Abstract

Although much is known about the quantitative effects of exposure to ionising radiation, considerable uncertainties and divergent views remain about the health effects at low doses. Many of the European states have national research programmes in this area, however, beyond the Euratom research programme, little has been done to integrate these programmes in the past. The European High Level and Expert Group (HLEG) recently made a motion for the establishment of a Multidisciplinary European Low Dose Research Initiative (MELODI) that would create a platform for low dose research under a jointly agreed Strategic Research Agenda (www.hleg.de). The research agenda would focus on the key policy questions to be addressed and provide a road map for such research in the coming years and decades. The Letter of Intent expressing the will for the stepwise integration of low dose research activities was initially signed by five national organisations, BfS, CEA, IRSN, ISS and STUK. Since 2009, several other organisations have expressed their commitment on long-term integration of research and their interest to join MELODI. In 2010, a Network of Excellence called DoReMi was launched by the Euratom FP7 programme. DoReMi will act as an operational tool

for the development of the MELODI platform during the next six years. The joint programme for research focuses on the areas identified by the HLEG as the most promising in terms of addressing/resolving the key policy questions, namely: the shape of dose response curve for cancer, individual susceptibilities and non-cancer effects. Radiation quality, tissue sensitivities and internal exposures will be addressed as cross cutting themes within the three main research areas.

High Level and Expert Group on European Low Dose Risk Research

Both natural and man-made sources of ionising radiation contribute to human exposure and constitute a hazard for human health. The exposure of workers, and to a smaller extent of the public, to low levels of ionising radiation from nuclear energy production and other industrial uses of radiation have become an integral part of industrialised society. Radiation protection standards rely on current knowledge of the risks from ionising radiation exposure. Any over-, or under- estimation of these risks could lead either to unnecessary restriction or to a lower level of protection than intended. There has been a gradual decline in scientific and regulatory expertise in radiobiology and radiotoxicology during the past decades and the individual groups tend to be small. Moreover, several experimental infrastructures have been closed down during the years. For example, there is currently no place in Europe where larger numbers of animals could be exposed to radiation at low dose rate. At the same time, biomedical sciences are developing very fast and the new understanding on the molecular and systems biology should be transferred to radiation research.

To address these issues, six national funding (or regulatory) bodies with significant programmes/activities or with a policy interest in low dose risk research came together in the beginning of 2008 and Commission, created a group called “High Level and Expert Group on European Low Dose Risk Research” (HLEG). The group consisted of the representatives of the mentioned bodies, the EC as well as experts covering a wide range of disciplines in radiobiology, epidemiology, dosimetry and modelling. The European Commission provided support for the technical secretariat.

The HLEG drafted a Report that was posted in the HLEG website (www.hleg.de), opened to public consultation and published in the final version on the website at the beginning of 2009. A printed version was also published later by the European Commission (High Level and Expert Group, 2009). The Report has three parts, reflecting three objectives: a) Policy Issues, b) State of Science and research challenges, c) Proposed European research strategy. In the third part, a *trans-national organisation* is proposed considering that the complex and multidisciplinary nature of these issues is such that their resolution can be achieved only through the integration of research at a European, (or even international) level. To this aim a platform was proposed called “Multidisciplinary European LOw Dose Initiative” (MELODI), as an instrument capable to guarantee a sustainable, long-term integration of European national R&D programmes.

The HLEG Report identified topics that are important for the radiation protection policy point of view (Figure 1).

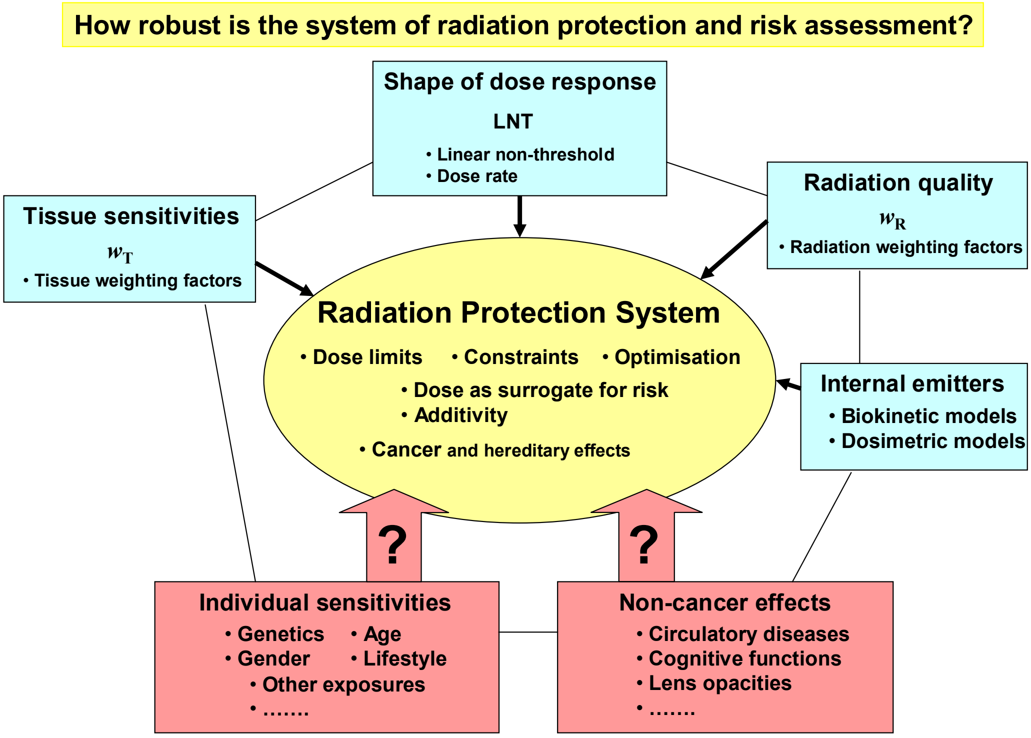

Fig. 1. The main issues where judgements are made in the current system of radiation protection. The four upper boxes denote judgements that fall directly within the main ICRP dosimetric system, while the two lower boxes include issues that are at present included only to a relatively minor degree (from HLEG Report, 2009).

MELODI Initiative

In April 2009 five of the national organisations present in the HLEG, with the support of the EC, signed a Letter of Intent (LoI) in order to create the initial core of the platform, with a view to integrate in a step by step approach EU institutions with significant programmes in the field and to be open to other scientific organizations and stakeholders. These organizations were Bundesamt für Strahlenschutz (Federal Office for Radiation Protection, BfS) - Germany, Commissariat a l'Energie Atomique (Atomic Energy Commission, CEA) - France, Institut de Radioprotection et de Surété Nûcleaire (Institute for Radiation Protection and Nuclear Safety, IRSN) - France, Istituto Superiore di Sanità (National Institute of Health, ISS) - Italy, and Radiation and Nuclear Safety Authority, STUK - Finland.

MELODI is intended as a mean to establish trans-national governance structure to integrate national, bi- and multi- lateral research programmes within an agreed SRA. Therefore, a key role of MELODI is to develop and maintain over time a strategic research agenda (SRA) and a roadmap of scientific priorities within a multidisciplinary approach, and to transfer the results for the radiation protection system. Other aims are to interface with broad range of stakeholders, to oversee investments in key infrastructures, to coordinate knowledge management and education and training and to ensure consistent research methodologies.

The MELODI signatory organisations have taken a number of initial steps in 2009 to set up a provisional operational governance and organisational structure for MELODI. The first ones were to create a MELODI Governing Board, constituted of the designated representatives of the signatory bodies (presently chaired by W. Weiss, BfS, Germany), and to produce some documents defining the process of setting up the final MELODI research platform. An introductory document setting out the key steps and the expected deliverables is available at the MELODI website http://www.melodi-online.eu/. In the beginning of 2010, four more organisations from four additional EU countries had joined the MELODI platform and several others have expressed their willingness to do so.

DoReMi Network of Excellence

The aim of DoReMi is to promote the sustainable integration of low dose risk research in Europe in order to aid the effective resolution of the key policy questions identified by the High Level Expert Group (HLEG) on Low Dose Risk Research (www.hleg.de). DoReMi provides an operational tool for the development of the proposed MELODI platform (Multidisciplinary European Low Dose Risk Research Initiative) consisting of major national bodies and research programmes that have long term commitment in low dose risk research in Europe.

DoReMi
Integrating Low Dose Research

The Joint Programme of Activities (JPA) of DoReMi includes: (i) a Joint Programme of Research (JPR) covering the issues outlined above and providing an overview of the needs for research infrastructures of pan-European interest and facilitating multilateral initiatives leading to better use and development of research infrastructures; (ii) a Joint Programme of Integration (JPI) to develop a coordinated European roadmap for the long term needs of the key players in Europe; and (iii) a Joint Programme for the Spreading of Excellence (JPSE), covering knowledge management, training and mobility and its implementation. The JPR focuses on the areas identified by the HLEG as the most promising in terms of addressing/resolving the key policy questions, namely: the shape of dose response curve for cancer, individual susceptibilities and non-cancer effects. Radiation quality, tissue sensitivity and internal exposures will be addressed as cross cutting themes within the three main research areas. A substantial proportion of the activities will be dedicated to the joint programme of research. The programme describes a multidisciplinary approach including interfaces with the broader biological toxicological and epidemiological communities. Strategic planning will be carried out in close collaboration with MELODI. The long term Strategic Research Agenda (SRA) will be developed by MELODI, whereas DoReMi research priorities are based on a shorter term Transitional Research Agenda (TRA), focusing on goals that are feasible to achieve within the 6 year project and areas where barriers need to be removed in order to proceed with the longer term strategic objectives. The work package structure of DoReMi is shown in Figure 2.

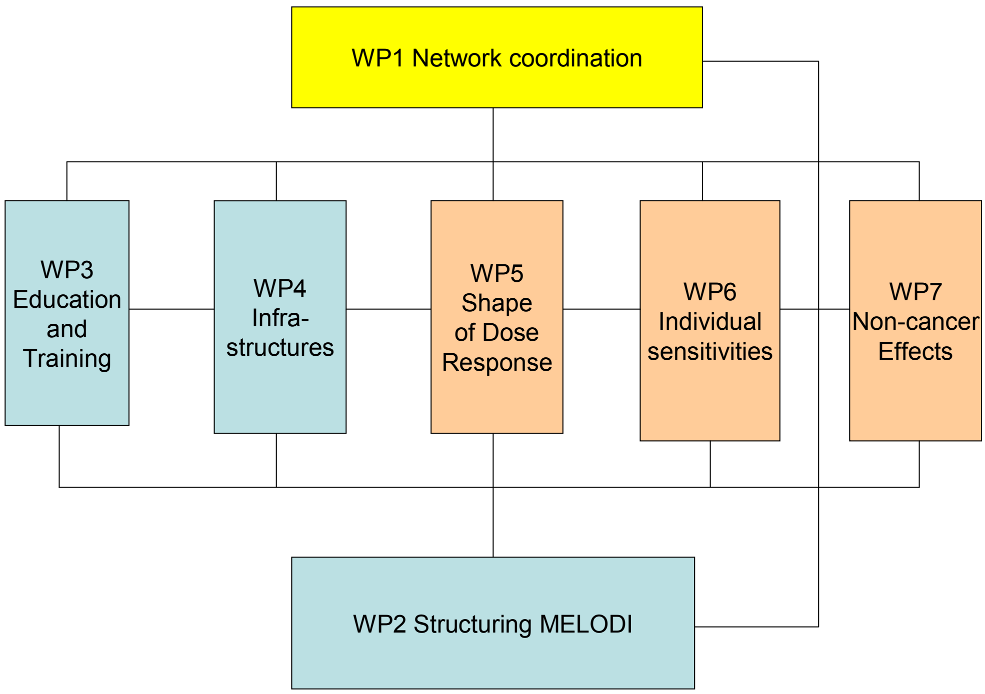

Fig. 2. The Work package structure of DoReMi Network of Excellence. Network coordination is carried out by STUK - Radiation and Nuclear Safety Authority (Sisko Salomaa). DoReMi has three main scientific work packages: WP 5 (Shape of Dose Response) is led by HPA (Simon Bouffler), WP 6 (Individual Sensitivities) is lead by Helmholz Zentrum Munich (Mike Atkinson) and WP 7 (Non-cancer Effects) is lead by IRSN (Patrick Gourmelon and Jean-René Jourdain). WP 3 (Education and Training) is led by University of Pavia (Andrea Ottolenghi) and WP4 (Infrastructures) by CEA (Laure Sabatier). WP2 (Structuring of MELODI) deals with integration activities and strategic planning and is led by IRSN (Dietrich Averbeck).

The network of Excellence started with 12 partners (beneficiaries). New partners are expected to join via open calls, searching for new competencies as well as necessary infrastructures and other platforms for research, such as suitable animal and tissue model systems for low dose risk research. These areas will be defined in more detail in the Transitional Research Agenda and Call Plan. The first open call of DoReMi is planned to take place in autumn 2010. DoReMi web site will be opened in September 2010: www.doremi-noe.net

DoReMi is the necessary complement to MELODI, aiming to achieve fairly short term results in order to prove the validity of the HLEG approach, and to contribute to the development of MELODI. Such objectives and timeframe are typically consistent with what can be expected from a NoE, which is why the EC included the possibility of such a scheme in its 2008 call. The resources invested by the EU and by member organisations in the NoE will therefore aim to:

1) develop and implement a "transition research agenda" (TRA) with a short to medium term time scale, which would attempt to capture the essence of the HLEG strategy,
2) implement the TRA within the limited time frame and organisational perimeters of the NoE,
3) contribute to the wider development of MELODI, by bringing its scientific input into the open dialogue of the Platform and by supporting it through its dedicated resources,
4) take into account the results of MELODI work on the SRA for the successive calls for R&T actions within the NoE. These open calls are expected to progressively bring in new partners into the working structures of both organisations.

The NoE will also be able to take advantage of the MELODI Scientific Committee structure in order to optimize its own independent scientific evaluation process. In practice, DoReMi Work Packages WP2, WP3, and WP4 will develop support structures for MELODI, on research infrastructure in Europe and on education and training operating in such a way that their deliverables feed directly as "draft contributions" into the working groups of MELODI. DoReMi WP5, WP6, and WP7, which are concerned with the scientific issues of the shape of the dose effect relationship, the individual radiation sensitivity and non-cancer effects of radiation, respectively, will produce scientific deliverables from their research and training operational activities, which should constitute the first operational stepping stones on the SRA roadmap. These results as well as the experience feedback from such should also contribute to the furthering of MELODI goals, particularly at the time when the NoE will be nearing its completion. For this purpose, scientists in DoReMi WP's should become also actively involved in MELODI working groups, where the ongoing Low Dose Risk research strategies will continue to be developed year after year. The complementarity of DoReMi and MELODI is illustrated in Figure 3.

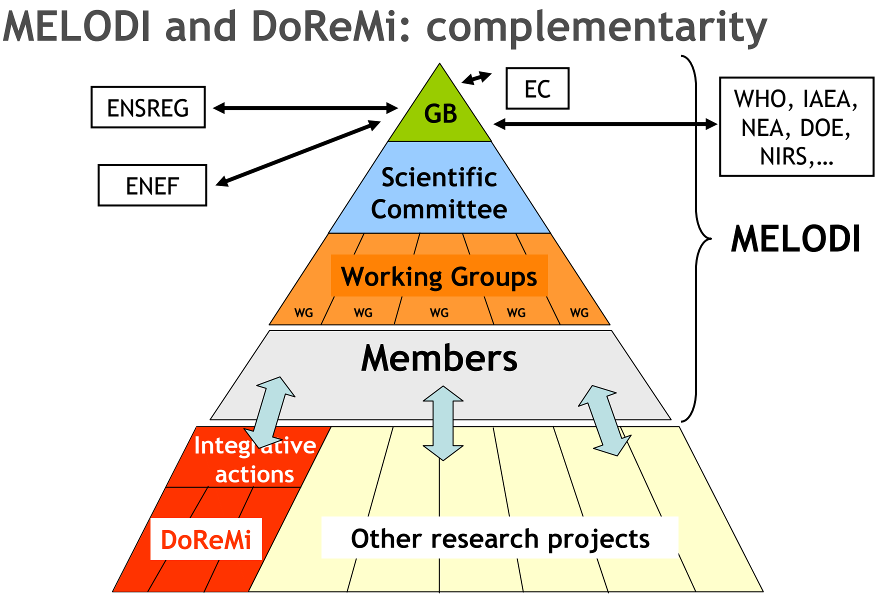

Fig. 3. DoReMi is the necessary complement to MELODI, aiming to achieve fairly short term results in order to prove the validity of the HLEG approach, and to contribute to the development of MELODI. Other research projects based on the joint low dose risk strategy are foreseen. These projects would be funded by EC or by national funding bodies.

Important fora for the scientific discussions and development of the strategic research agendas are the MELODI workshops and DoReMi exploratory workshops that engage the scientific community in low dose risk research. The first MELODI workshop was organised by BfS in Stuttgart on 28-30 September 2010, and the second MELODI workshop will be arranged by IRSN in Paris on 18-20 October, 2010.

Acknowledgements

The authors wish to thank members of the High Level and Expert Group that contributed to the original report, in particular Dr. Pierre Legrain, Prof. Mauro Belli, Dr. Hilary Walker, Prof. Alex Elliot, Dr. Roger Cox, Dr. Dudley Goodhead and Dr. George Neale Kelly. The DoReMi Network of Excellence has received funding from the European Atomic Energy Community's Seventh Framework Programme (FP7/2007-2011) under grant agreement n° 249689.

Public health perspective in radiological protection

Eggermont, Gilbert; Smeesters, Patrick
[1] University Brussels, EC Art31, Belgian Health Council, BVS/ABR, BELGIUM
[2] FANC, UCL, EC Art31, BVS/ABR, BELGIUM

Abstract
Recent new insights about radon risk and increasing patient exposure due to medical imaging, as well as unexpected cardiovascular effects of ionizing radiation are challenging our classical radiological protection approaches and should be viewed in a larger public health perspective. Concepts as global indoor air quality, long term sustainability, risk awareness or precaution ask for a wider approach encompassing scientific vigilance, value judgements, risk communication and sociological participation in risk governance. Progress in radiological protection needs a new transdisciplinary framing of complexity where social sciences and humanities are more actively involved to complete scientific insight.

Text
Recent new insights about radon risk and the increasing patient exposure due to digitalisation of medical imaging are challenging our classical radiological protection approaches. Unexpected cardiovascular effects of ionizing radiation (at least for relatively low cumulative doses) and some other present science foci are challenging our expert culture and are questioning why the radiological protection community clarifies and embarks such health topics so late. In these important areas for *public health*, the current dose limitation system has been till recently almost not operational while justification and optimisation were not given the priority they deserve.

These – and other- health concerns regarding ionizing radiation occur in a *changing societal context* where scientific paradigms such as LNT are questioned (bystander effects), where members of the public and patients interact actively www based, where the attention is drawn on ambiguities in values and where controversial communication is fed by media polarisation. Amazing bio-monitoring opportunities confront expert beliefs, regulatory concepts and responsibilities in health care and are opening new perspectives for multi-factorial epidemiology. Dose as unique risk indicator is no longer self-evident.

Based on the new evidence, radon risk requires stricter standards. However, hygiene should be reformulated to integrate *global indoor air quality* at home as well as at work. The *collective* dose, currently threatened to be abandoned, was and is still useful for characterising the impact on public health of radon (as well as for radiology).

In the NORM area, where standard settings are currently driven by utilitarian ethics, *sustainability* checks for long term (radon) health impact should be introduced.

A more *effective* implementation of operational justification of medical exposures and the integration of optimised radiological protection in medical Quality Assurance could allow controlling the detrimental health impact. Paediatrics and pregnancy ask in this respect for particular attention. However, *risk awareness* is the major challenge for the future and gives an ethical dimension to the new digital imaging resolution opportunities.

Radiotherapy as well as other oncology practices are facing late multi-factorial secondary effects (like circulatory diseases). They require better scientific insight but also science based communication skills.

Radiological protection in the future cannot continue to refer to the virtual average individual when *susceptibility* is demonstrated.

More generally, a major issue is the capacity of taking into account, without undue delay, new relevant data emerging from ongoing research and having a potential impact on public health in situations involving a risk from exposure to ionizing radiation – as for example the new data regarding the risk of radiation induced circulatory diseases. In this context, the European Commission organises every year, in cooperation with the Group of Experts referred to in Article 31 of the Euratom Treaty, a scientific seminar (called RIHSS seminar, for "*Research Implications o*n Health Safety Standards") to discuss in depth relevant issues emerging from ongoing research. The aim is to identify the potential implications on the European Basic Safety Standards of recent research results and to take this into account *in due time*, while debating on the need of a precautionary approach, if uncertainties are present (which is often the case).

Risk communication, as difficult search for transparency (RISCOM), should not only disclose technical black boxes and messages but demonstrate a respectful approach of the different perceptions. Perception as impression of a health risk reality is not only a characteristic of lay people. The mental construct of experts needs attention as well. Ethical guidance studied by think tanks (such as PISA in Belgium) and elaborated by IRPA could help to better distinguish the common good and to manage conflicts of interests as experienced in Health Councils. IRPA recently launched stakeholder engagement in radiological protection and successful experiences with local communities open new perspectives. They are based on sociological partnership innovations, mutual respect and considerations of distributive justice in decision making. Such new risk governance processes join prudent precaution strategies as put forward by EEA and the Dutch Health Council. They could facilitate to transform public health opportunities into real perspectives. Precaution requires the systematic specification of uncertainties. This is not as evident in expert culture as scientific method requires. Moreover it takes into account ambiguities related to *value judgements*. This extends the scope of risk assessment and management. For example, in the radiological protection system, where ALARA can be considered as a precursor of precaution, an ecosystem approach is still missing.

Our scientific progress in radiological protection needs a new *transdisciplinary* framing of complexity where social sciences and humanities are more actively involved to complete scientific insight.

RPA Radiation Protection Culture initiative: An opportunity for the nuclear industry

Le Guen, Bernard
EDF and IRPA EC, Nuclear Power operation, FRANCE

Abstract

Considerable progress has been made in all the fields of application of radiation protection over the past 40 years, supported by an enthusiastic generation of professionals. We are observing now significant development in the nuclear industry throughout the world and the profession is faced with renewal of the generation who thought up today's radiation protection. We must remain vigilant as all the conditions are fulfilled for radiation protection to make no further progress and in this case even to go backwards. One way of preventing or at least limiting the risk is to root radiation protection in culture, to develop a radiation protection culture. Sharing of our know-how and simultaneous optimisation initiatives set up for constant improvement of our practices are common radiation protection values. IRPA is proposing a brainstorming with other radiation protection societies with a view to possibly drawing up the IRPA's "Guiding Principles" for Radiation Protection Culture. This presentation will present the first results of the First international IRPA workshop in Paris (December 2009).

Medical management of radiation accidents

Novel measurement and analysis technology for safety, security and safeguards

Toivonen, Harri; Peräjärvi, Kari; Pöllänen, Roy
STUK – Radiation and Nuclear Safety Authority, Laippatie 4, 00880 Helsinki, FINLAND

Abstract
Nuclear interactions have been measured through molecular phenomena since the early days of radiation research. Rutherford used ZnS(Ag) to convert the kinetic energy of alpha particles into visible light in his famous experiments some 100 years ago. Recent technical advances have again made molecular phenomena attractive as a basis of nuclear instrumentation. Current detection technology has provided single photon counters, and there is no need to rely on human eyes. The present paper reviews scientific advances that may ultimately lead to operational methods for safety, security and safeguards. Examples of novel approaches and technologies are given.

1 Introduction
Radiation protection aims at the safety of individuals, society and the environment. Radiation measurements are critical tools to ensure safety and security. Recent technical advances have provided new types of instruments for daily work. One such example is the $LaBr_3$ detector, which provides sufficient energy resolution for continuous real-time radiation surveillance in the environment with a hundred times better sensitivity than the old approach based on Geiger counters (Toivonen et al. 2008). On the other hand, the ruggedized instruments make mobile spectroscopy possible for security applications directly operated by law enforcement.

The radiation risks to society are not limited to the consequences of accidents. The malevolent use of nuclear or other radioactive material is a threat to society that may be realized any day. The proliferation of nuclear weapons is another international security challenge. Key material control, based on nuclear safeguards, is the best way to prevent such an undesirable development. For these tasks, authorities need novel technology. The new safety and security threats have to be eliminated, or if realized, their consequences need to be mitigated.

Nuclear safeguards are measures to verify that states comply with their international obligations not to use nuclear materials for explosives. The objective of nuclear security is the prevention of theft, sabotage, unauthorised access, illegal transfer or other malicious acts involving nuclear material, other radioactive substances or their associated facilities. Crucial elements of the nuclear security regime are effective detection and response measures. For this, novel technology is required.

The term “novel technology” refers to physical phenomena, instruments or systems which have not yet been applied or that are immature for in-field applications. Typical examples are optical methods to detect radionuclide contamination or to identify and reveal indicators and signatures (I&S) specific to the nuclear fuel cycle or weapons programmes.

The term “novel approach” refers to an application that attacks an old problem in a non-conventional manner. For example, alpha spectrometry without sample treatment, or completely without sampling, is an example of a novel approach. Other examples include algorithms or analysis systems that are able to treat measurement results much more thoroughly than conventional methods.

The borderline between new and novel is not sharp. Conventional technologies need to be improved, sometimes in a novel manner, to achieve better analytical performance of instruments. We apply these concepts in a loose manner.

The following review is intended to discuss a few promising novel methods for safety, security and safeguards. The text is by no means exhaustive or complete. It deals with the needs of international organisations and associations, such as the International Atomic Energy Agency (IAEA) and the European Safeguards Research and Development Association (ESARDA). The purpose of the discussion is to introduce novel approaches and technologies to:

- improve destructive analyses (DA);
- improve non-destructive analyses (NDA);
- develop new methods to support the non-proliferation of nuclear weapons;
- support treaty verification;
- combat nuclear terrorism; and
- provide powerful tools for consequence management of nuclear accidents.

2 Sampling – a basis for improvements to spectroscopy

Samples have traditionally been analyzed in laboratories, where several destructive analytical techniques are available. However, if sample treatment could be significantly improved, similar results could be achieved by non-destructive analyses.

NDA of samples has three general advantages (Ihantola 2009):

1. The productivity and timeliness of field missions can be improved. If the measurements are too complicated to be performed on-site, preparation of the samples in the field would nevertheless speed up the process in the laboratory, since it would eliminate the need for complex chemical treatment. For nuclear security applications, rapid methods are of particular importance.
2. On-site analysis of samples enables direct feedback. Therefore, inspections can be focused on those areas appearing most suspicious.
3. The production of high-quality or matrix-free samples would simplify the whole chain-of-custody as compared to traditional swipe sampling and later laboratory analysis. When the samples are prepared for counting and dispatched directly to the laboratory involved, there is no risk of cross-contamination, since the sample treatment is carried out far from the laboratory.

NDA measurement methods have not been fully exploited, either in field conditions or in laboratories. Currently, the detection of penetrating gamma radiation is widely used, whereas direct spectrometry with non-penetrating radiation, i.e., with alpha and beta particles, low-energy X-rays and conversion electrons, is considered to be too complicated. With a careful design of sampling, these measurements are possible (see section 4.1 for alpha measurements), including analysis, particularly when remote expert support (reachback) is available.

3 Novel approaches to spectroscopy

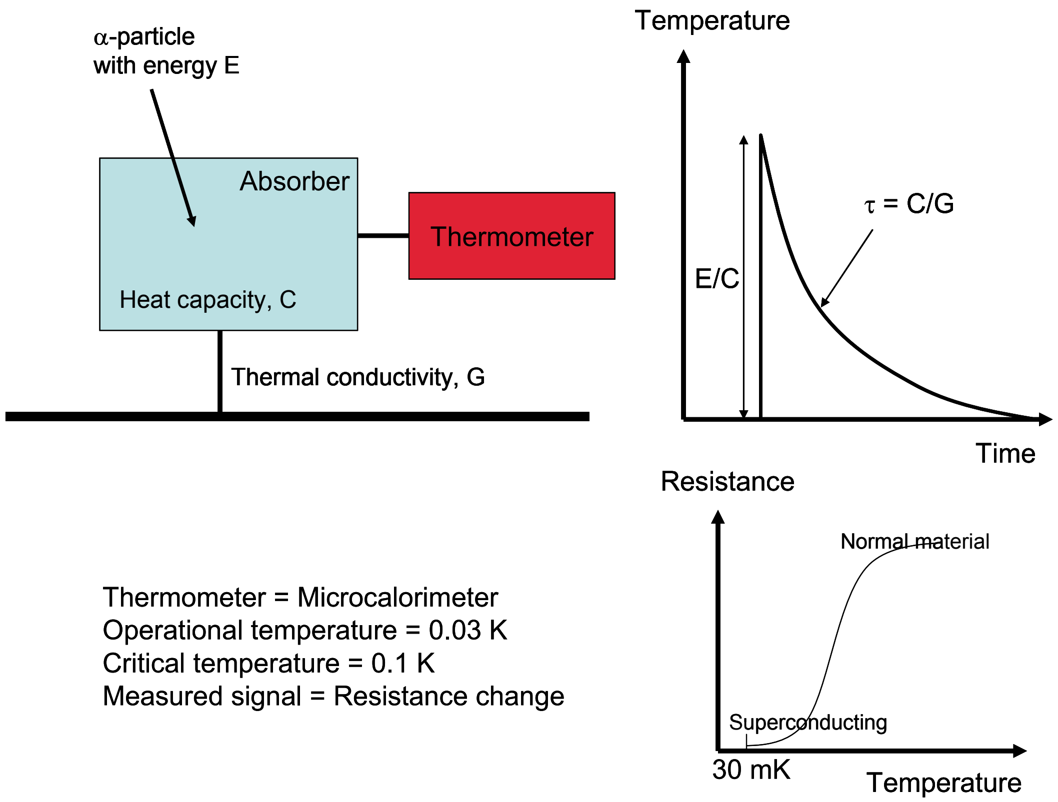
Spectroscopy is the basic work horse of every analytical laboratory. The quality of the measurements and related analyses has continuously improved. Recently, however, scientific and technical innovations have taken place in several domains. Some breakthroughs are elaborated below.

3.1 Microcalorimeters – spectrometry with ultra-high resolution

Microcalorimeters respond to the deposited energy and not to charge (Figure 1). Therefore, they do not have any dead layer characteristic of semiconductors. Transition-edge-sensor microcalorimeters consist of molybdenum and copper. The element ratio defines the critical temperature of the device. The best energy resolution is achieved at a critical temperature of around 0.1 K. The energy signal is derived from the change in the resistance in the circuit after the absorption of radiation quanta. While detecting penetrating radiation, a bulk absorber needs to be attached to the thermometer (= microcalorimeter). These are typically made of tin. There may be several contacts between the absorber and the thermometer. This arrangement eliminates the variability in the energy resolution, which would otherwise depend on the position of the interactions. The measured energy resolution, *FWHM*, of the microcalorimeter detectors is 25 eV for 103 keV photons and 1.06 keV for 5.3 MeV alpha particles (Doriese et al. 2007, Horansky et al. 2008). The corresponding resolutions with a planar HPGe and Si detector are ~450 eV and ~8.5 keV, respectively (Ullom 2008).

In the future, microcalorimeters may significantly impact on alpha spectroscopic procedures, since the achieved resolution of 1 keV is so good that separation of the elements is no longer required, i.e., only rapid chemistry is needed to get rid of the sample matrix. Presently challenging cases such as the analysis of ^{239}Pu (5.157 MeV) and ^{240}Pu (5.168 MeV) in samples will become much easier, since the relevant alpha peaks are completely separated. This also loosens the requirements related to the counting statistics. Therefore, microcalorimeters may in the future take part of the workload away from mass spectrometers. Note also that the routine use of microcalorimeters would reduce the time needed for the chemistry and counting, thus improving the throughput of the laboratory.

The nature of gamma and X-ray spectrometry would drastically change if microcalorimeters entered into routine use. For example, a currently major problem in nuclear security applications is the interference of ^{226}Ra with ^{235}U (Figure 2). However, a microcalorimeter provides a clear separation between the transitions of ^{235}U (185.71 keV) and ^{226}Ra (186.21 keV) (Hoover et al. 2009).



