	1980	Khanti-Mansiysk AO 61.7° N, 67.1° E	2485	15	Stimulation of oil production
Quartz-3	1984	Khanti-Mansiysk AO 61.9° N, 72.1° E	726	8.5	Deep seismic sounding of the Earth's crust
Dnepr-2	1984	Murmansk region 67.8° N, 33.6° E	175	2×1.8 (3.6)	The breakage of ore

Fig. 1. The mountain of Kuel'por (Khibiny, Kola Peninsula) is the site where nuclear explosion technologies were used for the experiments on breakage of the phosphate ore in 1972 and 1984 (project "Dnepr"). The group of tourists and researches is on the road which connects the tourist's camp (to the right) with the site of explosions. July 2008.

Fig. 2. A bed for this beautiful lake had been created by a simultaneous detonation of three thermonuclear devices in 1971. The "Taiga" experiment was conducted with the purpose to obtain some field data for the final elaboration of the project on Kama-Pechora canal. The lake "Taiga" has a length of ca. 700 m and a width of (350 to 380) m. The photo was taken from a helicopter in August 2009.

Fig. 3. Measurements of γ-ray dose rate in air using the gamma dosimeter EL-1101. The plot is located on the axis of the Kraton-3 radioactive trace at a distance of approximately 1.5 km from the borehole. 100% mortality in the larch tree (*Larix gmelinii*) population is observed. July 2002.

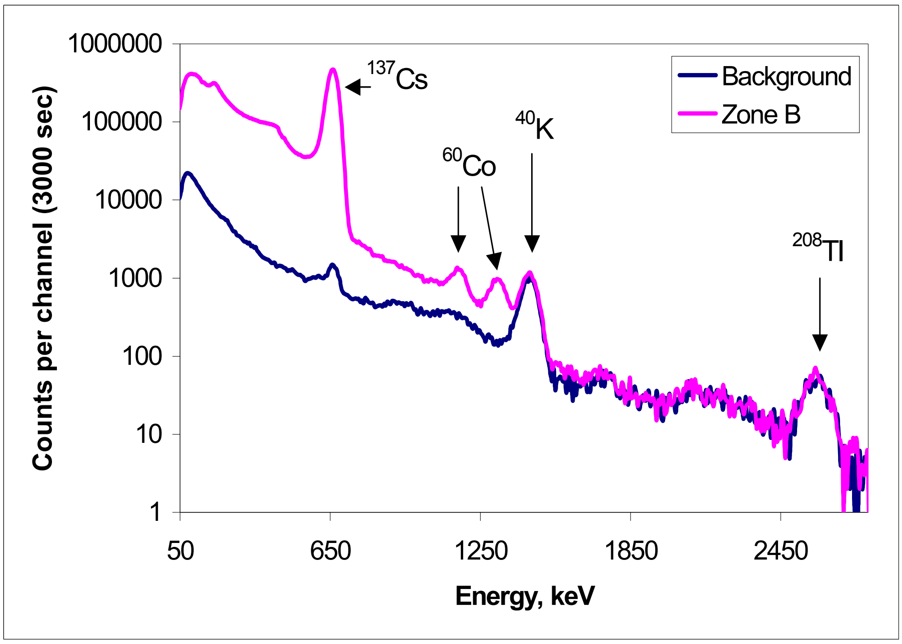

Fig. 4. The γ-ray spectra were recorded on a background plot in Yakutia and on a plot located within a boundary of the affected forest (zone B) at the Kraton-3 site in July 2002. Note a strong excess the ^{137}Cs peak on the spectrum from the Kraton-3 site above the background one (actually, 662 keV peak is related to the short-lived meta-stable daughter of ^{137}Cs – ^{137m}Ba). Two peaks from ^{60}Co (1173 keV and 1332 keV) can also be seen here. There is no difference between the background and *on site* spectrum with respect of peaks from the natural radionuclides of ^{40}K (1460 keV) and ^{208}Tl (2615 keV).

Although the experiments (excluding, perhaps, the Crystal UNE) were conducted at remote areas, the sites are frequently used by tourists and local population for collecting mushrooms and berries, as well as for angling and hunting. The investigators, who conduct field studies, form another group of the exposed individuals.

We suppose that a total duration of a person's staying at the area of an UNE is equal to 14 days in a year. A representative individual was assumed to have stayed within the contaminated site 8 hours each day, totally 112 hours in a year. During 224 hours in a year the person is staying at the background locations: in a camp, forest, on the bank of a river, etc. The scenario is based on our own experience and the results of interviewing other investigators, local citizens and tourists.

For the measurements of γ-ray dose rate (DR) in air at a height of 1 m above the ground, portable γ-ray dosimeters EL-1101, EL-1117 and AT-1121 (ATOMTEX, Belarus) were used (Fig. 3). Technical characteristics of the dosimeters are given in Ramzaev et al. (2006, 2010b). The registered values of DR (Table 2, column 5) include intrinsic noise of the device, cosmic radiation response, contribution from the natural radionuclides, and contribution from the man-made radionuclides. The routine measurements of dose rates in air were supplemented by *in situ* γ-ray spectrometry (Fig. 4) and GPS mapping (Ramzaev et al. 2010b). Soil samples were collected in the plots that might be contaminated as a result of the UNEs and in the "background" plots, which do not lie on sectors affected by the radioactive plume

Table 2. Mean±standard deviation values of the ground surface contamination with ^{137}Cs (kBq m^{-2}), total measured γ-ray dose rate in air (nSv h^{-1}), and calculated external γ-ray dose (µSv y^{-1}) to a representative individual. The dose is attributed solely to the man-made radionuclides: ^{137}Cs and some others, as indicated in column 4. The dose that has been calculated using formula (2) marked (*). Number of sampling plots is given in brackets. The experimental data are obtained from EKORANT (2007), Federal Scientific (2008, 2009), Ramzaev et al. (2007, 2009a) and St-Petersburg Research (2002). The reference date is the sampling date given in the first column.

Name of UNE, year	Location	^{137}Cs, kBq m^{-2}	Other man-made γ-ray emitters	Total dose rate in air, nSv h^{-1}	Dose, µSv y^{-1}
Taiga, 2009	site of UNE	452 ± 421 (6)	^{60}Co, ^{207}Bi, ^{241}Am	274 ± 274 (498)	22*
	background	1.4 (1)	Not detected	76 ± 20 (9)	0.2
Globus-1, 2008	site of UNE	17400 ± 19300 (3)	Not detected	174 ± 240 (189)	14*
	background	2.5 (2)	Not detected	46 ± 4 (5)	0.3
Dnepr, 2008	site of UNE	1.9 ± 0.9 (4)	Not detected	180 ± 202 (60)	0.1
	background	2.2 (1)	Not detected	108 ± 18 (25)	0.3
Crystal, 2001	site of UNE	21 ± 25 (5)	^{60}Co, ^{241}Am	104 ± 70 (6)	7.1*
	background	0.8 ± 0.1 (6)	Not detected	41 ± 8 (8)	0.1
Kraton-3, 2001-2002	site of UNE	955 ± 1870 (14)	^{60}Co, ^{241}Am	240 ± 230 (332)	22*
	background	0.8 ± 0.1 (6)	Not detected	41 ± 8 (8)	0.1
Angara, 2007	site of UNE	1.3 (2)	Not detected	62 ± 12 (34)	0.1
	background	1.3 (1)	Not detected	57 ± 4 (6)	0.2
Quartz-3, 2007	site of UNE	1.4 ± 0.2 (4)	Not detected	43 ± 7 (61)	0.1
	background	1.4 (1)	Not detected	34 ± 4 (3)	0.2

trajectories. Between three and seven cylindrical samples, each with a ground surface of 20 cm^2, were taken at a plot to determine the man-made radionuclides activity per unit area. The depth of such cores ranged from 10 cm to 40 cm, depending on tasks of sampling and presence of pebbles and stones in the underlying ground. Additional details on the soil sampling procedure may be found in Ramzaev et al. (2006, 2007). Content of the man-made γ-ray emitting radionuclides in soil samples was determined by direct gamma-spectroscopy using shielded high-purity Ge detectors and multi-channel analysers.

Results

^{137}Cs is the only one man-made γ-ray emitting radionuclide detected in the top-soil samples that had been collected at the background plots (Table 2). Levels of ^{137}Cs deposit in individual plots varied from circa 0.7 kBq m^{-2} in Yakutia to 3.1 kBq m^{-2} in Ivanovo region. Global fallout might be considered as the main source of ^{137}Cs for background plots in the Asian part of Russia (the UNE Angara, Kraton-3, Crystal and Quartz-3), while for the plots in the European part (the UNE Globus-1, Dnepr, and Taiga) some contribution from Chernobyl source should be anticipated.

^{137}Cs ground contamination at sites of the UNE Dnepr, Quartz-3 and Angara did not deviate from the respectful background levels; for the UNE Quartz-3 and Angara there were also no principal difference between the background and *on site* measured DR (Table 2). At the same time, the DR values registered at the Dnepr site, which is located at a mountainous area, were on average somewhat higher than the background values. The *in situ* gamma-spectroscopy indicated that this might be attributed to the local leakage of the underground air, which is enriched with the radon and its daughters. The DR measured near the mouth of one of the tunnels, which connect intramountain cavities with the Earth's surface, was about an order of magnitude higher than levels determined at background plots (Scientific Enterprise… 2008).

Levels of ^{137}Cs surface contamination at sites of the UNE Kraton-3, Crystal Globus-1 and Taiga exceeded the background values drastically (Table 2). The maximum contamination density (40000 kBq m^{-2}) was deduced for the Globus-1 site (Scientific Enterprise… 2008). Some other man-made radionuclides that were found at UNE sites are listed in Table 2, column 4. Elevated levels of DR have been measured at all four sites that had been significantly contaminated as a result of UNE (Table 2). At the Kraton-3 and Taiga sites, the contamination is observed at an area covering more than 1 km^2. A smaller spatial contamination may be deduced with respect of the Crystal and Globus-1 sites – about 6 ha and 2 ha, respectively (Ramzaev et al. 2007; Scientific Enterprise… 2008).

The effective external dose (E_{ext}) from ^{137}Cs to a human at a background location can be calculated according to:

$$E_{ext} = T_{loc} \cdot A^{137} \cdot K^{E} \cdot g^{137}, \qquad (1)$$

where
T_{loc} – is duration of staying at a location, h. T_{loc} is 224 h;
A^{137} – is the ground surface contamination with ^{137}Cs, kBq m^{-2};

K^E – is a coefficient converting the absorbed dose in air to effective dose for a human, Sv Gy^{-1}. The numeric value of K^E is 0.71 Sv Gy^{-1} (Golikov et al. 2007);
g^{137} – is a transfer factor from the ground surface contamination by ^{137}Cs to absorbed dose rate in air, (μGy h^{-1})/(kBq m^{-2}). The numeric value of g^{137} is $0.71 \cdot 10^{-3}$ (μGy h^{-1})/(kBq m^{-2}) (United Nations 2000).

Formula (1) has also been applied for calculating the effective dose for a human staying at sites of the UNE Dnepr, Quartz-3 and Angara where no excess of the man-made contamination was observed. Duration of staying at the site of an UNE, T_{loc} has been taken as 112 h. The results of estimation of the external γ-ray dose from the man-made sources are given in the last column of Table 2. As expected, negligible doses (much less than 1 μSv y^{-1}) have been calculated for sites of these three UNE and for all background locations.

For calculating the external doses (E_{ext}) at contaminated sites, the other approach based on a difference between DR measured *on site* and on background plots was adopted. The equation used for these four sites of UNE is:

$$E_{ext} = T_{site} \cdot (P_{site} - P_{bg}), \qquad (2)$$

where
P_{site} – is the total averaged DR at a site, μSv h^{-1};
P_{bg} – is the total averaged DR at a background location, μSv h^{-1};
T_{site} – is duration of staying at an UNE site, 112 h.

For the three sites of UNE (Taiga, Kraton-3 and Globus-1) the effective dose exceeded a negligible limit of 10 μSv y^{-1} (Table 2).

Discussion

The legislative status of the peaceful UNEs conducted at the territory of Russia is not yet established officially (Ramzaev et al. 2009b). Nonetheless, the situation of "existing exposure" is, perhaps, the most closely related definition that can be applied for describing general radiological status of the UNE sites nowadays. A short-term staying (during days or weeks in a year) of a very limited number of people on the contaminated areas is a specific feature of the exposure conditions at such sites.

Our estimations of external exposure to a human at the seven sites of peaceful UNEs indicates that for three cases the technogenic dose may exceed a negligible limit of 10 μSv y^{-1}. At the same time, for all these sites the current doses appeared to be far below a value of 300 μSv y^{-1}, which is the threshold for application of countermeasures, accordingly to the Russian legislation (Federal Service 2009).

The annual effective external dose, which has been calculated according to formula (2), includes contributions from a total suite of the man-made γ-ray emitting radionuclides and some bremsstrahlung radiation from interaction of beta-rays with nuclei in soil and air. The latter source may be of significance at the areas contaminated with ^{90}Sr/^{90}Y, for example at the Kraton-3 site (Ramzaev et al. 2009a). The direct beta exposure to the skin and eyes of a person in a radiation field at the UNE sites may somehow contribute to the total dose (see Ramzaev et al. 2009a and references therein). The issue related to the beta-ray exposure requires further studies because relevant quantitative estimations are not presented.

Additionally to the external exposure, which is an inevitable component of the total dose for the UNE situation, a human, in principle, may be exposed from the man-made radionuclides ingested with food products of natural origin and water. Inhalation of the radioactive aerosols may be another pathway of internal exposure at the UNE sites. Contribution of internal exposure to the total may vary significantly. Accordingly to preliminary conservative assessments, the input from internal sources is approximately 20 % at the Taiga, site and it is more than 90 % at the Dnepr site (Scientific Enterprise 2008, 2009).

Conclusions

The residual levels of the surface ground contamination with ^{137}Cs at the sites of UNE Kraton-3, Crystal, Globus-1 and Taiga are significantly higher than those detected for background areas.

Our estimations show that, presently, the UNE-relevant effective external dose to a representative individual may exceed a negligible limit of 10 μSv y^{-1} with respect of the Kraton-3, Globus-1 and Taiga sites.

For some sites of UNE, the external gamma radiation may constitute the major contribution to the total technogenic dose.

Periodical monitoring of radiation conditions at the sites of UNE is recommended (Ramzaev et al. 2010a).

Radionuclides and heavy metals bioavailability in a Norwegian area rich in naturally occurring radioactive materials

Mrdakovic Popic, Jelena; Salbu, Brit; Skipperud, Lindis
Department of Plant and Environmental Sciences, Norwegian University of Life Sciences,NORWAY

Abstract

Recent study on environmental samples from thorium rich Norwegian area showed high gamma dose rate and significant transport of radionuclides into environmental compartments giving multiple stressors action in natural conditions.