Thermometer = Microcalorimeter
Operational temperature = 0.03 K
Critical temperature = 0.1 K
Measured signal = Resistance change

Figure 1. Operation principle of a microcalorimeter.

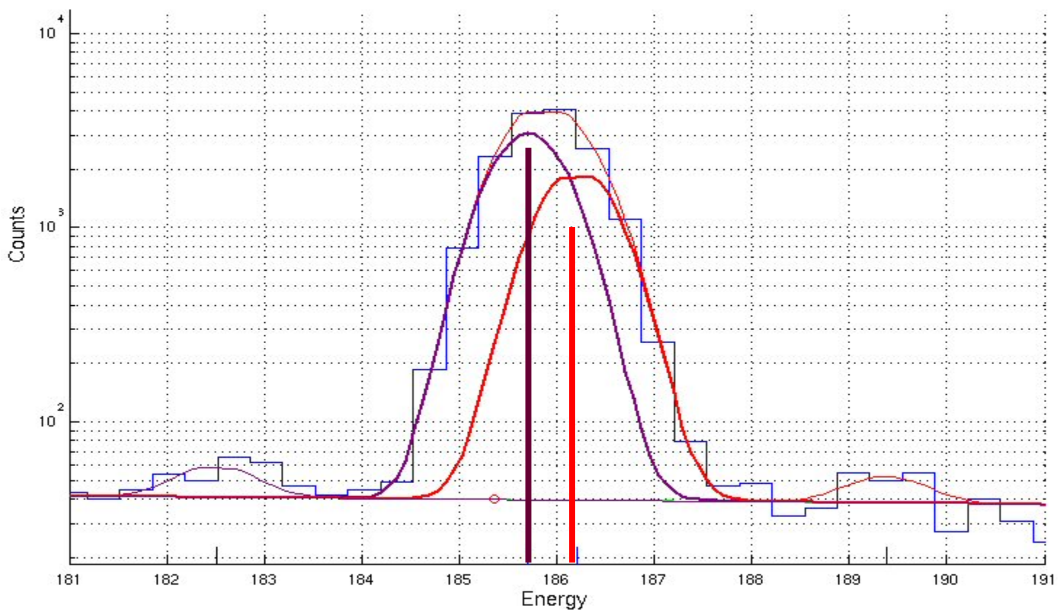


Figure 2. ^{235}U and ^{226}Ra doublet in a high-resolution gamma spectrum. The doublet is difficult to deconvolute, even with a state-of-the-art unfolding algorithm. If the measurement had been performed with a microcalorimeter, the peaks would have been fully resolved. The *FWHM* is smaller than the bar width shown in the figure.

3.2 Scintillation detectors and pulse shape analysis

Scintillation detectors that operate at room temperature can be used for measurements on particles and photons. Much work has been devoted to improving the neutron-gamma discrimination capabilities of scintillators. Such discrimination is achieved by introducing lithium gadolinium borate crystals (particle size ~1 mm) into a plastic scintillator matrix (Menaa et al. 2009). Neutron events are separated from gamma-ray events via the use of pulse shape analysis. Namely, the characteristic (n,α) reaction generally occurs within 10 μs after the recoil pulse. The resulting double peak structure provides an excellent means to disentangle neutrons from gammas.

Another development that we wish to highlight is based on pulse shape analysis and phoswich detectors. Phoswich detectors have layers of different scintillation materials with different properties. The layers are optically connected, and the entire packet is connected to a single photomultiplier tube. The energy signals from such a detector can be elegantly analyzed if the response of the different types of radiation is known. For example, when a beta particle and a gamma ray simultaneously hit the detector, their individual energies can still be determined (de la Fuente et al. 2008). Thus, these detectors, in addition to conventional singles spectrometry, are also capable of beta-gated and alpha-gated gamma-ray spectrometry. This is very significant for their possible use *in situ*, since coincidence spectrometry may remove the need for shielding around the detector. The resulting measuring system could be very compact.

Novel signal processing and data analysis techniques improve the performance and applicability of scintillation detectors. It is a technological, rather than a scientific challenge to bring these techniques into routine use. Furthermore, research and development of new scintillation materials will provide even better detectors for future in-field applications (Bourret-Courchesne et al. 2010).

3.3 Event-mode data acquisition and position-sensitive detectors

The simultaneous use of several state-of-the-art semiconductor detectors provides powerful tools for the analysis of samples (Keillor et al. 2009, Turunen et al. 2010). Multi-detector setups are often meant to be operated in laboratories. In addition to the quality in terms of resolution, the technical maturity of the semiconductors makes these detectors an attractive choice. For example, imaging silicon detectors capable of spectrometry are already commercially available. Position information is useful to investigate the distribution of alpha-particle-emitting radionuclides in various samples or to search for “hot” spots or radioactive particles. For safeguards and nuclear security, the characteristics of the individual particles are of interest; they reveal the history of the radioactive materials handled at the site.

Data acquisition is performed in event mode, also known as list mode. This means that any event, for example the absorption of alpha energy in a certain pixel of the alpha detector, triggers a gate signal for the energy depositions of the other detectors to be registered during a small time slot, typically for one microsecond. Later, the data storage allows the generation of various types of spectra, depending on the query requirements.

Of particular interest are the software-based coincidence spectra, such as position-gated and alpha-gated gamma-ray spectra. The knowledge that the gamma-rays in question have been detected in coincidence with alpha decay of a certain energy and impact location in a silicon detector makes the spectrum analysis and interpretation much more reliable and detailed. Due to the coincidence analysis, the spectrum background is lowered by orders of magnitude, and very low minimum detectable activities are consequently achieved (Turunen et al. 2010, Peräjärvi et al. 2010).

Techniques such as alpha-gamma coincidence spectrometry do not require chemical manipulation of the sample before measurement. For example, $^{240}Pu/^{239}Pu$ atom ratio can be determined directly from the resulting data (Peräjärvi et al. 2010).

4 Alpha radiation – difficult to detect in field conditions, or is it?

Alpha spectrometry is often considered as a mature technology for sample analysis in laboratory conditions, but there is still room for development. The method is based on radiochemical sample processing with radioelement separation and subsequent data acquisition in a vacuum chamber with an alpha spectrometer. In some applications, such as continuous aerosol monitoring, the processing is simplified by sampling the radionuclides on the surface of the sample material and performing the data acquisition in NTP air. In these cases, spectrum unfolding may be complicated because of the omission of radioelement separation. In addition, the alpha-particle energy loss in air between the sample and the detector, and thus the varying path lengths of the alpha particles, may lead to an energy resolution that is far from optimal.

In-field alpha spectrometry is challenging from the technical point of view. Scientifically, there is not much new. A step forward would be if alpha spectrometry could be conducted in the same way as *in-situ* gamma spectrometry. At present, the most common field application is surface contamination measurement, i.e., the number of alpha counts is registered per time interval. However, high-resolution alpha spectrometry using handheld equipment would provide much more detailed information on the nuclides involved. In this case, the overall approach is as follows:

- Radiochemical sample processing should be completely omitted or drastically simplified. The samples should be as thin as possible, but thick samples should not be excluded if they are homogeneous. This means the development of novel sampling procedures. Minor processing, such as water evaporation under an infrared lamp or sample cutting, is acceptable. Alpha spectra should also be registered from smooth surfaces, allowing radionuclide identification.
- Measurements should be performed without a vacuum and the energy resolution should still remain good.
- The size of the equipment for data acquisition should be similar to that of present hand-held monitors.
- Efficient and validated software must be used for data analysis. If this is not possible, an ability to send the spectra to a remote location should exist if the analysis cannot be performed on-site. Reachback is of utmost importance in security applications.

4.1 Novel sampling and measurement techniques facilitate in-field applications

The development of appropriate sampling and sample manipulation procedures for rapid measurements has been conducted for years in different organizations. Particularly for swipe samples and liquid samples, there is room for development (Figure 3a), although some progress has already been achieved in this field (Ihantola 2009, Semkow et al. 2009).

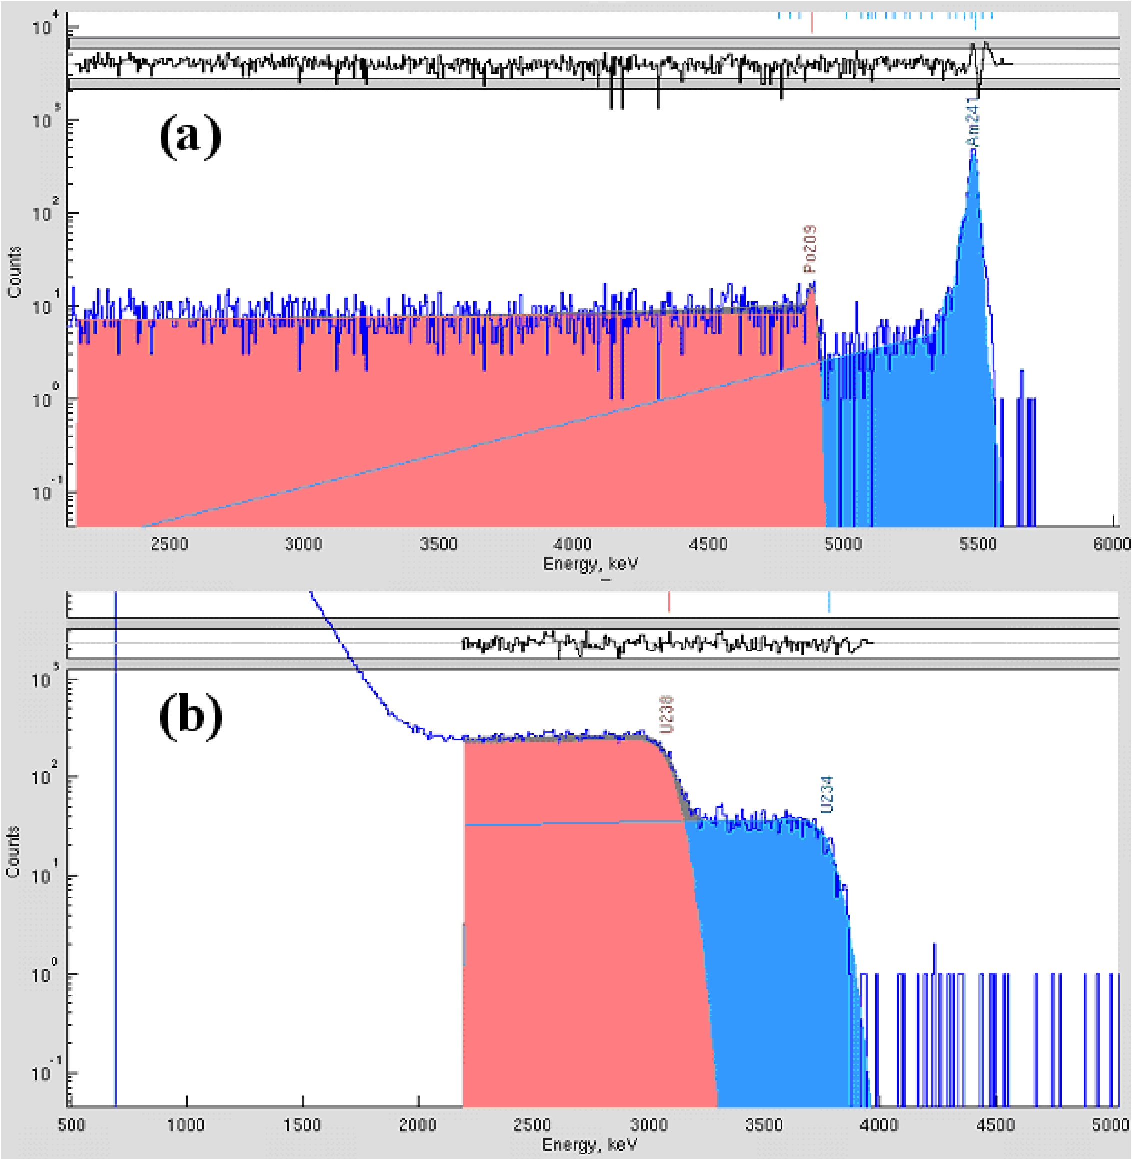

Figure 3. (a) Alpha particle energy spectrum from filtered liquid (3 mL beer) doped with ^{209}Po and ^{241}Am. The spectrum was measured in a vacuum chamber from the filter. (b) Alpha spectrum from the surface of a depleted uranium penetrator. The spectrum was measured in NTP air at a source-to-detector distance of 9 mm. The energy region used in the fitting was 2.2–4 MeV (the energy scale refers to the energy of detected alphas). The large number of counts at small energies is due to the high-energy betas originating especially from ^{234m}Pa.

Nuclide-specific activities cannot necessarily be obtained accurately if the sample is too thick and the peak shapes are different (reflecting differences of radionuclide distribution in the source, see Fig. 3). Reliable estimates for the nuclide ratios may also be impossible in this case. However, the identification of radionuclides is possible. As an example, an alpha spectrum was registered from a depleted uranium penetrator (Figure 3b) in air, i.e. no vacuum was used in the data acquisition. ^{238}U and ^{234}U can be clearly identified from the spectrum, but their activities cannot be measured. Because the shapes of ^{238}U and ^{234}U "peaks" are equal, the activity ratio ^{238}U/^{234}U (in reality ^{238}U / ^{234}U + ^{235}U + ^{236}U) can easily be determined. Here, the value of 6.32 was obtained, whereas 7.05

was reported in Pöllänen et al. (2003). Thus, alpha spectrometry of surfaces of thick sources is possible, even though the measurements are performed in NTP conditions.

4.2 Vacuum is not necessary to obtain alpha spectra with good energy resolution

High-resolution alpha spectra can be acquired in NTP conditions (Pöllänen et al. 2010). A thin source containing ^{239}Pu, ^{241}Am and ^{244}Cm, normally used in the energy calibration of the alpha spectrometers, was used for testing different counting configurations. Using the conventional approach, the energy resolution is far from optimal. The reason is the varying path length of the alpha particles in air. Much better resolution can be achieved by optimizing the measurement system.

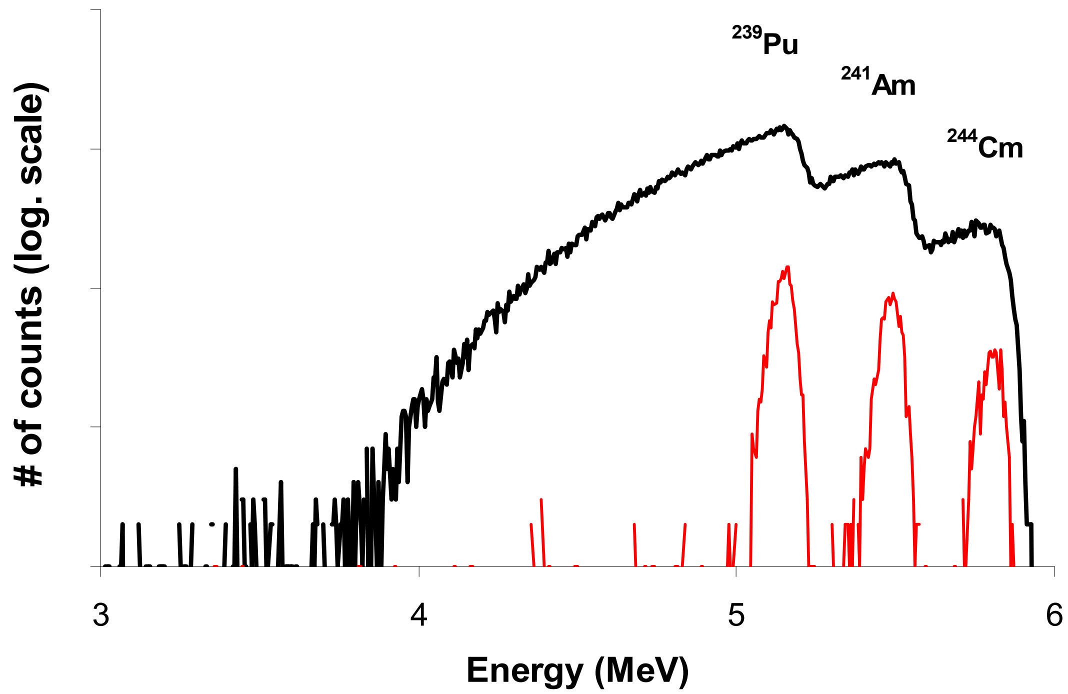

Figure 4. Alpha particle energy spectrum from a calibration source measured at NTP (black line) and with a modified system (red line). In both cases the source-to-detector distance was 9 mm. The number of counts is arbitrarily normalized.

4.3 Efficient data management and spectrum analysis are needed for in-field applications

Alpha spectra from three-dimensional sources or those measured in NTP conditions are different from those obtained from radiochemically processed samples. Multiple overlapping peak groups appear in the spectrum if several radioelements are present in the source. In addition, the shape of the alpha peaks is completely different and depends on the measurement geometry and the radioelement in question. Energy calibration should also be performed with great care because concepts such as peak “location”, “centroid” or “energy” do not characterize the peaks optimally. A prerequisite for a viable method for spectrum unfolding is that the phenomena mentioned above are properly taken into account in the analysis software.

A novel computer code known as ADAM (Toivonen et al. 2009) has recently been developed to cope with the requirements mentioned above. The program is able to unfold complex alpha spectra measured in a vacuum or in NTP conditions. As an example, an alpha spectrum from a radiochemically processed source, and containing ^{238}Pu, ^{239}Pu, ^{240}Pu and ^{242}Pu, was analyzed (Fig. 5). In contrast to several other programs, the activities of ^{239}Pu and ^{240}Pu can easily be reliably determined. This is because the uncertainties of the fit are in good statistical control (covariance calculus). The spectra presented in Figure 3 were also analyzed by ADAM.

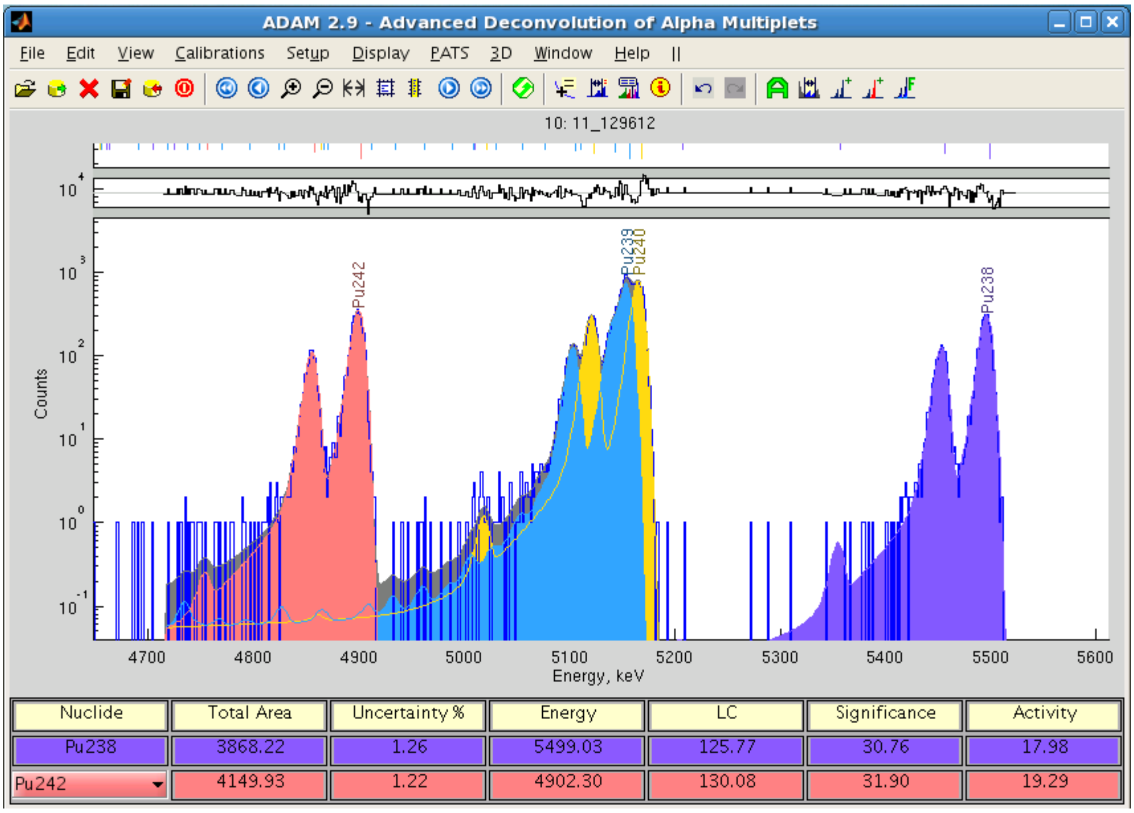

Figure 5. Unfolding an alpha particle energy spectrum from a radiochemically processed sample containing ^{238}Pu, ^{239}Pu, ^{240}Pu and ^{242}Pu. A semicoductor detector of 50 mm^2 in area and 5 cm source-to-detector distance was used in the measurement. The measurement time was 1.5 d.

Spectrum unfolding in the field may be too challenging, especially when the measurement has been carried out by a person who is not familiar with alpha spectrometry and the analysis tools. Efficient reachback is then needed. Such data processing is very demanding. However, if successfully implemented, the operational capability is drastically improved. Timely and high-quality nuclear spectroscopy is available for police, fire fighters and other first responders.

5 Optical sensing

In revealing the I&S of nuclear processes, optical measurements provide advantages that cannot be achieved with traditional nuclear instrumentation. For example, optically stimulated luminescence (OSL) could reveal crucial information on a suspected location that may previously have been a storage site for radioactive materials.

The review below is a short introduction to optical methods useful for safety, security and safeguards. Only some key applications are covered.

5.1 Light Detection And Ranging

Light Detection And Ranging (LIDAR) is an optical remote sensing system that measures scattered light to find information on a distant target. Laser pulses are sent to excite the target molecules. The operating principle of LIDAR is similar to radar, which uses radio waves and measures the time delay between the transmission of a pulse and the detection of the reflected signal. LIDAR uses short wavelengths in the ultraviolet, visible or infrared range. Thus, LIDAR is highly sensitive to aerosols and cloud particles and has many applications in atmospheric research and meteorology.

A laser has a very narrow beam, which allows the mapping of physical features at a very high resolution. In addition, many chemical compounds interact strongly at visible wavelengths, resulting in a good image of these materials. Remote mapping of atmospheric contents is possible by using specific lasers and then studying wavelength-dependent changes in the intensity of the returned signal.

LIDAR has been extensively used for atmospheric research and meteorology. For safeguards, it is envisaged that a mobile laboratory, in the vicinity of a suspected location, could use laser at a certain wavelength stimulating airborne molecules that emanate from nuclear processes. A light sensitive telescope could then scan the stimulated atmosphere, detecting the presence or absence of the signature molecules.

5.2 Laser-Induced Breakdown Spectroscopy

Laser-Induced Breakdown Spectroscopy (LIBS) is based on the analysis of the optical emission of the induced plasma. A LIBS system has a high-power laser to ablate the surface of the material. This creates a micro-vapour that emits optical radiation. A spectrometer is then used to analyze the constituent components. The resolution of LIBS depends on the design of the spectrometer. Instruments can be built to provide elemental results and even isotopic analysis has been envisaged.

LIBS has the power to identify I&S (Kosierb et al. 2009). High-quality gas centrifuges require special construction materials, such as maraging steel. LIBS was able to detect the unique chemical composition of maraging steel, and it could be distinguished from other iron or steel alloys. The origin (site of production) of U_3O_8 (yellowcake) could also be demonstrated.

LIBS is already widely used by research groups and industry. Technology miniaturization has been successful and handheld devices have been developed. LIBS provides many advantages for safeguards. For example, LIBS requires no sample preparation and the results are available in real-time.

The Novel Technology Unit of the IAEA has a portable LIBS. It has been developed by the Canadian Member State Support Programme to the IAEA safeguards.

The future in-field missions will test the power of LIBS to identify I&S related to clandestine nuclear activities.

5.3 Remote sensing of alpha emitters

Alpha emitters are difficult-to-detect nuclides, especially in field conditions. This is because alpha particles have a short range in air (< 4 cm). Remote alpha detection could be possible if there were a suitable energy converter, i.e., a secondary mechanism that carries part of the energy far away from the source. The best known converter is ZnS(Ag), which was used by Rutherford some 100 years ago in his famous experiments to reveal the characteristic properties of alpha radiation. In those days, a pair of human eyes with a microscope formed the optical detector. Air contains natural energy converters - nitrogen and oxygen. Nitrogen molecules (N_2), in particular, serve well for remote sensing of alpha radiation.

Delta electrons are created near the track of the alpha particles in air. These electrons induce the fluorescence of N_2 molecules. Most of the light is at the wavelengths of UV, i.e., between 300 nm and 400 nm. The main challenge in optical detection is to discriminate the weak fluorescence signal from the background. Outside, in sunlight, this is difficult or impossible, but in darkness or in dim light very promising results have been achieved (Bashenko 2004, Lamadie et al. 2005, Hannuksela 2009).

The following goals, inter alia, are fully achievable and merit intensive research:

1. A handheld surface contamination meter with fast response. The device should detect alpha radiation at a distance of 20–50 cm. Efficient and convenient screening of nuclear workers would then be possible (safety). The search for contaminated spots would be much easier than in the past (nuclear security, cases such as the aftermath of Mr Litvinenko). Best sampling sites would be identified (safeguards, nuclear forensics). A prototype of such a device has already been built (Hannuksela et al. 2010).
2. Scanning of people and goods at border crossing points. The optics should be tailored for a distance of 2–5 m. Passengers and their luggage could be silently screened for any spot containing alpha emitters.
3. Imaging room, factory hall or laboratory. An alpha camera could be built for long exposure times in complete darkness. Superimposing the normal visible image and the alpha image would show the overall contamination at the site. A prototype has already been built using CCD technology (Lamadie et al. 2005).
4. Scanning or imaging glove boxes. The device should operate through plexi glass and identify the most interesting locations for further studies.
5. Reconnaissance of a target of interest at very large distances. For special applications, suitable optics could be designed taking into account that the photons arrive at the detector from a very small angle.

6 Challenges to technology

Many laboratories worldwide are developing active and passive detection methods that have great potential for safety, security and safeguards. Examples of active detection methods include the use of neutron beams or high-energy photons to induce characteristic radiation in the target material for detection through coincidence techniques. These systems produce a high radiation dose and cannot be used to screen human beings. An example of the low-dose devices is a person scanner, i.e., a device that sees through the clothes using either low-energy photon scattering or non-ionising radiation at teraherz frequencies.

It is not possible within the framework of the present paper to review the safety and security domain in detail. Therefore, only a few striking examples are given in relation to passive detection methods.

6.1 Compton imaging

Remote location of gamma-emitting sources has traditionally been realized by collimating the gamma detector. These collimators are heavy and the screening may take a long time due to the limited spatial view of the detector. Such a collimator is not needed if the detector is replaced with a stack of position-sensitive silicon and germanium detectors (Vetter et al. 2007). Detailed analysis of the multiple interactions of the incoming gamma radiation, in addition to conventional spectrometry, provides a means to locate the source. To facilitate the interpretation of the results, the radiation information can be combined with visual images.

6.2 Screening of cargo with muons

Cosmic muons are continuously bombarding the Earth with a flux of about 10^4 /(min×m^2). The muons easily pass through matter, i.e., they have long ranges in materials. However, they scatter more easily from heavy and high density materials than from light materials. The object to be scanned is surrounded with appropriate detectors for registering the trajectories of the individual muons. This reveals heavy materials inside the object (Pesente et al. 2009).

Interesting devices have been proposed for future use to complement regular X-ray systems for payloads that cannot be imaged with X-ray devices, for example in the search for stowaways or smugglers. Note that a 300 kV (9 MV) X-ray source is required to make an image through 5 cm (35 cm) of steel. The only drawback related to this technique is the relatively low muon flux on Earth. Scattering information can also be used to classify the inspected materials (density measurements).

6.3 Neutrinos reveal nuclear chain reactions

Antineutrino detectors relying on the $\overline{\nu} p \rightarrow e^+ n$ reaction can be used to monitor nuclear reactor power and fuel composition. The most interesting developments on this field are related to the use of plastic scintillators instead of liquid ones (Battaglieri et al. 2009). Namely, plastic scintillators are preferred since they do not have problems with flammability or toxicity. This is obviously very important if the detector is placed in the vicinity of a nuclear reactor. Solid state antineutrino detectors are composed of scintillator bars that have photomultiplier tubes attached to both ends. Additionally, plastic detector bars are wrapped with gadolinium foils to trigger (n,γ) reactions in the foils. Signals related to the stopping of positrons and 511 keV annihilation radiation together with the gamma-rays following neutron capture by gadolinium form a unique fingerprint for the identification of antineutrino events. The active volume of the detector is 1 m^3. If such a detector is placed at a distance of 25 m from a 3 GW reactor core, it is expected to detect about 5000 antineutrino events per day. This is enough for independent monitoring of the reactor operation.

7 Discussion

Novel approaches and technologies for safety, security and safeguards are a challenge to the scientific community. In-field operations in particular can be much improved using technology that may fall outside the traditional nuclear instrumentation or that is developed from a new perspective.

Basic research has long been using methods that would be very useful in applied research or monitoring. These methods will find their way to applied radiation sciences and to field operations. A typical example of such methods is the recording of radiation interactions as events and then utilizing coincidences for spectrum generation through software. This kind of data acquisition is slowly creeping into standard nuclear instrumentation, but no mature application is widely available. There is room for the development of equipment and for application software that would make the system user-friendly.

Extensive research and development will inevitably lead to better radiological and nuclear detection capabilities. In the aftermath of September 11, major new resources have been allocated to nuclear security, but the achievements in this field will ultimately also be useful for safety and safeguards. In the future, the detection of I&S - regardless of the domain - will be more sensitive, rapid and reliable. Science is for safety, security and safeguards.

Good regulators and good operators – in search of mutual trust

Valentin, Jack
Grev Turegatan 86, IV; SE-114 38 Stockholm, SWEDEN

Abstract

Everybody ‘knows’ what is expected of a regulatory body and how a licensee establishment is supposed to behave. This presentation aims to show that these concepts can be more elusive than first impressions may indicate. Well-known facts are frequently forgotten by new generations of regulators and operators, and ground once conquered and regarded as secured must be re-captured, time and again.

Obviously, a regulatory body needs to trust each operator: a license (for instance, to use x-ray equipment) constitutes proof of that trust, and indicates that the licensee is perceived as having sufficient competence, responsibility, and resources in view of the risks involved in the licensed activity. However, all too often, inexperienced regulators focus on prescriptive instructions and follow-up of minute details, thus ‘stealing’ responsibility from the licensee. And all too often, inexperienced operators focus on compliance with prescriptive instructions instead of finding out the reasons behind the instructions and negotiating when required the best way of ensuring that goals are met and deviations are spotted before they turn into incidents.

Similarly, an operator needs to trust the regulator: licenses must be awarded, denied, or retracted on relevant grounds only. However, the operator must also be convinced that the regulator’s primary aim is safety rather than punishments. Incident reporting is a vital safety tool, but it can only work if the operator is reasonably sure that an incident report will not generate undue punishments.

Performance-based regulation does not mean lax control compared to prescriptive regulatory systems, nor does it permit careless or non-uniform operating procedures. It does call, however, for genuine mutual trust, and collaboration towards a common goal of safety. Good examples are available in other safe industries, such as aviation.

These concepts are discussed in the 2007 ICRP Recommendations, but only briefly and actually the 1990 ICRP Recommendations provided more advice in this respect. They are also discussed in various IAEA publications, but unfortunately there is some scope for un-necessarily prescriptive solutions, for instance if ‘immaturity’ is invoked.