The main objective of this work was to investigate distribution and uptake of ^{232}Th, ^{238}U and heavy metals such as Cd, Cu, Zn and Pb from soil and rocks into biota samples in natural conditions.

Soil samples, plant samples of the most abundant species in area and earthworms were sampled on high gamma dose rate location in Fen (Norway). Radionuclides and heavy metals were analyzed by ICP-MS.

Soil analysis showed high level of radionuclides, 4040 and 111 Bq/kg, for ^{232}Th and ^{238}U, respectively. Pb and Zn were in moderate high levels, but comparable with other Norwegian soils, Cd and Cu were in range of non contaminated natural soil. Among the plants collected, the highest uptake of both ^{232}Th and ^{238}U was found in moss. Distribution of these radionuclides was positively correlated with levels found in soil taken below. Different earthworms species showed high levels of ^{232}Th, ^{238}U, Cd and Pb what could suggest bioconcentration from soil – worms' habitat and food. It was shown that these Fen invertebrates had significantly higher levels of several contaminants in comparison to those from chosen reference site in the vicinity.

These preliminary obtained results will form the basis for future work in aspect of:

- determination of sensitive plant, fish, earthworm and mice species,
- determination of transfer factors and possible bioconcentration,
- investigation of different plant parts ability to concentrate naturally occurring radionuclides and study on dependence between uptake and change of natural conditions,
- investigation of target organs for radionuclides and metals deposition and possible biological effects,

which will be presented in the conference.

Introduction

Data on the activity concentration of naturally occurring radionuclides in the environmental media (i.e., soil, water, sediment) and organisms of interests are of high importance when assessing radiation impact on non-human organisms. Parameters obtained in investigation of terrestrial and aquatic biota uptake of radionuclides in natural conditions are highly relevant when it comes to estimate consequences of nuclear pollution or accidents problems. However, the knowledge gap and lack of data considering many organisms must be considered (Jones et al., 2003; Beresford et al., 2008). Additionally, biota is rarely exposed to only radiation, but also very often to some heavy metals. Thus, it is significant to predict the most probable exposure scenario and to investigate both levels of radionuclides and heavy metals in living organisms, as well as to investigate possible diverse i.e., additive, synergistic or antagonistic biological effects (Salbu et al., 2005).

Fen central Complex in southern Norway is geologically specific area of magmatic, carbonatite rocks rich in naturally occurring radioactive materials (NORM), in first place thorium (Th) and uranium (U), but also in iron (Fe) and rare earth elements (REE). This part of the country is well known with its high exposure radiation doses to humans, mainly due to high levels of radon (Sundal and Strand, 2004). Several mining sites were exploited in this area for Fe, niobium (Nb) and scandium (Sc) during the past centuries. All mining activities were finished in 1960s, but technologically enhanced naturally occurring radioactive materials (TENORM) sites are still important sources of environmental pollution. Beside NORM sites, the TENORM sites also contribute to the high exposure dose to the Fen human population (Sundal and Strand, 2004; Mrdakovic Popic et al., 2010, in preparation).

The main objective of this study was to investigate the correlation of high soil concentrations of naturally occurring radionuclides ^{232}Th and ^{238}U and some heavy metals such as Pb, Cd, Zn and Cu and their uptake in the living organism in the NORM rich area. According to that, transfer factors were calculated using organisms concentration and soil concentration. Assessment of environmental impact considering radionuclides is done on the basis of obtained activity concentrations of radionuclides using the ERICA assessment tool (Brown et al., 2008). Further activities will be to investigate possible biological effects on organisms that were shown to be the most sensitive and under risk.

Material and methods

Fen Central Complex is a specific geological area positioned 120 km southeast of Oslo. It is an area rich in volcanic carbonatite rocks: Søvite, Rødberg, Rauhaugit and Fenite (Fig.1). Some of these rocks were first described by Brøgger (1921) and named worldwide after these geographical names. This part of Norway is known with its high thorium ore deposits (USGS, 2007, Thorium report, 2008) and high radon levels and consequently high annual radiation exposure doses (Stranden E., 1986; Solli et al., 1986; Sundal and Strand, 2004; Smerthust et al., 2006).

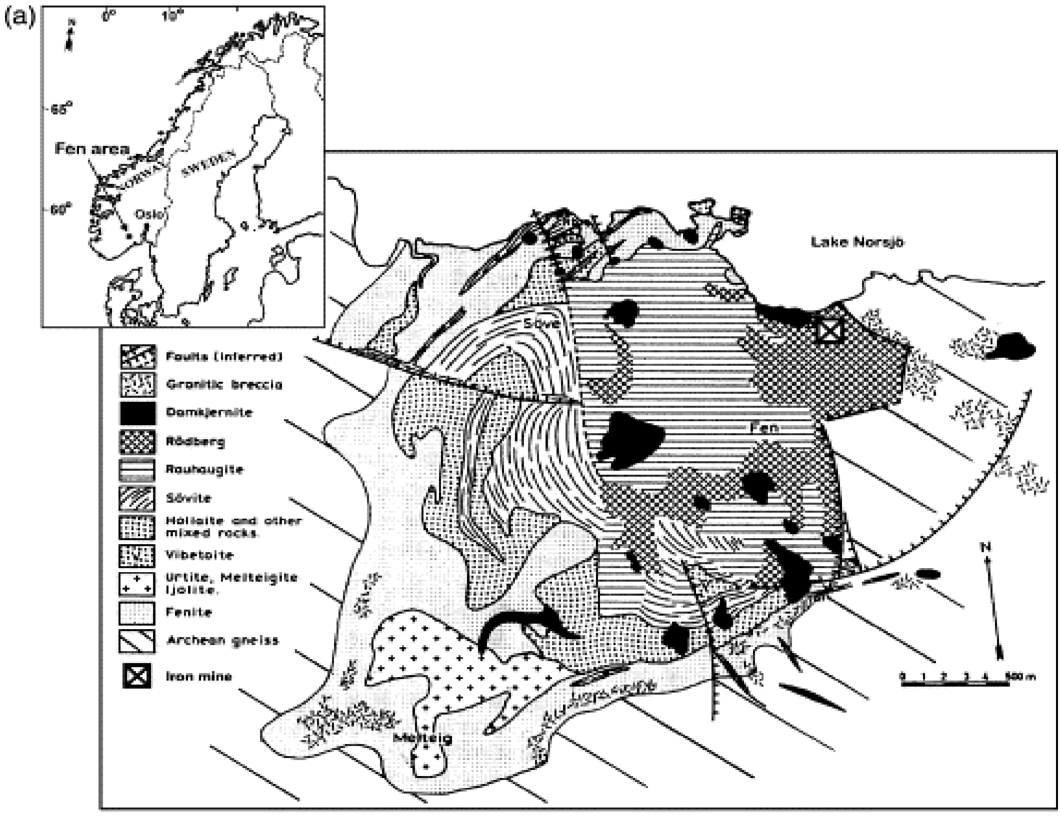

Fig. 1. Bedrock geology of Fen Central Complex (Ramberg and Barth, 1966).

Collection of soil, plants and earthworms were done during the fieldwork at spring 2008, in Fen, Telemark, Norway. Sampling location was chosen according to increased terrestrial gamma exposure dose rate, measured by hand detector type Automess AD4LF, type 6150. Soil samples were collected from depth 0-20 cm as bulk samples. Earthworms (40 adult organisms) were collected from several points at chosen location by hand sorting, and after identifying in the laboratory they were washed and starved for 2 days until their gut contents were completely egested. Earthworms were then frozen in liquid nitrogen, freeze dried and ground to a fine powder. Plants, that were found to be the most abundant in the area i.e., lichen, moss, birch, pine and spruce were collected in paper bags, at least 10 different plants from each species. All plants were, further in the laboratory, cleaned from visible soil, washed several times with distilled water and dry for several weeks at temperature 40°C. They were homogenized by milling. Soil samples were air dried for several weeks, crushed to a fine powder and finally homogenized by sieving through 2 mm sieve. Aliquots of soil were dried at 80°C to constant mass and analyzed for pH, water and organic matter content prior to decomposition for analysis.

Concentrations of radionuclides ^{232}Th, ^{238}U and heavy metals in all samples were measured with ICP-MS after extracting with microwave decomposition (Milestone Inc., Ultraclave High performance reactor, Shelton, CT), employing high-grade purity HNO_3 acid for soil and HNO_3/H_2O_2 for plant and earthworms samples. ICP-MS analysis was done using a Perkin ElmerSciex Elan 6000 (Norwalk CT, USA). Quality control assurance was performed by substantial use of internal standard, method and instrument blanks and by using proper certified reference materials.

Results and discussion

Results of soil analysis (Table 1) showed high concentrations of ^{232}Th and considerably lower concentrations of ^{238}U, 4040 and 111 Bq/kg, respectively. These values clearly exceed the world average values for soil 30 Bq/kg for ^{232}Th and 35 Bq/kg for ^{238}U given by UNSCEAR (2000). Average value for Pb was approximately 2-3 times higher than non-polluted soil values given by Norwegian Pollution Control Agency, SFT (2009), and values given by Arctic Monitoring and Assessment Programme, AMAP (1998). Local contamination of terrain by physical and chemical weathering of bedrock and rock-forming minerals is the most probable cause of obtained high concentrations. Concentrations of Cd and Cu found in Fen soil samples were in range for non-polluted soil and similar to results obtained for soil from other Norwegain parts (Salbu and Steinnes, 1995; Steinnes and Ruhling, 2002). Zn in our study was present in soil at 2.5 times higher concentrations that given by SFT (2009). These high levels in Fen area are, probably as in the case of Pb, results of local loading of Zn due to weathering of bedrocks and leaching upon different environmental conditions.

Table 1. Thorium and uranium concentrations in soil samples from Fen.

Sample	^{232}Th (mg/kg)	^{238}U (mg/kg)	^{232}Th (Bq/kg)	^{238}U (Bq/kg)
Fen site	995±284	9±3	4040±1153	111±37
UNSCEAR (2000)	-	-	30	35

Table 2. Heavy metals concentrations in soil samples from Fen.

Sample	Pb (mg/kg)	Cd (mg/kg)	Cu (mg/kg)	Zn (mg/kg)
Fen site	126±78	0.5±0.1	8.5±10.5	508±151
SFT (2009)	60	1.5	100	200

To obtain a kind of initial screening and an overall picture about radionuclides and heavy metals bioavailability for living organisms uptake, the typical and the most abundant species in the area were chosen for analysis. In addition to the five plant species we analyzed two different species of earthworms that have habitat in the inner layers of soil. Results obtained in Fen plants and earthworms analysis are given in Tables 3 and 4.

Among the plants, the highest uptake of radionuclides was noticed in moss, 90 and 6.4 Bq/kg for ^{232}Th and ^{238}U, respectively. Obtained values for ^{232}Th and ^{238}U in plant samples were higher than reference values for leafy plants given by UNSCEAR (2000), 0.016 Bq/kg and 0.062 Bq/kg for ^{232}Th and ^{238}U respectively,. Lower but comparable results for moss and grass samples were obtained in similar investigations of Ramli et al. (2005) and Vandenhove at al. (2006). Metals Pb and Cd were also in the highest concentrations in moss. Essential metals like Cu and Zn were in the highest concentration in birch leaves.

Radionulides concentrations of two different endogeic species of earthworms were significantly high, 316 ad 178 Bq/kg, for *Aporectodea caliginosa* and *Dendrodrilus rubidus*, respectively. These two species, living in the soil, were chosen with expectance that both the internal and external exposure to a cocktail of radionuclides and heavy metals could affect them.

Table 3. Radionuclides and heavy metals concentrations in plant samples from Fen.

Sample	^{232}Th (Bq/kg)	^{238}U (Bq/kg)	Pb (mg/kg)	Cd (mg/kg)	Cu (mg/kg)	Zn (mg/kg)
Pine	0.8	0.2	0.32	0.06	4.4	70
Spruce	0.2	0.04	0.06	0.05	6.1	67
Birch	2.2	0.2	0.27	0.15	8.3	95
Moss	90	6.4	10.2	0.21	4.1	63
Lichen	20	2.6	3.5	0.08	2.2	29

Table 4. Radionuclides and heavy metals concentrations in earthworms from Fen.

Earthworms	^{232}Th (Bq/kg)	^{238}U (Bq/kg)	Pb (mg/kg)	Cd (mg/kg)	Cu (mg/kg)	Zn (mg/kg)
A.caliginosa	316	15	19	4	7	-
D.rubidus	178	5	9	6	6	-

In order to obtain the information on uptake in biota, radionuclide transfer factors (TF) were calculated. TF were calculated as a ratio between radionuclide concentration in organism and radionuclide concentration in soil (Table 5).

Table 5. Transfer factors for ^{232}Th and ^{238}U in Fen plant and earthworms samples.

Sample	TF ^{232}Th	TF ^{238}U
Pine	2E-04	2E-03
Spruce	5E-05	4E-04
Birch	5E-04	2E-03
Moss	3E-02	6E-02
Lichen	5E-03	2E-02
Earthworms	6E-02	9E-02

Average values for plants transfer factors in this study are one order of magnitude lower or comparable with values in ranges published by IUR (1994) and ERICA (2008), for ^{232}Th: 0.001-0.11 and for ^{238}U: 0.002-0.23. The highest transfer factors for

^{232}Th and ^{238}U were obtained for moss and earthworms. Uptake of ^{238}U in the earthworms was higher than the average values given by ERICA data base (2008).

The total exposure rates and risk presented in Fig.2 were obtained by ERICA assessment tool (Brown et al., 2008) on the basis of media concentrations of selected radionuclides. It is also confirmed that bryophytes and earthworms are the most sensitive and potentially vulnerable organisms in this area.

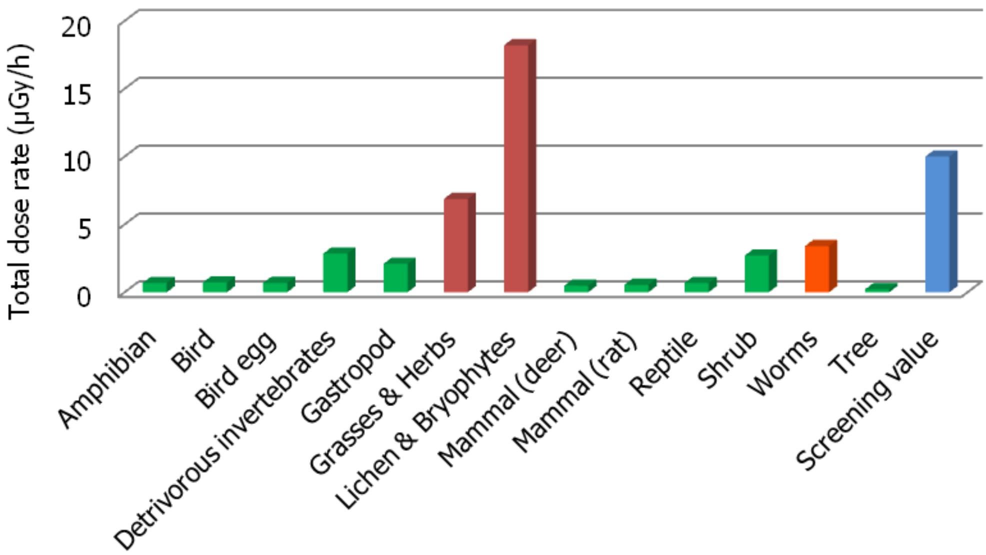

Fig. 2. Total exposure dose per terrestrial organism groups, calculated on the basis of internal exposure.

Conclusions

The main objective of this study was to investigate the correlation of high soil concentrations of naturally occurring radionuclides ^{232}Th and ^{238}U and some heavy metals such as Pb, Cd, Zn and Cu and their uptake in living organism in the area. Data on the activity concentration of naturally occurring radioactive materials in the environmental media (i.e., soil, water, sediment) and organisms of interests are of high importance when assessing radiation impact on non-human biota. Results from this study show some organisms groups that are under high risk and provide information on groups that should be more investigated in terms of early biological responses.

Analysis of Fen soil samples showed high concentrations of both ^{232}Th and ^{238}U, significantly higher than reference values given by UNSCEAR (2000). The found radionuclides concentrations in the soil suggested very inhomogeneous distribution and various influence on living organisms.

When it comes to assessing the radiation risk for terrestrial non-human species the knowledge gap and lack of data must be considered (Jones et al., 2003; Beresford et al., 2008). In our study the selected plant and earthworm species, representative samples from the Fen area, were analyzed for radionuclides and transfer factors were calculated. Levels of both ^{232}Th and ^{238}U in moss and lichen samples were higher than those found in similar plant species (Ramli et al.,2005; Vandenhove at al.,2006). However, no much data for comparison purposes is available on the species grown in natural conditions and on especially species that are not important when it comes to human consumption. Still, despite the fact that high levels of radionuclides were found in some plants, obtained transfer factors were approximately one order of magnitude lower that those published by IUR (1994) and ERICA (2008). Opposite, the concentrations and transfer factors obtained for earthworms are higher than those published by ERICA (2008) and suggest active biological uptake of these organisms. Considering only radionuclides, the organism groups that are under the highest risk in this area, are bryophytes and earthworms.

Radionuclides and heavy metals levels in environmental samples from thorium rich Fen area in Norway

Skipperud, Lindis; Mrdakovic Popic, Jelena; Salbu, Brit
Department of Plant and Environmental Science, Norwegian University of Life Sciences, Ås, NORWAY

Abstract

Fen area in southern Norway is documented to be among the highest natural world reservoirs of thorium ore. It is geologically well investigated area with ^{232}Th rich carbonatite rocks. Dose risk assessment and radon investigations, done in the past, showed total indoor effective dose up to 14 mSv/year. However, there are still huge knowledge gaps when considering environmental impact from the natural occurring radioactive material. This paper is a result of the first investigation phase on a multiple stressors study which comprises identification of contaminants, distribution in natural compartments, biota uptake and total environmental impact assessment.

Gamma dose rate measurements gave an average dose rate of 4.2 μGy/h, much higher than world's average dose rate of 0.059 μGy/h. Rock levels of radionuclides were consistent with previous findings and positively correlated with recorded gamma dose rates in the area. Total soil analysis showed concentrations in the range 69-6098 Bq/kg for ^{232}Th and 49-128 Bq/kg for ^{238}U. Concentrations of Cd in soil were higher than world average, but in range of Norwegian soil values. However, concentrations for Pb ranged from 47 to 287 ppm and for As from 4 to 20 ppm, probably due to mobilization and weathering from rocks. Despite high soil levels, total and size fractionated water samples showed neither radionuclides nor heavy metals contamination. Size fractionation showed that ^{238}U was more soluble and in the low molecular mass fraction, while ^{232}Th was in colloidal and particulate phase, confirming typical behavior in nature.

Considering both radionuclides and heavy metals found in rock and soil from this area, future work will focus on investigation of mobilization conditions, transfer to biota, biological effects and possible synergistic action of different radionuclides and heavy metals.

Introduction

Increasing world's energy demands and limited sources, as well as pollution problems, put the nuclear energy production recently in focus in many different countries worldwide. Considering thorium resources, the Fen area (county of Telemark, southern Norway) is assumed to be among the world's largest with estimated total of 170 000 tones (USGS, 2007).

Related to these high levels of naturally occurring radioactive material (NORM) and technologically enhanced naturally occurring radioactive material (TENORM), the Fen area is well known as area with high mean value of the annual total effective radiation dose to the population. Doses up till 4 times higher than the estimated average effective radiation dose to the Norwegian people are found (Stranden E., 1986; Stranden and Strand, 1986; Sundal and Strand 2004).

Previously, investigations in Fen complex showed unique geology formation with enhanced content of ^{232}Th, ^{238}U and rare earth elements (Brøgger 1921; Landreth 1979; Dahlgren S., 1983, Stranden E, 1982.) and increased gamma radiation dose rates (Sundal and Strand, 2004; Smerthust et al., 2006). Since the main contributor to the total effective radiation dose from naturally occurring radionuclides is exposure to radon, many studies have investigated the indoor radon concentrations in Fen area dwellings, relationship of indoor and outdoor radiation doses and their dependence on geology formation of terrain (Stranden E., 1982; Solli et al., 1986, Sundal and Strand, 2004; Smerthurst et al., 2006).

Typical Fen complex rock types, first described by Brøggger 1921., occupying the largest fraction of the surface, are carbonatite rocks of magmatic origin. Intensive mining activities in the area for iron and niobium production were performed from 17th to 20th century. The radiological and epidemiological impact of these former mining activities, evaluated by Stranden E., 1982, showed that workers received an annual dose equivalent of 150 mSv, obviously much higher than occupational dose limits of 20 mSv/y for radiation workers.

Similar investigations of radioactivity in high background natural radiation areas have been conducted worldwide (Malanca et al., 1993; Quindos et al., 1994; Vera Tome et al., 2002; Ramli et al., 2005; Vandenhove et al., 2006; Prasad et al., 2008). Some studies showed various pathways of radionuclides and heavy metals leaching from rocks and soil and their transportation and concentration into the water, plants and animals in different degrees (Bernhard et al., 1996; Apps et al., 1998; Vandenhove et al., 2006).

The main objective of this work was to determine the concentration of the radionuclides ^{232}Th and ^{238}U and heavy metals such as As, Pb, Cd and Cr in different Fen samples in order to obtain an overall picture on dispersion to different environmental compartments. Relation between radionuclides levels and outdoor radiation doses, together with preliminary estimation of total contamination degree due to former mining activities, were also performed.

Material and methods

The Fen Central Complex is located in Nome municipality, Telemark County in Norway. This complex has carbonatite rocks of volcanic origin, with the most abundant rock types: Søvite (calcite carbonatite), Rauhaugite (dolomite carbonatite), Rødberg (hematite-calcite-carbonatite) and Fenite (alkali-metasomatised granitic gneiss) (Barth and Ramberg, 1966). As mentioned above, intensive mining activities in these locations ended during the 1960s. After that, several recordings of elevated natural gamma radiation doses in this complex were seen, either in portable hand detectors measurements (Dahlgren, 1983; Stranden, 1982) or in helicopter measurements (NGU, 2007).

Field work was conducted in May, 2008 (Fig.1). Terrestrial gamma radiation dose rates were measured by gamma detector (Automess AD4LF type 6150), at approximately 1 m distance above the ground. External gamma dose rates for different locations were calculated as the mean values from separate measurements done at each location. Eleven sampling sites were chosen in NORM and TENORM areas and outside these areas but within Fen. Geographical coordinates of sampling locations were read and recorded with portable GPS (Germin, USA).

Soil samples were collected at seven separate locations, with different gamma radiation levels. At each sampling site, soil was collected as bulk samples from minimum five points, at depth 0-20 cm, and then mixed to combine composite samples for every location. Rock samples of different sizes (3-15 cm) were taken randomly and later identified as rock type Søvite and Rødberg, typical for Fen geology complex. At least ten separate rocks were taken at every sampling location. After identification, rocks were laboratory milled to fine powder, homogenized and further decomposed for ICP-MS analysis of ^{232}Th, ^{238}U and heavy metal contents. Water samples were taken at five different locations. Water of Nordsjø Lake was sampled at four sites within the Fen public area and with different distance to area with high background radiation and at one site in Fengruve area rich in thorium bearing rocks. Physical and chemical parameters were measured *in situ* with portable pH-meter (WTW Multi 340i), previously calibrated with acid and neutral standard solutions. To study size distribution of radionuclides and heavy metals, i*n situ* size filtration with 0.45 µm membrane filter and ultrafiltration with 10 kDa hollow-fiber (Milipore) filter were conducted on Nordsjø lake samples from area with high background radiation. This was done to study behavior, mobility and possible impact on environmental compartments (Salbu et al., 2000). Water on other sampling sites was taken as total samples. All samples were conserved by acidifying with concentrated HNO_3 to obtain pH approximately below 2.

Soil samples were air dried in the laboratory, at ambient temperature for several weeks. Then, they were crushed and homogenized by sieving through 2 mm sieve. Aliquots of each were oven dried (105ºC) to constant mass prior to HNO_3 acid and microwave decomposition (Milestone Inc., Ultraclave High performance reactor, Shelton, CT) and analysis of heavy metals and radionuclides.

Concentrations of radionuclides ^{232}Th, ^{238}U and heavy metals As, Pb, Cd and Cr were measured with ICP-MS analysis using a Perkin ElmerSciex Elan 6000 (Norwalk CT, USA). In order to ensure analysis accuracy and precision, internal standards were added systematically to each sample before decomposition and appropriate standard reference materials were analyzed alongside the samples. All rock and soil samples were 1 % acid solutions. Each sample was ICP-MS determined by 3 injections. Detection limits were calculated as three times of standard deviation of measured blank samples.

Results and discussion

Measurements of gamma ray radiation dose rates (Table 1) showed values ranging from 0.15 to 9.20 µGy/h for different Fen locations. These values are significantly higher than world average terrestrial dose rate of 0.059 µGy/h (UNSCEAR, 2000) and higher than gamma radiation dose rates found in similar investigations of other high NORM areas (Morales et al., 1996; Ramli et al., 2005; Prasad et al., 2008). Maximum gamma dose rate was measured at site G13, in area called Gruveåsen. These readings are related to the significant concentrations of ^{232}Th and ^{238}U found in rødberg rocks and soil samples from the same locations. High readings were also obtained at sampling locations in Fengruve area (F2, F3, F4 and F5) and in Søve area (S1). Locations Gruveåsen, Fengruve and Søvegruve (Fig.1) are previous mining sites and high values for radiation dose rates are directly consequence of TENORM. However, similar values (up till 3.24 µGy/h) were obtained for the measurements done at NORM site Rullekol, away from past mining sites and in the vicinity of houses. Other locations in Fen had lower gamma radiation dose rates measured, i.e. 0.11-0.25 µGy/h. Still, these values are approximately 2-4 times higher than world average level of 0.059 µGy/h published by

UNSCEAR (2000). Values obtained in this study are part consistent with previous measurements done in this Norwegian area (Stranden, E., 1982; Dahlgren, S., 1983; NGU 2007).

Table 1. Terrestrial gamma radiation dose rates at Fen sites.

Sampling sites	Terrestrial gamma dose rates (µGy/h), range
S1	2.09 - 8.50
F2	1.90 - 4.40
F3	3.30 - 3.70
F4	0.80 - 3.80
T1	0.15 - 0.35
F5	2.30 - 4.45
L1	0.11 - 0.34
R1	1.09 - 3.24
G11	4.11 - 5.08
G13	7.20 - 9.20
G14	3.80 - 4.50

The average concentration of ^{232}Th for rødberg rocks collected at Gruveåsen and Fengruve locations (Table 2) was 1552 mg/kg. The average concentration for ^{232}Th for søvite rock samples was found to be considerably lower, 64 mg/kg.

Table 2. Concentrations of ^{232}Th and ^{238}U in rocks from Fen area.

Rock type	^{232}Th (mg/kg)	^{238}U (mg/kg)	^{232}Th/^{238}U ratio
Rødberg	1552	6	342
Søvite	64	6	11

Results of previously reported rock samples analysis (Dahlgren 1983; Sundal and Strand 2004; NGU 2007), showed comparable concentration ranges for ^{232}Th in these rocks. Values for rødberg are much higher than typical values of 0.1-87.5 mg/kg for Norwegian bedrock (Nordic, 2000), giving the highest ^{232}Th level in Norwegian bedrock (Sundal and Strand, 2004). Uranium in rocks was present in much lower concentrations, 6.47 mg/kg and 5.53 mg/kg, for rocks rødberg and søvite, respectively. As presented in Table 2. value for ^{232}Th/^{238}U ratio for søvite rock type was 11.11 and for rødberg rock type was 342. These clearly distinguished values are reflecting the high difference in ^{232}Th concentrations and similar ^{238}U concentrations in the two different rock types.

Results of soil analysis (Table 3) showed wide ranges in radionuclides activity concentrations, 69-6098 Bq/kg and 49-128 Bq/kg, for ^{232}Th and ^{238}U, respectively. These values are obviously higher than the world average values for soil 30 Bq/kg for ^{232}Th and 35 Bq/kg for ^{238}U, given by UNSCEAR (2000).

Table 3. Activity concentrations of radionuclides and concentrations of heavy metals in soil from Fen area.

Sampling sites	^{232}Th (Bq/kg)	^{238}U (Bq/kg)	As (mg/kg)	Pb (mg/kg)	Cd (mg/kg)	Cr (mg/kg)
S1	69 ± 8	49 ± 12	4±4	47 ± 5	0.26±0.01	26±23
F3	4007 ± 1108	111 ± 37	20±5	134 ± 95	0.60 ± 0.14	33±19
F4	4563 ±93	111 ±37	17±1	121 ± 23	0.73 ±0.07	40±8
T1	1059 ±28	128 ± 4	7.1±0.6	287± 10	0.48±0.02	30.0±0.3
G11	6098 ± 1429	74 ± 62	20±6	55±7	1.88±0.59	54±14
G13	5781 ± 848	68 ± 6	20.3±0.9	65± 10	0.68 ± 0.07	66±4
G14	4843 ± 126	85 ± 5	16.7±0.2	59 ± 2	0.54 ± 0.07	89±3

The highest ^{232}Th value was found in soil in the area Gruveåsen (G11), and the lowest in the area Søvegruve (S1). The pattern of ^{232}Th distribution in soil is correlated with the abundance of rock type rødberg (with high ^{232}Th level) in Gruveåsen and Fengruve areas and with the abundance of rock type søvite (considerable lower ^{232}Th level) in area of Søvegruve. In general, soil concentration results suggest that erosion and weathering of rocks containing minerals rich in radionuclide during the time led to formation of soil layers significantly enriched in radionuclides.