A plausible radiobiological model of cardiovascular disease at low or fractionated doses

Little, Mark; Gola, Anna; Tzoulaki, Ioanna
Imperial College, Epidemiology and Public Health, UNITED KINGDOM

Abstract

Atherosclerosis is the main cause of coronary heart disease and stroke, the two major causes of death in developed society. There is emerging evidence of excess risk of cardiovascular disease at low radiation doses in various occupationally-exposed groups receiving small daily radiation doses. Assuming that they are causal, the mechanisms for effects of chronic fractionated radiation exposures on cardiovascular disease are unclear. We outline a spatial reaction-diffusion model for atherosclerosis, and perform stability analysis, based wherever possible on human data. We show that a predicted consequence of multiple small radiation doses is to cause mean chemo-attractant (MCP-1) concentration to increase linearly with cumulative dose. The main driver for the increase in MCP-1 is monocyte death, and consequent reduction in MCP-1 degradation. The radiation-induced risks predicted by the model are quantitatively consistent with those observed in a number of occupationally-exposed groups. The changes in equilibrium MCP-1 concentrations with low density lipoprotein cholesterol concentration are also consistent with experimental and epidemiologic data. This proposed mechanism would be experimentally testable. If true, it also has substantive implications for radiological protection, which at present does not take cardiovascular disease into account. The Japanese A-bomb survivor data implies that cardiovascular disease and cancer mortality contribute similarly to radiogenic risk. The major uncertainty in assessing the low-dose risk of cardiovascular disease is the shape of the dose response relationship, which is unclear in the Japanese data. The analysis of the present paper suggests that linear extrapolation would be appropriate for this endpoint.

Quantification of γ-H2AX foci in Jurkat cells following irradiation with α-particles and γ-rays

Unverricht-Yeboah, Marcus[1]; Giesen, Ulrich[2]; Kriehuber, Ralf[1]

[2] Physikalisch-Technische Bundesanstalt Braunschweig, GERMANY

Abstract

Objectives: Phosphorylation of histone H2AX occurs at sites flanking DNA double-strand breaks (DSBs) and can provide a measure of the number of DSBs within a cell. We investigated whether the mean intensity and the mean number of radiation-induced γ-H2AX foci per cell vary as a function of radiation quality and dose.

Materials and methods: Jurkat cells were irradiated with different doses of either low linear energy transfer (LET) ^{137}Cs γ-rays or high LET ^{241}Am α-particles. The γ-H2AX foci were detected using immunocytochemistry and quantified by measuring the mean signal intensity of γ-H2AX foci per cell using flow cytometry and by counting the number of γ-H2AX foci with a fluorescence microscope.

Results: The mean numbers of γ-H2AX foci per cell increase with dose and they are fairly identical at 1 Gy for both investigated radiation qualities. The mean intensity of γ-H2AX foci per cell after α-irradiation is significantly increased when compared to γ-irradiation at the same radiation dose. A more advanced flow cytometry analysis reveals that the percentage of γ-H2AX-negative cells as well as the distribution of single γ-H2AX fluorescence signals depend on the radiation quality.

Conclusion: The mean signal intensity, but not the mean number, of γ-H2AX foci per cell depends on the LET in Jurkat cells. When comparing the induction of γ-H2AX foci in Jurkat cells after exposure to γ-rays and α-particles, the analysis by flow cytometry is more appropriate than the microscopical quantification by eye, considering the LET-dependence of foci-size and -intensity, the cell cycle dependence of γ-H2AX frequencies and the distributions of single γ-H2AX fluorescence signals.

Radiation-induced transgenerational instability and genetic risk

Dubrova, Yuri E.
University of Leicester, Department of Genetics, UNITED KINGDOM

Abstract

Mutation induction in the directly exposed cells is currently regarded as the main component of the genetic risk of ionizing radiation. However, recent data on the delayed effects of exposure to ionizing radiation represent a new challenge to the existing paradigm. The results of numerous studies show that ionizing radiation can not only induce mutations in the directly exposed cells, but can also lead to delayed effects, with new mutations arising many cell divisions after irradiation.

Apart from the studies on mutation rates in somatic cells, considerable progress has been made in the analysis of radiation-induced instability in the mammalian germline, where the effects of radiation exposure were investigated among the offspring of irradiated parents. Our results show that mutation rates at tandem repeat DNA loci and protein-coding genes are substantially elevated in the germline and somatic tissues of non-exposed offspring of irradiated male mice. According to our data, the transgenerational destabilization can be attributed to the presence of a subset of endogenous DNA lesions. We have recently shown that paternal treatment by the alkylating agent ethylnitrosourea also results in the transgenerational effects, thus implying that this phenomenon is most probably triggered by a stress-like response to a generalized DNA damage.

Our data imply that instability detected in the non-exposed offspring is caused by some DNA-dependent signal transmitted from the irradiated father and implicate an epigenetic mechanism for the transgenerational instability. The potential implication of these results for the estimates of genetic risks for humans will be discussed.

Low doses of irradiation on nervous cells impairs neurite outgrowth and causes neuronal degeneration

Abstract

Brain damage induced by prenatal irradiation is a major concern and an important issue in radiation protection. The embryonic stage of brain development is known to be highly sensitive to radiations, since most of the concerned cells are still mitotic. Thus, an acute irradiation during pregnancy could selectively damage cells, which at that particular time of exposure, are proliferating or migrating. Data collected from the epidemiological studies on the children that were irradiated in utero during Hiroshima and Nagasaki's A-Bombing, showed an increase of some mental and/or cognitive disorders. Depending on the received radiation dose, the severity of the damage occurs at crucial embryonic stages for neuronal survival, proliferation, migration, and/or neural network formation. In this study, we investigate the main cellular and molecular mechanisms involved in radiation-induced neurite outgrowth and apoptosis. Various time points and irradiation doses were compared at different neuronal maturation stages. Image analysis of immuno stained control compared to irradiated neuron cells with low and moderates doses (0.1, 0.2 and 0.5 Gy), showed a clear negative radiation effect on neurite outgrowth depending on the maturation stage of neurons. In particular, the main radiation-induced morphological effects were: shortened neurite length, decreased number of neurite per neuron and reduced synapse branching. These effects could lead to a defect in neural network formation and consequently to possible cognitive disorders at the adult age. The molecular and biochemical events will be further analysed using transcriptomic, proteomic and metabolomic technologies in order to identify the compromised molecular and signaling pathways in neuron cells after exposure to moderate and low doses of X-rays. Molecular strategies (overexpression or silencing) would help to validate the identified pathways.

The European Radiobiological Archives: online access to data from radiobiological experiments

Birschwilks, Mandy[1]; Adelmann, Clemens[1];Gruenberger, Michael[2];

Abstract

Today's research is providing us more and more with the opportunity to quantify radiation risks at the individual level. New approaches allow the re-analysis of old data using new techniques. Thus, the retrospective analysis of earlier studies is an important resource for modelling and evaluating risk parameters. The European Radiobiology Archives (ERA), together with corresponding Japanese and American databases, hold data from nearly all experimental animal radiation studies carried out between the 1950s and the 1990s, involving more than 400,000 animals. These experiments were performed on different species with the aim of understanding the effects of irradiation. This mass of information has led to the requirement for a computerized database to store, organize and index this data. The previously existing ERA archive has now been transferred to a web-based database to maximise its usefulness to the scientific community and bring data coding and structure of this legacy database into congruence with currently accepted semantic standards for anatomy and pathology. The accuracy of the primary data input was assessed and improved. The original rodent pathology nomenclature was recoded to Mouse Pathology (MPATH) and Mouse Anatomy (MA) ontology terms. A pathology panel sampled histopathological slide material and compared the original diagnoses with currently accepted diagnostic criteria. The mean non-systematic error rate was low with only 1.7%. Detected errors were corrected. The majority of the original pathology terms have been translated into a combination of MPATH and MA ontology terms. The database is accessible online at *http://era.bfs.de*. It has the potential of becoming a world-wide radiobiological research tool for numerous applications, such as the re-analysis of existing data and using the database as an information resource for planning future animal studies.

A large-scale gene expression database on the effect of low doses of radiation: a systems biology approach

Monsieurs, Pieter; Quintens, Roel; Janssen, Ann; Michaux, Arlette; Jacquet, Paul; Baatout, Sarah; Benotmane, M. Abderrafi

Abstract
Current radiation protection regulatory limits are based on the linear non-threshold theory using epidemiological data from atomic bombing survivors. Recent studies sparked debate on the validity of the theory, especially at low doses. Recent advances in molecular biology have shown that different genes and pathways might be triggered by low doses and by high doses of ionising radiation. Identifying the genes and pathways involved in the response to low doses is therefore critical for a better prediction of a possible clinical outcome following radiation exposure.

The increasing interest in the effect of low doses of radiation coincides with the breakthrough in the development of new high-throughput technologies in molecular biology. The microarray technology allows simultaneous measurement of the expression of thousands of genes. As gene expression is the predominant level controlling cell functioning, this technology has become a powerful tool to measure the impact of low doses of radiation.

A major challenge is how to integrate all data resulting from a wide range of experiments and use them to improve our global understanding of the general molecular response of a cell after radiation exposure to low doses. Therefore, we organized into one microarray compendium all radiation expression studies performed within our laboratory. In total, our compendium comprises 233 arrays representing 89 different biological conditions. Applying a systems biology approach on these data will shed light on the relationship between gene expression and different parameters like dose, tissue and organism. Additionally, identification of pathways triggered upon low doses of radiation might open new opportunities towards biodosimetry and appropriate regulation regarding medical exposure and intrinsic radiation sensitivity.

Introduction
The last decade, molecular biology has been revolutionized by the development of many high-throughput technologies *e.g.* in DNA sequencing, gene expression analysis, electrophoresis, and mass spectrometry. A major advancement herein was the invention

of microarrays allowing the transcriptional analysis of thousands of genes in a single experiment. This technological progress now allows analyzing simultaneously the expression of genes at a genome-wide scale. The usage of this technology is certainly not new, as different research groups – including ours - already used this technology to study the influence of radiation on different tissues like blood, brain, liver, kidney, thyroid and others (Amundson et al. 2000, Franco et al. 2005, Paul and Amundson 2008, Pawlik et al. 2009, Tachiiri et al. 2006, Taki et al. 2009, Zhao et al. 2006).

However, to our knowledge it is the first time that a systematic approach is developed to analyse a large and diverse compendium of microarray data using a systems biology approach. Over the last three years, a large number of microarray experiments using Affymetrix technology were performed within the radiobiology group of the Belgian Nuclear Research Center (SCK•CEN), exposing different tissues from human and mouse origins to various doses of ionising radiation (ranging from 0.025 Gy to 8 Gy of X-rays). This resulted in a total of 233 arrays, representing 89 different conditions. The aim of this study is to combine the knowledge present in all these data sets and explore the influence of different parameters (species, tissue, dose) on the genome-wide transcription profiles. In a first stage, a high-level analysis of the data is performed, applying traditional data mining techniques, and exploring the clustering of the different microarray data in the light of the here above mentioned parameters. In a second stage, the data are analysed at the functional level by classifying them based on their annotation, and mapping the gene expression data on existing pathways in order to identify new pathways triggered upon ionizing radiation.

Material and methods

Data sets

All samples from various organisms (mice or men) and various tissues (blood, thyroid, brain and embryo) were irradiated using X-rays ranging from 0.025 Gy to 8 Gy with a Pantak HF420 RX machine operating at 250 keV, 1.5 or 15 mA, 1 mm Cu filtration and a dose rate of 0.375 Gy/min. Dosimetry was performed on a regular basis with a 0.6 cm^3 ionisation chamber (NE 2571), which was connected to a dosemeter (Farmer dosemeter 2570). The chamber was placed in parallel to the irradiated mouse cages. Dose homogeneity was evaluated as being <1.5%. From all samples, RNA was extracted and converted to biotin-labelled cDNA, which was hybridized to GeneChip® Human Gene 1.0 ST Array and Mouse Gene 1.0 ST Array (Affymetrix, Santa Clara, USA) for human and mouse samples respectively (Table 1).

Table 1. Overview of microarray data.

Species	Tissue	Doses (Gy)	# Arrays	# Conditions
Human	Blood	0.1, 1	60	30
Human	Thyroid	0.0625, 0.5, 4	12	4
Mouse	Thyroid	0.025, 0.05, 0.0625, 0.1, 0.5, 1, 4, 8	86	30
Mouse	Embryonic brain	0.1, 0.2, 0.5, 1	37	10
Mouse	Whole embryo (early gastrula)	0.2, 0.4	38	15
		Total	**233**	**89**

Data preprocessing

Raw Affymetrix data were preprocessed using the "Affy" package (version 1.22.0) in BioConductor (version 2.4) as follows: 1) background correction based on the Robust Multichip Average (RMA) convolution model (Irizarry et al. 2003), 2) quantile normalization to make expression values from different arrays more comparable (Bolstad et al. 2003), 3) summarization of multiple probe intensities for each probeset to one expression value per gene using RMA (Irizarry et al. 2003). To test for differential expression between the different irradiated conditions and the reference conditions (no irradiation) we used the Bayesian adjusted *t*-statistics as implemented in the "LIMMA" package (version 2.18.0) (Smyth 2004). P-values were corrected for multiple testing using the Benjamini and Hochberg's method to control the false discovery rate (Benjamini and Hochberg 1995).

Statistical and data mining applications

All statistical and data mining analyses like principal component analysis, correlation analysis and hierarchical clustering were performed with "Stats" package within the statistical software R (version 2.9.0).

Differentially expressed genes and overlapping gene sets

In order to identify differentially expressed genes, a fixed cutoff on the fold change of 1.5 was used. Statistical significance of the overlap of differentially expressed genes between different experiments was calculated using the hypergeometric distribution. This distribution allows calculating the overlap of genes between two conditions, taking into account the number of differentially expressed genes in both conditions separately.

Functional enrichment

A gene set enrichment analysis (GSEA) determines to which extent a specific gene set is associated with a particular pathway or biological function. In order to calculate the statistically significant enrichment of a set of differentially expressed genes towards a specific pathway or biological process, the KEGG (Kanehisa et al. 2010) and Gene Ontology (Ashburner et al. 2000) databases were used respectively. This analysis was performed using the "GOstats" package (version 2.10.0) (Falcon and Gentleman 2007) of BioConductor (version 2.5)

Results

Data preprocessing

All data were preprocessed as explained in the "Material and methods" section. The relative expression of genes was measured by comparing the gene expression in irradiated tissues with gene expression in control samples of the same tissue. This prevented that we would only find tissue-specific genes when comparing different experiments, which would not be related to irradiation but rather to the intrinsic function of the cells in specific tissues. By recalculating the expression levels to fold changes (*i.e.* the ratio of the expression level in irradiated tissues over the expression level in control non-irradiated samples), the number of conditions was reduced from 89 to 63 experiments. By applying a variation filter, all genes showing minimal variation across different experiments were excluded.

Classification of radiation expression profiles

Using Principal Component Analysis (PCA), a first approach focused on the general similarities or dissimilarities between transcription profiles of different experiments. PCA is an algorithm that reduces the dimensionality of the data while retaining most of the variation in the data set. Experiments grouping closely together in a PCA biplot can be considered as sharing a similar transcriptional response after irradiation.

The extreme position of two thyroid irradiation experiments is a first emerging pattern (see Figure 1). The position of these experiments on the PCA plot could be more easily explained by the experimental setup, than by an effect of dose or tissue. Indeed, in contrast to other irradiation experiments where messenger RNA (mRNA) was isolated at most a few hours after irradiation, the mice in those experiments were irradiated at a specific time point, and the mRNA of the thyroid was isolated after 9 or 18 months respectively.

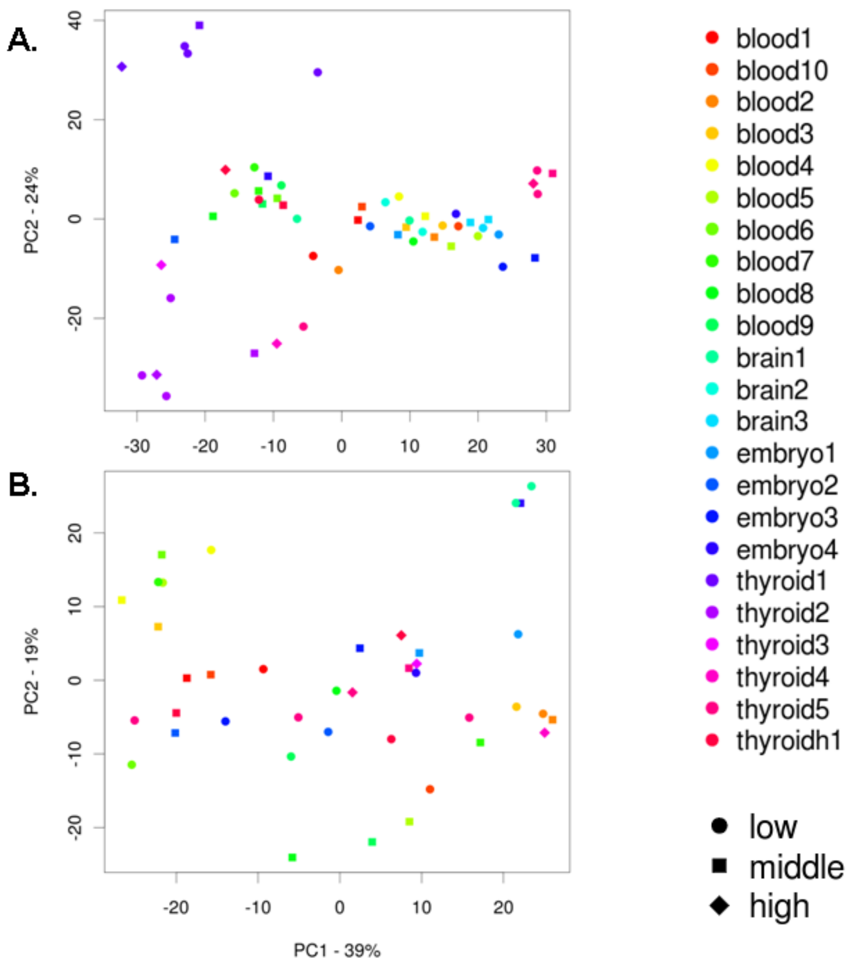

Fig. 1. PCA biplot of A) all irradiation experiments. B) all irradiation experiments with exception of long-term thyroid experiment (mRNA extraction after 9 [thyroid1] and 18 months [thyroid2]). Colour codes represent the different experiments, symbols indicate the radiation dose: low (<0.2Gy), middle (0.2Gy – 1Gy) and high (> 1Gy)

As a second observation, no tight clustering was found for the parameter of dose. This is remarkable as the data set included samples irradiated over a wide dose range, varying from low doses as 0.025 Gy up to doses as high as 8 Gy. The same conclusion could be drawn concerning the species-effect: no clear distinction could be made between the gene expression profiles originating from human or mouse samples. On the contrary, all microarray data seemed to cluster together rather on the type of experiment, even when irradiated with largely different radiation doses. For example considering the arrays measuring the gene expression after irradiation of the thyroid followed by immediate extraction of mRNA, all arrays cluster tightly together regardless irrespective of the irradiation dose (0.1 or 4Gy). Such effect could hardly be explained by an artefact resulting from a batch effect, since experiments performed with the same settings but at time points lying at least one year from each other, tend to cluster together as observed in the irradiated human blood samples.

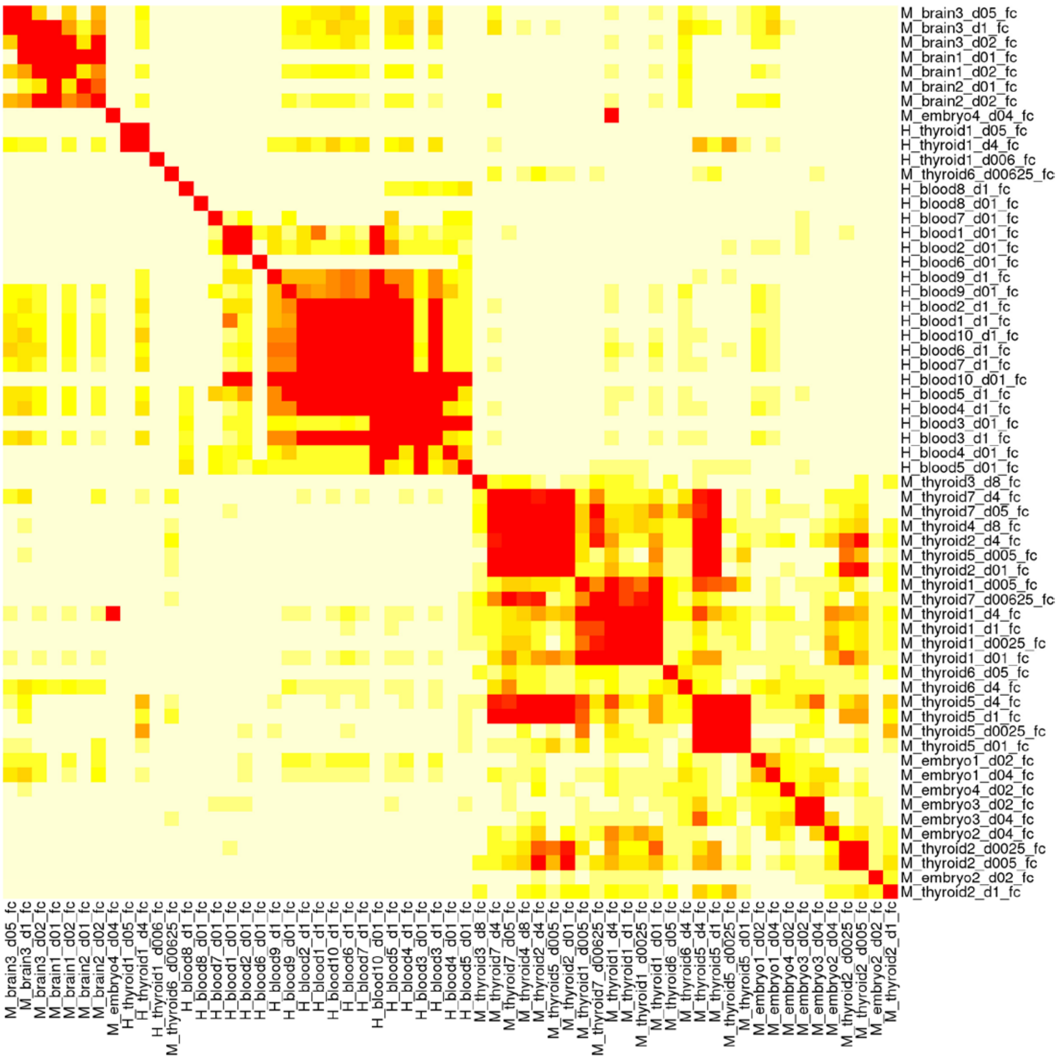

Fig. 2. Clustering of 63 experiments based on the statistical significance (P-value) of the number of overlapping genes shared between two experiments. The red colour indicates a highly significant overlap, the white colour means no significant overlap.

Differentially expressed genes

Whereas previous high-level analysis was based on simultaneous analysis of thousands of genes with the highest variance over the different conditions, analysis of the differentially expressed genes within the various conditions allows interpretation from an alternative angle. Taking into account the number of upregulated genes with a cutoff on the fold change of 1.5, the highest number of differentially expressed genes was observed for the thyroid irradiated samples with late mRNA extraction (after 9 and 18 months respectively) and for a subset of irradiated embryo (gastrula stage) samples. The former observation is in agreement with the PCA results reported in the previous paragraph. When taking into account the overlap of differentially expressed genes between various conditions, clustering based on the statistical significance of the overlap was done according to the tissue type (blood, brain, thyroid, and embryo) (Figure 2). These results suggest the presence of a tissue-specific transcriptional response towards radiation. From a species-specific point of view, the number of overlapping genes between human and mouse irradiated thyroid is very limited.

Focussing on the blood samples, a significant increase in the number of differentially expressed genes is observed when increasing the radiation dose from low (0.1 Gy) to high (1 Gy). Moreover, taking into account the overlap of differentially expressed genes between all blood samples, a tight grouping of the 1 Gy samples is observed, while a less robust overlapping set of genes is observed for the lower dose (0.1 Gy).

Functional interpretation of radiation response

Using a gene set enrichment strategy, functional enrichment of the differentially expressed genes in all irradiation experiments was performed using the KEGG pathway database (Kanehisa et al. 2010) and the Gene Ontology classification system.

No KEGG pathway or GO biological process could be found to be commonly enriched in all (or a majority of) experiments. This corresponds with the observation of differentially expressed genes being tissue specific, as discussed in previous paragraph. As such, clustering based on functional enriched categories results in grouping of the experiments based on tissue.

The most significantly enriched KEGG pathways (cut-off on p-value on 0.05) were the p53 signalling (KEGG:04115), the nucleotide excision repair (KEGG:03420) and the cell cycle (KEGG:04110) pathways, enriched respectively in 28, 22 and 13 out of the 63 experiments. The first pathway was significantly enriched in roughly all irradiated blood samples (0.1 Gy and 1 Gy) and almost all irradiated embryonic brain samples (0.2 Gy and 0.4 Gy) (Figure 3.A). With regard to the blood samples, a clear dose dependency could be observed. The other two pathways could not be assigned to a specific subset of experiments. Remarkably, the apoptosis pathway (KEGG: 04210) was only enriched in four experiments. However, zooming in onto the individual expression values of the genes belonging to this pathway revealed an interesting pattern: a consistent set of genes was found to be upregulated within the thyroid experiments where extraction of mRNA was performed after several months compared with the non-irradiated sample at the same time (Figure 3.B).

Similarly, the most enriched GO biological processes were related to DNA damage and repair (e.g. GO:0006974, GO:0006281) and cell cycle (e.g. GO:0051726, GO:0007067), all enriched in at least 14 out of the 63 experiments, with a maximum of 24 for response to DNA damage stimulus (GO:0006974). The response to DNA damage stimulus was mostly enriched in the irradiated blood samples, as well as in a subset of the embryonic experiments.

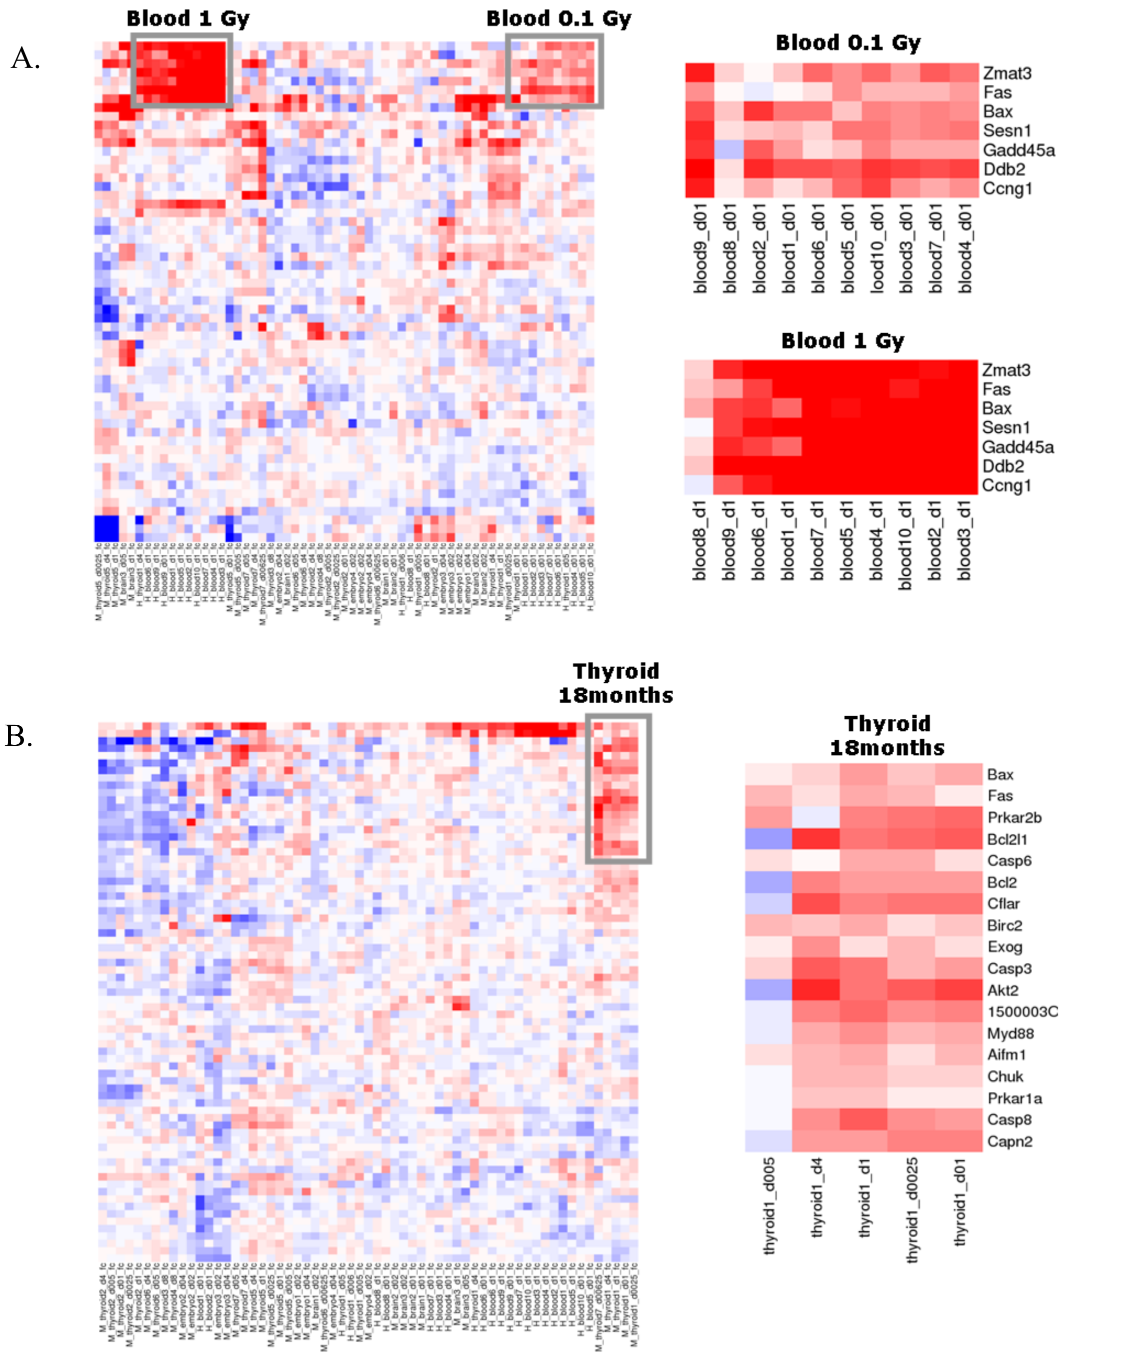

Fig. 3. Heatmap of expression of all genes belonging to A) the p53 signalling (KEGG:04115) and B) the apoptosis (KEGG:04210) pathways. For the p53 signalling pathway, a subset of genes appears to be upregulated in a dose dependent manner in the blood samples. For the apoptosis pathway, a set of genes is upregulated in the long-term experiment with mRNA extraction 18 months after irradiation with low and high doses.

Discussion

The advances in high-throughput technologies like microarrays have revolutionized the field of molecular biology. This microarray technology has already been used extensively to study the effect of low and high doses of ionising radiation at the transcriptional level. However, until now most studies have focussed on the impact of radiation on single specific tissues. In this paper, a more systematic approach was applied to study the radiation effect over various parameters.

A first remarkable observation in the PCA analysis was the aberrant transcriptional profile of two long-term experiments where mRNA was extracted from mouse thyroid tissue several months after low and high doses of irradiation. This deflected transcriptional behaviour was confirmed by the increasing number of upregulated genes in this long-term experiment compared to the acute stress experiment. These data obtained on mouse thyroid tissues are in line with the observation of Fält *et al.* (2003) who noticed that the number of differentially expressed genes increased dramatically with increasing culture time. In their experiment, primary human lymphocytes were irradiated, and mRNA was extracted at different time points (7, 17 and 55 days), showing a clear increase with the time in the number of modulated genes. Moreover, while the changes in the pattern of gene expression reported by Fält *et al.* (2003) occurred after a high radiation dose (3 Gy), the observations in the present study allow to extend their conclusions to doses as low as 0.05 and 0.025 Gy. In contrast with their study in which a limited overlap of genes was found between the immediate and long-term data, our results point towards a significant overlap with the acute response based on the number of upregulated genes shared between short- and long-term experiments. Interestingly, one of these long-term experiments (18 months) showed a significant enrichment of apoptosis related genes when compared to gene expression in a non-irradiated mouse of the same age.