To check the possibility for a multiple radiological and metal contamination in this area, soil samples were also analyzed for metals such as As, Cr, Cd and Pb. Obtained concentrations are given in Table 3. Arsenic concentrations in soil samples were higher than norm value of 8 mg/kg for non-polluted Norwegian soil (SFT, 2009). The range of Cd concentrations in soil was from 0.26 mg/kg up till 1.88 mg/kg. These values are higher than the average natural abundance of Cd in the earth's crusts, but are in ranges for soil in the vicinity of sedimentary or Fe rich rocks, 0.1-5.0 mg/kg (Cook and Marrow, 1995; Salbu and Steinnes, 1995). The average Pb concentration in samples of soil taken in Fen area was 110 mg/kg. Non-disturbed Norwegian soil has the average Pb concentration of 15 mg/kg, and range 10-19 mg/kg (Berg et al., 2003), but some places in southern part of country are more exposed to Pb pollution due to long range transport of pollutants and have 10 times higher concentrations than in central part of the country (Steinnes and Ruhling, 2002). A map of Pb distribution in Norway, given by Arctic Monitoring Assessment Program (AMAP, 1998), gave an approximately level of 40-60 mg/kg for Pb in Fen, Telemark area. Cr concentrations exceeded SFT (2009) norm values in samples taken at sites G11, G13 and G14, in wooden area of Gruveåsen.

Radionuclide concentrations in water taken in the Fen area ranged from 0.038-0.187 µg/L and 0.136-4.414 µg/L for ^{232}Th and ^{238}U, respectively. These numbers exceed values given by UNSCEAR (2000) for world average concentration in water that contribute to exposure from natural sources (0.012 and 0.083 µg/L for ^{232}Th and ^{238}U, respectively). However, values for both radionuclides are still far below the significant contamination levels in the guideline for drinking water (WHO, 2003). Previously, Stranden (1982) also reported no radiation dose contribution for Fen people, regarding Nordsjø lake water. Comparison of ^{232}Th and ^{238}U levels showed several times lower levels of dissolved thorium species in all water samples. This is in agreement with theory and generally low solubility of thorium due to high affinity for sedimentation and particle formation. Results obtained for heavy metals As, Pb, Cd and Cr were below the limit levels for non-polluted water (SFT, 2009).

Size fractionation of ^{232}Th in Nordsjølake samples gave results (Fig.3) as follows: 43.75% were present in particulate fraction, 48.44% as colloids and 7.81% as low molecular mass species. Regarding typical chemical behavior of ^{232}Th, we expected considerable higher percentage in particulate phase. However, more than 50% of ^{232}Th was present in form of mobilizable colloidal and low molecular mass species. Thus, colloidal transportation is expected and might induce further distribution and bioaccumulation in living species of this water system.

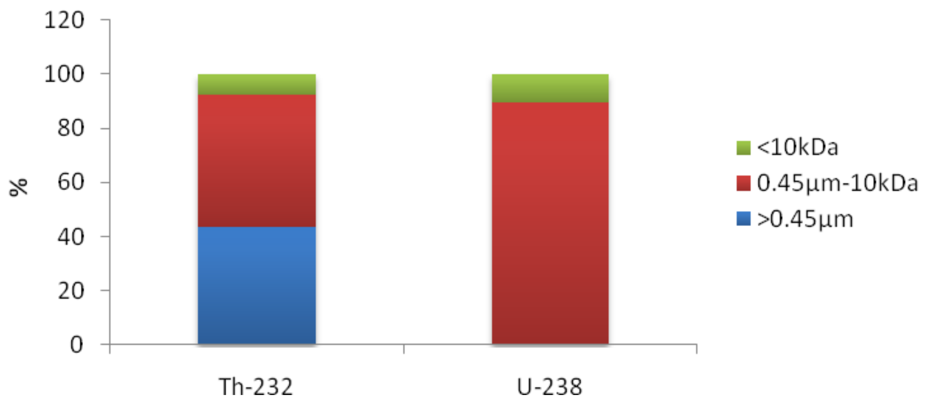

Fig. 2. Size fractionation of ^{232}Th and ^{238}U radionuclides in water samples from lake Nordsjø.

Analysis of uranium showed that ^{238}U was present mainly as colloids (90%) (Fig.2). On the basis of these results, ^{238}U is expected to be mobile, more soluble and could be subject of active uptake by aquatic biota in this water. Values for all measured metals were far below the levels that are expected to pose detectable effects on water living biota (SFT, 2009).

Conclusions

Measurements of gamma radiation dose rates due to NORM and TENORM and investigation of soil, rocks and water concentrations of radionuclides and metals were done in Fen area, Ulefoss, Norway. These activities were conducted as the first stage of environmental impact assessment of this specific area.

Obtained values for exposure dose rates ranged from 0.15 to 9.20 µGy/h. These values clearly exceed world average terrestrial dose rate of 0.059 µGy/h (UNSCEAR, 2000) and highly reflect the presence of radionuclides bearing minerals in volcanic rocks of this terrain. Two typical rock types rødberg and søvite analysis showed different levels of ^{232}Th and ^{238}U, but the results were consistent with previously reported studies (Dahlgren 1983., Sundal and Strand, 2004; NGU, 2007). The high concentrations of ^{232}Th in rødberg place this rock as the highest in ^{232}Th of Norwegian bedrocks.

Soil ^{232}Th and ^{238}U concentrations were found to be much higher than the Norwegian average soil values and obviously highly correlated with the presence of thorium and uranium rich rock types. Inhomogeneous distribution of radiation was found in the whole area. Radionuclides and heavy metals were particularly high in the vicinity of former iron mining sites. Analyzed water samples showed no contamination, neither with radionuclides nor with heavy metals, despite the high levels in surrounding media. It implicates that there are minor leaching or other transportation from these sites. Still, despite the low total levels, results of size fractionation, i.e., presence of all metals and high percentage of both radionuclides in the biologically most important - low molecular mass fraction, could be reasonable basis for investigation of possible accumulation in fish living in the lake.

Abstract

During the period 2007-2009 long term indoor concentrations of thoron gas and airborne thoron progeny were measured using passive detectors in 205 dwellings in Ireland. Passive alpha track detectors of different types were used to make these measurements in the indoor air over a typical exposure period of at least three months. Thoron concentrations were measured using Raduet detectors supplied by Radosys, Budapest while thoron progeny concentrations were measured using passive detectors designed by the National Institute of Radiological Sciences (NIRS), Chiba, Japan. Radon concentrations were also measured in these dwellings using the standard alpha track detectors employed by the Radiological Protection Institute of Ireland (RPII). The main results obtained are given below. It should be noted that these results are based on the actual measurements made and are not seasonally adjusted. The estimated annual doses for thoron progeny (ThP) and radon (Rn) were calculated using dose conversion factors (DCF). The DCF_{ThP} used was based on the dosimetry models of Kendall and Phipps (2007) and of Ishikawa et al (2007). Exposure to indoor air containing thoron decay products at a concentration of 1 Bq/m^3 EETC (Equilibrium Equivalent Thoron Concentration) was estimated to result in an annual effective dose of 0.75 mSv. For radon a DCF_{Rn} of 1 mSv/year for indoor exposure under standard conditions to 40 Bq/m^3 was used.

Thoron gas activity concentrations ranged from < 1 to 174 Bq/m^3 with an arithmetic mean of 22 Bq/m^3. Radon gas concentrations ranged from 4 to 767 Bq/m^3 with an arithmetic mean of 75 Bq/m^3. The corresponding estimated annual doses are 0.1 (min), 19.2 (max) and 1.9 (arith.mean) mSv/year .Thoron progeny ranged from < 0.05 to 3.8 Bq/m^3 (EETC) with an arithmetic mean of 0.47 Bq/m^3 (EETC). The corresponding estimated annual doses are 2.9 (max) and 0.35 (mean) mSv/year.

It is of interest to note that in 14 of the 205 dwellings investigated the estimated annual dose from thoron progeny exceeded that from radon.

Introduction

There are over 30 known isotopic forms of radon. Most of these have very short half-lives in comparison to radon-222. Due to their very short half-lives they cannot migrate far from their origins and consequently are of no radiological health significance. One of them, however, is radon-220 (usually called thoron) and despite its short half-life (55.6 sec) may be present in indoor air at a sufficiently high concentration to be of some radiological significance. Thoron is a member of the thorium-232 decay series. A simplified version of the thoron decay scheme is shown in Figure 1. Henceforth in this paper, for convenience and in keeping with common practice, radon-222 will be referred to as "radon" and radon-220 will be referred to as "thoron". Unlike radon,which can enter a dwelling from the ground underneath it, indoor thoron due to its short half-life almost exclusively comes from the materials of the internal surfaces of rooms in dwellings.On a global basis ,in comparison with radon, information on the concentrations of thoron gas and in particular of its airborne progeny in dwellings is not very extensive (UNSCEAR 2000). Many of the values quoted in the literature are as a result of short-term or grab sampling and therefore are not suitable for estimating long term exposures in dwellings. For this and other reasons in most countries it has been difficult to estimate the long–term radiation dose and risk from indoor thoron and its progeny. In this paper exposure to indoor air containing thoron progeny at a concentration of 1 Bq/m^3 EETC (Equilibrium Equivalent Thoron Concentration) is estimated to result in an annual effective dose of 0.75 mSv. This dose conversion factor (DCF_{ThP}) is based on the dosimetry models of Kendall and Phipps (2007) and of Ishikawa et al (2007). For radon a DCF_{Rn} of 1 mSv/year for indoor exposure under standard conditions to 40 Bq/m^3 was used in this work. It should be noted that this DCF_{Rn} is presently under review and it is anticipated that a dose conversion factor of 1 mSv/year resulting from residential exposure to 30 Bq/m^3 will become the norm in many EU countries. This dose conversion factor is already being used by the World Health Organisation (WHO 2009).

Study outline

A pilot study of 40 Irish dwellings was carried out by University College Dublin in 2005 using passive CR-39 based detectors which give long term measurements of thoron and its progeny. This study found,for these dwellings, that the mean value of indoor thoron gas was 30 Bq/m^3 and the mean value of airborne thoron decay products was approx.1 Bq/m^3 (EETC) (Ní Choncubhair *et al*. 2008.) On the basis of the dosimetric modelling of Kendall and Phipps (2007) and Ishikawa et al (2007) the mean annual dose from thoron progeny in these dwellings is estimated to be 0.75 mSv/year. This is about 38 % of the estimated 2 mSv/year radiation dose that would be expected to be received by occupants of a typical Irish dwelling due to exposure to radon. Even though this pilot study cannot in any way be considered as representative of the national housing stock nevertheless it indicated that doses from thoron decay products are not always negligible and should not be ignored. It was therefore decided to carry out a larger survey of the concentrations of indoor thoron gas and its airborne decay products in Irish dwellings. This survey was carried out during the period 2007-2009 and was a collaboration between the Radiological Protection Institute of Ireland (RPII) and the National Institute of Radiological Sciences (NIRS), Chiba, Japan.

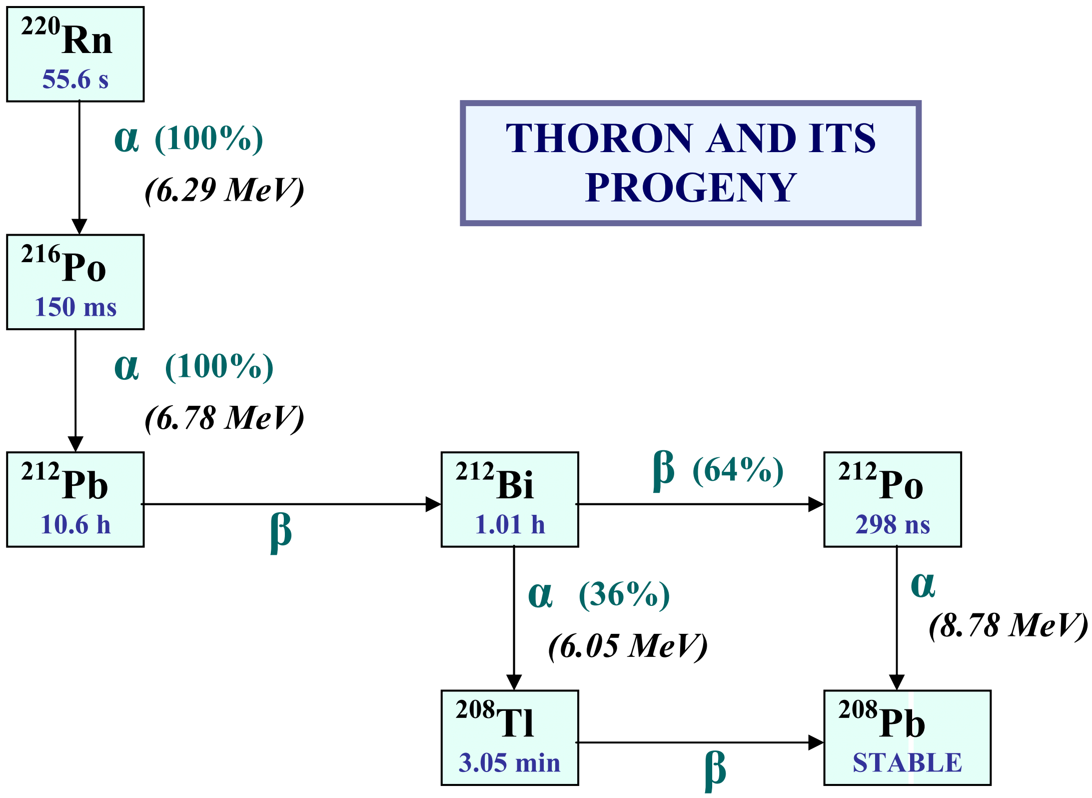

Figure 1. Thoron decay scheme.