Based on analysis by PCA, irradiation experiments are grouped together according to the experiments rather than by the irradiation dose. Accordingly, clustering based on the number of overlapping upregulated genes shows clear links with the tissue origin. As such, the gene expression in irradiated biological material seems to be tissue-specific rather than dose-specific. A similar, small scale analysis comparing two sets of differentially expressed genes after irradiation of kidney and brain with a high dose of 10 Gy, basically resulted in the same conclusion: only a very limited number of overlapping genes could be identified (Zhao et al. 2006), also pointing towards a tissue-specific response. Similarly, Pawlik *et al*. (2009) found that the expression profile of irradiated liver tissue correlated only to a small extent to the one in other tissues.

As a consequence of the tissue specificity of the transcriptional response after irradiation, no common pathway could be identified yet over different experiments or doses. However, certain pathways e.g. related to p53 signalling, cell cycle, DNA damage and repair were activated in a wide range of experiments, but mainly in the irradiated blood samples. This manifest activation of pathways related to DNA repair and cell cycle is probably related to the increased sensitivity of haematopoietic cells to radiation. Moreover, for the p53 signalling pathway, a dose specific transcriptional response was observed within irradiated blood samples, which is in agreement with similar results by other research groups aiming at identifying a potential set of radiation responsive biomarkers in blood (Dressman et al. 2007, Paul and Amundson 2008).

However, a new trend in disease classification also incorporates pathway information in order to classify diseases based on the activity of entire pathways instead of expression levels of individual genes (Lee et al. 2008, Svensson et al. 2006). Therefore, based on this and previous studies, the p53 signalling cascade might be a good candidate to be used as pathway-based biodosimetry classifier. However, the absence of a non-perturbed basal expression profile of this pathway in biodosimetry application is still a challenging issue (Paul and Amundson 2008).

Conclusions

First, results presented here point towards an important tissue-specific aspect in response to ionzing radiation. Secondly, gene expression results confirm the importance of performing studies on the long-term effect of radiation, as differential expression increased with longer post-irradiation times.

In this paper, the data are only interpreted from a bird's-eye view. However, a more thorough analysis is necessary and currently under progress. Generally, our studies point towards subtle but undeniable changes in gene expression. Therefore, an important future challenge is extracting these subtle changes in a statistically significant way by exploiting additional systems biology tools.

[2] BfS, GERMANY
[3] SURO, CZECH REPUBLIC

Abstract

Objectives: Three case-control studies nested in the French, German and Czech cohorts of uranium miners were conducted in the frame of Alpha-Risk, a European research project on the quantification of health risks associated with multiple radiation exposures. These studies aimed at investigating the joint effects of radon and smoking on lung cancer risk. A combined analysis of individual data of the three studies is presented.

Methods: The combined data set includes 1476 cases and 3389 matched controls. Cumulated radon exposure during employment was obtained from measurements or a job exposure matrix. Smoking habits were determined from medical archives and questionnaires. Analysis was performed by conditional logistic regression using a linear excess relative risk model.

Results: Smoking status was established for 1046 cases and 2492 controls. Ninety four percent of cases and 76% of controls were ex- or current smokers. Mean five-year lagged cumulated radon exposure was 335 Working Level Months (WLM) for cases and 211 WLM for controls. The excess relative risk per WLM adjusted for smoking was 0.79% (95% confidence-interval: 0.44 –1.41%). Lung cancer excess relative risk per unit exposure was about two times higher among non-smokers than among smokers and the results suggest a sub-multiplicative interaction between smoking and radon exposure on lung cancer mortality risk.

Conclusions: This collaborative study is the largest uranium miners case-control study on lung cancer with smoking information in Europe. It confirms the persistence of radon effect on lung cancer risk when smoking is taken into account and allows investigating the interaction between radon and smoking.

Cerebrovascular diseases in the cohort of Mayak PA nuclear workers

Abstract

Incidence of and mortality from cerebrovascular diseases (CVD) have been studied in a cohort of 12210 workers first employed at one of the main plants of the Mayak nuclear facility during 1948–1958 and followed up to 31 December 2000. Information on external gamma doses was available for virtually all of these workers (99.9%); the mean (± standard deviation, SD) total external gamma dose was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and 0.65±0.75 Gy (99% percentile 2.99 Gy) for women. In contrast, plutonium body burden was measured only for 30% of workers; amongst those monitored, the mean (± SD) absorbed cumulative liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women. 4418 disease cases and 753 deaths from CVD were identified in the study cohort. Having adjusted for non-radiation factors and internal alpha exposure from incorporated plutonium-239, there was statistically significant increasing trend in CVD incidence with total external gamma dose; the excess relative risk per Gy (ERR/Gy) was 0.464 (95% CI 0.360, 0.567). Much of the evidence for the raised incidence in relation to external dose arose for workers with cumulative doses above 1 Gy, although the data are consistent with a linear trend in risk with external dose. There was no statistically significant trend in CVD mortality risk with external dose or differences in mortality rates between categories for external dose. Having adjusted for non-radiation factors and external gamma exposure, there was statistically significant increasing trend in CVD incidence with total absorbed internal liver dose; the ERR/Gy was 0.155 (95% CI 0.075, 0.235). CVD incidence was statistically significantly higher among workers with a plutonium liver dose above 0.1 Gy, although the trend estimates differed between workers at different plants. There was a statistically significant increased risk of CVD mortality among workers exposed to internal alpha exposure with total liver dose of 0.1–0.5 Gy as compared with workers exposed to lower doses. There was no statistically significant trend in CVD mortality risk with absorbed internal liver dose. The risk estimates for external radiation are generally compatible with those from other large occupational studies, although the incidence data point to higher risk estimates compared to those from the Japanese A-bomb survivors.

Introduction

Ischemic heart disease and cerebrovascular diseases (CVD) are currently among the main death causes in developed countries. CVD are multifactorial diseases, and different endogenous (genetic predisposition, gender, age, hypertension etc.) and exogenous (smoking, emotional stress etc.) factors contribute to their development. Over the last two decades several studies have examined the possible effects of ionizing radiation exposure on circulatory diseases, including CVD. Most of the studies (McGeoghegan et al 2008; Kreuzer et al 2006; Muirhead et al 2009; Shimizu et al 2010; Vrijheid et al 2007) focused on CVD mortality, whereas several studies (Yamada et al 2004; De Bruin et al 2009; Ivanov et al 2006) focused on CVD incidence.

This study was aimed at estimating risks of both CVD incidence and mortality in the cohort of Mayak PA nuclear workers first employed at one of the main plants (reactors, radiochemical, or plutonium) during 1948-1958 in relation to external gamma and internal alpha exposures, taking non-radiation factors into account.

Material and methods

Mayak PA began operations in 1948 as the first and largest nuclear weapons facility in the former Soviet Union and included all the plants necessary for weapon-grade plutonium production, namely, reactors, radiochemical plant, plutonium production plant and auxiliary plants.

From the first days of Mayak PA operation, the special system of personnel medical observation included an obligatory pre-employment medical examination and routine medical examinations of all the workers based on a common standard program. After quitting their job at Mayak, if the former worker stayed in Ozyorsk, he/she was examined at the same specialized medical hospital based on the same standard program. This system of medical observation of Mayak PA personnel health allowed a unique archive of primary medical data to be accumulated and formed the basis for establishment of the unique "Clinic" medical-dosimetry database for the Mayak PA workers cohort (Azizova et al 2008).

The study cohort included 12210 Mayak PA workers, 3552 (29.1%) of whom were women, first employed at one of the main plants from the start of operations through the end of 1958 independently of gender, age, nationality, occupation, and other characteristics. The method of identifying this cohort has been described previously elsewhere (Koshurnikova et al 1988, 1998a, 1998b, 1999).

Vital status as of 31 December 2000 was known for 88.4% of cohort members; of these workers, 52.7% were known to have died and 47.3% were known to be alive as of that time. 53.7% of the 12210 members of the study cohort were known to have left Ozyorsk by 31 December 2000. For persons who continued to be residents of Ozyorsk, vital status was known for all but one person (99.98%). Cause of death was known for 93.5% of deceased cohort members. Morbidity data for the whole period of follow-up were collected for 11597 (95.0%) workers in the study cohort. Only for 5.0% of workers could information not be collected, owing to the loss of their medical documentation. It should be noted that the CVD incidence analysis was restricted to the period of residence in Ozyorsk.

Data on vital status and on dates and causes of death for those workers who migrated from Ozyorsk were provided by the SUBI Epidemiology Laboratory; data on date and causes of death for those Ozyorsk residents whose medical cards and/or case histories had been lost, were provided by the SUBI Occupational Health Laboratory.

Individual dosimetric control of external exposure was performed at Mayak PA from the beginning of operations there. Regular monitoring of internal exposure among those who might have been exposed to plutonium-239 began later, during the 1960s (Vasilenko et al 2007a; Khokhryakov et al 2000). The results of individual monitoring of external and internal exposure were recorded in individual dosimetric cards and journals. The data contained in these documents formed the basis for the establishment of the dosimetric database of Mayak PA workers (Vasilenko et al 2007a, 2007b; Bess et al 2007; Smetanin et al 2007a, 2007b; etc).

Dose estimates from the *Mayak-Doses 2005* dosimetric system were used in this study. Annual doses of external gamma exposure were available practically for all persons in the study cohort (99.9%). The mean (± SD) total gamma dose for the whole period of work at Mayak was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and 0.65±0.75 Gy (99% percentile 2.99 Gy) for women. The range of total gamma doses was very wide, with 32.6% having a total gamma dose greater than 1 Gy.

Plutonium body burden was measured only for 30.0% of workers. Among workers monitored for plutonium exposure, absorbed dose to liver from alpha radiation was used as a surrogate for the dose to muscle; this latter dose is likely to be similar to the dose to blood vessels and the chambers of the heart. Although doses to the liver and muscle would differ, they should be highly correlated with each other. Consequently, the liver dose can be used to look for any *dose–response* relationship between plutonium exposure and circulatory disease. Amongst those who were monitored, the mean (± SD) total liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women.

Data on occupational histories and external gamma exposures for the study cohort were provided by the Mayak PA Radiation Safety Department; data on internal alpha exposure from incorporated plutonium-239 were provided by the SUBI Internal Dosimetry Department.

This study focuses on incidence of and mortality from CVD (ICD-9 codes: 430–438). Follow-up started on the date of first employment at one of the main plants and continued until the earliest of: date of the first diagnosis of CVD (for the incidence analysis) or the date of death from whatever cause (for both the mortality analysis and the incidence analysis); 31 December 2000 for those known to be alive at that time; the recorded date of departure from Ozyorsk (for the incidence analysis); and the date of "last medical information" in the case of unknown vital status. Comparisons were performed within the Mayak PA workers cohort first employed during 1948–1958.

The analyses included the calculation of relative risks (RRs) for categories of one or more factors, having adjusted for other variables. The relative risks for these categorical analyses were calculated by maximum likelihood, using the AMFIT module of EPICURE (Preston et al 1993). 95% confidence intervals for the RRs and p-values from tests of statistical significance were obtained via likelihood-based methods, using AMFIT. Attention was initially directed to non-radiation factors, following which measures of radiation exposure were analysed with adjustment (through stratification) for non-radiation factors. Analyses of internal radiation exposures were restricted to workers known to have been monitored for possible plutonium exposure.

In addition to the categorical analyses, models for trends in disease rates with level of radiation exposures were also fitted to the data, using Poisson regression methods. These models again were fitted using the AMFIT module in EPICURE. In particular, the excess relative risk (ERR) (ie. the relative risk minus 1) was modeled by a linear trend with external or internal dose, with adjustment for non-radiation factors.

In these main analyses, adjustments were made – through stratification – for gender, attained age, calendar period, period of first employment at the main plants of Mayak PA, plant, smoking and alcohol consumption.

Sensitivity analyses were conducted to examine the impact of: a) modifying the set of non-radiation factors (extra adjustment for hypertension, body mass index, employment duration) for which adjustment was made in the analyses of radiation factors; b) restricting the mortality follow-up (like that of incidence) to Ozyorsk, because some migrants were lost to follow-up and because of lower autopsy rates among those who left the city; c) adjusting for internal dose in analyses of external dose and vice versa; d) using various lag periods for external and internal doses. Furthermore, examination was made of how radiation risks might vary by gender, or between plants at Mayak or by attained age.

To allow for the possibility that radiation might affect CVD risk by modifying levels of blood pressure (Preston et al 2003; Ivanov et al 2001) and body mass index (Telnov 1985), the level of these factors at the time of preliminarily medical examination (before employment at Mayak PA) was considered, in order to avoid systematic errors that might arise through adjusting for values of these factors at later times. In contrast, smoking and alcohol consumption were classified at the time of last information (for the mortality analysis) or at the time of last information prior to the first diagnosis of CVD (for the incidence analysis).

Results

By 31 December 2000, 4418 disease cases of CVD were diagnosed during 197344 person-years of follow-up and 753 death cases from CVD were identified during 443350 person-years of follow-up.

Non-radiation factors

It is known that CVD are multifactorial diseases, therefore analyses of incidence and mortality risks in relation to non-radiation factors were performed first. Our analyses revealed statistically significant effects of well-known factors such as gender, age, hypertension, body mass index and smoking, which were taken into account in the analyses of radiation risks, either in the main analysis or in sensitivity analyses.

Radiation factors

External gamma exposure: Table 1 shows that CVD incidence was statistically significantly higher among workers chronically exposed to external gamma exposure with a total dose above 0.5 Gy as compared with workers externally exposed to lower doses.

Table 1. RRs and ERR (95% CI) for CVD incidence and mortality in relation to total dose of external gamma exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.5 Gy)		ERR/Gy
	0.5-1.0 Gy	>1.0 Gy	
Incidence	1.137 (1.036, 1.248)	1.599 (1.465, 1.746)	0.464 (0.360, 0.567)
Mortality	1.150 (0.923, 1.434)	0.994 (0.799, 1.237)	-0.022 (-0.117, 0.073)

Sensitivity analyses (results not shown) revealed that when comparing gamma doses of 0.5-1.0 Gy with lower doses, statistically significantly raised risks of CVD incidence were seen among radiochemical plant workers and among females; in other sub-groups, the findings were very close to statistical significance. CVD incidence was statistically significantly higher among workers with a gamma dose above 1.0 Gy relative to workers with a gamma dose below 0.5 Gy, irrespective of the lag period used, whether additional adjustment was made for other non-radiation factors and internal exposure as well as whether analysis was restricted to workers at different plants or by gender.

There was a statistically significant increasing trend in CVD incidence with increasing external dose (Table 1). Sensitivity analyses (results not shown) revealed that adjustments for other non-radiation factors and internal exposure as well as restriction to workers at different plants or by gender had little impact on this finding. There was also no evidence of variation in the ERR per Gy by attained age.

There was no statistically significant trend in CVD mortality risk with external dose, and for the most part mortality rates did not differ to a statistically significant extent between categories for external dose.

Internal alpha exposure: Table 2 shows that CVD incidence was statistically significantly higher among workers exposed to total absorbed dose to liver from internal alpha exposure above 0.1 Gy, as compared with workers exposed to lower doses. This finding held irrespective of the lag period used, whether adjustment was made for other non-radiation factors and external exposure as well as whether analysis was restricted to workers at different plants or by gender (results not shown).

Table 2. RRs and ERR (95% CI) for CVD incidence and mortality in relation to total absorbed liver dose from internal alpha exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.1 Gy)		ERR/Gy
	0.1-0.5 Gy	>0.5 Gy	
Incidence	1.233 (1.126, 1.350)	1.576 (1.346, 1.844)	0.155 (0.075, 0.235)
Mortality	1.401 (1.020, 1.924)	1.047 (0.609, 1.800)	0.120 (-0.116, 0.356)

There was a statistically significant increasing trend in CVD incidence with increasing internal liver dose from alpha exposure. The ERR/Gy for CVD incidence increased with increasing lag period, with values of 0.155 (95% CI 0.075, 0.235), 0.218 (95% CI 0.111, 0.326) and 0.330 (95% CI 0.174, 0.487), 0.508 (95% CI 0.269, 0.747) and 0.853 (95% CI 0.443, 1.262) based on 0, 5, 10, 15 and 20 year lags respectively.

There was a non-linearity in the trend based on zero lag, although the evidence for non-linearity appeared to be weaker when a 5-year lag was used. Adjustments for arterial hypertension, body mass index, duration of work and external exposure had little impact on the estimated trend (results not shown). Much of the evidence for this trend appeared to arise at attained ages of 50 years or more, but the variation in the ERR/Gy by attained age was not statistically significant. Furthermore, the evidence for a dose trend came mainly from males rather than females, as well as from workers at the radiochemical plant rather than plutonium production plant workers.

CVD mortality was statistically significantly raised among workers exposed to internal alpha exposure in total liver doses of 0.1–0.5 Gy as compared with workers exposed to lower doses irrespective of lag period and whether adjustment was made for other non-radiation factors as well as whether follow-up was restricted to Ozyorsk and whether adjustment was made for external exposure. However, when comparing internal doses of >0.5 Gy with doses <0.1 Gy, statistically significantly raised risks were not seen for CVD mortality, possibly reflecting the relatively small number of deaths in this subgroup.

There was no statistically significant trend in CVD mortality in relation to total absorbed liver dose from internal alpha exposure.

Discussion

Our analyses of CVD incidence and mortality revealed statistically significant effects of well-known factors such as gender, age, hypertension, body mass index and smoking, which are consistent with findings of other studies. In contrast, our analyses did not reveal any statistically significant effect of alcohol consumption on CVD incidence or mortality, either for males and females, whereas some studies (Donahue et al 1986; etc) indicated an increase in stroke mortality associated with excess alcohol consumption.

The evidence for associations with radiation in this study relates mainly to CVD incidence. For CVD mortality, the data did not show a statistically significantly increasing trend with either external or internal dose, and the estimates of these trends were lower than those for CVD incidence. There were far fewer deaths from CVD than cases in this study. A complication to interpretation is the lack of knowledge as to those tissues or organs for which radiation exposure might increase the risk of CVD, which is particularly problematic in the case of plutonium intakes. For this analysis, liver dose has been used as a surrogate for the dose to muscle, which is likely to be similar to the dose to blood vessels and the chambers of the heart. Furthermore, the liver and muscle doses should be highly correlated with each other. However, there is uncertainty about which tissue or organ dose is appropriate for this type of analysis. A further complication relates to uncertainties in estimates for internal doses for Mayak workers. In addition, whilst the results for external doses appeared to be broadly consistent with a linear *dose-response* (albeit with uncertainties in estimates at relatively low doses), the results for internal doses appeared to show some degree of non-linearity. Also, whilst the trend estimates in relation to external exposure were similar across sub-groups of workers, the trend in CVD incidence with internal dose differed not only between males and females but also between workers at the radiochemical plant and the plutonium production plant. It should be noted that – because the dose to the liver from intakes of plutonium would be greater than that to the circulatory system – the ERR/Gy estimated here based on liver dose would be lower than that based on dose to blood vessels and the chambers of the heart. At present information is not available from other studies of populations exposed to plutonium that would allow comparison of risk estimates for CVD in relation to such exposures. For these reasons, the findings in relation to internal exposure need to be interpreted with caution.

Comparison with other studies

Table 3 presents estimates of the ERR per Gy from the current study and from other studies of groups exposed to external low-LET radiation in which this trend was estimated.

Table 3. Estimates of ERR per Gy (95% CI) for CVD following exposure to external low-LET radiation.

Cohort	Mean total dose (Gy)	Mortality or incidence?	Lag period (years)	No. of deaths or cases	ERR/Gy
Japanese A-bomb survivors: Life Span Study (Shimizu et al 2010)	0.20	Mortality	5	9622	0.09 (95% CI 0.01, 0.17)
Japanese A-bomb survivors: Adult Health Study (Yamada et al 2004)	0.57	Incidence	13	729	0.07 (95% CI -0.08, 0.24)
Mayak PA workers (this study)	0.84	Mortality	10	744	-0.02 (95% CI -0.12, 0.08)
Mayak PA workers (this study)	0.84	Incidence	10	3840	0.45 (95% CI 0.34, 0.56)
Nuclear workers (international) (Vrijheid et al 2007)	0.018	Mortality	10	1224	0.88 (95% CI -0.67, 3.16)
BNFL workers (UK) (McGeoghegan et al 2008)	0.053	Mortality	15	1018	0.43 (90% CI -0.10, 1.12)
UK National Registry for Radiation Workers (Muirhead et al 2009)	0.025	Mortality	10	1817	0.16 (95% CI -0.42, 0.99)
German uranium miners (Kreuzer et al 2006)	0.041	Mortality	5	1297	0.09 (95% CI -0.6, 0.8)
Chernobyl recovery operations workers (Ivanov et al 2006)	0.109	Incidence	–	12832	0.45 (95% CI 0.11, 0.80)

Whilst the estimated ERR/Gy for mortality among Mayak workers is consistent with the A-bomb survivor findings, some of the occupational studies point towards higher risk estimates. The statistically precise estimate for CVD incidence among Mayak workers is higher than that for the A-bomb survivors but is consistent with the incidence estimate for Chernobyl recovery operation workers and the mortality estimates from the international and BNFL worker studies. The central estimates for the ERR/Gy from the UK National Registry for Radiation Workers and the German uranium miner study are not statistically significantly different from zero and are close to the estimates from the Mayak mortality data, but the confidence intervals also encompass the Mayak incidence findings.

Conclusions

Having adjusted for non-radiation factors and internal alpha exposure, there was an increasing trend in CVD incidence – but not mortality – among Mayak PA workers with total external gamma dose. Much of the evidence for a raised risk of CVD incidence in relation to external dose arises for workers with cumulative doses above 1 Gy. Although the dose response is consistent with linearity, the statistical power to detect non-linearity at external doses below 1 Gy was low. Having adjusted for non-radiation factors and external gamma exposure, there was an increasing trend in CVD incidence among Mayak PA workers with total internal alpha dose to liver. CVD incidence was statistically significantly higher among workers with a plutonium liver dose above 0.1 Gy, although the trend estimates differed between workers at different plants. There was statistically significant increased risk of CVD mortality among workers exposed to internal alpha exposure with total liver dose of 0.1–0.5 Gy as compared with workers exposed to lower doses. There was no a statistically significant trend of CVD mortality risk with absorbed internal liver dose or difference in mortality rates between categories for internal dose. The risk estimates for external radiation are generally compatible with those from other large occupational studies, although the incidence data point to higher risk estimates compared to those from the Japanese A-bomb survivors.

This study was conducted with support from the European Commission (EC)’s Euratom Nuclear Fission and Radiation Protection Programme and the Russian Federation’s Federal Medico-Biological Agency, through contract №FP6-516478 “Southern Urals Radiation Risk Research” (SOUL).

Abstract

Incidence of and mortality from ischemic heart disease (IHD) have been studied in a cohort of 12210 workers first employed at one of the main plants of the Mayak nuclear facility during 1948–1958 and followed up to 31 December 2000. Information on external gamma doses was available for virtually all of these workers (99.9%); the mean (± standard deviation, SD) total external gamma dose was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and 0.65±0.75 Gy (99% percentile 2.99 Gy) for women. In contrast, plutonium body burden was measured only for 30% of workers; amongst those monitored, the mean (± SD) absorbed cumulative liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women. 3751 disease cases and 1495 deaths from IHD were identified in the study cohort. Having adjusted for non-radiation factors, there was statistically significant increasing trend in IHD incidence with total external gamma dose; the excess relative risk per Gy (ERR/Gy) was 0.109 (95% CI 0.049, 0.168). This trend with external dose was little changed after adjusting for internal dose. Much of the evidence for the raised incidence in relation to external gamma dose arose for workers with cumulative doses above 1 Gy, although the data are consistent with a linear trend in risk with external dose. The trend with external dose in IHD mortality was not statistically significantly greater than zero, but was consistent with the corresponding trend in IHD incidence even once adjustment for internal dose was made. There was stronger evidence for an association with internal alpha dose to liver in the IHD mortality data than in the corresponding incidence data, although the associated confidence intervals overlap. Furthermore, the estimated trend in IHD mortality with internal dose was lower and not statistically significant once adjustment was made for external dose. The risk estimates for IHD in relation to external radiation are generally compatible with those from other large occupational studies and the Japanese A-bomb survivors.

Introduction

The first evidence of excess mortality from heart disease following radiation exposure came from the study of Japanese A-bomb survivors, who received single whole-body doses in the range 0-4 Gy; the most recent findings are described by Shimizu et al (2010). However, the corresponding data on ischemic heart disease (IHD) incidence in a subset of these survivors provided less evidence of an association (Yamada et al 2004). An increased risk of cardiovascular diseases has also been observed in patients who underwent radiotherapy for breast cancer or for Hodgkin lymphoma with doses of 40 Gy or more to mantle or limited fields (UNSCEAR 2006). In contrast, studies of radiation workers have yielded mixed findings. McGeoghegan et al (2008) reported an association between mortality from non-cancer causes of death, particularly circulatory disease, and external exposure to ionizing radiation in a cohort of nuclear industry workers with a mean cumulative external dose of 0.053 Sv and a 99% percentile of 0.59 Sv. However, a study of radiation workers from 15 countries did not find a statistically significant association between circulatory disease mortality and radiation dose (mean cumulative radiation dose of 0.019 Sv, with some workers receiving more than 0.5 Sv), although – in common with other studies of nuclear workers – the power of this analysis was low (Vrijheid et al 2007).

This study was aimed at estimating risks of both IHD incidence and mortality in the cohort of Mayak PA nuclear workers first employed at one of the main plants (reactors, radiochemical, or plutonium) during 1948-1958 in relation to external gamma and internal alpha exposures, taking non-radiation factors into account.

Material and methods

Mayak PA began operations in 1948 as the first and largest nuclear weapons facility in the former Soviet Union and included all the plants necessary for weapon-grade plutonium production, namely, reactors, radiochemical plant, plutonium production plant and auxiliary plants.

From the first days of Mayak PA operation, the special system of personnel medical observation included an obligatory pre-employment medical examination and routine medical examinations of all the workers based on a common standard program. After quitting their job at Mayak, if the former worker stayed in Ozyorsk, he/she was examined at the same specialized medical hospital based on the same standard program. This system of medical observation of Mayak PA personnel health allowed a unique archive of primary medical data to be accumulated and formed the basis for establishment of the unique “Clinic” medical-dosimetry database for the Mayak PA workers cohort (Azizova et al 2008).

The study cohort included 12210 Mayak PA workers, 3552 (29.1%) of whom were women, first employed at one of the main plants from the start of operations through the end of 1958 independently of gender, age, nationality, occupation, and other characteristics. The method of identifying this cohort has been described previously elsewhere (Koshurnikova et al 1988, 1998a, 1998b, 1999).

Vital status as of 31 December 2000 was known for 88.4% of cohort members; of these workers, 52.7% were known to have died and 47.3% were known to be alive as of that time. 53.7% of the 12210 members of the study cohort were known to have left Ozyorsk by 31 December 2000. For persons who continued to be residents of Ozyorsk, vital status was known for all but one person (99.98%). Cause of death was known for 93.5% of deceased cohort members. Morbidity data for the whole period of follow-up were collected for 11597 (95.0%) workers in the study cohort. Only for 5.0% of workers could information not be collected, owing to the loss of their medical documentation. It should be noted that the CVD incidence analysis was restricted to the period of residence in Ozyorsk.

Data on vital status and on dates and causes of death for those workers who migrated from Ozyorsk were provided by the SUBI Epidemiology Laboratory; data on date and causes of death for those Ozyorsk residents whose medical cards and/or case histories had been lost, were provided by the SUBI Occupational Health Laboratory.

Individual dosimetric control of external exposure was performed at Mayak PA from the beginning of operations there. Regular monitoring of internal exposure among those who might have been exposed to plutonium-239 began later, during the 1960s (Vasilenko et al 2007a; Khokhryakov et al 2000). The results of individual monitoring of external and internal exposure were recorded in individual dosimetric cards and journals. The data contained in these documents formed the basis for the establishment of the dosimetric database of Mayak PA workers (Vasilenko et al 2007a, 2007b; Bess et al 2007; Smetanin et al 2007a, 2007b; etc).

Dose estimates from the *Mayak-Doses 2005* dosimetric system were used in this study. Annual doses of external gamma exposure were available practically for all persons in the study cohort (99.9%). The mean (± SD) total gamma dose for the whole period of work at Mayak was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and 0.65±0.75 Gy (99% percentile 2.99 Gy) for women. The range of total gamma doses was very wide, with 32.6% having a total gamma dose greater than 1 Gy.

Plutonium body burden was measured only for 30.0% of workers. Among workers monitored for plutonium exposure, absorbed dose to liver from alpha radiation was used as a surrogate for the dose to muscle; this latter dose is likely to be similar to the dose to blood vessels and the chambers of the heart. Although doses to the liver and muscle would differ, they should be highly correlated with each other. Consequently, the liver dose can be used to look for any *dose–response* relationship between plutonium exposure and circulatory disease. Amongst those who were monitored, the mean (± SD) total liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women.

Data on occupational histories and external gamma exposures for the study cohort were provided by the Mayak PA Radiation Safety Department; data on internal alpha exposure from incorporated plutonium-239 were provided by the SUBI Internal Dosimetry Department.

This study focuses on incidence of and mortality from IHD (ICD-9 codes: 410–414). Follow-up started on the date of first employment at one of the main plants and continued until the earliest of: date of the first diagnosis of CVD (for the incidence analysis) or the date of death from whatever cause (for both the mortality analysis and the incidence analysis); 31 December 2000 for those known to be alive at that time; the recorded date of departure from Ozyorsk (for the incidence analysis); and the date of "last medical information" in the case of unknown vital status. Comparisons were performed within the Mayak PA workers cohort first employed during 1948–1958.

The analyses included the calculation of relative risks (RRs) for categories of one or more factors, having adjusted for other variables. The relative risks for these categorical analyses were calculated by maximum likelihood, using the AMFIT module of EPICURE (Preston et al 1993). 95% confidence intervals for the RRs and p-values from tests of statistical significance were obtained via likelihood-based methods, using AMFIT. Attention was initially directed to non-radiation factors, following which measures of radiation exposure were analysed with adjustment (through stratification) for non-radiation factors. Analyses of internal radiation exposures were restricted to workers known to have been monitored for possible plutonium exposure.

In addition to the categorical analyses, models for trends in disease rates with level of radiation exposures were also fitted to the data, using Poisson regression methods. These models again were fitted using the AMFIT module in EPICURE. In particular, the excess relative risk (ERR) (ie. the relative risk minus 1) was modeled by a linear trend with external or internal dose, with adjustment for non-radiation factors.

In these main analyses, adjustments were made – through stratification – for gender, attained age, calendar period, period of first employment at the main plants of Mayak PA, plant, smoking and alcohol consumption.

Sensitivity analyses were conducted to examine the impact of: a) modifying the set of non-radiation factors (extra adjustment for hypertension, body mass index, employment duration) for which adjustment was made in the analyses of radiation factors; b) restricting the mortality follow-up (like that of incidence) to Ozyorsk, because some migrants were lost to follow-up and because of lower autopsy rates among those who left the city; c) adjusting for internal dose in analyses of external dose and vice versa; d) using various lag periods for external and internal doses. Furthermore, examination was made of how radiation risks might vary by gender, or between plants at Mayak or by attained age.

To allow for the possibility that radiation might affect IHD risk by modifying levels of blood pressure (Preston et al 2003; Ivanov et al 2001) and body mass index (Telnov 1985), the level of these factors at the time of preliminarily medical examination (before employment at Mayak PA) was considered, in order to avoid systematic errors that might arise through adjusting for values of these factors at later times. In contrast, smoking and alcohol consumption were classified at the time of last information (for the mortality analysis) or at the time of last information prior to the first diagnosis of IHD (for the incidence analysis).

Results

By 31 December 2000, 3751 disease cases of IHD were diagnosed during 205249 person-years of follow-up and 1495 death cases from IHD were identified during 443350 person-years of follow-up.

Non-radiation factors

Our analyses revealed statistically significant effects of well-known factors such as gender, age, hypertension, body mass index and smoking, which were taken into account in the analyses of radiation risks, either in the main analysis or in sensitivity analyses.

Radiation factors

<u>External gamma exposure</u>: Table 1 shows that IHD incidence was statistically significantly higher among workers chronically exposed to external gamma exposure

with a total dose above 1.0 Gy as compared with workers externally exposed to doses below 0.5 Gy.

Table 1. RRs and ERR (95% CI) for IHD incidence and mortality in relation to total dose of external gamma exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.5 Gy)		ERR/Gy
	0.5-1.0 Gy	>1.0 Gy	
Incidence	1.017 (0.919, 1.126)	1.198 (1.087, 1.320)	0.109 (0.049, 0.168)
Mortality	0.918 (0.778, 1.084)	1.115 (0.959, 1.295)	0.065 (-0.017, 0.148)

Sensitivity analyses (results not shown) revealed that IHD incidence was statistically significantly higher among workers with a gamma dose above 1.0 Gy relative to workers with a gamma dose below 0.5 Gy, irrespective of the lag period used, whether additional adjustment was made for other non-radiation factors and internal exposure. The RRs above 1 Gy for IHD incidence were statistically significant only among men as well as reactor or plutonium plant workers.

There was a statistically significant increasing trend in IHD incidence with increasing external gamma dose (Table 1). Sensitivity analyses (results not shown) revealed that using different lag periods, adjustments for other non-radiation factors and internal exposure had little impact on this finding. Much of the evidence of the raised risk related to men as well as reactor and plutonium plant workers. The findings were too imprecise to judge whether the relative risk in relation to external dose varied by attained age.

There was no statistically significant trend in IHD mortality risk with external dose, and for the most part mortality rates did not differ to a statistically significant extent between categories for external dose.

Internal alpha exposure: Table 2 shows that IHD incidence and mortality were statistically significantly higher among workers with a total absorbed dose to liver from internal alpha exposure of either 0.1-0.5 Gy or above 0.5 Gy, as compared with workers exposed to doses below 0.1 Gy.

Table 2. RRs and ERR (95% CI) for IHD incidence and mortality in relation to total absorbed liver dose from internal alpha exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.1 Gy)		ERR/Gy
	0.1-0.5 Gy	>0.5 Gy	
Incidence	1.171 (1.060, 1.295)	1.225 (1.036, 1.447)	0.032 (-0.014, 0.079)
Mortality	1.332 (1.082, 1.640)	1.591 (1.158, 2.185)	0.276 (0.050, 0.501)

Table 2 shows that the estimates of the RRs and of the ERR/Gy were higher in the mortality data than in the corresponding incidence data. These findings were maintained when different lag periods were used (with a tendency for the estimated ERR/Gy to increase with increase lag), when (for the mortality analysis) follow-up was restricted to Ozyorsk, and – for the most part – when additional adjustment was made for other non-radiation factors (results not shown). For IHD mortality, the trend in risk with internal liver dose was statistically significantly greater than zero, but the estimated ERR/Gy was lower and was not statistically significant once adjustment was made for external dose. Overall, there was no statistically significant trend in IHD incidence with internal liver dose, either with or without adjustment for external dose, although the ERR estimate was greater for males than for females and the difference between the gender-specific values was statistically significant. The findings were too imprecise to judge whether the relative risk in relation to internal dose varied by attained age.

Discussion

Our analyses of IHD incidence and mortality revealed statistically significant effects of well-known factors such as gender, age, hypertension, body mass index and smoking, which are consistent with findings of other studies. In contrast, our analyses did not reveal any statistically significant effect of alcohol consumption on IHD incidence or mortality, either for males and females.

There was a statistically significant increasing trend in IHD incidence with total external gamma dose. Much of the evidence for this trend in IHD incidence appeared to relate to external doses in excess of 1 Gy. Adjustments to other non-radiation factors as well as internal exposure did not have much effect on this trend. The trend with external dose in IHD mortality, whilst not statistically significantly greater than zero, was consistent with the statistically significantly trend estimate in IHD incidence. Among workers with internal liver doses there was stronger evidence for an association with these doses in the IHD mortality data than in the corresponding incidence data, although the associated confidence intervals overlap. Furthermore, the estimated trend in IHD mortality with internal dose was maintained when adjustment was made for non-radiation factors, but was lower and not statistically significant once adjustment was made for external dose.

A complication to interpretation is the lack of knowledge as to those tissues or organs for which radiation exposure might increase the risk of IHD, which is particularly problematic in the case of plutonium intakes. For this analysis, liver dose has been used as a surrogate for the dose to muscle, which is likely to be similar to the dose to blood vessels and the chambers of the heart. Furthermore, the liver and muscle doses should be highly correlated with each other. However, there is uncertainty about which tissue or organ dose is appropriate for this type of analysis. A further complication relates to uncertainties in estimates for internal doses for Mayak workers. It should be noted that – because the dose to the liver from intakes of plutonium would be greater than that to the circulatory system – the ERR/Gy estimated here based on liver dose would be lower than that based on dose to blood vessels and the chambers of the heart. At present information is not available from other studies of populations exposed to plutonium that would allow comparison of risk estimates for IHD in relation to such exposures. For these reasons, the findings in relation to internal exposure need to be interpreted with caution.

Comparison with other studies

Table 3 presents estimates of the ERR per Gy from the current study and from other studies of groups exposed to external low-LET radiation in which this trend was estimated. It can be seen that the estimates from the various studies are mostly consistent. In particular, the incidence findings for Mayak PA workers are consistent with incidence and mortality results for the Japanese atomic studies. The wide confidence interval from the 15-country nuclear worker study means that these results are not greatly informative, whilst the morbidity data reported by Chernobyl clean-up workers – although yielding a trend estimate higher than that found here – are consistent with the Mayak findings. The only finding that is inconsistent with the Mayak results arises for workers at BNFL in the UK, whereas a larger study of UK radiation workers that included BNFL workers yielded a lower ERR estimate.

Table 3. Estimates of ERR per Gy (95% CI) for IHD following exposure to external low-LET radiation.

Cohort	Mean total dose (Gy)	Mortality or incidence?	Lag period (years)	No. of deaths or cases	ERR/Gy
Japanese A-bomb survivors: Life Span Study (Shimizu et al 2010)	0.20	Mortality	5	3252	0.02 (95% CI 0.10, 0.15)
Japanese A-bomb survivors: Adult Health Study (Yamada et al 2004)	0.57	Incidence	13	1546	0.05 (95% CI 0.05, 0.16)
Mayak PA workers (this study)	0.84	Mortality	10	1461	0.07 (95% CI 0.02, 0.15)
Mayak PA workers (this study)	0.84	Incidence	10	3133	0.12 (95% CI 0.05, 0.19)
Nuclear workers (international) (Vrijheid et al 2007)	0.018	Mortality	10	5821	-0.01 (95% CI 0.59, 0.69)
BNFL workers (UK) (McGeoghegan et al 2008)	0.053	Mortality	15	3567	0.70 (95% CI 0.33, 1.11)
UK National Registry for Radiation Workers (Muirhead et al 2009)	0.025	Mortality	10	7168	0.26 (95% CI 0.05, 0.61)
Chernobyl recovery operations workers (Ivanov et al 2006)	0.109	Incidence	–	10942	0.41 (95% CI 0.05, 0.78)

Conclusions

Having adjusted for non-radiation factors, there was statistically significant increasing trend in IHD incidence with total external gamma dose. This trend with external dose was little changed after adjusting for internal dose. Much of the evidence for the raised incidence in relation to external gamma dose arose for workers with cumulative doses above 1 Gy, although the data are consistent with a linear trend in risk with external dose. The trend with external dose in IHD mortality was not statistically significantly greater than zero, but was consistent with the corresponding trend in IHD incidence even once adjustment for internal dose was made. There was stronger evidence for an association with internal alpha dose to liver in the IHD mortality data than in the corresponding incidence data, although the associated confidence intervals overlap.

Furthermore, the estimated trend in IHD mortality with internal dose was lower and not statistically significant once adjustment was made for external dose. The risk estimates for IHD in relation to external radiation are generally compatible with those from other large occupational studies and the Japanese A-bomb survivors.

This study was conducted with support from the European Commission (EC)'s Euratom Nuclear Fission and Radiation Protection Programme and the Russian Federation's Federal Medico-Biological Agency, through contract №FP6-516478 "Southern Urals Radiation Risk Research" (SOUL).

Abstract

Aims: While the increased risk of thyroid cancer is well demonstrated in children exposed to radioactive iodines in the most contaminated areas around the Chernobyl power plant, the effect of exposure on adults remains unclear. The objective of the study was to evaluate the radiation-induced risk of this disease among Chernobyl liquidators.

Methods: A collaborative case-control study of thyroid cancer was conducted, nested within cohorts of Belarussian, Russian and Baltic liquidators of the Chernobyl accident. The liquidators were mainly exposed to external radiation, although substantial dose to the thyroid from iodine isotopes may have been received by those who worked in May – June 1986 and who resided in the most contaminated territories of Belarus. Individual doses to the thyroid from external radiation and from iodine-131 were estimated for each subject.

Findings: 107 case patients and 423 matched controls were included in the study. Median age at the moment of first exposure was 37 years. Most subjects received low

doses (median 69 mGy). The doses were much higher for women (median 196 mGy) than for men (median 64 mGy).

A significantly elevated Odds Ratio was seen at doses of 300 mGy and above. The overall Excess Relative Risk (ERR) per 100 mGy was 0.38 (95% confidence interval (CI): 0.10, 1.09). Risk estimates were similar for iodine-131 and external exposure – ERR per 100 mGy was 0.45 (95% CI: 0.10, 1.61) and 0.38 (95% CI: -0.11, 2.07), respectively.

Conclusions: Although higher than risk estimated from a-bomb survivors exposed as adults, the significantly elevated risk observed in the present study is similar to that obtained in the recent studies of thyroid cancer following exposure to iodine-131 in childhood in the areas contaminated after the Chernobyl accident. The increased risk appears to be related to iodine-131 exposure, as well as to doses from external radiation.

Lens opacities among physicians occupationally exposed to radiation

Abstract
We estimated the prevalence of lens opacities in physicians occupationally exposed to radiation.

Based on a nationwide registry of 1312 physicians, mostly radiologists with occupational exposure to ionising radiation, 120 subjects were invited to participate and 59 (49%) consented. The inclusion criteria included age 45-70 years, cumulative recorded radiation dose >10 mSv, and duration of work with dose monitoring >15 years. The participants filled in a questionnaire regarding occupational history and other risk factors for lens opacities. A full ophthalmological examination was performed. Lenticular changes were graded using the Lens Opacities Classification System, version II (LOCS II).

Any lens opacities were detected in 42% (95% confidence interval [CI] 29-56) of the 57 physicians without prior cataract surgery. Nuclear opacities were found in 11% (95% CI 4-22), cortical 8% (95% CI 2-19) and posterior subcapsular in 5% (95% CI 1-15) of the subjects. The prevalence of lens opacities increased with age, smoking and cumulative recorded radiation dose. After controlling for age, sex and smoking, cumulative radiation dose was positively associated with any lens opacities (p=0.06). Intervention radiologists and cardiologists had higher rates of cortical and posterior lens opacities than the other physicians.

Our preliminary results show posterior subcapsular lens opacities in physicians exposed to occupational radiation, consistent with recent studies on low dose radiation exposure. A full study with an unexposed reference group for risk estimation is warranted.

Introduction
The prevalence of lens opacities varies by age and diagnostic criteria used. The aetiology of cortical cataract is related to ultraviolet radiation and diabetes, whereas established risk factors for nuclear cataract include nutritional factors and smoking (Taylor et al. 1988, West et al. 1989, Klein et al. 1999). Other factors associated with

cataracts include diabetes, steroid use, ocular injury, myopia and cardiovascular disease (Taylor et al. 1988, Leske et al. 1991, Delcourt et al. 2000).

Radiation cataract is a well established effect of high doses shown in experimental studies and also in humans among survivors of the Hiroshima and Nagasaki atomic bombs (Otake v1992, 1996, Minamoto et al. 2004, Nakashima et al. 2006). Radiation induces changes in the lens epithelium, typically in the posterior subcapsular part of the lens. Radiation-related cataract has been regarded as a deterministic effect, which occurs only after high doses, with a threshold of approximately 1 Gy.

However, this view has been challenged by recent studies, which have shown increased risk of lens opacities even after low dose exposure (Ainsbury et al. 2009). Re-analyses of atomic bomb survivor data have demonstrated that the findings are compatible both with threshold (about 1.5 Sv) and linear models (Otake et al. 1992, 1996, Minamoto et al. 2004, Nakashima v2006). Besides posterior subcapsular opacities, dose-dependence in frequency of cortical cataracts has been shown among A-bomb survivors. Posterior subcapsular opacities were also more frequent among Ukrainian children affected by the fallout from the Chernobyl nuclear power plant accident (with a prevalence of 1%) than in controls (Day et al. 1995). More than 50% of Icelandic airline pilots exposed to cosmic radiation had some lens opacities, and 7-8% of them had posterior subcapsular cataracts (Rafnsson et al. 2005).

We conducted ophthalmological examinations among radiologists and other physicians exposed to occupational radiation in order to determine the frequency of lens opacities, especially posterior subcapsular ones, and evaluated the relation of lens changes to occupational factors.

Material and methods

The population at risk was identified from the national occupational radiation exposure registry maintained by STUK - Radiation and Nuclear Safety Authority, a governmental institution responsible for radiation protection in Finland. At the time of the study, the registry covered a total of 1312 physicians monitored for radiation exposure.

Eligible subjects were physicians included in the occupational exposure registry aged 45-70 years, history of dose monitoring for 15 years or more, and a recorded cumulative effective dose exceeding 10 mSv. The information for assessment of eligibility was obtained from the dose registry. No separate dose estimates for the lens were available. For logistic reasons, the subjects had to be current residents of the Uusimaa region. All 120 subjects who fulfilled these criteria were invited to participate.

The year of start and duration of dose monitoring, as well as the recorded cumulative dose were obtained from the registry. The recorded doses are based on film dosimeters worn outside the lead apron at work and therefore they overestimate the effective dose by at least a factor of 10. The relation of the recorded dose to the exposure to the eye is complex and it is unclear if measurements above or below the lead apron are better indicators of ocular doses. Furthermore, the registry covers only doses exceeding the recording threshold, which was decreased over time from 3.0 mSv to 0.1 mSv in a three-month monitoring period (3.0 mSv in 1964 until 1974, 1.5 mSv in 1975-1979, 0.5 mSv in 1980-1988, 0.3 mSv in 1989-1997 and finally 0.1 mSv from 1998 onward). Recorded doses were not available before 1969 and earlier doses were missing. The frequency of missing dosimeter readings was very low (<0.1%).

The study was approved by the ethical committee of the Helsinki University Central Hospital (tracking no. 352/E9/06) and followed the tenets of the Helsinki Declaration.

All the 120 eligible subjects were approached by mail and invited to participate in the study. The radiological society was contacted prior to the study and it informed its members in advance. The letter explained the purpose and procedures of the study and included also the study questionnaire for collection of information on medical and work history, use of radiation shielding, and smoking. The 59 subjects who gave their consent were asked to fill in the questionnaire. Based on questionnaire data and ophthalmological examinations, two subjects with prior cataract surgery were excluded from the study.

The study subjects underwent a comprehensive eye examination at Department of Ophthalmology, Helsinki University Hospital after pupillary dilatation. The Lens Opacities Classification System, version II (LOCS II), was used to grade lens changes (Chylack et al. 1989). LOCS II utilises a set of standard slit-lamp and retroillumination color transparencies for grading different degrees of nuclear, cortical, and subcapsular cataract. The system has four grades for nuclear opalescence and colour, five grades for cortical, and four subcapsular opacities. If the two eyes differed in grade, the worse grade was recorded.

The 95% confidence intervals for prevalences were calculated using the binomial distribution. Frequencies of categorical variables were compared using the chi square test and for small frequencies the Fisher's exact test. Differences in mean age, cumulative dose and duration of work career between subjects with and without lens opacities were evaluated with the non-parametric Kolmogorov-Smirnov test (due to the skewed distribution). Logistic regression analysis was conduced with presence versus absence of lens opacities as the binary response variable. The main results are based on any lens opacities (LOCS grade I-II nuclear, cortical and posterior subcapsular opacities), but a separate analysis was also conducted for posterior and cortical changes combined (excluding nuclear opacities).

Results

The mean age at examination of the 57 physicians in the final analysis (28 men and 29 women) was 58 years (median 60, range 46-70). Of them, 42 were radiologists (including 9 interventional radiologists), 14 cardiologists and a surgeon. The mean duration of radiation work was 24 years (median 25, range 4-45). Eleven subjects (19%) reported having used protective eyewear (lead glass spectacles), but only six (11%) had used them regularly.

Thirty-three (58%) of the 57 examined physicians were free of any lens changes, while a lens opacity (LOCS II grade 1-2) was found in 24 (42%, 95% CI 29-56%; Table 1). Nuclear opacities were most common (six subjects; prevalence 11%, 95% CI 4-22%), followed by cortical changes (4 cases with LOCS grade 1-2, prevalence 8% 95% CI 2-19; with 7 additional subjects showing cortical traces 19%, 95% CI 10-32%). The physicians with any lens opacities were older (mean age 64 versus 54 years among subjects without any lens changes, $p<0.001$) and more commonly smokers than those without such eye changes. They also had had a longer career (30 versus 20 years, $p>0.001$) and a higher cumulative radiation dose (84 vs. 42 mSv, $p=0.02$).

Posterior subcapsular opacities were found in two subjects (4%, 95% CI % 1-15). One had bilateral changes and the other a grade II opacity. The two physicians with posterior subcapsular opacities were aged 68 and 70 years, and had radiation work histories of 31 and 36 years with cumulative doses of 11 mSv and 22 mSv. One was a radiologist and the other an intervention radiologist. In addition, an intervention radiologist with a previously operated cataract in one eye had a posterior subcapsular opacity in the other, non-operated eye.

All lens opacities combined, as well as posterior and cortical changes combined were associated with increasing age. Smoking was significantly associated with all lens opacities combined, but not with cortical and posterior lens changes. Starting radiation work prior to 1975 was associated with all types of lens changes, as well as cortical and posterior changes combined. Having been monitored for radiation exposure for at least 20 years was associated with all lens opacities and working with radiation on a daily basis with cortical and posterior changes combined.

Age and smoking status were associated with significantly increased prevalence of lens opacities in the logistic regression analysis even after mutual adjustment. Duration of radiation work was associated with the presence of any lens opacities in the bivariate analysis, but the association was no longer significant after adjusting for age.

When nuclear changes were excluded, the cumulative radiation dose was not associated with cortical and posterior opacities. Intervention radiologists and cardiologists had higher risk of cortical and posterior lens changes compared with other specialists (mainly other radiologists).

Discussion

Lens opacities were common among Finnish physicians exposed to ionising radiation, but the majority of them were nuclear opacities, which generally are not thought to be related to ionising radiation. Posterior subcapsular opacities, which classically are associated with ionising radiation, were found in 4% of the participants. Cortical opacities were found in 7% subjects, but another 12% had cortical traces, and if these findings are included the proportion of subjects with cortical opacities is as high as 19%, exceeding the number of nuclear findings. None of the subjects had a cataract that would require surgery. However, two had already undergone cataract surgery.

There was some indication for an association of lens opacities with the cumulative radiation dose, though the relation was no longer significant after adjustment for age. Further, this association was not observed when the analysis was restricted to cortical and posterior opacities only (the types of changes associated with radiation in earlier studies). The main limitations of our study are the small size and lack of an unexposed reference group.

Overall, the exposure levels were well below those traditionally thought as the threshold for cataract induction in the entire study group (mean 60 mSv, maximum 300 mSv), as well as those with the posterior subcapsular and cortical opacities (mean 65 mSv, maximum 72 mSv). However, recent studies have suggested increased cataract rates among subjects with occupational, environmental and medical radiation exposures with similar dose levels.

Radiation exposure varies substantially between radiologists. Those who perform interventional procedures such as catheterisations may receive doses approaching the annual dose limits (currently, 20 mSv), whereas others are subjected to almost no radiation during their entire career. We selected the study subjects among those with the highest recorded doses, long work history and tasks with potential for radiation exposure. Yet, detailed information on frequency of performing various procedures was not collected. Nevertheless, those working with fluoroscopic intervention procedures (intervention radiologists and cardiologists) had a higher frequency of cortical and posterior opacities combined than the other physicians.

We had access to results of dose monitoring based on personal dosimeters. However, their readings are not a direct indicator doses for the eye. The recorded doses are likely to substantially overestimate ocular doses, because the dosimeters were worn at the chest level outside the lead apron. The radiation dose is primarily due to scatter from the patients and is highly non-uniform (Martin 2009). The dose to the eyes depends heavily on the amount of radiation delivered to the patient, proximity of the physician to the x-ray tube and use of protective devices such as lead spectacles or ceiling-mounted shields.

Infrequent use of eye protection may reflect a prevailing perception that risk for cataract is minimal or irrelevant. In our study, only one in five exposed physicians used any eye protection at all and only one in ten used them regularly.

Few previous studies have evaluated occurrence of lens opacities among medical personnel. Case reports indicate lens injuries following exposures substantially exceeding the dose limits (Vano et al. 1998). A recent study, without dosimetric information, showed a significantly increased frequency of cataracts among 35,705 U.S. radiologic technologists (Chodick et al. 2008). Similarly, an Italian showed increased prevalence of lens changes among radiologists and radiological technicians compared with unexposed medical workers (Milacic 2009). Further, posterior subcapsular cataracts in 8% and smaller dot-like lens opacities in 37% of the 59 participants of the annual meeting of the Society of Interventional Radiology (RSNA 2004).

Conclusions

Radiologists with any signs of cataract had a longer history of radiation work and a larger cumulative radiation dose than those not affected. Yet, risk of cataracts is strongly age-dependent and also cumulative dose and career length increase with age. After adjustment for age, sex and smoking the effect of dose was of borderline significance and duration of radiation work was no longer significant. Yet, a higher frequency of cortical and posterior lens changes was associated with interventional procedures even after adjustment for other factors. The study indicates the need for a more comprehensive study on radiologists to assess the effect of radiation on the lens of the eye.

Abstract

Interventional cardiologists are repeatedly and acutely exposed to scattered ionizing radiation (X-rays) during their diagnostic or therapeutic procedures. These exposures may cause damages to the eye lens and induce early cataracts known as radiation-induced cataracts. The O'CLOC study is a French epidemiological study designed to test the hypothesis of an increased risk of cataracts among interventional cardiologists as compared with unexposed cardiologists. This multicenter cross-sectional study will include a total of 300 cardiologists aged > 40 years: a group of interventional cardiologists (approx. 2/3 of coronary interventionists and 1/3 of electrophysiologists) and a group of unexposed cardiologists (clinicians or echocardiographists), matched for age, sex and place of work. Individual information, including risk factors of cataracts (age, diabetes, myopia, etc. ...), will be collected during a telephone interview. For the exposed group, a specific section of the questionnaire is focusing on their occupational history, the procedures description (type, frequency, use of radiation protection tools) and will be used to classify "comparable exposure level" groups according to their estimated cumulative dose. For all participants, clinical eye examinations will be performed to specifically detect cataracts even at the early stages (lens opacities, LOCS according to the international standard classification). The overall analysis will provide an estimation of the risk of cataract in interventional cardiology comparatively to not-exposed reference group, taking into account other risk factors. A complementary comparative analysis of risks according to the level of exposure is also planned. This epidemiological study will provide further knowledge on the potential risk of occupational radiation-induced cataracts in interventional cardiology and will contribute to the awareness of cardiologists in radiation protection.

Cardiovascular disease and radiation – review and meta-analysis of epidemiological evidence at low doses

Abstract

Although the link between high doses of ionizing radiation and damage to the heart and coronary arteries has been well established for some time, the association between lower dose exposures and late occurring cardiovascular disease has only recently begun to emerge, and is still controversial. In this paper, we extend an earlier systematic review by Little and colleagues on the epidemiological evidence for associations between low and moderate doses of ionizing radiation exposure and late occurring blood circulatory system disease. Excess relative risks per unit dose in epidemiological studies vary over at least two orders of magnitude, possibly a result of confounding and effect modification by well known (but unobserved) risk factors, and there is statistically significant ($p < 0.00001$) heterogeneity between the risks. This heterogeneity is reduced, but remains significant, if adjustments are made for the effects of fractionated delivery or if there is stratification by endpoint (cardiovascular disease vs stroke, morbidity vs mortality). One possible biological mechanism is damage to endothelial cells and subsequent induction of an inflammatory response, although it seems unlikely that this would extend to low dose and low dose-rate exposure. A recent paper of Little et al. proposed an arguably more plausible mechanism for fractionated low-dose effects, based on monocyte cell killing in the intima. Although the predictions of the model are consistent with the epidemiological data, the experimental predictions made have yet to be tested. Further epidemiological and biological evidence will allow a firmer conclusion to be drawn.

Co-exposure to radiation and methyl mercury during critical phase of neonatal brain development in mice enhances developmental neurobehavioral defects

Abstract

Organisms, including man, are continuously exposed to low doses of ionizing radiation as well as persistent and nonpersistent chemicals in the environment. Hence, in the process of developing numerical limits for environmental protection, there is a strong need to consider interactive effects between radiation and other environmental stressors. It is known that ionizing radiation, as well as methyl mercury, can give rise to neurotoxicological and neurobehavioural effects in mammals and that developmental neurotoxic effects can be seen after exposure during gestation. However, there is a lack of knowledge concerning effects and consequences from low-dose exposure during critical phases of perinatal and/or neonatal brain development and the combination of ionizing radiation and environmental chemicals. Epidemiological studies of patients with haemangioma have indicated that radiation exposures to the brain during infancy might deteriorate cognitive ability in adulthood. Ten-day old neonatal NMRI male mice were exposed to a single oral dose of MeHg (0.40 or 4.0 mg/kg bw). Four hours after the MeHg exposure the mice were irradiated with 60Co gamma radiation at doses of 0,2 and 0,5 Gy. The animals were subjected to a spontaneous behaviour test at the ages of 2- and 4-months, and the water maze test at the age of 5 months. Neither the single dose of MeHg (0.4 mg/kg bw) nor the radiation dose of 0.2 Gy affected the spontaneous behavior, but the co-exposure to radiation and MeHg caused developmental neurotoxic effects. These effects were manifested as disrupted spontaneous behavior, lack of habituation, and impaired learning and memory functions. Studies are continuing to verify the effects ant to elucidate possible underlying mechanisms.

DNA-Triplex-forming-oligonucleotides as a tool to target specific DNA sequences

Dahmen, Volker; Kriehuber, Ralf
Radiation Biology Unit S-US, Department of Safety and Radiation Protection,
Forschungszentrum Jülich, 52425 Jülich, GERMANY

Abstract

Purpose: Triplex-forming-oligonucleotides (TFOs) are able to bind complementary DNA sequences in a sequence specific manner and are therefore a promising tool to manipulate genes or gene regulatory units in a cellular environment. TFOs might have also therapeutic potential e.g. as a carrier for Auger-Electron-Emitter (AEE) to target DNA of tumour cells. A main obstacle is the access of the TFOs to their targets in the cell nucleus. Thus we studied the intracellular biokinetics of TFOs with the focus in the intracellular transfer from the cytoplasm into the nucleus.

Methods: TFOs specific for the genes *cdkn2a*, *bcl2*, *brca1*, *chk2*, *cdk4* were designed using TFO Target Sequence Search (Univ. of Texas). DNA-Triplex-formation was confirmed by electrophoretic-mobility-shift assay (EMSA) in vitro. For biokinetic studies SCL-II cells were transfected by electroporation with Alexa488-labelled TFOs. Transfected cells were subsequently cultured for 1 h, 6 h, 12 h, 18 h, 24 h, 30 h, 48 h and 72 h and TFO signal intensity was determined in single cells and in isolated cell nuclei by flow cytometry (FACS-Canto II, BD) at each time point.

Results: Sequence design of TFOs by TFO Target Sequence Search (Univ. of Texas) for the desired genes is generally not suitable to predict DNA-Triplex-formation in vitro as could be demonstrated by EMSA. The desired Triplex-DNA-formation could be confirmed for 57 % of all tested TFOs by EMSA. The biogenetic studies showed that TFO-Alexa488 positive cells were detectable as soon as 1 h after transfection and the signal intensity remained constant for at least 30 h. 72 h after transfection the signal was less intense but still detectable. A substantial loss of Alexa488-labelled TFO positive cell nuclei was observed within the first 6 h post-transfection followed by a significant increase up to 18 h post-transfection.

Conclusions: Stable Triplex-DNA-formation in vitro can not be predicted by the sequence of TFOs only. TFOs initially located in the cytoplasm are re-located to the cell nucleus within 12 h after delivery of the TFOs probably during cell division.

Introduction

Triplex-forming-oligonucleotides (TFO) are short oligodeoxyribonucleotides, able to bind complementary DNA sequences in a sequence specific manner. They are major groove binding ligands which are associated to the DNA duplex via hydrogen bonds known as Hoogsteen-Bonds. Triplexes can only be formed with homopurine-homopyrimidine regions of the DNA (Kamenetskii 1995). The orientation to the target duplex can be parallel and antiparellel depending on the base composition of the TFO. While the bases thymine, cytosine and guanine are able to bind in both orientations, triplexes with adenine as the third base can only form a triplex in antiparallel conformation. TFOs containing cytosine form triplexes only under acidic conditions as the cytosine has to be protonated (Praseuth et al. 1988).

Regions containing homopurine-homopyrimidine sequences are quite common in the human genome as could be demonstrated by Goni et al. 2003. The presence of a third strand in the major groove can influence the behaviour of the DNA, changing its ability to recognize specific proteins and consequently altering mechanisms controlling DNA function. Despite the direct interaction of TFO and DNA it can also serve as a strong tool, for example as a carrier system in biotechnological and biomedical applications (Vekhoff et al. 2008).

During the decay of 125I a shower of low-energy Auger-electrons is emitted leading to the deposition of very high energies in a rather small volume (Pomplun et al. 1987). Panyutin et al. 1994 showed that 125I-labelled TFOs binding to DNA lead to a significant increase of double strand breaks. Though the energy deposition of the Auger electrons is limited to a 10 to 100 nm sphere at the decay site, the damage to the cellular environment will be only minor, even at high activity concentrations of 125I (Sedelnikova et al. 1998, Kriehuber et al. 2004). On the contrary, the decay of 125I close to its target will induce significant damage which is difficult to repair (Sedelnikova et al. 1998). Referring to these characteristics the TFO can serve as a tool to silence genes very specifically without necessarily killing the cell itself. This application could be useful for Antigene Radiotherapy (Panyutin 2003), which is the generic term for damaging of selected genes by a high dose of radiation from radionuclides delivered to this gene by specific DNA-binding molecules.

One of the main problems, despite the binding of the TFO to its target sequence, is the delivery of the TFO to the point of action, usually the cell nucleus. Alexa488-labelled functional TFOs were used to examine the dispersion and distribution of TFOs in cells and isolated cell nuclei after transfection of tumour cells by electroporation employing flow cytometry at different time points post-transfection. Viability and apoptosis induction was analyzed in parallel.