The survey was conducted in two phases. Phase 1 comprised households which had participated in the past in the RPII national radon survey in the period 1992-1997 (Fennell et al.,2002) and which were in or around the major population centers of Dublin, Cork and Limerick. Phase 2 households were selected to increase the proportion of new houses in the survey and were comprised mainly of the houses of RPII staff and their families. Phase 2 participants were not part of the national radon survey but did have a previous radon measurement carried out in their home. As explained below the packages of detectors sent to the participating households gave a measurement of radon as well as of thoron and its progeny. Therefore, in addition to thoron/thoron decay product measurements the opportunity was also taken to make comparisons between the present radon concentrations in these dwellings and those in the past. Invitations to participate in the project were sent by post. In phase 1 a total of 365 invitations were issued of which 200 agreed to participate. Detectors for these households were issued in December 2007. During phase 2 detectors were issued to 40 households in June 2008. Of the 240 dwellings surveyed 82 were in or around Dublin, 82 in or around Cork and 69 in or around Limerick. Pre-paid post envelopes for return of detectors were supplied to participating households. A questionnaire dealing with house and household characteristics accompanied the detectors. Detectors were exposed in the dwellings for a minimum of three months in order to obtain long-term average measurements of thoron, thoron progeny and radon.

Satisfactory measurements of thoron and its progeny as well as of radon were completed in a total of 205 dwellings in Ireland. Due to the manner in which they were chosen the 205 dwellings investigated cannot be taken to be an unbiased or fully representative sample of the national housing stock. Nevertheless this number of dwellings,while small in absolute terms, should be seen in the context of the population of the Republic of Ireland which is approximately 4.5 million.

In this survey the long term measurements of thoron and its progeny and also of radon were made using three types of passive CR-39 alpha track detectors. Thoron gas concentrations were measured using Raduet detectors supplied and processed by Radosys (Budapest). The Raduet thoron detector,derived from an original design of NIRS, consists of two small diffusion chambers one of which is designed to admit both thoron gas and radon gas while the other admits only radon gas (Tokonami et al (2005)). The difference in the CR-39 alpha track density between the two diffusion chambers yields the mean thoron gas concentration over the exposure period at the measurement point in a dwelling. Airborne concentrations of the thoron decay product lead-212 were determined using a passive detector designed and developed by NIRS (Zhou and Iida,2000). In this detector CR-39 is covered with a Mylar film equivalent to an air thickness of about 7 cm so that only the 8.78 MeV alpha particles from polonium-212 can penetrate the Mylar film and are recorded by the CR-39. All other alpha particles from both the thoron and radon decay series , up to and including the 7.68 MeV alpha from polonium-214, have insufficient energy to penetrate the Mylar and are thus not recorded by the CR-39. Thus this detector type is sensitive only to polonium-212 even in the presence of radon and its progeny in the air. On the basis of laboratory calibrations at NIRS the concentration in the air of polonium-212 is determined .This in turn yields the concentration of lead-212 from which the airborne thoron progeny concentration can be expressed as Bq/m^3 EETC (Zhou and Iida (2000)). Radon gas concentration measurements were obtained by using the black SSI type diffusion detectors normally used by the RPII in its various radon surveys.In addition independent measurements of radon were obtained from the Raduet detectors.

As shown in Figure 2 detectors were mounted on a specially designed bar-coded plastic frame which could be easily hung on walls. For each dwelling two such detector frames were supplied. Householders were instructed to mount one of these in the livingroom and the other in the principal bedroom on a wall or other suitable surface. In Figure 2 the thoron/radon Raduet detectors are the two black detectors mounted at the bottom of the frame The NIRS thoron decay product detector is the square metal object mounted in the centre of the frame. The black detector at the top of the frame is the RPII detector.

Figure 2. Typical deployment of detectors in a dwelling.

Results and discussion

In this project thoron,thoron decay products and radon were measured in a total of 205 Irish dwellings. The results obtained are summarized in Table 1 and Table 2.

Table 1.

Thoron Concentration. Bq/m^3		Thoron Decay Products Concentration. Bq/m^3 (EETC)		Estimated Annual Effective Doses from Thoron Decay Products (mSv/year)	
Arith Mean	Maximum	Arith Mean	Maximum	Arith Mean	Maximum
22	174	0.47	3.8	0.35	2.9

Table 2.

Radon Concentration. Bq/m^3		Estimated Annual Effective Doses from Radon Decay Products (mSv/year)	
Arith Mean	Maximum	Arith Mean	Maximum
75	767	1.9	19.2

There are a number of observations that can be made regarding the estimated doses from thoron and radon progeny in the 205 investigated dwellings.

Tables1 and 2 clearly show that ,as not unexpected, in absolute terms the doses from radon and its progeny are much greater than those from thoron and its progeny. It is interesting to note,however, that in 14 or 7% of the dwellings the estimated doses from thoron progeny were greater than those from radon and its progeny.

The total per caput radiation dose in Ireland has most recently been estimated to be 3.95 mSv/year (Colgan *et al 2008)*. This includes an estimated contribution of 0.28 mSv/year from thoron decay products based on the 2005 pilot study of 40 dwellings (Ní Choncubhair *et al*. 2008.) If the measured data from the present study of 205 dwellings given in Table 1 were nationally representative the estimated mean dose of 0.35 mSv /year from thoron decay products would bring the total per caput annual dose to 4.02 mSv. The contribution from thoron progeny would then be about 9% of this total. It should be emphasized that this is a preliminary estimation and is subject to further review but does indicate that thoron derived doses are not always negligible.

Radiation from geological samples in museums and showrooms

Janzekovic, Helena; Krizman, Milko
Slovenian Nuclear Safety Administration, Zelezna cesta 16, Ljubljana, SLOVENIA

Abstract

In the last two decades a considerable attention of the radiation safety community is paid to exposures due to natural radioactive materials based on fact that doses when handling such materials can be considerable. In general, the doses are mainly a result of inhalation of radon decay products. In order to identify all practices related to radiation sources, the Slovenian Nuclear Safety Administration (SNSA) as a regulatory authority preformed an extensive campaign of inspections in museums, research institutions, educational institutions and companies handling geological samples. Many radioactive items, mainly radioactive minerals and ores were identified. In some cases the dose rates at the contact of a specimen were few orders of magnitude higher than a natural background and elevated radon concentration was measured in rooms where specimens were collected. In general, users were not aware of risks associated with handling and storing such specimens. As a result of SNSA campaign radiation safety measures were implemented.

Countries use very different approaches regarding radioactive specimens in collections e.g. uranium and thorium minerals, radioactive fossils, petrified wood. No harmonisation on the international level exists regarding handling radioactive specimens in state and private collections resulting in difficulties in posing effective radiation protection control over such specimens.

Introduction

In the nature approximately about 340 nuclides can be found and among them around 70 are radioactive (Eisenbud 1997). Usually they are classified regarding their origin, i.e. primordial radioisotopes (e.g. ^{40}K, ^{87}Rb, ^{238}U, ^{232}Th), secondary radioisotopes and cosmogenic radioisotopes. Primordial radioisotopes have half-lives sufficiently long that they survived since their creation, i.e. comparable to the age of the universe. The secondary radioisotopes are the result of the decay of primordial radioisotopes while the cosmogenic radioisotopes are the result of the continuous bombardment of stable nuclei by cosmic rays (Holmes-Siedler 2006). In addition, the military activities and operation of nuclear installations affected the concentrations of some isotopes in the Earth (UNSCEAR 2000).

In the last two decades the international radiation safety communities e.g. IAEA, EC (IAEA 2003, EC 1999, EC 2002) paid a considerable attention to naturally occurring radioactive materials (NORM) as defined for example in ICRP publications (ICRP 2007) or to technologically processed materials and existence of technologically enhanced naturally occurring radioactive materials (TENORM). Exposures of workers handling such materials can be very high, in some cases even substantially higher than occupational exposures of workers dealing with the licensed radiation sources. Being aware of that, the radiation safety community has published first safety standards related to NORM e.g. given in (IAEA 2004). The natural radioactive materials are mainly used in industry with the highest radioactivity levels in uranium mining and lower levels in phosphate processing, oil and gas industry etc. The working conditions in industry are a subject to a control not only due to the exposure to the radiation but in many cases the good general safety practice to handle materials is enough also in order to provide sufficient radiation protection. For example, a use of a mask when handling dust materials can provide at specific circumstances a sufficient protection against internal exposure.

Natural radioactive materials are also quite frequently present in research laboratories and educational institutions. For example, the geological faculties usually have a collection of samples. Among more than 4000 minerals which are known today, some are highly radioactive e.g. uraninite, pitchblende, brannerite, coffinite or thorite. Even more, radioactive minerals are often present in museums and showrooms of minerals causing exposure of workers and the public. Private collectors of minerals very often handle natural radioactive materials. In addition, geological institutes usually keep geological samples during research projects which might be radioactive e.g. radioactive minerals or sands. Very often even after finishing research projects they keep such materials in their storages, which therefore can contain quite a lot of radioactive samples.

The radioactive samples are not only in a form of ores, minerals or sand, sometimes they are in form of petrified samples or even radioactive fossils. Such samples are for example handled outside geological departments of natural museums or faculties for natural sciences. Furthermore, radioactive samples can be a part of collections for a long period without noticing that they require special safety attention. They can be a part of private or institutional donations and they do not necessary have any connection to samples taken from local area, e.g. radioactive samples can be brought from very distant areas. The collectors from states with known areas of radioactive fossils or uranium mines could have higher probability to keep radioactive samples in museums, showrooms, storages of geological institutions and elsewhere where such samples were collected.

The persons handling such materials are very often not aware about the radiation risks they are exposed to when handling or storing such materials. Especially, when the above mentioned radioactive geological samples are not handled due to theirs characteristics related to radioactivity, users of such samples are not aware that they are actually handling radioactive materials and do not pay any attention to safety precautions.

Identification of radioactive samples

In order to establish the safety regime in institutions and other sites where radioactive geological samples are handled the identification of radioactive samples is necessary. A detailed analysis should follow regarding the main principles of radiation protection, namely justification, optimisation and dose limitation. According to the experiences radioactive samples are very often handled without basic knowledge of a justification principle and without any basic knowledge of safety measures. When the owners are faced radiation protection issues they often decide to reduce the number of exhibited samples. In such cases waste management issues also occur. Once the identification of samples is done the assessment of public and occupational doses when handling radioactive geological samples should be prepared and safety measures put in place.

The extensive campaign of identification conducted by the inspection of the Slovenian Nuclear Safety Administration in Slovenia, (SNSA, (http://www.ursjv.gov.si/en/), started a few years ago and the preliminary results of the campaign were published elsewhere (Janzekovic 2008). The SNSA is the responsible authority for control of radiation sources outside medicine and veterinary medicine. The campaign mainly focused on institutions which were also related to former uranium mine in Slovenia, the Zirovski vrh uranium mine. In a period 2007-2010 the SNSA identified many radioactive items in educational and research institutions, dealing with geological samples. The samples containing uranium and thorium can have different forms e.g. ores, minerals and petrified samples. The fossil of a mastodon tusk with elevated dose rate level at the contact was identified for instance and the analysis of its radioactivity is underway. Some samples inspected during the campaign are shown in Figure 1. The figures show a small portable radiation monitor named the radiation pager. The indication "9" shown on the pager indicates that the actual photon dose rate is above 38 μSv/h and the indication "4" indicates that the actual photon dose rate is above 12 μSv/h.

Fig. 1. Identification of elevated dose rates due to enhanced radioactivity of minerals (left, 2007) and a mastodon tusk (right, 2010).

The process of searching radioactive geological samples is similar to the process of detecting and finding other orphan sources described elsewhere (Janzekovic 2006). A well kept documentation regarding the origin of samples can facilitate the identification of radioactive material among usually a large number of non radioactive samples. The detection of photons originating from radioactive material was performed by detection of external radiation using instruments like hand held gamma spectrometry unit Fieldspec shown in Figure 2, already mentioned radiation pager and even contamination monitor as a very sensitive instrument. It should be noted that in many cases inspection identified higher dose rate at the lower part of the showcases where actually radioactive minerals were stored and were not exhibited. In addition, the staff of the institutions frequently stored radioactive items in their office, frequently in a very vicinity of their own working place.

Fig. 2. Measurements of the photon dose rate of the geological specimen using Fielspec and a use of a radiation pager for identification of elevated dose rates in 2007.

The detected photon dose rates at the contact with samples could be a few orders of magnitude above the natural background and no provisions to avoid internal exposure are usually in place. Besides the presence of uranium and thorium and theirs daughters, elevated levels of ^{40}K can be present in some samples e.g. in coal samples.

The geological samples with enhanced radioactivity were stored in collections, laboratories, offices, halls and storages. Very seldom only one radioactive sample is present at a particular site and usually few tens of them were collected or exhibited together. The shapes of specimens are very different as well as their homogeneity. The shielding of radioactive object by other objects can be a considerable problem in order to identify radioactive geological samples. Slightly elevated levels of radiation at some distances from the showcases can indicated the presence of radioactive samples with high radioactivity.

After the inspections the majority of samples were carefully investigated by qualified experts while the investigation of others is still underway. Because of a huge amount of items, namely few hundreds, the identification of radioactive specimens, e.g. uraninite minerals specimens from local uranium mine and the worldwide uranium mines, was very difficult. It was based on the exemption levels valid for ^{238}U and ^{232}Th in secular equilibrium given in EU directive (EC 1996) which are given in Table 1. The qualified expert developed simplified identification methodology by using data on measured dose rate, mass of an object and conversion factor between photon dose rate and activity concentration in order to compare the estimated activity concentration and appropriate exemption level. Details are given in (Stepisnik 2007). According to data from this reference less than 5 % of potentially radioactive samples identified at inspections in 2007 were later not identified as radioactive specimens.

Table 1. Exemption levels for ^{238}U an ^{232}Th in secular equilibrium taken from (EC 1996).

Series	Exemption levels	
$^{238}U_{sec}$	1 kBq/kg	1kBq
$^{232}Th_{sec}$	1 kBq/kg	1kBq

As reported in (UNSCEAR 2000) the global average values of ^{238}U and ^{232}Th in soil are about 30-50 Bq/kg. In specific soil and rocks the concentration can be some orders of magnitude higher. While processing natural radioactive material in secular equilibrium some elements are usually extracted and no secular equilibrium is present any more.

The enhanced external dose rate due to presence of radioactive geological specimen was used as an indicator for presence of enhanced radioactivity in specimens during inspections. From radiation safety point of view the presence of radon and corresponding dose to inhalation should be controlled. The staff, e.g. guardians of showrooms are present actually whole working day in showrooms. The preliminary results of measurement radon concentration in showrooms with mineral collections and in a storage with radioactive samples showed that the maximum ^{222}Rn concentration exceeded 1000 Bq/m^3 in a room with a mineral collection and reach about 1800 Bq/m^3 in a storage in a basement. Additional measurements are necessary in order to investigate the actually concentrations. The concentrations were measured in springtime and could be even higher in winter. The concentrations should be at least compared to concentrations recommended by the EC from (EC 1990), the IAEA from (IAEA 1996) and WHO levels published in (WHO 2009) and given in Table 2. It shows that the reference level for workplaces given by the IAEA is lower than measured concentrations. It should be taken into account that geological radioactive specimens are sometimes exhibited in numerous private collections mostly in private houses. As a result the reference levels for the members of the public should be applied in such cases.