Material and methods

Oligonucleotides and TFO Labeling

TFOs and biotinylated oligonucleotides were designed employing TFO Target Sequence Search (Univ. of Texas) and synthesized by Metabion (Martinsried) in standard quality. Alexa488-labelled TFOs were purchased by TIB Molbiol (Berlin). Labeling of TFOs with ^{125}I was performed employing the Primer Extension Method. Therefore the preTFOs (TFOs used for the Primer Extension reaction) and template

(200 pmol each) were annealed in 1 x Klenow buffer (500 mM Tris-HCl, pH 8.0, 50 mM $MgCl_2$, 10 mM DTT) for 10 min incubation at 90 °C followed by slow cooling (1 °C/min) to room temperature. Primer extension reaction was carried out in the presence of 10 µCi ^{125}IdCTP (Perkin Elmer, Rodgau) by 2.5 units of exonuclease-free Klenow fragment (Fermentas, Leon-Rot) in a total volume of 10 µl. After 15 min at 37 °C the reaction was stopped by heating to 70 °C for 10 min. The duplex-DNA product was purified by ethanol precipitation and resuspended in TEN_{100}-Binding Buffer (10 mM Tris-HCl, pH 7.5, 1 mM EDTA, 100 mM NaCl). The labelled duplex-DNA was bound to Streptavidin Magnetic Particles (Roche, Mannheim) by incubation for 10 min at room temperature followed by two washing steps with TEN_{1000} Wash Buffer (10 mM Tris-HCl, pH 7.5, 1 mM EDTA, 1 M NaCl). The magnetic particles were resuspended in TES Buffer (50 mM Tris-HCl, pH 7.5, 1 mM EDTA, 150 mM NaCl). The duplex-DNA was denatured by addition of NaOH to a final concentration of 200 mM for 5 min. The magnetic particles were then removed with a magnet and the supernatant containing the ^{125}I-TFOs was collected, ethanol precipitated and resuspended in nuclease free water (Qiagen, Hilden). At this step the amount of incorporated ^{125}I-dC was calculated by activity measurement on a PerkinElmer 1480 Automatic Gamma-Counter. Labelled TFOs were stored at -70 °C.

Amplification of Target DNA-Fragments from DNA isolates of SCL-II cells

PCR Primer sets were designed for the amplification of DNA fragments containing the specific target-sequence for the labelled TFOs. The primers were synthesized by Metabion in standard quality. The sequence lengths varied from 200 bp to 2000 bp and the amplification was carried out on a TProfessional Gradient Cycler (Biometra, Goettingen). After the amplification the DNA fragments were ethanol precipitated, resuspended in water and stored at -20 °C.

In Vitro Triplex Formation and Binding Assay

^{125}I-labelled TFO (~ 0.6 µCi) were mixed with the amplificated DNA fragment (~ 10 µg) containing the specific TFO target sequence and TFO-binding-buffer (10 mM Tris-HCl, pH 5.8 and pH 7.5, 10 mM $MgCl_2$, 1 mM Spermidine) in a total volume of 24 µl. The mixture was incubated at 37 °C for 24 h. After the incubation the triplex was frozen for at least 30 days (0.5 half-life of ^{125}I) at -70 °C for decay accumulation. For *in vitro* verification of triplex formation an electrophoretic mobility shift assay (EMSA) was performed. Aliquots of the samples were loaded on a 12% native polyacrylamid gel containing 10 mM $MgCl_2$ and ran at 150 V for 20 h in TBE buffer (Tris-Base 89 mM, pH 8.0, boric acid 89 mM, EDTA 2 mM). Afterwards the gel was silver stained for visualization. Triplex formation was detected by band shift in silver stained gels and additionally verified by exposition to Fujifilm MS Imaging Plates BAS-MS3543 and visualization with a FLA-5000 Imaging System (Fujifilm, Düsseldorf).

Cell Line and Culture Conditions

SCL-II (squamous carcinoma cell line II) cells were grown in minimum essential medium Eagle (MEM, PAA Laboratories GmbH, Cölbe) with L-Glutamine, supplemented with 16 % fetal bovine serum (FBS , PAA Laboratories GmbH, Cölbe) in a water-saturated atmosphere of 5 % CO_2 at 37° C as previously described (Kriehuber et al. 2004) and cultivated at standard conditions.

Transfection experiments

Cells were grown in cell culture flasks (PAA Laboratories GmbH, Cölbe) to 70-80 % confluency, trypsinized and resuspended in MEM. The required number of cells ($2x10^6$) was centrifuged for 10 min at 90 x g and resuspended in 100 µl Nucleofector Solution (Lonza AG, Cologne). 5 µl of Alexa488-labelled TFO [20 pmol/µl] (TIB Molbiol, Berlin) was added and the electroporation reaction was performed on the Amaxa Nucleofector Device I (Lonza AG, Cologne) employing transfection program L-013. Immediately after the reaction 500 µl of MEM was added and the cell solution was transferred into a 6-well plate at a cell concentration of $3x10^5$ cells/well and, after adding 2 ml MEM, incubated at 37 °C.

Flow cytometric Analysis of Transfected Cells

SCL-II cells transfected with Alexa488-labelled TFO were incubated at 37 °C. After 1 h, 6 h, 12 h, 18 h, 24 h, 30 h, 48 h and 72 h at each time samples were trypsinized and washed two times in PBS buffer. For analysis of cell nuclei the cells were further processed following a nucleic isolation protocol. Cells were incubated with Cell-Extraction buffer (Sucrose 320 mM, Hepes 10 mM, $MgCl_2$ 5 mM, Triton X-100 1%, pH 7.4) for 10 min on ice followed by two wash steps with Nucleic-Wash buffer (Sucrose 320 mM, Hepes 10 mM, $MgCl_2$ 5 mM, pH 7.4). Finally, cell nuclei were resuspended in Nucleic-Wash buffer. According to the samples, controls transfected with non-labelled TFOs and without any TFO were performed according to the above protocol. Transfected cells and isolated cell nuclei were analyzed in a flow cytometer (BD, Canto II) for presence of Alexa488 signal. Apoptosis induction was quantified employing non-labelled TFOs using the Annexin-V-FITC/PI-assay (BD, Heidelberg) according to the manufacturer's recommendation.

Results

Triplex formation *in vitro*

A variety of oligonucleotides (Table 1.) were analyzed for their ability of triplex formation with their specific DNA-target *in vitro*, employing electrophoretic mobility shift assay (EMSA). About 43 % of the tested oligonucleotides (not all displayed), all having a suitable sequence to form a Triplex-DNA with their specific DNA-targets, failed to form a DNA-triplex in the EMSA *in vitro* (Fig.1, Lanes 2, 17 and Table 1.). Triplex formation *in vitro* can therefore not be predicted on TFO and DNA-target sequence only. Target sequences for the functional TFOs were located in the genes *cdkn2a*, *bcl2*, *brca1*, *chk2* and *cdk4* (Table 1.). Non-complementary TFOs (Non-sense TFOs) failed in all cases, as expected, to form DNA-triplexes (Fig.1, lanes 3, 6, 9, 12, 15, 18, 22, 25).

Triplex formation of ^{125}I-labelled TFO with its specific target sequence could be demonstrated and verified using an autoradiographic assay (Fig.2 a; red arrow). The lower band (green arrow) represents an enrichment of fragments, resulting from the special gel running conditions and characteristics of a low pH electrophoresis (pH 5.8)

(Osafune 2004). After verification of triplex formation, samples were frozen at -70°C for decay accumulation.

Biokinetic of TFOs in human cells *in vitro*

The flow cytometric analysis showed that immediately after transfection Alexa488-labelled TFOs were distributed throughout the cells as TFOs could be detected 1 h post-transfection in whole cell samples and in isolated nuclei (Fig.3). A transfection efficiency of ~ 80 % in whole cells and ~ 60 % in isolated nuclei was observed. Within the first 6 h post-transfection a substantial loss of TFO positive cells and cell nuclei (~ 65 % and ~ 15 % respectively) occurred, which corresponded to an increase of apoptotic cells (Fig.3, black line), followed by a significant increase of TFO-positive cells and nuclei up to 18 h post-transfection (~ 85 % and ~ 25 % respectively) where it remained constant for further 6 h. Between 30 h and 72 h after transfection a smooth decline of TFO positive cells and cell nuclei was detected. The percentage of apoptotic cells reached its maximum 12 h post-transfection and constantly declined to control level at 72 h post-transfection.

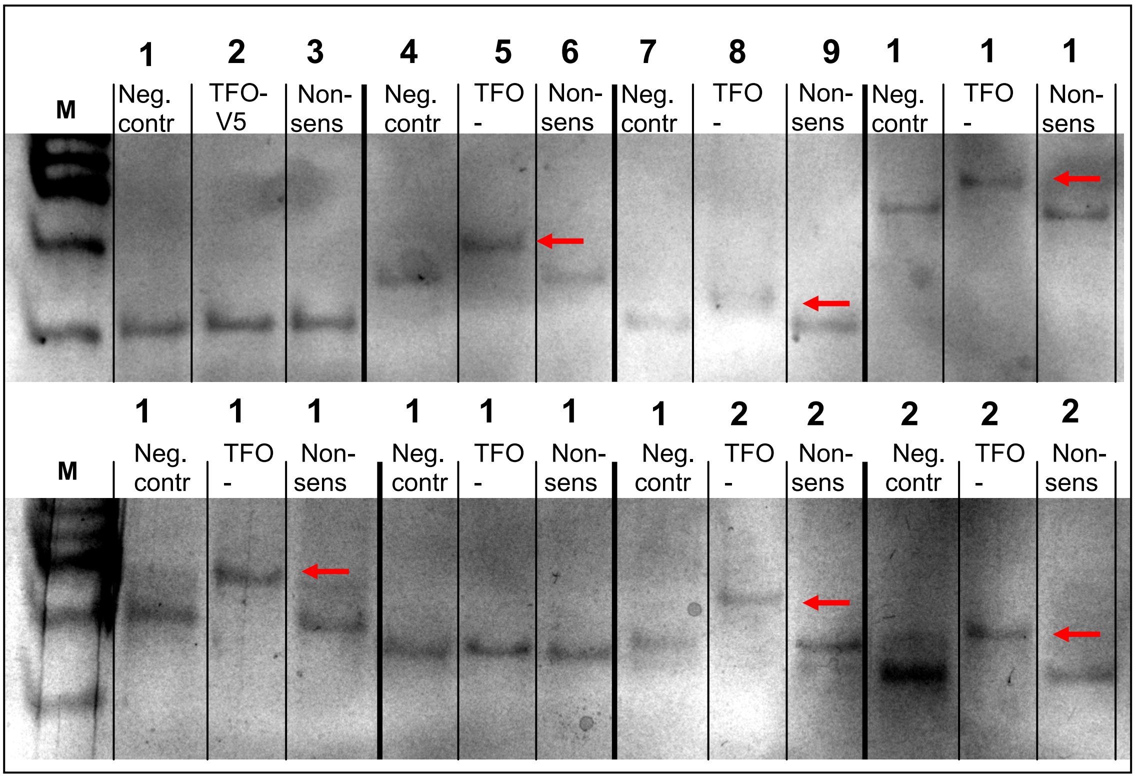

Fig. 1. Triplex formation *in vitro* visualized with electrophoretic mobility shift assay. A band shift shows successful triplex formation (red arrow; lane 5, 8, 11, 14, 20 and 24); TFO-V5 and TFO-V11 failed to form a DNA-triplex (lane 2 and lane 17). Native polyacrylamid gel; silver staining; Neg. contr.: Controls containing the dsDNA target fragment only (lane 1, 4, 7, 10, 13, 16, 19 and 23). TFO: Triplex forming oligonucleotides with their specific target sequence (lane 2, 5, 8, 11, 14, 17, 20 and 24). Non-sense.; Non-sense samples containing the target sequence with a non-specific (non-sense) TFO; TFO-V4 (lane 3, 6, 9, 12, 15, 18, 22 and 25).

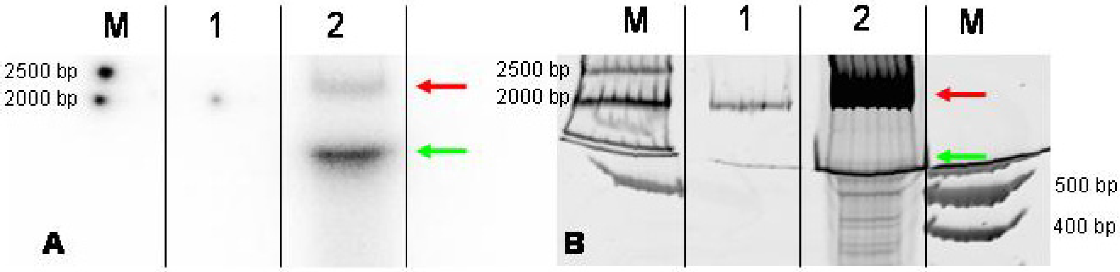

Fig. 2. Triplex formation of ^{125}I-labelled TFO-V13 with its specific target on a 1910 bp dsDNA fragment *in-vitro*. Electrophoresis in 10 % native Polyacrylamide gel (pH 5.8). (A) Autoradiographic scan. M; marker. Visualization of labelled TFO bound to its target (red arrow). Concentration of shorter fragments (green arrow) in lane 2. (B) Same gel stained with ethidium bromide. M: marker. Lane 1: dsDNA target fragment. Lane 2: TFO with high concentrated target fragments (red arrow). Concentration of shorter fragments (green arrow).

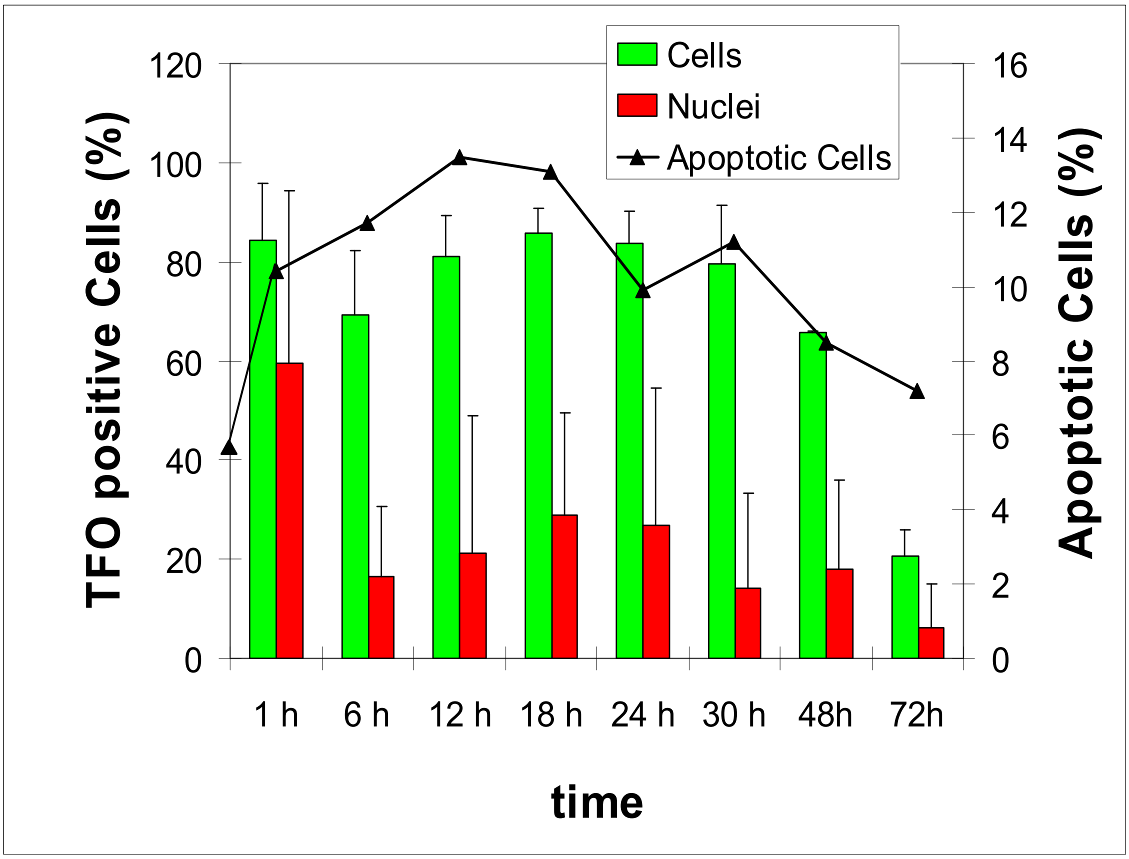

Fig. 3. Flow cytometric analysis of SCL-II cells after transfection with Alexa488-labelled TFO-V2 (N=4). Cells were transfected by electroporation with 100 pmol of Alexa488-labelled TFO-V2 and incubated at 37 °C. Cell and nucleic samples were prepared for flow cytometric analysis after different time points (1 h – 72 h). Percent of TFO positive cells (green bars, left axis) and cell nuclei (red bars, left axis) plotted against time after transfection. Cell samples transfected with non-labelled TFO-V2 were additionally analyzed for apoptotic cell death (black line); percent of apoptotic cells (right axis) plotted against time after transfection.

Table 1. Nucleotide sequence of binding TFOs and corresponding target sequence. Marked in red and bold-typed the nucleotide which were used for ^{125}I-labelling. Asterisks (*) indicates no triplex formation could be detected for these TFOs.

Discussion

The TFO Target Sequence Search (Univ. of Texas) proposed functional TFO sequences, which did not form DNA triplexes *in vitro* with their specific target sequence (Fig.1 and Table 1). Although all TFOs were designed according to the following special criteria: - minimum length of 15 bp, - guanine content minimum 50 %, - no pyrimidine interrupts allowed, - default settings for TFO-target binding at near-physiological conditions (pH 7.2, 37°C, 10 mM $MgCl_2$), it could be clearly demonstrated that every single TFO has to be confirmed in EMSA.

To obtain sufficient Triplex formation with ^{125}I-labelled cytosines the pH of the binding buffer had to be adjusted to pH 5.8 to protonate the cytosine in order to get proper Hoogsteen hydrogen bonds. However, pre-testing confirmed triplex formation for non-labelled TFOs with a maximum of two cytosines under physiological conditions, which is consistent to the findings of Duca et al. 2008.

The biokinetic studies confirmed that the applied Amaxa transfection protocol caused an initial efficient transfer of TFOs into the cell nucleus (Fig.3.). The substantial loss of TFO-positive nuclei (- 40 %) within the first 6 hours is probably caused by the chosen transfection procedure, by which a direct initial transfer of TFO into the cell nucleus occurs (Hamm et al. 2002). After transfection, a pronounced increase of apoptotic cells was recorded. Though this effect is not described in the literature for TFO after electroporation, it might be assumed that the high TFO concentration led to the observed increased apoptotic cell death by a nucleotoxic effect, as described by Shen et al. 2003 in human lung carcinoma cells transfected with TFOs by a liposome-based transfection method.

The increase of TFO positive cell nuclei 6 – 24 h post-transfection reflects either an active transfer of TFOs into the cell nucleus by still unknown processes or a passive relocation of TFOs into the cell nucleus during mitosis. The observed transfer to the cell nucleus is in good agreement with the data published by Sedelnikova et al. 1998 and 1999, showing a rapid relocation of radionuclide-labelled TFOs into the nucleus within 3 h after delivery to the cytoplasm using DMRIE-C liposomes.

The observed significant decrease of TFO-positive cells 48 h post-transfection is probably due to dilution caused by ongoing cell division. Degradation processes cannot be generally excluded but are unlikely since Sedelnikova et al. 1999 could confirm triplex stability in HeLa cells for at least 48 h and Kadenbach et al. 2005 showed non-degradation of TFO by FRET in SCL-II cells for at least 24 h post-delivery.

Conclusions

TFOs, either non-labelled, fluorochrome-labelled or ^{125}I-labelled, are suitable to form stable DNA-triplexes with their specific target sequences *in vitro*. It can be concluded from our results that the prediction of DNA-triplex-formation shall not be based on the TFO sequence alone, but has to be approved by additional experimental methods, like the electrophoretic mobility shift assay. Within the first 18 h after transfection a fraction of TFOs was relocated from the cytoplasm into the nucleus, probably by the break-down of the nuclear envelope during cell division. TFOs can be detected in considerable amounts in the cytoplasm and in the cell nucleus at least 48 h post-transfection. Electroporation is a suitable method to deliver TFOs in cells and cell-lines, although the used transfection procedure induced enhanced apoptotic cell death in the transfected cells, especially in cells, where TFOs were initially directly transfected into the cell nucleus.

Abstract

The release of radioactive iodine isotopes into the atmosphere in the wake of the Chernobyl disaster and the subsequent increase in the cases of thyroid cancer amongst children provided us with solid evidence of the link between irradiation and thyroid cancer. The link between the radiation dose and the adverse effects on human health has been established and a linear correlation drawn. However, that correlation only holds for doses higher than a certain threshold, below which there is lack of unanimity in the scientific community. We attempted to subject TPC-1, a cell line of human papillary thyroid carcinoma origin to a range of X-ray doses from low to high (0.0625 to 4 Gy) and test their effect on cellular proliferation, apoptosis and molecular signaling to uncover the effect of low doses of radiation on them. We observed a decrease in proliferation concomitant with a decrease in cells in the S phase of the cell cycle even at the lowest dose. On the other hand, there was no significant increase in apoptotic or necrotic cells at the same time point. On the protein level, an increase in p53 and some of its targets (e.g. p21 and mdm-2) was observed whereas an absence of p73 was apparent. An up-regulation of anti-apoptotic proteins such as Bcl-2 and Akt was also noted. A microarray run was performed and revealed an up-regulation in the p53 pathway whereas one gene, RFLP-1, appeared to be consistently up-regulated at all doses tested. Further research into this gene are underway. In addition, analysis of the metabolic profile of control and irradiated cells will be done on the supernatants of these cells. Metabolomics is a relatively new high throughput technique and is sensitive enough to hopefully measure the effect of low doses of radiation. Finally, analysis of the changes in microRNAs in irradiated versus control cells is currently underway.

Abstract
Studies under way in our laboratory aim at investigating how heterozygous mutations in important genes might influence the radiation sensitivity of early embryos. We mainly focus on the zygote (first day of gestation in mammals), which occurs while women cannot be aware of pregnancy. Moreover, x-irradiation of wild-type zygotes has been reported to result in the development of a genomic instability in two different mouse strains. The results presented here concern the development of such effect after x-irradiation of zygotes of other strains, carrying a mutation in either the p53 gene or the PARP gene. P53+/- embryos were obtained by mating CF1 p53+/+ females with CF1 p53-/- males, while PARP+/- embryos were obtained by mating PARP-/- females/males (C57BL genetic background) with C57BL males/females. Females showing a vaginal plug were x-irradiated 2 h after fertilization (0.2 or 0.4 Gy) and sacrificed on day 8 of gestation. Their gastrulas were collected and cultured for 7 h in rat serum supplemented with colchicine and their cells were fixed for chromosome analysis. The frequencies and types of chromosome anomalies did not differ between control p53+/- and p53+/+ cells or between control PARP+/- and PARP+/+ cells. Anomalies were essentially of the chromatid-type, with a majority of chromatid gaps. No increase of chromosome damage was found after irradiation of p53 +/- or PARP +/- zygotes and, again, chromatid-type anomalies largely predominated over chromosome-type anomalies. These results differ from those obtained by others in wild-type embryos irradiated with higher doses. Moreover, they suggest that the presence of one mutated allele for two important genes would not result into an increased risk of developing a chromosomal instability after irradiation with moderate doses at the zygote stage. Similar studies are under way with other important DNA responses genes (supported by a contract between the SCK•CEN and the Federal Agency for Nuclear Control).

Individual sensitivity in targeted and non-targeted effects of radiation – ATM as a model for characterizing individual susceptibility

Kämäräinen, Meerit[1]; Kiuru, Anne[1]; Lindholm, Carita[1]; Koivistoinen, Armi[1]; Chapman, Kim[2]; Winqvist, Robert[3]; Kadhim, Munira[2]; Launonen, Virpi[1]

Abstract
The aim of this study is to investigate the role of genetic heterogeneity in the *ATM* gene with respect to the individual variation of response to ionizing radiation. The issues of targeted and non-targeted effects particularly at low doses will be addressed. ATM is a major activator of cellular response to DNA-double strand breaks. *ATM* germ line mutations cause ataxia-telangiectasia (AT), a rare resessive autosomal disorder. Female carriers are phenotypically normal but there is evidence of increased risk of breast cancer among these women. We hypothesize that cells from *ATM* mutations carriers are more susceptible to bystander signals than ATM-proficient cells. The experimental system is based on co-culture technique where irradiated cells communicate through media with unirradiated cells. The co-culture system will be established by using human lymphoblastoid cell line TK6 cells that are irradiated by X-rays with doses of 0.01, 0.1, 1, and 2 Gy and co-cultured with unirradiated bystander cells for 1 hour and 18 hours. The induction of direct and bystander effects of radiation will be analyzed using MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide] cell viability assay, apoptosis and chromosomal aberration assays. In addition to results from TK6, corresponding data from experiments using cell lines with different *ATM* mutations will be evaluated against the wildtype *ATM* gene.

Influence of genetic polymorphisms on the yield of chromosomal aberrations among Estonian Chernobyl cleanup workers

Abstract

The frequency of chromosomal aberrations (CAs) in peripheral blood lymphocytes has been applied as a biomarker for biodosimetry of radiation. Individual variability in CA frequency is known to be caused by several factors such as age and various kinds of exposures as well as genetic factors. The aim of the present study is to evaluate the effect of individual susceptibility to the amount of CAs in Estonian Chernobyl cleanup workers. The data- and biobank of a study cohort of 4832 men contains detailed information of, e.g., recorded doses, smoking habits, medical radiation exposure, and health history. From this cohort, 300 men with doses of 48–300 mSv were chosen to the present study. In addition, 100 unexposed Estonian men were used as a control group. CAs were analyzed in peripheral blood lymphocytes using the fluorescence in situ hybridization (FISH) technique. In order to investigate the generic susceptibility, we studied single nucleotide polymorphisms (SNPs) in DNA repair genes, i.e., ATM (Phe858Leu, Pro1054Arg, Asp1853Asn, intron 5, rs228599 and intron 61, rs664143), LIG4 (Thr9Ile, Asp568Asp), XRCC1 (Arg194Trp, Arg280His, and Arg399Gln), XRCC3 (Thr241Met), XRCC5 (intron, rs3835 and 5' near gene, rs11685387), and XRCC6 (Gly593Gly and 5' near gene, rs2267437) and in an apoptosis gene, i.e., CASP8 (Asp302His and 5' near gene, rs6747918). The individual yield of CAs (particularly translocations) will be statistically analysed with respect to the SNPs, recorded dose, and other confounders. The results will bring more knowledge to the underlying mechanisms of individual variation in the induction of CAs. The information is also essential in the context of the well-established association between high CA frequency and increased cancer incidence.

The frequency of the chromatid breaks in G2 peripheral blood lymphocytes as an *in vitro* indicator of human individual sensitivity to ionizing radiation

Szymańska, Monika; Kowalska, Maria
Central Laboratory for Radiological Protection, POLAND

Abstract

Individuals differ in their response to ionizing radiation related to human individual radiosensitivity. This radiosensitivity has been linked with the sensitivity of human cells to radiation and other DNA-damaging agents. The radiosensitivity of human lymphocytes is commonly assessed by the frequency of micronuclei or chromatid breaks after *in vitro* irradiation of peripheral blood lymphocytes in the G_0- or G_2-phase of the cell cycle.

This study was performed to test the ability of these predictive indicators of intrinsic radiosensitivity for the identification in the normal population of individuals with increased radiosensitivity. The study was carried out with blood samples taken from 29 healthy donors and irradiated with 1 Gy of X rays to induce DNA damage converted into micronuclei or chromatid breaks scored in cultured peripheral blood lymphocytes at interphase (G_o assay) or metaphase (G_2 assay).

The results obtained indicate that chromatid breaks in peripheral blood lymphocyte can be the indicator of choice for the assessment of individual radiosensitivity because they are sensitive and specific to radiation and have low background frequency.

Introduction

Individuals differ in their response to ionizing radiation related to human individual radiosensitivity. There are radiosensitive sub-groups with hypersensitivity to carcinogenic risks (stochastic effects) and hypersensitivity to deterministic effects (Hoeller *et al.*,2003). Identification of individuals with increased inherent radiosensitivity is of relevance for their protection from the adverse effects of radiation after occupational or environmental exposure and after radiotherapy in oncology.Both situations require, however, a good indicator of individual radiosensitivity.

Radiation can induce a large spectrum of DNA damage in human cells. In general, damage located on one DNA strand is more effectively repaired than that affecting both strands. Misrepaired or non-repaired double strand breaks (DSB) are considered as the main lesions involved in cellular radiosensitivity and predisposition to cancer (Pichierri *et al*.,2000). In this regard, radiosensitivity would result from mutations or polymorphism of cancer predisposition genes, which are involved, in the repair of radiation-induced DSBs or their conversion in chromosome damage, which is linked to the signaling of the DSB to the checkpoint mechanism (Terzoudi *et al.,*2009). If the chromosomal radiosensitivity in human cells has been attributed to low DSB repair activity or to an impaired cell cycle control, increased yield of chromosomal damage after in vitro cell irradiation, can be a predictive indicator of radiosensitive individuals and patients. To date two such indicators are commonly used for predicting individual radiosensitivity. These are: micronuclei scored at interphase after the in vitro irradiation of human peripheral blood lymphocytes in the G_o-phase of the cell cycle (Champion *et al.,* 1995) and chromatid breaks scored at first metaphase following in vitro G_2-phase lymphocyte irradiation (Terzoudi *et al.,* 2006, Terzoudi *et al.,* 2009). Micronuclei and chromatid breaks are considered to result from non- or misrepaired DSBs (Natarajan, 1993). They are known to be repaired by the two processes non-homologous end joining (NHEJ) and homologous recombination (HR) that depends on the phase of the cell cycle. While NHEJ was shown to be active in all cell phases, HR is involved only in late S and G2 phase (Bentomane, 2004; Jeggo, 1990). In cultured peripheral blood lymphocytes DSBs induced in G_o-phase are processed during G_1 to S-phase transition so that the yield of residual lesions visualized and quantified at interphase cells as micronuclei reflects the G_1 checkpoint potential to facilitate recognition and repair of radiation induced DSBs before entering the S phase. Consequently, the yield of G_2 chromatid breaks represents the effect of the G_2 checkpoint during G_2 to M- phase transition of cultured peripheral blood lymphocytes. A variation in the yield of micronuclei or chromatid breaks between individuals has been correlated to variations in individual radiosensitivity (IR). Since inter-individual variation in radiosensitivity obtained for examined individuals are described by normal distribution with a mean value (MV) and a standard deviation of the mean (SD), individuals may be classified as normal when IR=MV±SD, resistant when IR< MV-SD and sensitive when IR> MV+SD (Terzoudi *et al*., 2006).

Both predictive assays for individual radiosensitivity were adapted at the CLOR for monitoring of occupation health and safety. The aim of this study was to test the ability of these assays for the identification of individuals with increased radiosensitivity in order to direct to more relevant screening for cancer susceptibility.

Material and methods

Subjects and blood donors

The subjects of this study comprised 29 healthy female and male donors employed at CLOR. Informed consent was obtained from each of the donor after an explanation of the objective of the study.

Whole blood samples (about 5 ml) were collected into heparinized tubes. Half of blood was irradiated with 1 Gy of X-rays for inter-individual analysis of variations in radiosensitivity measured using G_0- and G_2 -assays, while the other half was kept as a non-irradiated control. Peripheral blood lymphocytes were cultured adding 0.5 ml of whole blood to 4.5 ml PB-MAX Karyotyping Medium (Gibco). This medium was composed of liquid PRMI-1640 basal medium supplemented with 10% Fetal Bovine Serum, 1% phytohemagglutinin (PHA), 1% L-glutamine, gentamicin sulfate at 35 mcg/ml and 1% heparin (Sigma).

Irradiation

Irradiation of whole blood or proliferating peripheral blood lymphocytes was performed at room temperature using a PANTAK X-ray machine operating at 243,0 kV, 10 mA with additional filtration by 1,62 mm Cu and 4 mm Al. The average energy of X-rays was 122 kV. The measured dose rate at the distance of 50 cm from a focus, which was a point of irradiation, was 0,35 Gy/min. Before every irradiation the standard value of dose was measured by PTW-UNIDOS electrometer with 0,6 cc volume ionization chamber.