Table 2. EC, IAEA and WHO recommendations related to reference levels for consideration of remedial actions, details are given in (EC 1990), (IAEA 1996) and (WHO 2009).

Exhibition site	Reference	Reference levels of radon indoor concentration
Public museums (workers)	Occupational exposure (IAEA 1996)	1000 Bq/m^3
Private collections (members of the public)	Existing buildings (EC 1990)	400 Bq/m^3
	Future constructions (EC 1990)	200 Bq/m^3
	Buildings (WHO 2009)	100 Bq/m^3
	Buildings in special circumstances (WHO 2009)	300 Bq/m^3

After the campaign of the SNSA remedial actions took place, e.g. around altogether 100 kg of radioactive materials were transported from an old storage of geological samples to the Storage for radioactive waste and a few hundreds of kilograms of radioactive waste originated from the educational institution were stored in the Storage for radioactive waste. The specimens which are still in use at other sites, e.g. geological samples used at a faculty, are subjects of regulatory control.

After the SNSA campaign the actual exposures of workers, students, collectors and visitors were efficiently lowered because the majority of sources were put in suitable storages and many safety precautions were implemented.

Radiation safety and radioactive geological specimens

Many radiation safety requirements during handling and storing the samples were ignored because they were not identified as radioactive materials or sources. The risk associated with radioactive geological samples originates manly from:

- external exposure due to decay of ^{238}U and ^{232}Th series
- internal exposure due to presence of long-lived radionuclides in a sample and radon with its short-lived decay products.

Both components should be actually assessed prior the handling, preparing and exhibition of geological samples. The assessment should be done for all lifetime phases of a use of radioactive samples i.e. from “its cradle to its grave” in order to avoid unjustified exposure of workers, including guardians of showrooms, researchers, students, visitors or private collectors. While prevention from external exposure can be achieved without huge expenses, the presence of accumulation of ^{222}Rn can be an important and even major issue. In order to safely handle radioactive geological samples many measures can be applied, either administrative or physical, e.g.:

- exhibit replica specimens in museum collections and limit handling radioactive specimens as much as possible
- ventilate a room before or during, as appropriate, when entering storages with radioactive materials
- use protective glass as for example lead glass to prevent exposure from beta and gamma radiation
- use gloves and other personal protective belongings when handling radioactive samples
- encapsulate specimens in showrooms in order to prevent contamination and radon dispersion
- control the contamination when handling specimens which crumble
- use separate and suitable storages for radioactive geological samples
- define the specific area in laboratory or showrooms where radioactive samples are handled, make the dose mapping, assess the doses and control the area
- put radioactive samples at remote area also if they are present in private collections
- control the donation of specimens from radiological point of view
- prepare the waste management plan
- establish written working procedures and maintain the records of samples
- inform students, researchers, guardians of showrooms and other stakeholders about working procedures and importance of following established rules.

Conclusions

Regarding the fact that external radiation and internal exposure due to radon are mostly neglected when handling radioactive geological samples, the need for action provided by a regulator is unavoidable in order to keep the system of radiation protection effective. The countries use very different approaches when handling radioactive geological and other specimens in museum and showrooms. No international guidelines are given in order to harmonise the approaches.

Due to a fact that radioactive samples can be easily transferred from one state to another, harmonisation of national legislations can be very useful. In general, four approaches are identified.

a. The authorisation of practice is required and radioactive minerals and other geological radioactive specimens are controlled as all radioactive sources, according to requirement of the (EC 1996). Such approach requires substantial work of qualified experts and regulatory authorities in order to implement the requirements.

b. The practice is registered under specific conditions e.g. handling of only ten radioactive geological specimens while authorisation is required, for example, for more than ten specimens.

c. The handling of radioactive specimens in a workshop is an authorised practice and a full scope of authorisation is required. The exhibition of a single specimen requires less stringent requirements e.g. a dose rate at a place of a visitor should be less than 20 µSv/h because the exposure of a visitor is a "transient one" e.g. a person will receive only a small dose due to staying a short time at that place.

d. The practice is exempted from the legislation.

Approaches b and c are based on a graded approach and try to balance the burden posed by the full scope authorisation and neglecting of radiation safety.

In general, no international harmonisation is achieved in the area of natural radioactive specimens. While some countries pose full scope control as for any other radioactive material, some countries use graded approach. In addition, in some countries no precaution principles are applied when handling radioactive samples e. g. fossils. In view of a basic radiation protection principles and taking into account that in general collecting such specimens does not require huge effort it would be beneficial to prepare specific international standards or guidelines in this area. In addition, controlling numerous private collectors is even more challenging issue.

Natural radiation background time series from gamma detector stations in Iceland

Halldórsson, Óskar; Sigurðsson, Þorgeir; Guðnason, Kjartan
Icelandic Radiation Safety Authority (IRSA), ICELAND

Abstract

We present here for the first time data from four continuously monitoring gamma detector stations in Iceland along with basic analysis. The results from all four stations show an average dose rate of 44-49 nSv/hr, and standard deviation around 5 nSv/hr (10 minute sampling cycle), with a distribution consistent with a Gaussian one.

Introduction

In 2005, the Icelandic Radiation Safety Authority (IRSA) began operating two gamma monitoring stations. In 2007, two more were added so now there is one station in each of the island's four corners, all near sea level (see Figure 1). The stations are maintained in cooperation with the Icelandic Met Office. Each station also collects pressure, temperature, precipitation and wind data for its location. The gamma dose rate and accumulated rainfall data is continuously relayed to a web server and can be monitored by visiting IRSA's web page here[1]. The data is monitored for extreme values and sudden changes.

Iceland's rock foundation contains relatively little uranium and its daughter products. Hence the environmental radioactivity there is rather low. Dust and radon gas carried by global weather systems from the continents on either side of the Atlantic and brought to the ground with precipitation can have a measurable effect on the background radiation signal.

This is the first publication of the collected data, but these stations are being added to the European Radiological Data Exchange Platform (EURDEP) real time gamma monitoring station network to ease access to the data.

[1] http://www.gr.is/gammastodvar/

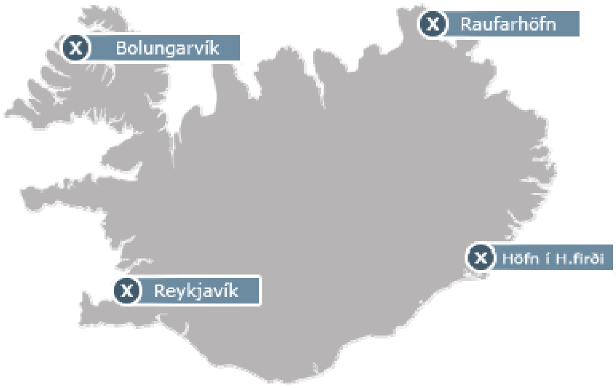

Fig. 1. Locations of IRSA's four gamma monitoring stations. Gamma background, rainfall, temperature, pressure, windspeed and wind direction is collected at these sites.

Material and methods

The gamma monitoring stations are equipped with a GammaTracer XL detectors from Saphymo[2]. Their measuring range is from 10 nSv/h - 10 Sv/h and their energy dependence is +/- 40% (over the range 45keV - 2MeV). The manufacturer provides the calibration (6% calibration error), and the tubes are recalibrated at each battery replacement (every 3-5 years). The measuring cycle is set to 10 minutes, with an estimated 1-sigma measuring error of approximately 5%. The gamma tracers are set to count for 10 minutes and write out to file.

The raw gamma dose rate data were at first cleaned to remove spurious data and obviously false readings. Further gaps (of order of a month and more) in the time stream are due to periods when the GammaTracer tubes undergo battery change and recalibration at the manufacturer's facilities. Due to growing pains (possibly a mistaken calibration) for the first year of operations, the first half year of data from the Reykjavik station has a clear upwards bias and was discarded off for the rest of the analysis. Cleaning these gaps out via automated algorithms proved tricky, so the time streams were trimmed 'by eye and hand'. Between 0.2 and 20% of the total data was thus discarded, most from the Reykjavik station.

For clarity and to reduce the effect of sampling irregularities, the data was collected into bins of 24 hours, and also into bins of 7 days.

We used the statistical computing environment R for this analysis.

Results

Summary statistics

The trimmed time streams are shown in figure 2 and a summary of the statistics from the cleaned data streams is given in Table 1. The bulk of the measurements values range from 40-60 nSv/hr, with a mean ranging from 44-49 nSv/hr and a standard deviation around 5 nSv/hr for the different stations.

[2] Manufacturer's information: `http://genitron.de/products/gamma_data_xl.html`

Table 1. Summary statistics of gamma dose rate data from the four stations. Note that data from each station come from strongly overlapping but not identical periods. All numbers in units of nSv/hr.

Station ID	Min	1Q	Median/Mean	3Q	Max
Bolungarvík	26	41	44 / 44.42	47	104
Höfn í Hornafirði	31	46	50 / 50.14	53	116
Raufarhöfn	30	47	50 / 49.97	53	161
Reykjavík	31	46	49 / 49.16	52	96

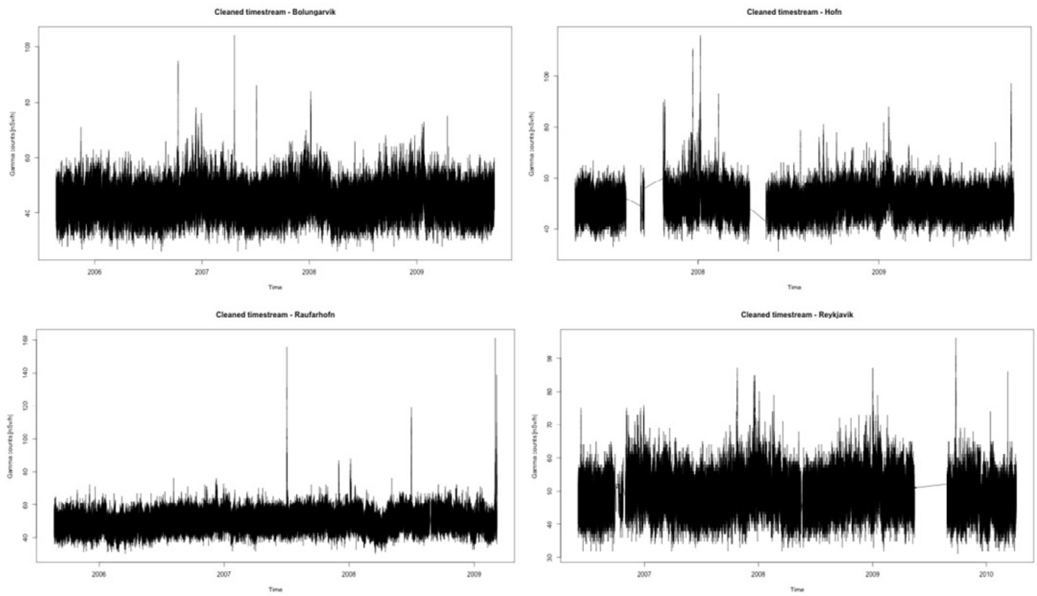

Fig. 2. Gamma dose rate time series data for the four stations, after pruning. The range can discerned, as can the larger gaps and some outlier values which were not obviously spurious.

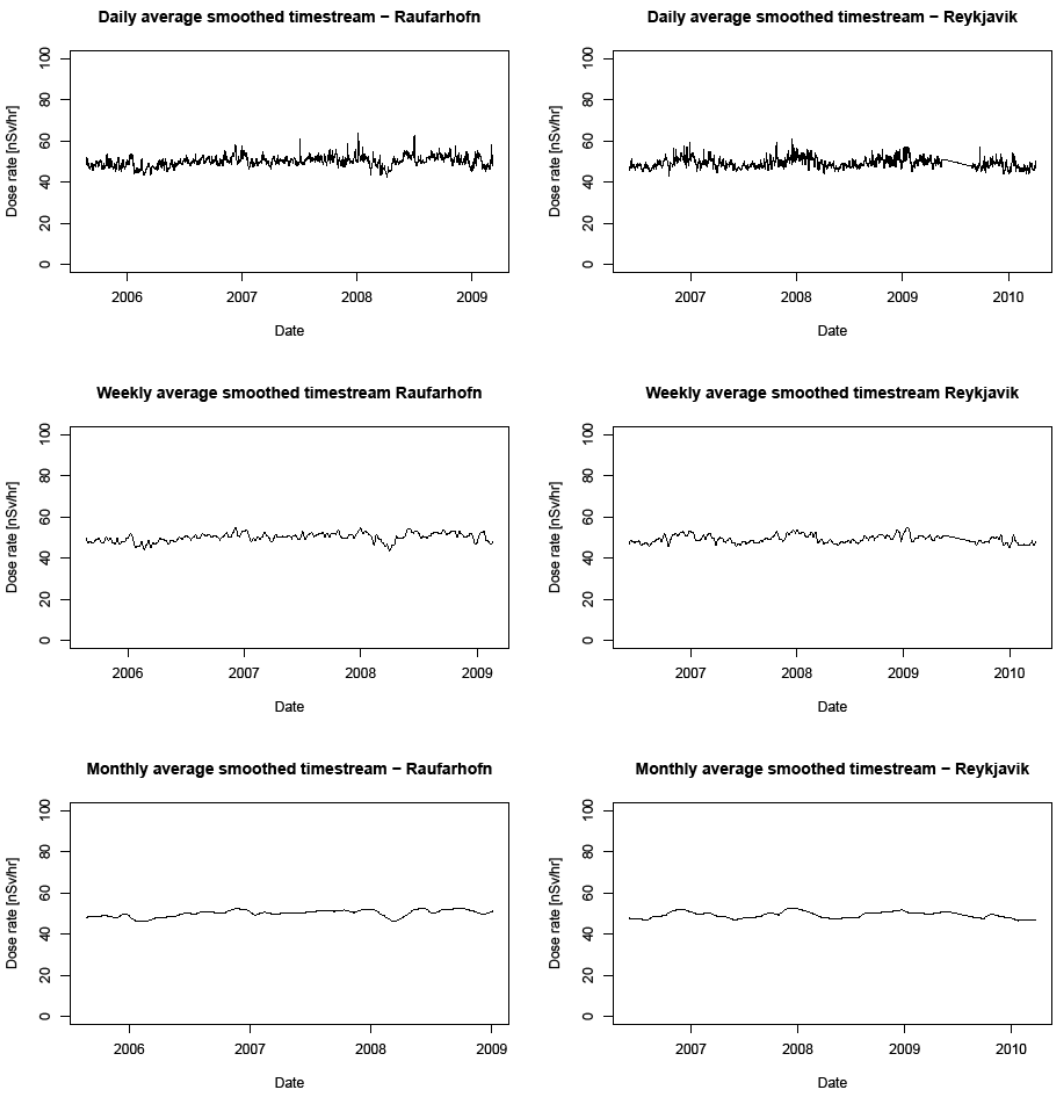

Fig. 3. 1-day, 7-day and 30-day moving average smoothing of cleaned gamma dose rate time series data for the Raufarhöfn (left) and Reykjavík (right) stations.