G_o-assay

G_o-assay was performed according to the cytochalasin-B-blocked micronucleus assay described by Fenech *et al.,* 1986. Briefly, immediately after irradiation duplicate lymphocyte cultures were incubated for 72 hours at 37^{o}C in a humidified incubator in an atmosphere of 5% $C0_2$ and 95% air. After 48 h of stimulation with PHA, cells were treated for 24 h with 6µl/ml of cytochalasin-B (Sigma) in order to block cytokinesis. Thereafter, cells were submitted to hypotonic stress (0.075M KCl) for 20 minutes and fixed three times in 3:1(v/v) methanol/acetic acid. Fixed cells were pooled and dropped on preclined wet slides, air-dried for at least 24 h and stained with 2 % Giemsa solutions for 10 minutes. Micronuclei were scored in binucleated cells with well-preserved cytoplasm with a light microscope (Nikon) using a 1000x magnification. 1000 binucleated cells from various slides were scored for each donor and at a given dose. Micronuclei were considered if their dimension did not exceed one third of the diameter of the main nucleus, with the exception micronuclei touching the main nuclei as well as free-lying nuclei.

G_2-assay

G_2-assay was carried out as described by Terzoudi and Pantelias, (2006). Duplicate lymphocyte cultures were incubated for 69-70 hours at 37^{o}C in a humidified incubator in an atmosphere of 5% $C0_2$ and 95% air before their use for radiosensitivity measurements. Half of proliferating cells were then irradiated with 1 Gy and incubated for 30 minutes at 37^{o}C to allow division of cells irradiated at mitosis. Lymphocytes were than blocked in metaphase by the addition of 0.15µl/ml Colcemid (Gibco) to the cell cultures (Gibco) for 60-90 min. Further preparations of metaphase arrested cell was similar to that described for the G_o-assay. However, for better scoring of chromatide beaks an additional wash with 5% acetic acid was added after the hypotonic stress. The aim of this modification was to produce metaphases with well spread chromosomes as free as possible from the surrounding cytoplasm or nucleoplasm. For each donor and dose, 250 metaphase cells were scored for chromatid breaks. Chromatid gaps were scored as breaks only when they were longer than a chromatid width (Fig.2.).

Results

To classify healthy individuals according to their radiosensitivity, we analysed the frequency of chromatid breaks in peripheral blood lymphocytes from 19 donors. The mean age in this group was equal to 41 years and the range of age was between 25 and 64 years. Only for one donor we found 2 spontaneous chromosome breaks in 250 scored cells that was substracted to obtain the radiation-induced yield of aberrations. The mean, standard deviation of the mean, median, lowest and highest values of chromatid breaks frequency in control and irradiated cells are sumarized in Table 1. When data were analysed using a normal distribution, the mean value of the frequency of radiation-induced chromatid breaks was determined to be 0.237 ± 0.073 per lymphocytes. The ratio of highset to lowest values is also given and indicates the range of individual variability. The ratio is 2,61. In Table 1 are also presented the mean, lowest and highest values of the micronuclei frequency for both spontaneous and radiation induced micronuclei. Results were obtained in our preliminary experiments with the chromosomal sensitivitiy of human lymphocytes. Blood samples were taken from 10 healthy donors in the age between 22 and 61 years. The mean micronucleus frequency was determined to be 0.019±0.013 (ratio 0,004-0,048) per cell for spontaneous micronuclei and 0.061±0.011(ratio 0,042-0,076) for radiation-induced ones. The ratios of highest/lowest values for spontaneous and induced micronuclei are 12 and 1,81, respectively. This indicates that a significant variation exists between individuals in the frequency of spontaneous micronuclei, which reflects the level of cumulative damage occuring during the live time of lymphocytes. Radiation-induced micronuclei that reflect chromosomal radiosensitivity of human limphocytes also vary between individuals. However, our results indicate that the variability of radiation-induced micronuclei among the10 donors appears to be about one and half fold lower that found for radiation-induced chromatid breaks (Table 1).

The inter-individual variation in radiosensitivity obtained using chromosomal radiosensitivity determined in G_2- phase lymphocytes shows Figure 1. The theoretical clasification (Terzoudi *et al.*, 2006) in resistant (< MV-SD), normal (MV±SD) and sensitive (> MV+SD) results in this case in 16 normal and 3 sensitive donors. Figure 3 shows the inter-individual variation in chromosomal radiosensitivity in G_0-phase lymphocytes. According to above criteria 1 of 10 donors was classified as resistant, 7 as normal and 2 as sensitive.

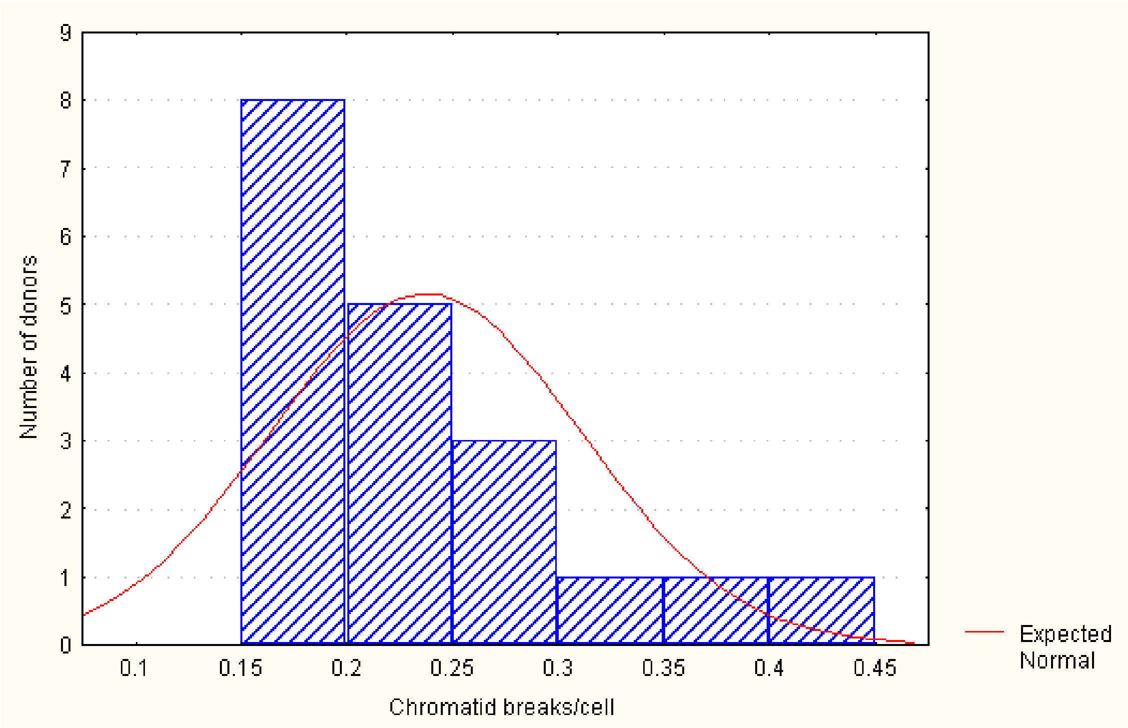

Fig. 1. Inter-individual variation in radiosensitivity obtained from 19 healthy blood donors using the G_2 assay.

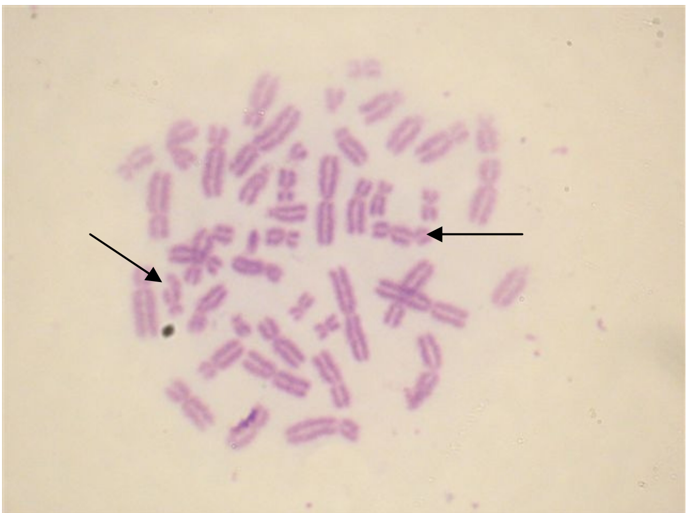

Fig. 2. Chromatid brekas after 1 Gy of X-ray irradiation as visualized at methaphase pheripheral blood lymphocyte from a healthy donor using G_2 assay. Notice two chromatid breaks.

Table 1. Mean, standard deviation of the mean, median, lowest and highest values of micronucleus (MN) frequency in 10 healthy donors and chromatid breaks(CB) frequency in 19 healthy donors.

Conclusions

In conclusion: micronuclei are less specific to ionising radiation than chromatid breaks because they detect not only radiation-induced chromosome breaks but also chromosome loss induced by chemical agents (Fenech *et al.,* 1986). They are also less sensitive than chromatid breaks (MV=0,061 vs. MV=0. 0.237), and have high and variable background frequency (range 4 - 48 per 1000 cells). Therefore, the increased frequency of radiation-induced chromatid breaks in peripheral blood lymphocyte can be the indicator of choice for screening a large number of individuals for hypersensitivity or for the assessment of individual radiosensitivity in radiation therapy.

Abstract

The aim of this research is determining correlation between the frequency of premature centromere division (PCD) in metaphases in persons professionally exposed to radionuclides and noted chromosome aberrations (CA). Biological dosimetry was performed by conventional cytogenetic technique. The presence of PCD was confirmed by fluorescent in situ hybridization (FISH). The assay of pL1.84a repetitive DNA for chromosome 18 was used for detection of centromeric region. The analysis included 50 subjects from the Clinical Centre of Serbia (C) (the average age of 45.24±1.18 and the average exposition time 17.96±1.15), and 40 subjects from the control group (K) (the average age of 44.40±0.98 and the average years of 19.67±0.98), which were not exposed to genotoxic agents in their workplaces. The results showed that frequencies of CA and PCD are statistically significantly higher in subject exposed to radionuclides than in the control group (Mann-Whitney U test, P<001). The number of isochromatid breaks was statistically significantly higher in group of exposed to radionuclides (smokers compared to non-smokers) (Spearman's test, r=0.32; P<0.05). Analysis showed that there was a positive correlation between PCD and dicentrics, acentric fragments and chromatide breaks (Spearman's test, r=0.49, 0.54, 0.29, P<0.05). Applying the FISH method showed the presence of PCD in metaphases and interphase nuclei in subjects exposed to radionuclides. Considering PCD as manifestation of genomic instability, our research suggest that this phenomenon could be used as a possible cytogenetic biomarker for proffesional exposure to ionizing radiation.

Key words: chromosome aberrations, ionizing radiations, lymphocytes of peripheral blood, premature centromere division

Introduction

In the occupational pathology, discovery of radiation damages is extremely important, especially in providing the proof that certain changes in health status of an patient may be the consequence of chronicle exposure to ionizing radiation. A number of researchers have examined the impact of small radiation doses among the people employed by health institutions, and it was concluded that there was an increase in incidence chromosome aberrations in comparison to the control group (Ghiassi-Nejad et al 2002, Jovićić et al 2009, Milačić 2005, Garaj-Vrhovac et al 2006).

Beside the classical researches related to the impact of ionizing radiation to lymphocytes in peripheral blood in the exposed persons, attention has been recently paid to new approaches and manners of analyzing necessary for definition of cytogenetic markers, all aimed at recognition of harmful effects of ionizing radiation. In addition to classical analysis of chromosome aberrations (CA), the attention is focused to the detection of premature centromere division (PCD).

This phenomenon, found in lymphocytes of peripheral blood, is characterized by divided chromatides of chromosomes already in metaphase of cell cycle. However, if premature division of constitute heterochromatin occurs at centromere level (PCD), then we may observe the phenomenon of aneuploidy, which has been confirmed in large number of papers (Vig et al 1974).

Disturbance of centromere in the form of premature centromere splitting (Eng-centromere splitting, centromere spreading), centromere puffing, actually presents manifestation of disturbance in spatial and time mechanisms of mitosis process with various types of neoplasia, which may further lead to genetic instability (Litmanović et al 1998). The answer to the question whether PCD causes aneuploidia in carcinogenic cells is not known, but it is sure that there are indications today which support the thesis which pertains to correlation between PCD and aneuploidia. The aim of our research was focused on determination of PCD prevalence, as well as on determination of correlation between PCD and chromosome aberrations among people who are occupationally exposed to radionuclides. In addition, the idea whether PCD could be observed as a possible cytogenetic biomarker among people occupationally exposed to radiation was also taken into consideration. In order to confirm presence of PCD at certain chromosome in metaphases and interphase nuclei and in order to answer the question at which stage of cell cycle centromere regions split, we have applied fluorescent *in situ* hybridization (FISH).

Material and methods

Our research included a group of 50 patients employed by Clinical Centre of Serbia, who are occupationally exposed to radionuclides (C) and 40 patients from the control group (K), who have never been exposed to physical or chemical agents in their workplaces (Table 1). The effective radiation doses were measured by thermoluminiscent dosimeter (TLD) once a month during their occupational exposure. Biological dosimetry was carried out by the means of modified micromethod for lymphocytes of peripheral blood and conventional cytogenetic technique for the analysis of chromosome aberration (Moorhead et al 1983, IAEA: Biological dosimetry 1986). The analysis of CA and PCD was examined in 200 metaphase cells. In order to confirm the results of premature segregation of centromere regions, FISH was applied.

The results in this paper were processed by applying Statistics 5 (StatSoft, Inc) and SAS 6.12 software for PS.

Table 1. General characteristics of the exposed and control patients groups

Results and discussion

The results obtained in the researches of CA and PCD in persons occupationally exposed to the low doses of ionizing radiation are provided in Table 1. On the basis of statistic data (Mann-Whitney U test), we have reached the conclusion that frequency of CA and PCD is more significant in lymphocytes of peripheral blood of people from the exposed group than of those from the control one ($p>0.05$), Table 2. We may pose a question whether frequency of PCD may be related to artifacts, or presence of PCD really may be seen as biological response of a cell to the effects of ionizing radiation. Some authors suggest that presence of PCD in human kariotype is not accidental (Bühler et al 1987).

If the presence of PCD was accidental, than such presence should be recorded in the control group as well. However, frequency of PCD is far lower in the control than in the exposed group. Presence of PCD recorded to a smaller extent in the control group implies a conclusion that PCD may have occurred there as a consequence of the effects of outer environmental factors.

Table 2. Frequency of CA and PCD in limphocytes of the exposed groups and control ones (ACF - acentric fragments, HB – chromatide breaks, iHB – isochromatide breaks, tPCD – metaphases with more than 10 PCD)

		Control	Exposed	*P*-value
No of aberrated cells	Mean±SE	0.85±0.16	4.06±0.15	0.000
	Min-Max	0-4	2-7

	Min-Max	0-1	0-2	
Ring	Mean±SE	/	0.12±0.05	0.334
	Min-Max	/	0-1	
ACF	Mean±SE	0.37±0.09	2.64±0.17	0.000
	Min-Max	0-2	0-5	
HB	Mean±SE	0.33±0.07	0.68±0.07	0.004
	Min-Max	0-1	0-1	
iHB	Mean±SE	0.17±0.06	0.5±0.07	0.008
	Min-Max	0-1	0-1	
tPCD	Mean±SE	0.25±0.09	2.12±0.25	0.000
	Min-Max	0-2	0-7	
PCD 1-5	Mean±SE	4.05±0.25	8.5±0.41	0.000
	Min-Max	1-7	2-14	
PCD 5-10	Mean±SE	1.72±0.22	4.64±0.23	0.000
	Min-Max	0-5	2-9	

Statistic data have shown that there was no difference in frequency of CA and PCD between smokers and non-smokers in the exposed group. Our researches are partially in accordance with the authors' researches (Chung et al 1996, Lovreglio et al 2006) who have established that smoking does not affect chromosome aberrations, although there are studies which proove opposite (Sierra-Torres et al 2004). However, further statistic analysis has shown that there is a significant correlation between smoking and frequency of isochromatide breaks in the exposed group of patients (Spearman's test, r=0.32; $P<0.05$). Among the patients from the control group, statistic data indicate that frequency of chromatide breaks is significantly higher among smokers than among non-smokers (means±SE: smokers 0.67±0.14 vs. non-smokers 0.18±0.07). In addition, it was established that frequency of acentric fragments was significantly higher among women than among men in the control patients group (women 0.54±0.12 vs. men 0.12±0.09).

It is important to emphasize that frequency of tPCD among the occupationally exposed people was positively correlated with the dicentric frequency, acentric fragments and chromatide abruptions (Spearman's test, r=0.49, 0.54, 0.29, $P<0.05$).

Further analysis has established that there was no positive correlation between the measured effective doses among patients and frequency of chromosome breaks and PCD (Andreassi et al 2009).

Applying the FISH method we have established that centromere division occurs already in the cell cycle interphase, i.e. in G2 phase of the cell cycle. In addition, we have confirmed the presence of PCD in metaphases and interphase nuclei of patients exposed to radionuclei (Table 3).

Table 3. Distribution of fluorescent signals for centromere region of chromosome 18 in metaphases and in interphase nuclei by applying DNA repetitive probe, both to the exposed and control groups

	INTERPHASE NUCLEI		
Patients	**Number of analyzed nuclei**	**Without PCD**	**With PCD**
1.	83	70 (84.337%)	13 (15.663%)
2.	102	95 (93.137%)	7 (6.863%)
		METAPHASES	
	Number of analyzed metaphases	**Without PCD**	**With PCD**
1.	28	14 (50%)	14 (50%)
2.	24	24 (100%)	0 (0%)

Conclusions

Our researches suggest the possibility to use PCD as possible cytogenetic biomarker in persons occupationally exposed to radionuclides. It is necessary to emphasize that these results include preliminary researches in relatively small sample. Our future researches will include larger number of patients in combination with *in vitro* researches, which will surely contribute to better understanding of this phenomenon.

Population study of chromosomal aberrations in aircrew members compared to a control group

Prieto, María Jesus; Moreno, Mercedes; Zapata, Leonor; Herranz, Rafael
Hospital General Universitario Gregorio Marañón SPAIN

Abstract

Aircrew was included as an occupational exposed radiation group in the last report of the International Commission for Radiation Protection (ICRP 90).

Chromosome translocations are a biomarker of cumulative exposure to external ionising radiations better than chromosome dicentrics, we analysed the frequency of translocations from peripheral blood of a group of aircrew members and controls matched for the age, smoking habits and gender.

Metaphases spreads obtained after incubation of peripheral blood lymphocytes in a PHA enriched culture medium for 48 hours at 37ºC (laboratory routine procedures). Chromosomes 1 and 2 painted red and a pancentromeric probe used simultaneously to coloured all centromers green; to distinguish translocations and dicentrics, this procedure gives an efficiency of 28% when extrapolating to the full genome. There was analysed around 2000 metaphases per person, which means 560 cell equivalents.

Our results do not show statistically significance differences in translocations frequency between both populations.

Introduction

The presence of chromosomal aberrations in peripheral blood lymphocytes provides a good biomarker of exposure to ionizing radiation. The analysis of dicentric chromosomes is the "gold standard" for estimating doses in cases of accidental overexposure to ionizing radiation. The main limitation of this type of dosimeter is its instability, because of altered morphological involved, cells carrying dicentric fail its mitosis and these alterations are not transmitted to daughter cells, so the post exposure frequency of dicentric decreases over time.

The translocations are another type of chromosomal aberration induced by ionizing radiation by the same mechanism as dicentric chromosomes, but do not lead to morphological changes that hinder the cell mitosis, so its frequency will remain constant throughout the time and also because of its potential accumulation, allow the identification of chronic exposures.

The development of hybridization techniques with specific DNA probes has facilitated "paint" chromosome translocations to identify quickly and easily, allowing the analysis of a large number of cells and thus calculating the frequency of translocations routinely in biological dosimetry studies.

To study the biological impact of ionizing radiation on chronically exposed populations, the most appropriate method is fluorescence in situ hybridization (FISH) as it has proven that it can detect an increase in the frequency of translocations due to such exposure.

With increasing altitude increases exposure to ionizing radiation from solar and cosmic origin, so many countries has included aircrew as occupationally exposed, as recommended by the UNSCEAR 2000 (United Nations Scientific Committee on the effects of atomic radiation). Ionizing radiations at altitudes used in long haul flights are mainly from neutron and gamma radiation but are also detected protons, alpha particles and heavy nuclei. It has estimated that 60% of crew exposure to cosmic radiation is due to radiation of high linear energy transfer (LET), especially from neutrons generated by its interaction with the atmosphere.

Because of the proven relationship between the frequency of chromosome aberrations and increased cancer risk, is necessary to perform frequency studies in populations exposed to ionizing radiation, among which are the air crews.

This report describes the work done at the Biological Dosimetry laboratory in Hospital General Universitario Gregorio Marañón, on the collaboration agreement between the Foundation for Biomedical Research at University General Hospital Gregorio Marañón, Iberia Airlines of Spain, and Co-Muprespa Fraternity.

Material and methods

Population Description

To determine the increased risk of a given population associated with a factor, it is important to compare it with another population with similar characteristics but not exposed to that factor. Therefore, since the objective of this work is to determine whether there is an increased risk of disease associated with exposure to ionizing radiation of cosmic origin, between the flight crew in Iberia, this work includes the comparison of two group's persons:

- Aircrew members for intercontinental flights above 9000 meters, which must meet the following requirements:
  Being active
  At least 10 years of continuous service with full schedules.
  At least 5 years of continuous service in long-haul fleets, preferably A-340
- Iberia ground staff.

Matching populations for age, gender and smoking habits
The grounds for exclusion to be part of the study are:

- Being younger than 45 years at the time of blood collection
- Radiological studies in the last year TGI type, barium enema, urography descending, thoracoabdominal CT, and interventional radiology.
- Previous diagnosis of cancer or other disease treated with chemotherapy and / or radiotherapy
- Work history in professions associated with cancer risk
- Substance abuse

All individuals who are part of the work were selected by The Iberia Medical Service, which has also obtain and complete the necessary information and informed consent in addition to blood collection and shipment to Biological Dosimetry Laboratory at HGUGM.

LABORATORY METHODOLOGY

Sample consists of three tubes of blood per person, sent to the laboratory together with the informed consent document and the name. Manipulation of samples performed as appropriate to the laboratory culture and processing protocols.

Fluorescence in situ hybridization FISH

Hybridization is performed on 3 consecutive days following the standardized protocol in the laboratory which allows the hybridization of chromosomes 1 and 2 with rhodamine labelled probes, a FITC pancentromeric labelled probe, and a DAPI counterstained.

Analysis of metaphases

The analysis done blind, ie the slides coded with a number assigned by the laboratory so that the analyst does not know the origin and characteristics of the individual studied.

The analysis performed by fluorescence microscope (Leica DM5000B) with appropriate filters for visualization of rhodamine, FITC and DAPI. We analyzed about 2000 metaphases per individual, discarding people who could not be analyzed more than 600 metaphases.

There have photographed all chromosome abnormalities found but for the study only account translocations in stable cells, ie those without dicentric and acentric fragments or rings, and selected only cells where there are close to 46 chromosomes and in which all material paint is present.

Results

The study done in a total number of 80 people, 38 controls and 42 aircrews, analysed 67.297 metaphases from control samples and 69.690 from aircrew samples.

We analysed translocations involving chromosomes 1 and 2 which constitute about 16% (16.32 in males or 16.05 in women) of the cellular genome, we calculate the genomic frequency of translocations using the formula described by Lucas Group 1992, for our technique we obtain an approximate efficiency of 28% (27.99% to 27.62% for men and women)

The following tables show the data obtained for each population: 38 controls and 42 crew (tables 1 and 2 respectively), as were sent to the Health Protection Agency (HPA, Chilton Didcot Oxford, UK) for statistical analysis.

Table 1. Control population data. 38 people analysed, genome equivalent = metaphases analysed x f. % translocations to genome = translocations / genome equivalent x 100. Smoking habits: S = smokers. NS = non smokers, included people who gave up smoking at least 10 years ago.

The following tables 3 and 4 show the statistics of the results obtained.

First two columns correspond to the expected frequencies due to age. These data are used to calculate excess of translocations observed, shown in the next column. Excess of translocations is less than expected; except for those marked with yellow, and both populations have the same number of cases with excess. Apparently, there is a difference between both populations but, when use t test we obtain a p value of 0.065 (when using only baseline due to sex and age) or 0.063 (when using risk rates estimated by the group of Sigurdson). These data imply that, although there is a difference between the two populations, is not statistically significant.

Table 3. Control population statistics.

Conclusions

The frequency of translocations has not statistically significant differences, although there was a slight increase in the frequency of translocations in the crew population that does not exceed observed frequencies in other populations described in other publications.

It would be interesting to extend the study with a larger number of people, as this would allow us to clarify if the trend continues and / or wide, although noted that the frequencies observed in our study are consistent with published for different population groups.

In the individual analysis, it was found that 6 people have a higher frequency of translocations than expected, but if you look at the data shows, that the number of analyzed genomic equivalent in these cases is low, so even if they can take into account the population study, individual study would require testing more metaphases to allow any conclusion.

Assessment of dose response for chromosome aberrations due to internal alpha-radiation

Sotnik, Natalia; Azizova, Tamara; Osovets, Sergey
Southern Urals Biophysics Institute (SUBI), Ozyorskoe Shosse 19, Ozyorsk, Russia

Abstract

Chromosome slides with Chromosome 5 painted using mBAND were analyzed for 40 employees of the Mayak Production Association. Mean frequency of stable intra-chromosomal aberrations per total cells analyzed was 0.005±0.007. Correlation analysis indicated the lack of a significant correlation between external dose and the yield of intra-chromosomal aberrations (r = -0.02). A linear dependence of the yield of intra-chromosomal aberrations on absorbed dose of internal exposure to incorporated ^{239}Pu was revealed: $Y = (0.0303 \pm 0.0065)D_{\alpha}$, where: Y is the yield of intra-chromosomal aberrations (in % per 100 cells); D_{α} is the absorbed dose to bone marrow due to internal alpha-radiation (cGy).

Introduction

The most sensitive and well-known bioindicator of radiation is the yield of chromosome aberrations in lymphocytes from peripheral blood in human (IAEA, 2001). The peripheral blood lymphocytes are a simple and unique model to study radiation-induced mutagenesis. A low spontaneous level of chromosome aberrations in lymphocytes from peripheral blood of healthy donors and high radiosensitivity allow detecting an excess in the yield of radiation-induced chromosome aberrations over spontaneous rate even at low doses (IAEA, 2001; Tucker JD, 2001; Balakrishnan S and Rao SB, 1999).

Many studies have demonstrated that radiation-induced chromosome aberrations are long-lasting in human and can be used as a biological indicator of radiation exposure Aberrations imply the DNA double-strand breaks and repair defects. Stable intra-chromosomal aberrations (e.g. para- and pericentric inversions) are produced by misrepair of pairs of chromosome breaks (DNA double-strand breaks) within a single chromosome; intra-chromosomal aberrations may be contrasted with inter-chromosomal aberrations, produced by misrepair of pairs of chromosome breaks in different chromosomes (Brenner DJ, Sachs RK, 1994).

The theoretical background relates to the observation that densely-ionizing radiations, such as alpha-particles or neutrons, produce uniquely elevated intra-chromosomal aberrations in contrast with almost all other mutagens, such as gamma-rays or general aging processes.

This implies that alpha-particles or neutrons produce multiple chromosome breaks in each of a small number of chromosomes, as compared to X-rays or chemicals, or endogenous aging processes, where a comparable exposure (i.e. yielding the same total number of chromosome breaks) results in fewer breaks in larger numbers of chromosomes, predominantly inter-chromosomal aberrations.

The objective is assessment of dose response for the yield of intra-chromosomal aberrations and internal dose from alpha-radiation.

Material and methods

A cytogenetic analysis of the peripheral blood lymphocytes was performed for 40 workers of the Mayak PA, who were exposed to external and internal radiation. Most individuals analyzed were males (77.5%). External doses from gamma-rays ranged from 0.021 up to 5.726 Gy; ^{239}Pu body burden was 0-10.5 kBq. External doses to red bone marrow (RBM) from gamma-rays ranged within 0.130-4.262 Gy; absorbed dose from alpha-radiation due to incorporated ^{239}Pu was 0.003-0.538 Gy.

For the purposes of cultivation, whole blood samples were drawn from ulnar vein by a heparinized syringe, 5 ml. The lymphocytic pellet and 10 ml of PB-MAX medium were placed in a culture flask. The flask was then incubated in the CO_2 incubator at 37°C for 48 to 68 hrs. Four hours prior to fixation, 0.01 μg/ml colchicine was added in the flask. The pellet was resuspended in 0.075 M KCl and placed in a 37°C water bath for 15 minutes. The pellet was then resuspended in fixative (3:1 ethanol: glacial acetic acid, cooled to 0^0C). The cell suspension was placed on slides and allowed to air dry.

Hybridization of chromosome slides using mBAND was performed in compliance with the XCyte Lab Manual (Metasystems, Germany). The slides were denatured in 0.07 N NaOH for 1 minute at room temperature. mBAND probes were denatured in parallel with denaturation of the slides. The slides were placed in a humidified chamber in a 37°C incubator for 48 hrs. For detection of hybridization signals, a mixture of blocking buffer and detection solution was used. DAPI/antifade was applied as a counterstain.

The slides were analyzed using a fluorescence imaging microscope (Leica DM RA2) with filter sets for DAPI, FITC, Texas Red, Spectrum Orange, DEAC, Cy5. Images were captured using the MetaSystems camera. Although using mBAND only two chromosomes were colored, whole metaphases were also captured to observe any translocations. Karyotyping was performed using Isis 4 software (MetaSystems, Germany). Statistical analysis was performed by standard linear regression methods using Statistica software (Borovikov V, 2003).

Results

Chromosome slides from 40 Mayak workers were analyzed using mBAND fluorescence *in situ* hybridization for chromosome 5. The slides were analyzed to account for stable intra-chromosomal aberrations, such as para- and pericentric inversions, terminal and interstitial deletions, and insertions. Aberrations were scored per 100-150 metaphases. Total 4,825 cells were analyzed. The mean yield of stable intra-chromosomal aberrations per total number of analyzed cells was 0.005 ± 0.007.

A high yield of intra-chromosomal aberrations (4.1 per 100 cells) was found for one worker. Analysis of medical records indicated malignant neoplasm for this individual. Thus, results of cytogenetic analysis based on chromosome slides from this worker were excluded from the statistical analysis.

As demonstrated earlier, the yield of intra-chromosomal aberrations in a group of workers at the reactor complex did not actually differ from that in the control group (Hande MP et al, 2003; Mitchell CR et al, 2004). In addition, no correlation of the yield of intra-chromosomal aberrations with age was found. The correlation analysis revealed no significant correlation between the yield of intra-chromosomal aberrations and external dose (r = -0.02). The analysis indicated a linear dependence of the yield of stable intra-chromosomal aberrations in the peripheral blood lymphocytes on absorbed dose to red bone marrow (RBM) from internal exposure to alpha-radiation from incorporated ^{239}Pu:

$$Y = (0.0303 \pm 0.0065)D_{\alpha}, \qquad (1)$$

where:

Y is the yield of intra-chromosomal aberrations (in percentage per 100 cells);

D_{α} is absorbed dose from internal dose to RBM from alpha-radiation (Gy).

A coefficient, b = 0.0303, specifying the growth rate of aberrations per unit dose (%/cGy), showed high statistical reliability with increased absorbed dose ($p < 0.05$). The regression equation in general was significant by Fisher's ratio test ($p < 0.05$). The correlation coefficient ($r = 0.43$) was also significant ($p < 0.05$).

Fig. 1 illustrates Dependence (1) with the 95% CI and empirical points.