Dose rate distribution histograms

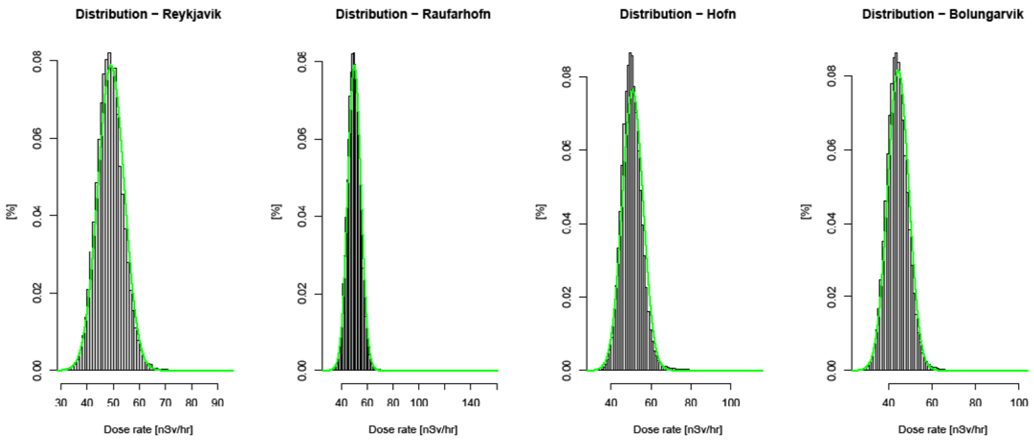

Fig. 4. Gamma dose rate distribution histograms for the four stations. The green line overlay shows a normal probability distribution with the data mean and standard deviation. The long tail towards higher values skews the distribution only slightly from a Gaussian.

Discussion & Conclusions

We see that environmental radioactivity levels are rather low and stable. The measurements are close to normally distributes, and the mild seasonality that can be spotted can be adequately explained with precipitation.

The data presented here will be made available to the network of gamma stations using the Eurdep data format. The data contain a many gaps and spurious values which need to be cleaned before a sensible analysis is made.

We thank Sigurður Emil Pálsson for his assistance and good advice.

Localities in Montenegro with elevated terrestrial radiation

Vukotic, Perko[1,4]; Svrkota, Ranko[2]; Andjelic, Tomislav[3]; Zekic, Ranko[3]; Antovic, Nevenka[4]
[1] Montenegrin Academy of Sciences and Arts, Podgorica, MONTENEGRO

[3] Centre for Ecotoxicological Investigation, Podgorica, MONTENEGRO
[4] Faculty of Natural Sciences and Mathematics, University of Montenegro, MONTENEGRO

Abstract

Research aimed to find localities in Montenegro with elevated terrestrial gamma background and recognize sources of their radiation was conducted during the period 2008-2009. For this purpose, 135 localities which have geological formations known to contain minerals with potentially high concentrations of U, Th and K, were selected throughout the country for dosimetric survey.

Knowing from earlier investigations that the average absorbed dose-rate in the air, 1 m above the ground, in Montenegro is 55 nGyh^{-1}, it was arbitrarily adopted that only localities with absorbed doses at least 50% above this average value will be considered as having relatively elevated radiation background. Field measurements have shown that 43 of the surveyed localities have such dose values. From these 43 localities, soil samples have been collected for further laboratory radiation characterization using a gamma spectrometry method. In that way, activity concentrations of ^{40}K, ^{232}Th, ^{235}U, ^{238}U, ^{226}Ra and ^{137}Cs were determined in the samples.

Among 10 sites with the highest radiation background in Montenegro (110-192 nGyh^{-1}), two sites are on andesite volcanic rock, one on fluvio-glacial sand and gravel, while the rest lie on bauxite deposits. Compared to the other known areas of high natural radiation background in the world, all these localities in Montenegro have a moderately elevated level of radiation background. Gamma spectrometry has revealed that a high content of K (up to 3341 Bqkg^{-1}) was the main source of elevated radiation at the sites on andesite rocks, and high U and Th content (up to 285 Bqkg^{-1} of ^{238}U, and up to 201 Bqkg^{-1} of ^{232}Th) at the sites on bauxite deposits.

Introduction

During the two-year period 2008-2009, within a project of the Montenegrin Academy of Sciences and Arts, a research was carried out with the aim to determine localities in Montenegro with relatively elevated terrestrial gamma background and to recognize sources of their radiation.

For planning field experiments, voluminous documentation on geology and pedology of Montenegro (Mirkovic et al. 1985; Djuretic et al. 1986) was used and analyzed. An earlier systematic investigation of terrestrial gamma radiation in Montenegro (Vukotic et al. 1997), performed 15 years ago, served as a base of this project. That investigation has shown that the average absorbed dose-rate in the air, 1 m above the ground, in Montenegro is 55 $nGyh^{-1}$ (according to the UNSCEAR 2000 Report, the average value for the other 7 countries of South-East Europe is 62 $nGyh^{-1}$). Therefore, we arbitrarily adopted that, within this project, a locality in Montenegro will be considered as having relatively elevated external radiation if the dose-rate in the air at that site is more than 50% higher than the country average, i.e. if the dose-rate is above 80 $nGyh^{-1}$. Soil samples were collected from such sites, and analyzed using a laboratory gamma spectrometry method.

In this article, only results for localities with dose-rates in the air which are at least twice higher than the country average ($D \geq 110$ $nGyh^{-1}$) are presented in detail.

Material and methods

Geological setting and selection of localities for survey

Before defining a sampling grid covering the territory of Montenegro and selection of localities where dosimetric measurements will be performed, a detailed analysis of structural-tectonic and structural-metallogenic regionalization of geological and ore formations was conducted. During this analysis, in planning field investigations, a special attention was directed towards the volcanic rocks and volcano-clastites of acid composition, Paleozoic sandstones and schists, flysh sediments, deposits of red and white bauxites, and Quaternary sediments (sands, clays, peats), for which there are indications they could contain minerals with elevated concentrations of U, Th and K. Less attention was given to carbonates (limestones, dolomites and marls) and to volcanic rocks of basic character.

Four geotectonic zones, with distinctive geological evolution during the last 200 million years, could be clearly recognized in Montenegro (Mirkovic et al. 1985), as presented in Figure 1. They are known as the Adriatic-Ionian Zone (JZ), the Budva-Cukali Zone (BZ), the High Karst Zone (VK), and the Durmitor Tectonic Unit (DTJ). The metallogenic zones in Montenegro correspond to these geotectonic units.

The coastal areas of the town of Ulcinj and partly of the towns of Tivat and Herceg Novi belong to the JZ zone, which is composed of Upper Cretaceous limestones, dolomites, dolomitic limestones; Middle Eocene foraminifer limestone and flysch; Middle and Upper Eocene flysch sediments and Middle Miocene sands, sandstones, clays and lithothamnium limestones.

The BZ zone encompasses the narrow coastal areas of the towns of Bar, Budva, Kotor and partly Tivat and Herceg Novi. Its geological structure consists of Mesozoic carbonates and eruptive rocks; Anisian and Paleogene flysch.

The central and southern parts of Montenegro belong to the VK geotectonic unit, whose geological structure is predominated by Mesozoic carbonate sediments, with occurrences of red and white bauxite formations, Triassic volcanic rocks, Paleogene flysch sediments and Quaternary sediments.

The DTJ zone encompasses the north-eastern part of Montenegro. Its terrains are composed of Paleozoic and Lower Triassic clastites; Triassic and Jurassic carbonates, with significant presence of Middle Triassic and Upper Jurassic volcanic rocks and volcano-clastites; sediments of Neogene age and Quaternary formations.

A sampling grid and a number of surveyed localities are planned for each of these four geotectonic unites individually. In total, 135 localities were selected in this manner for field investigations, 29 of them belonging to the JZ zone, 20 to the BZ, 38 to the VK zone and 48 to the DTJ, as it is presented in Figure 1. Geological, pedological and morphological characteristics of these localities were then described in detail.

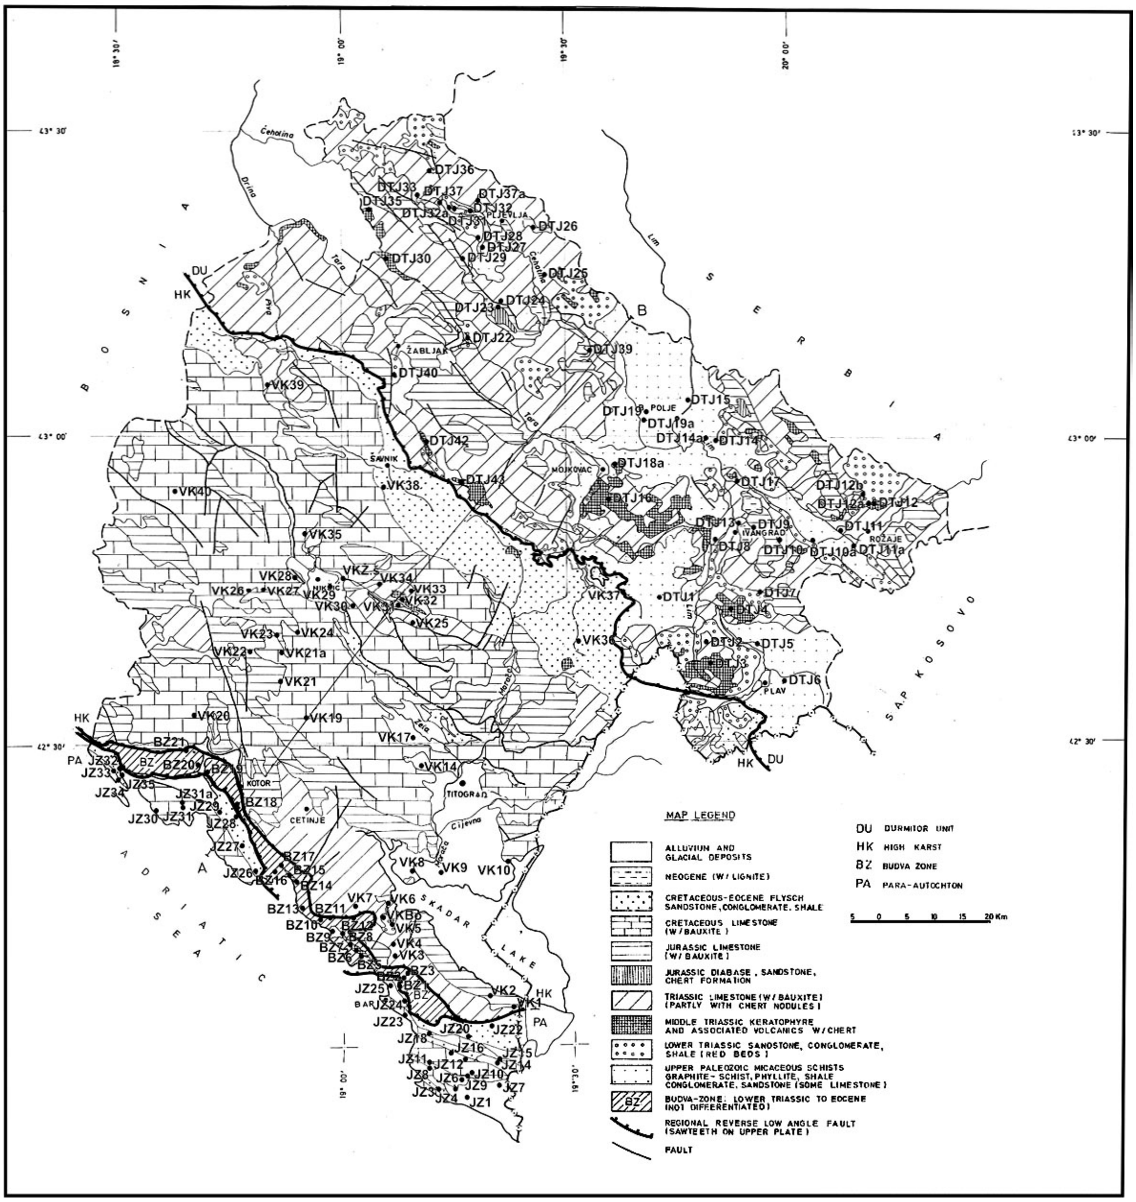

Fig. 1. Geological map of Montenegro, with indication of surveyed localities.

Dosimetry

Readouts of the gamma radiation count-rate meters CANBERRA Inspector (with NaI 1.5"x1.5" probe), VICTOREEN 190 SI (NaI 2"x2"), THERMO RadEye PRD (NaI probe) and THERMO FH 40 proportional counter were compared at several different sites under the same measuring conditions. This comparison has shown that the most consistent results were obtained with instruments VICTOREEN 190 SI and THERMO RadEye. Therefore, we decided to use the VICTOREEN 190 SI device for measurement of absorbed dose in the air, and to make control measurements, periodically, with the THERMO RadEye.

Dosimetry was then performed at all of the 135 selected localities, in the air 1m above the ground, during dry weather conditions. At each locality 10 measurements were carried out in an attempt to cover a broader area of the locality. The range of doses was then determined and the average dose-rate for the locality calculated on the basis of these 10 measurements. The GPS coordinates of the surveyed sites were also registered, as well as the geological and pedological observations.

Gamma spectrometry

Soil samples were taken, for a subsequent laboratory analysis, from all localities where an average dose-rate was found to be higher than 80 nGyh^{-1}. They were collected at the sites following a standard core sampling procedure (HASL-300). Sampled material was then ground, dried 8 hours at 100 °C, sieved through 2 mm mesh and packed into 1 liter Marinelli beakers. Analytical samples, prepared in this way, are counted 40 days later, after reaching radioactive equilibrium between ^{226}Ra and ^{222}Rn.

All these samples were analyzed using a low background gamma spectrometry system consisting of two HPGe detectors, which have 36% and 41% efficiency, 1.72 keV and 1.80 keV resolution (FWHM 1.33 MeV ^{60}Co), and 0.98 imps^{-1} and 1.22 imps^{-1} background count-rate at 40-2700 keV energy range, respectively. Activity concentrations of the following radioisotopes have been determined in the samples: ^{40}K (1460.75 keV), ^{232}Th (338.32 keV, 911.20 keV), ^{235}U (143.76 keV, 163.33 keV), ^{238}U (1001.03 keV), ^{226}Ra (295.22 keV, 351.93 keV, 609.31 keV, 1120.2 keV, 1764.4 keV), and ^{137}Cs (661.62 keV).

Results

An average dose-rate which is 50% higher than the country average was found at 43 localities: 5 in the JZ zone, 1 in the BZ, 18 in the VK, and 19 in the DTJ.

At only 10 of these localities the dose-rate is twice higher than the country average, i.e. D ≥ 110 nGyh^{-1}. These localities and characteristics of their radioactivity - dose-rates in the air and activity concentrations in the ground, are given in Table 1.

Discussion

It is evident from Table 1 that all localities with the most elevated radiation background belong to the VK zone, except one which is in the DTJ. There are none in the geotectonic zones JZ and BZ, which completely cover the coastal area of Montenegro and its hinterland.

As the highest dose-rate in the air 1 m above the ground was found to be 192 nGyh^{-1}, and while all the others are bellow 150 nGyh^{-1}, it can be concluded that these

10 localities with the highest external radiation in Montenegro, in comparison with other known areas in the world with high natural radioactivity (UNSCEAR 2000), form part of those areas with a moderately elevated radiation background.

Table 1. Dose-rates in the air and activity concentrations in the ground at the localities with the highest terrestrial background radiation in Montenegro.

Locality	D (nGy/h)	^{40}K (Bq/kg)	^{232}Th (Bq/kg)	^{235}U (Bq/kg)	^{238}U (Bq/kg)	^{226}Ra (Bq/kg)	^{137}Cs (Bq/kg)
VK/7a	192	2329 ± 75	51.2 ± 1.8	2.3 ± 0.9	64.8 ± 13.1	31.2 ± 1.1	5.6 ± 0.2
VK/20	125	27.4 ± 1.8	194 ± 6	4.1 ± 1.2	113 ± 14	73.0 ± 2.3	20.2 ± 0.6
VK/21a	131	159 ± 5	126 ± 4	7.8 ± 0.8	137 ± 13	92.3 ± 3	20.2 ± 0.7
VK/23	137	109 ± 4	129 ± 4	4.1 ± 0.7	73.5 ± 15.5	76.1 ± 2.4	< 0.43
VK/24	134	164 ± 6	169 ± 5	9.4 ± 1.3	151 ± 20	151 ± 5	5.2 ± 0.3
VK/25	149	173 ± 6	196 ± 6	2.7 ± 0.5	66.0 ± 9.5	48.8 ± 1.6	0.79 ± 0.11
VK/27	115	145 ± 5	166 ± 5	16.2 ± 1.1	285 ± 19	239 ± 7	1.40 ± 0.15
VK/33	110	109 ± 4	201 ± 6	4.9 ± 0.7	114 ± 13	66.8 ± 2.2	2.95 ± 0.17
VK/35	112	146 ± 5	198 ± 6	2.0 ± 0.5	38.0 ± 9.6	43.4 ± 1.4	4.3 ± 0.2
DTJ/42	148	3341 ± 106	71.9 ± 2.5	2.8 ± 0.7	65.0 ± 34.4	33.2 ± 1.1	0.41 ± 0.15

Two of 10 localities with the highest terrestrial radiation background in Montenegro, VK/7a (Virpazar settlement) and DTJ/42 (Savnik settlement), are characteristic with the presence of andesite volcanic rock of Middle Triassic, one (VK/20 near the town of Niksic) with fluvio-glacial gravel and sand, while the other 7 localities are above deposits of white and red bauxites (VK/25, VK/27, VK/33, VK/35 in the surroundings of Niksic, and VK/21a, VK/23, VK/24 in the surroundings of the town of Cetinje, towards Niksic).

Table 1 shows, and the same is with the other 33 samples analyzed using gamma spectrometry, that activity concentrations of ^{137}Cs are relatively low, mostly far below a level of 20 Bqkg^{-1}, which was the contamination level of the territory of Montenegro before the Chernobyl accident. This means that cesium of Chernobyl origin, after more than two decades of presence in this terrain, partly decayed and significantly migrated from surface into deeper layers of soil, and it is definitely not a cause of elevated radiation doses at the investigated 43 localities.

The average activity concentrations of ^{40}K, ^{232}Th, ^{238}U and ^{226}Ra for 7 countries of South-East Europe are 433 Bqkg^{-1}, 35 Bqkg^{-1}, 52 Bqkg^{-1} (for 4 countries), 35.5 Bqkg^{-1}, respectively (UNSCEAR 2000), while these values for Montenegro are somewhat lower: 246 Bqkg^{-1} for ^{40}K, 24 Bqkg^{-1} for ^{232}Th and 29 Bqkg^{-1} for ^{238}U (Vukotic et al. 1997). Accordingly, Table 1 reveals that the source of elevated radiation doses at the localities VK/7a and DTJ/42, which are characterized with the presence of andesite rock, is a high concentration of K (up to 3341 Bqkg^{-1}) and, in a certain measure, of U in the ground. At the 7 localities, where the bauxite is predominant, the elevated contents of Th (up to 201 Bqkg^{-1}) and U (up to 285 Bqkg^{-1} of ^{238}U) in the ground are the cause. This is in accordance with an earlier investigation of radioactivity of Montenegrin bauxites (Vukotic 1981) which has proved high concentrations of U and Th in them, and also with investigations of radon (Antovic et al. 2007; Vukotic et al. 2008) which have revealed that, in Montenegro, the highest indoor-radon level is in the town of Niksic (the main Montenegrin bauxite resources are on territory of this municipality), which is three times higher than the world average and two times higher than the average in the countries of South-East Europe.

Conclusions

The localities in Montenegro with the highest external radiation belong to those world areas with moderately elevated radiation background.

Cesium of Chernobyl origin, after more than two decades of presence in the terrains of Montenegro, partly decayed and migrated into deeper layers of soil, and is not a substantial cause of elevated radiation doses.

Identifying the presence of orphan radioactive sources in dwellings from the vicinity of former uranium mines (Portugal): a methodological approach

Pinto, Paulo; Pereira, Alcides; Neves, Luís
IMAR – Department of Earth Sciences, University of Coimbra, PORTUGAL

Abstract

Several radiological measurements were taken in two dwellings in the close vicinity of a former uranium mine (Urgeiriça, Central Portugal), in order to search for the presence of radioactive materials resulting from the mining activities. For the purpose, indoor radon concentration, gamma radiation flux, absorbed dose, radon gas flux from the floors and radon concentration measurements in crawl spaces were carried out.

The results showed important differences between the several parameters measured for both dwellings, reaching sometimes a few orders of magnitude. In one case, radioactive waste was identified in the crawl space, with the presence of these materials contributing to an excess dose of about 50 mSv/year, assuming as background the values measured in the second dwelling where no radioactive waste was found.

The methodology developed for this study proved to be a time/cost-effective procedure, capable of being applied in buildings of different construction types.

Introduction

For nearly one century, 61 uranium mines were exploited in central Portugal, generating 13 million tones of different kinds of wastes, accumulated normally in the vicinity of the exploitations. Over the years, some of these wastes were used as construction materials, usually in roads, but sometimes also in residential buildings; in this last case, the dose increase due to the exposure to ionizing radiation can be significant.

To assess the possible use of mining wastes in residential constructions, as well as the associated dose increase resulting from exposure to ionizing radiation, a methodology capable of being applied in buildings of different construction types and producing a time/cost-effective discriminating procedure was developed and tested. The methodology accounts for the challenge of discriminating between high radiation levels of purely natural origin, since the region is also radon prone, and those induced by the possible presence of radioactive materials resulting from mining activities.

Two dwellings located in the vicinity of the Urgeiriça mine (central Portugal) were used for test purposes. This was the most important uranium exploitation in Portugal, and also the place where industrial facilities were used to process ores extracted from all Portuguese mines. As a result, here can be found the largest amounts of mining wastes produced.

The uranium-bearing ore of Urgeiriça is of vein-type, striking N60ºE; it contains pitchblende and uraninite, as well as several secondary uranium minerals (Neiva, 1968). Hercynian porphyritic medium to coarse grained biotite granites are the dominant rocks observed in the area; non porphyritic two-mica granite rocks, as well as tertiary sedimentary, also occur in the region. Granites show uranium contents in the range 6 to 15 ppm, and soil gas radon measurements comprised between 29 and 593 kBq.m^{-3}, with a geometric mean of 110 kBq.m^{-3} (Neves et al. 2003). All granites are intersected by several sets of faults, with NNE to ENE dominant directions and frequently showing some degree of uranium enrichment (some dozens up to a few thousand ppm), resulting from the presence of secondary uranium phosphates (e.g. autunite, torbernite). In these faults and in their vicinity, soil gas radon measurements are frequently in the order of several hundred thousand up to a few million Bq.m^{-3}.

The referred geological setting results in a radon prone region, where indoor radon concentrations are in excess of recommended values for a large proportion of dwellings. In previous work, Neves et al. (2003) have studied 196 dwellings of the region with passive detectors, and obtained a geometric mean of 291 Bq.m^{-3} for indoor radon. Thus, distinguishing between natural or anthropogenic sources of indoor radon can be a challenge in this region.

Material and methods

In both dwellings used as a test case, a set of radiological data was collected, including the evaluation of indoor radon, gamma ray flux, absorbed dose, radon gas flux from the floors and also radon concentration in sub-slabs and crawl spaces.

Indoor radon concentrations were evaluated with CR39 detectors (n=7), exposed in several compartments for approximately 3 months; VOID labels were used to ensure that the detectors were not moved during the period of measurement (Fig. 1). After collection, the detectors were etched in a sodium-hydroxide solution during 270 minutes, at a temperature of 90ºC. The density of alpha impacts was estimated with an automated track-counting system (Radosys™), and the results converted to Bq.m^{-3} using appropriated factors, determined from the exposure of detectors in calibrated radon chambers.

Fig. 1. CR39 passive detector secured with a VOID label.

The gamma radiation flux from pavements, walls and ceiling materials of all rooms were measured using a NaI Saphymo^{TM} SPP2-NF gamma scintillation detector. The density of measurement points obtained in each room was controlled by the absorbed dose data; where this value was high, indicating the possible presence of radioactive materials, a more accurate screening was carried out, thus locating radioactive sources, its intensity and size. A total of 102 measurements were taken; results are given in cps.

The determination of the absorbed dose (external radiation) was carried out with an Exploranium™ GR130G, positioned at a height of approximately 1 meter from the floor. The values are given in µGy.h-1 and each measurement is representative of approximately 16 m2. A total of 16 measurements were performed. The purpose of this technique was to obtain an estimate of the environment gamma radiation that can immediately indicate the presence of radioactive materials, in the floor or walls of the analyzed room.

To determine radon gas flux from the floors, a radon-box was used as an accumulator, which remained sealed to the floor for 24h with the open surface downwards. The radon concentration was then measured with a Genitron-Saphymo™ AlphaGuard Pro (Fig. 2, left side) and radon gas flux from the floor/atmosphere interface were subsequently calculated. A total of 5 measurements were taken; results are given in Bq.m-2.h-1.

Radon concentration in crawl spaces was also measured with a Genitron-Saphymo™ AlphaGuard Pro, using appropriate probes to collect air samples (from 1.5m to 4.5m) through the outside vents (Fig. 2, right side). A total of 6 measurements were taken and the results are given in Bq.m^{-3}.

Fig. 2. Radon-box technique measurement with Genitron-Saphymo™ AlphaGuard Pro (left) and radon concentration measurement in a crawl space (right).

Results

Both dwellings were built in the 1950's with the same materials, by the same constructor and suffered minor refurbishment work over the years. Their plans are slightly different as a result of their size, but the construction techniques and project are basically the same.

Since both houses have wooden floor, they were built with crawl spaces beneath the floor, in some places more than 2 meters high.

Dwelling #1 is a two storey-house with 8 rooms in the ground floor and 2 rooms in the first floor. Indoor radon concentration was measured with CR39 detectors in the ground floor rooms D1 (living room), D2 (bedroom), D3 (bedroom) and D4 (dining room); results shown in table 1.

The minimum values for the absorbed dose, gamma radiation flux, radon flux from the floor and radon concentration in crawl space values were 0.20 μGy.h^{-}1 (D3), 250 cps (D7), 38.6 Bq.m^{-2}.h^{-1} (D1) and 5720 Bq.m^{-3} (D1), respectively. The highest absorbed dose, gamma radiation flux, radon flux from the floor and radon concentration in crawl space values were 0.69 μGy.h^{-}1 (D1), 1600 cps (D1), 314.7 Bq.m^{-2}.h^{-1} (D4) and 14160 Bq.m^{-3} (D6), respectively.

Table 1. Summary of the values measured for each room (mean values) in dwelling #1; n.d.-not determined; A-external radiation; B-gamma radiation flux; C-radon flux; D-radon concentration in crawl space; E-indoor radon concentration.

Room	A [μGy.h^{-1}]	B [cps]	C [Bq.m^{-2}.h^{-1}]	D [Bq.m^{-3}]	E [Bq.m^{-3}]
D1	0.60	859	38.6	7614	2948
D2	0.37	537	154.7	11341	3405
D3	0.20	310	60.1	n.d.	2371
D4	0.25	310	314.7	n.d.	2435
D6	0.43	838	n.d.	14160	n.d.
D7	0.40	650	n.d.	n.d.	n.d.
D8	0.31	453	24.2	n.d.	n.d.

Dwelling #2 is a one storey-house with 5 rooms built over a crawl space. Indoor radon concentration was measured with CR39 detectors in rooms D1 (bedroom), D2 (kitchen), and D4 (living and dining room); results are shown in table 1.

The minimum values for absorbed dose, gamma radiation flux and radon concentration in crawl space values were 0.14 μGy.h^{-}1 (D5), 160 cps (D1 and D5) and 1528 Bq.m^{-3} (D2), respectively. The highest values for absorbed dose, gamma radiation flux and radon concentration in crawl space values were 0.17 μGy.h^{-}1 (D3), 200 cps (D3) and 1629 Bq.m^{-3} (D3), respectively.

Table 2. Summary of the values measured for each room (mean values) in dwelling #2; n.d.-not determined; A-external radiation; B-gamma radiation flux; C-radon flux; D-radon concentration in crawl space; E-indoor radon concentration.

Room	A [μGy.h^{-1}]	B [cps]	C [Bq.m^{-2}.h^{-1}]	D [Bq.m^{-3}]	E [Bq.m^{-3}]
D1	0.15	175	n.d.	n.d.	351
D2	0.15	175	n.d.	1528	356
D3	0.17	188	n.d.	1629	n.d.
D4	0.15	177	n.d.	n.d.	312
D5	0.14	177	n.d.	n.d.	n.d.

Discussion

Given these results, it was possible to identify the presence of allochthonous radioactive materials in dwelling #1. These were only used in the crawl spaces beneath the floor, specially on it's dirt floor, foundation walls and footing; it's detection was possible due to the measurements of gamma radiation flux (maximum of 1600cps) and external radiation data (maximum of 0.69 μGy.h^{-}1).