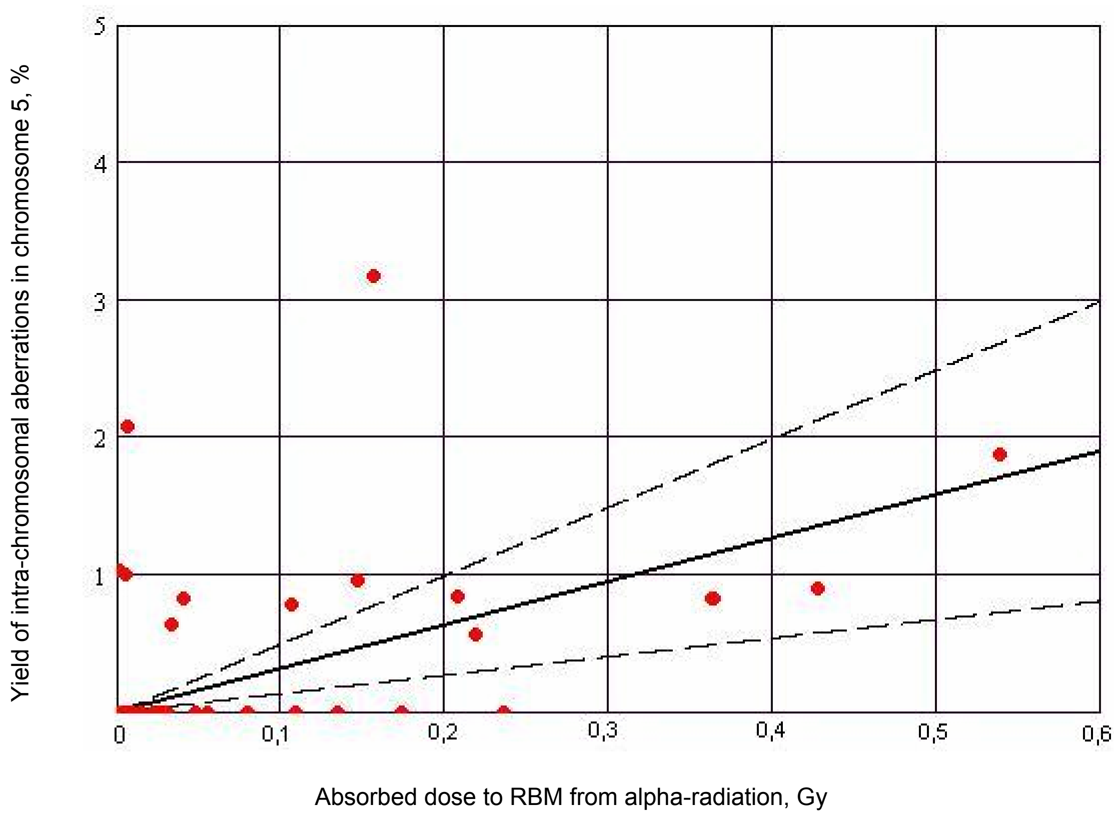

Fig. 1.1. Dependence of the yield of stable intra-chromosomal aberrations on absorbed dose to RBM from alpha-radiation.

Discussion

Our choice of chromosome 5 for this analysis was based on the findings by Mitchell et al., who had analyzed the yield of intra-chromosomal aberrations in three large chromosomes (1, 2, and 5) and demonstrated a higher intra-chromosomal yield per unit DNA length for chromosome 5 ($12.7 \pm 2.1 /10^5$ Mb) than either chromosome 1 ($5.6 \pm 1.4 /10^5$ Mb) or chromosome 2 ($4.5 \pm 2.1 /10^5$ Mb).

The derived linear dependence allows for the approximated assessment of absorbed dose from internal exposure based on the yield of stable intra-chromosomal aberrations. However, a small sample size (40 individuals) did not allow obtaining any statistically significant linear correlation coefficient. In the future, the derived dependence will be refined with the increased statistical data size.

Conclusions

The preformed analysis revealed a linear dependence of the yield of stable intra-chromosomal aberrations in the peripheral blood lymphocytes in human on absorbed dose to red bone marrow from internal exposure to alpha-radiation from ^{239}Pu in workers of the Mayak PA.

Cytogenetic damage in cells exposed to ionizing radiation under conditions of a changing dose-rate

Brehwens, Karl[1]; Staaf, Elina[1]; Haghdoost, Siamak[1]; Gonzales, Abel, J.[2]; Wojcik, Andrzej[1]
[1] Stockholm University, SWEDEN
[2] Argentine Nuclear Regulatory Authority, ARGENTINA

Abstract
The current international paradigm on radiation effects is mainly based on the effects of dose with some consideration for the dose rate. No allowance has been made for the influence of a changing dose rate (second derivative of dose) and biological effects of exposing cells to changing dose-rates have never been analyzed. Here, we provide evidence that radiation effects on cells may depend on temporal changes in the dose-rate. In the experiments cells were moved to and from a source of radiation. The speed of movement, the time of irradiation and temperature during exposure were controlled. Here we report the results of first experiments with TK6 cells which were exposed to a constant, to an increasing and to a decreasing dose-rate. The average dose rate and the total dose were same for all samples. Micronuclei were scored as the endpoint. The results show that the level of cytogenetic damage was higher in cells exposed to a decreasing dose-rate as compared both to an increasing and a constant dose-rate. This finding may suggest that the second derivative of dose may influence radiation risk estimates and it is expected to trigger further studies on this issue.

The effect of dimethyl sulfoxide on radiation induced chromosome aberrations in cultured CHO cells

Khvostunov, Igor; Pyatenko, Valentina; Korovchuk, Olga
Medical Radiological Research Centre, RUSSIAN FEDERATION

Abstract

The radioprotector properties of dimethyl sulfoxide (DMSO) are rather attractive for fundamental and applied implication in radiation biology and medicine. The cultured CHO cell line is a suitable model that allows estimation cell survival and chromosome aberration yield in mammalian cells. The goal of the current study was to investigate the redaction of radiation induced chromosome aberration yield in mammalian cells treated by DMSO. The CHO-K1 wild type cells were used as in vitro experimental model. The cells were grown in DMEM media containing 10% bovine serum albumine and antibiotics in monolayer culture. The cell samples with or without DMSO were irradiated to 1.0, 2.0, 3.0 and 4.0 Gy at a dose rate of 0.3 Gy/min, using 60-Co source. The DMSO was added to samples five min before irradiation in concentration of 0.5 and 1 M. The synchronized (G-1 phase) and logarithmic growing (cycling) cells were investigated. After exposure, cell were washed and fresh 10% bovine serum albumine was added to culture. The cells were fixed at 5, 7 and 9 h after irradiation. Approximately, 600 metaphases for chromosome-type aberrations were scored from each dose sample. It was found that DMSO treatment results in a 40–50% reduction of chromosomal aberrant cells as compared with non-treated cells irradiated to the same dose. The radiation-induced frequency of chromosomal aberrations decreased 2-fold having clear dose dependence. This reduction in chromosome aberration frequency is thought to be the result of a free radical scavenging and, perhaps, a suppressing radiation induced bystander effects in CHO culture. The experimental study was accompanied by theoretical Monte Carlo computer simulation of indirect action to DNA of cells by free water radical including OH scavenging in DMSO. The match of experimental and theoretical results is discussed.

The relative biological effectiveness of accelerated 73 MeV protons determined by CHO cell assay

Khvostunov, Igor; Pyatenko, Valentina; Korovchuk, Olga
Medical Radiological Research Centre, RUSSIAN FEDERATION

Abstract

The purpose of the study was to estimate relative biological effectiveness (RBE) of 73 MeV protons using CHO-K1 cells assay. The cells were grown at 37 0Ñ in DMEM media containing 10% bovine serum albumine and antibiotics in suspension. The synchronized (G-1 phase) cells were investigated. The cell samples were irradiated with single doses: 0.5, 1.0, 2.0, 3.0, 4.0, 5.0 and 4.0 Gy, using pulsed proton beam. Gamma-radiation of 60-Co at a dose rate of 0.5 Gy/min was used as a reference source. After exposure cell were washed and fresh 10% bovine serum albumine was added to culture. The cells were fixed at 18, 19 and 21 h after irradiation. Approximately, 500 metaphases for chromosome-type aberrations were scored from each dose sample using traditional Giemsa stain and light microscope. The experiment was carried out twice in a period of a year. The RBE values were determined by comparing the doses needed to obtain the same yield of chromosomal aberrations as with the reference 60-Co gamma source. It was found that the yield of dicentrics per 100 cells follows linear-quadratic model: Y=1.56D+2.48D**2 and Y=6.88D+2.11D**2 (where D – absorbed dose in Gy) for 60-Co rays and 73 MeV proton irradiation, respectively. Therefore, protons were somewhat more biologically effective than 60-Co gamma-rays according to criterion of chromosomal aberrations. The proton RBE values obtained by regression fitting ranged 1.1-2.6 for absorbed doses from 6.0 to 0.5 Gy respectively. The data obtained at other proton acceleration centers agree with our results. Although the RBE value for protons was found to be rather small, it could be of radiotherapy importance. Accurate determinations of the RBE are necessary when extra therapeutic dose is inadmissible.

Effect of low dose gamma-radiation upon antioxidant parameters in heart and skeletal muscle of chick embryo

Vilic, Marinko[1]; Jasna, Aladrovic[1]; Blanka, Beer Ljubic[1]; Saveta, Miljanic[2]; Petar, Kraljevic[1]
[1] Faculty of Veterinary Medicine, University of Zagreb, CROATIA
[2] Ruder Boskovic Institute, CROATIA

Abstract
This study was performed to investigate the effect of low-dose gamma-irradiation upon activity of glutathione peroxidase (GSH-Px), superoxide dismutase (SOD), catalase (CAT) and level of glutathione (GSH) and lipid peroxidation (TBARS) in heart and skeletal muscle of chick embryo and newly hatched chicks. Fertilised chicken eggs were irradiated with the dose of 0.3 Gy gamma radiation (source ^{60}Co) on the 19th day of incubation. The antioxidant parameters were measured in breast muscle (*m.pectoralis superficialis*), thigh muscle (*m. biceps femoris*) and heart of chick embryos on 1, 3, 6, 24 and 72 h after egg irradiation. All parameters were measured spectrophotometrically. On the 1st hour after irradiation lipid peroxidation significantly decreased in all type of muscles. At the same time GSH level and CAT activity were significantly decreased in the breast and thigh muscle of chick embryo while SOD activity was significantly decreased in thigh muscle. On the other side on the 1st hour after irradiation GSH-Px activity was significantly increased in thigh muscle. On the 3rd, 6th and 24th hour of experiment there were no significantly changes in the investigated parameters between the groups. On the 72nd hour after irradiation results showed decreased activity of SOD in thigh muscle; decreased activity of CAT in the breast and heart muscle; decreased TBARS level in thigh muscle; increased level of GSH in the breast and thigh muscle; and increased GSH-Px activity in the breast muscle. The obtained results suggest that acute irradiation of chicken eggs on the 19th day of incubation with the dose of 0.3 Gy gamma radiation causes an oxidative stress in all types of muscles immediately after irradiation. However, the results of GSH-Px activity and GSH level on the one-day old chicks (72nd hour after irradiation) in skeletal muscle suggest probably a stimulating effect of low dose irradiation.

Influence of the ionizing radiation on the individual variability of the antioxicant status indices

Shishkina, L. N.; Khrustova, N. V.; Klimovich, M. A.; Kozlov, M. V.; Kushnireva, Ye. V.
Emanuel Institute of Biochemical Physics, Russian Academy of Sciences, ul. Kosygin 4, Moscow 119334, RUSSIA

Abstract
The variability of the different parameters of the physicochemical regulatory system of the lipid peroxidation (LPO) in tissues of the laboratory mice (white outbreed and SHK) is studied in norm and under the action of radiation at the low doses and within the wide range of dose rate. It is shown that the different variability and the ability to normalization of the antioxidant activity and composition of lipids, intensity of LPO, the peroxide content of lipids and their antiperoxide activity in tissues are due to the antioxidant status of tissues and the radiosensitivity of mice. It was revealed that the radiation dose and dose rate result to the indefinite changes in the variability of the studied parameters. The data obtained allow us to conclude that the high variability of the LPO regulatory system parameters in the murine tissues plays the important role for the development of the biological consequences after the radiation action depending on the dose and dose rate.

Introduction
At present it is established that the lipid peroxidation (LPO) processes play the important role in the regulation of the cell metabolism [10]. The steady-state of the LPO in tissues of intact animals is provided by the physicochemical regulatory system, which is functioning not only at the membrane level [3], but the cellular and organ levels [13]. Among parameters of this regulatory system in the last case are the antioxidant (AOA) and antiperoxide (APA) activities and composition of lipids; the initial content of the peroxide in lipids, stipulated by their nonsaturation degree; the lipid oxidizability, which may be estimated as the ratio of sums of the more easily (EO) to the more poorly oxidizable (PO) fractions of phospholipids (∑EOPL/∑POPL); the LPO intensity and other. The biological consequences of the radiation action are due to the level of the AOA of the tissue lipids, the activities of the antioxidant defense enzymes and the LPO intensity in organs and tissues of animals and also their ability to repair and normalization after the radiation injury [4, 5, 12, 18].

The aim of this work is to reveal the variability of the different parameters of the antioxidant status in tissues of mice possessing different radiosensitivity both in norm and under the action of radiation at the low doses and within the wide range of dose rate.

Materials and methods

The experiments were carried out on 140 mice SHK (males, 17 – 23 g), 54 white outbreed mice (females, 23 – 30 g) and 20 mice SHK (females, 20 – 25 g). The γ-irradiation of mice SHK (males) was performed by a GUT-Co-400 apparatus (a source of γ -60Co). Mice SHK (males) were divided in 4 groups as follows:

1. The γ-irradiation at the dose of 15 cGy, the dose rate was 0,01 cGy/min (group 1; 30 mice); the irradiation interval was 25 h;
2. The γ-irradiation at the dose of 15 cGy, the dose rate was 0.25 cGy/min (group 2; 30 mice); the irradiation interval was 1 h;
3. The γ-irradiation at the dose of 15 cGy, the dose rate was 9 cGy/min (group 3; 30 mice); the irradiation interval is 100 s.
4. Intact mice from the same party (group 4, 20 mice) serve as biological control.

Mice were irradiated by storage of the food and the drinking-water (group 1) or only the drinking-water (group 2) in cells for animals per 10 mice. Mice of the group 3 were irradiated in the special container where the each mouse could easily drive.

The single acute X-irradiation of mice (females, 10 mice) at the dose of 16 cGy was performed by a RUT-200-20-3 apparatus in the same special container at the following conditions: current strength – 15 mA; filter 0.5 mm Cu; the dose rate is 44 cGy/min; the total irradiation interval 22 s.

Decapitation of mice after γ-irradiation was done within 1, 7 and 30 days and 1 month after X-irradiation. Decapitation of intact mice was performed simultaneously with the experimental group per 6 – 10 animals. As known, the lipid AOA level and the LPO intensity have the season variability [4, 9, 12]. It is need to note that experiments are performed on the mice SHK (males) in April and May, on the white outbreed mice in September and October, on the mice SHK (female) in October and November. All parameters of intact mice were determined for each animal. Mice in experimental groups were divided in subgroups per 1 – 4 animals. After decapitation of mice, blood was collected in test tubes treated by 5% solution of sodium citrate. The erythrocytes from the blood plasma were separated by centrifugation. The murine liver and brain was placed in ice-cooled weighting bottles immediately after decapitation.

Lipids were isolated by the method of Blay and Dyer in the Kates modification [8]. The AOA of lipids was determined by using the methyl oleate oxidation model [4] as the ratio of the differences in the induction period of methyl oleate oxidation in presence and absence of lipids to the concentration of the added lipid. Preliminary methyl oleate was purified by vacuum distillation. The lipid concentration in methyl oleate was 20 mg/ml. Oxidation was carried out in a temperature-controlled chamber at a constant temperature 37±0.1ºC by blowing air through at a rate providing oxidation in a kinetic range. In detail the lipid AOA analysis was described in [14]. The peroxide content in lipids was determined iodometrically. The antiperoxide activity (APA) of lipids, that is their ability to decompose peroxides, was evaluated as the ratio of the difference in the peroxide concentrations of methyl oleate in absence and presence of lipids to the amount of the added lipid [16].

The qualitative and quantitative composition of phospholipids (PL) was determined by thin-layer chromatography [2]. It was used type G or H silica gel (Sigma, USA), glass plates 9×12 cm and mixture of solvents chloroform : methanol : glacial acetic acid : water (25:15:4:2) as a mobile phase. All the solvents were of specially pure or chemically pure grade. The development of chromatograms was performed by iodine vapour. For the colour reaction for phosphorus we used ammonium molybdate and ascorbic acid (Serva, FRG) and perchloric acid of chemically pure grade. The amount of inorganic phosphorus was judged from the optical density of the solution at the wavelength 810 nm with Beckman Du-50 (Austria) or KFK-3 (Russia) instruments. The sterol content was determined spectrophotometrically by the method cited in [17]. In addition to quantitative analysis of the different fractions of PL and sterols the following parameters of lipid composition were also evaluated: the molar ratio of [sterols]/[PL]; the PL proportion in the total lipid composition (% PL); the ratio of the phosphatidyl choline to phosphatidyl ethanolamine content in PL (PC/PE) and the ratio of the sums of the more easily to the more poorly oxidizable fractions of PL (∑EOPL/∑POPL). The last value was calculated by the formula: (PI + PS + PE +CL + PA)/(LPC + SM + PC), where PI is phosphatidylinositol, PS is phosphatidylserine, CL is cardiolipin, PA is phosphatidic acid, LPC are lysoforms of PL, SM is sphingomielin.

The content of LPO products which have reacted with 2-thiobarbituric acid (TBA-reactive substances, TBA-RS) was determined spectrophotometrically by the method described in [1] with adding 10 µl of 0.01% 4-methyl-2,6-di*tert*.butylphenol (BHT) solution in ethanol. The diene conjugates and ketodiene amount in the liver and brain lipids were judged from the optical density of the lipid solutions in hexane (the range of concentration from 0.02 to 0.2 mg/ml) as their ratio at the wavelengths 230±2 nm and 270±2 nm to 205±3 nm, correspondingly [7] used UV-3101 PC (Japan) instrument. Protein was determined according [6].

The statistic treatment of the results were performed using standard method of the variational statistics. The variability of indices was evaluated as the ratio of mean square error of average mean to average mean for group expressed as a percentage.

Results

Earlier it is shown the existence of the reverse correlation between the lipid AOA value and the initial peroxide amount in the spleen lipids of the CBA mice [18]. The high ability to the peroxyl radical formation is also revealed by γ-irradiation of mice SHK at the dose of 15 cGy with the different dose rate for the spleen and erythrocyte lipids [11]. It is need to note that the lipids from these tissues characterize the prooxidant activity in the autooxidation reactions [16]. Besides, the highest heterogeneity of the peroxide content in the murine lipids within the experimental groups were namely established for the spleen and erythrocytes lipids of mice SHK after γ-irradiation at the low doses.

Usually the organ of the intact mice in accordance with their lipid AOA may be presented by following consequences: liver > brain > spleen [4, 12, 16]. The different initial level of these parameters is due to the differences in the sensitivity to the radiation injury another indices of the LPO regulatory system. Thus, the least changes of the LPO intensity which is usually evaluated by the TBA-reactive substances content in a complex biological system [7] were revealed in the liver lipids of mice SHK under their γ-irradiation at the dose of 15 cGy, especially at the 0.25 cGy/min dose rate [11]. Besides, the greatest changes of this parameter were obtained by the radiation of mice SHK at the low intensity dose rate (0.01 cGy/min) in the blood erythrocytes. The substantial dependence of the change scale on the dose rate was obtained for the lipid composition of liver, despite the fact that lipids of this organ characterize the most high level of AOA. The relative changes of generalized parameters in the liver lipids under γ-irradiation of mice with the different dose rate are presented in Fig. 1. It is seen the absence of the normalization practically for the all studied indices value within 1 month after irradiation. Besides, the more substantial changes are revealed for the molar [sterols]/[PL] ratio at the all dose rate. Although the PC/PE ratio is a more stable as compared with the another parameters there are the reliable changes in the relative content of both PC and PE in the PL liver of the irradiated mice especially at the dose rate of 0.01 cGy/min.

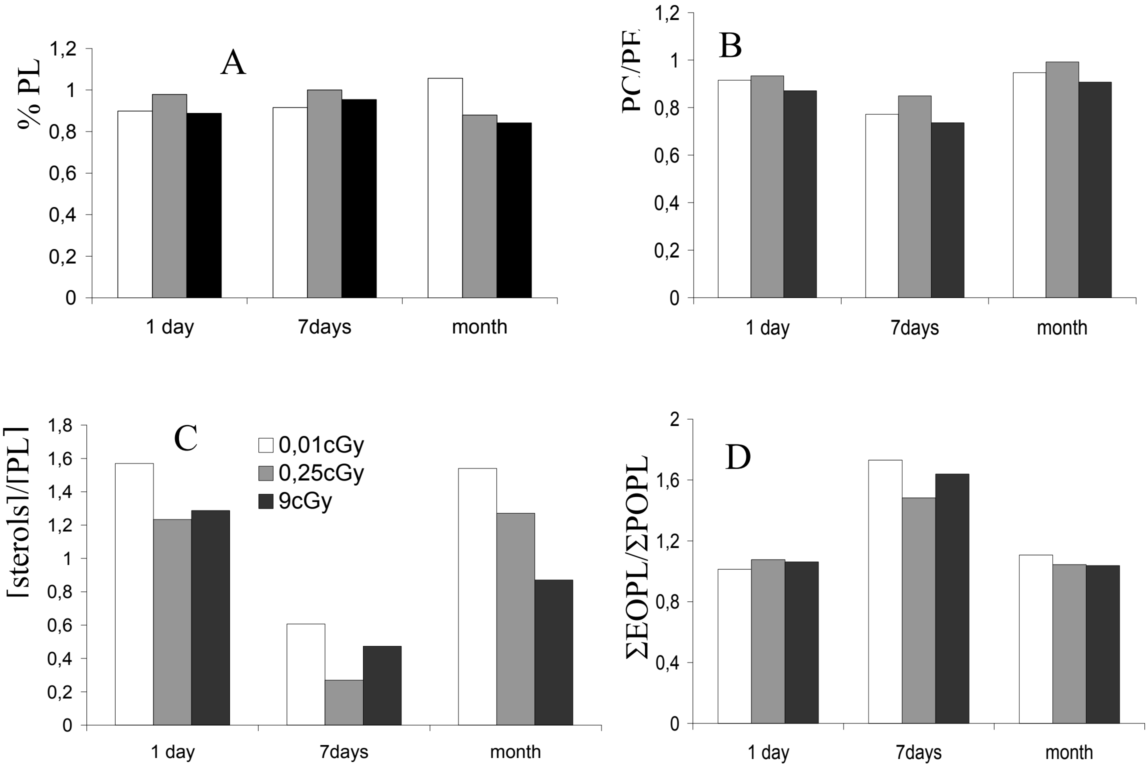

Fig. 1. Influence of the dose rate on the relative changes of the generalized parameters of the liver lipid composition under γ-irradiation of mice at the dose of 15 cGy.

Within 1 month after the acute X-radiation of mice SHK at the dose 16 cGy the reliable difference of the PC/PE and ΣEOPL/ΣPOPL ratio in the liver PL are obtained between the average values for the control and experimental groups. While the more high variability there is within the irradiated mice as compared with control group for the [sterols]/[PL] ratio, the another generalized parameters have a more limit of variance for the control mice. The data which are presented in Table are confirmed this conclusion.

Table. Limits of variations of the generalized parameters of the lipid composition in liver of mice SHK (females) within 1 month after X-radiation at the dose of 16 cGy.

Variant of experience	Parameters of the lipid composition			
	% PL	PC/PE	ΣEOPL/ΣPOPL	[sterols]/[PL]
Intact biological control X-irradiation at the dose of 16 cGy	10,7 – 60,8 21.3 – 83.6	1.19 – 2.28 2.01 – 2.39	0.30 – 1.06 0.43 – 0.53	0.54 – 1.09 0.58 – 0.53

It is necessary to note that the LPO intensity, the diene conjugate (DC) and ketodiene (KD) amount in the liver and brain lipids changes at mice of the different age (Fig. 2 and Fig. 3). As seen, the individual variability of these parameters differs both in the AOA of lipids and the analyzed parameter. So, the greatest variability for the TBA-reactive substance content in brain is revealed for the young mice (11.8 %), but in liver for the mice 18 weeks age (12.7 %). The DC content also has the highest individual variability in the brain lipids of the young mice (21.6 %) and in the liver lipids for mice 18 weeks age (35.5 %). The individual variability of the KD content decreases in the brain lipids from 13.6 % to 8.3 % at the aging of mice. Besides, this parameters has the most variability in liver lipids of the 18 week mice (29.0 %).

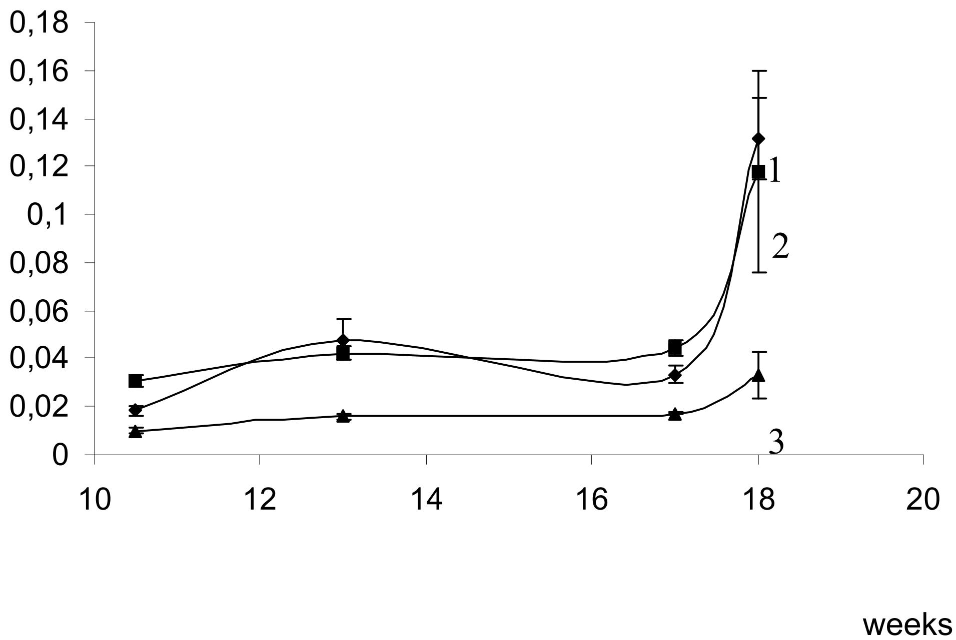

Fig. 2. The aging changes of the TBA-reactive substances (1, nmol/mg of protein), diene conjugate (2, a.u.) and ketodiene (3, a.u.) content in the liver lipids.

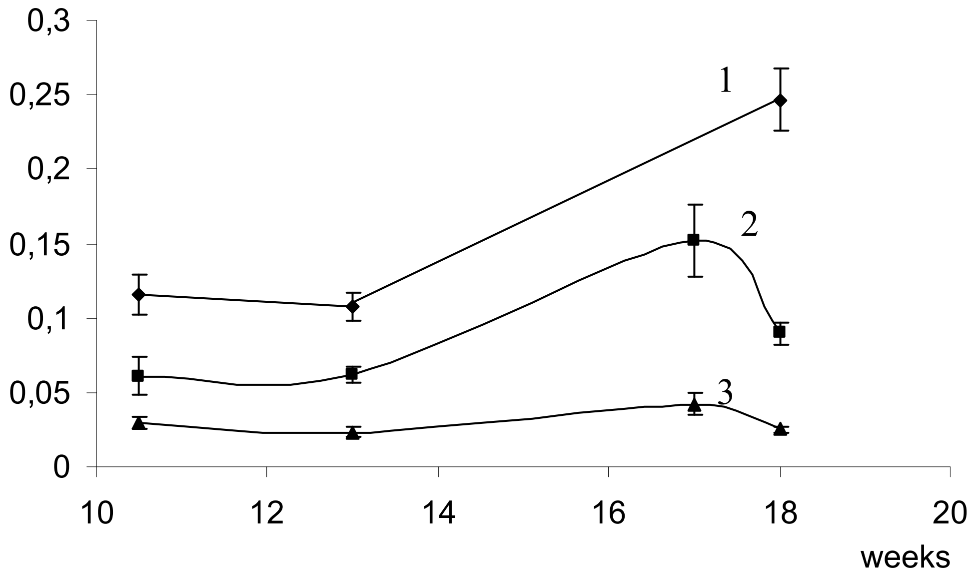

Fig. 3. The aging changes of the TBA-reactive substances (1, nmol/mg of protein), diene conjugate (2, a.u.) and ketodiene (3, a.u.) content in the brain lipids.

Conclusions

As early established, the oxidative processes in lipids have to influence on forming of the biological effects under the acute X-radiation of the laboratory animals which characterize the different radiosensitivity [18]. As also shown, the relationship of membrane and DNA damage with lipid peroxidation under the low doses of some technogenic factors [15]. Besides, the lipid AOA play the important role for the development of the biological consequences under the radiation action at the low doses [13]. The high variability of the physicochemical characteristics and the composition of lipids in norm has in influence on the forming of the biological effects in organs of the irradiated mice. The scale of changes are due to the radiation dose and dose rate and the antioxidant status of tissues. The data obtained allow us to conclude that the individual variability of the antioxidant activity and composition of lipids, intensity of LPO, the peroxide content of lipids and their antiperoxide activity in tissues takes into account for the development of the biological consequences after the radiation action on organism.

Abstract

Sharing of data and biomaterials from publicly-funded experimental radiation science will yield substantial scientific rewards through re-analysis and new investigations. To that end, the STORE Consortium will create a platform for the storage and dissemination of both data and biological materials from past, present and future radiobiological research, a so-called Data Warehouse. STORE will provide a single online portal to radiobiological information that is presently distributed over scientific centres worldwide, and it will provide the necessary standard operating procedures (SOP) for the evaluation of archived tissue usability. The final goal of the project will be to propose viable financial models for the long-term sustainability of both material and data emerging from radiobiological research.

Fig. 1. Logo of STORE (http://www.fp7store.eu).

The strategy to achieve these goals is multi-level: 1) to provide a "one-stop-shop" portal integrating international databases and other repositories currently active, such that the user can find material and data held remotely; 2) to archive primary (raw) data or pointers to data in public databases, from radiobiological experiments and studies, while this resource will be open to individual investigators and to funding agencies as a potential central repository for data sharing; 3) to physically archive threatened material resources which are considered to be a valuable resource to the Community, and whose state of preservation is consistent with STORE benchmarks; 4) to provide a single point of access to the integrated biomaterial resources through standardised request procedures.

The provision of a central portal is expected to help in the dissemination of awareness of the existence of these resources, many of which are, anecdotally, underused because their availability and existence is unknown. The generation of benchmarks for sample preservation and usability by preparation of SOPs will also help to disseminate formal standards by which the usefulness of archive material of this type can be assessed.

Introduction

Since the late 1950s, valuable data have been collected on the effects of experimental, accidental and medical irradiation of humans and animals. Sharing and re-use of data and materials from publicly funded experimental radiation science and clinical research adds huge value to the original investment and can yield substantial scientific rewards through re-analysis and investigation, but such activity requires an infrastructural resource in order to be realised.

High-throughput screening techniques, so called "omics", have been developing in recent years with a breathtaking speed. The question arises which modern techniques are suitable to be used with the FFPE tissue (Tapio et al 2008a). Finding novel methods to re-evaluate the archive material will provide us with a vast amount of research data, the concept of data banking becoming increasingly important. Combined with information on individual exposure, disease diagnostics, and available biomaterial this data become extremely valuable.

The principal aim of data sharing is to maximise the return from the scientific endeavour and make the best use of research and funding. Although opportunities and developments in technology allow rapid, efficient and independent dissemination of vast amounts of information and despite the existence of guidelines on access to data, good practice is not widespread (Schofield et al). Open access to quality-controlled data in interoperable formats would allow better use of the original investment in collecting the data. Re-analysis of experimental results could be used to validate and adjust previous results and, in an interdisciplinary setting, also open up new research avenues well beyond the initial context in which the data were collected. Consequently, current hypothesis could be tested and new hypothesis could be advanced.

STORE, a 3-year project running from 2009 to 2012 and supported by the European Commission, currently works to realise the vision of an open access to data gained from radiobiological studies on animals. The main challenge here is finding financial support for maintenance and development of data resources to best serve the scientific community (Chandras et al).

STORE wants to a) improve the quality of and accessibility to radiobiological data and to promote the awareness of the importance of data sharing and b) create a platform for the storage and dissemination of both data and biological materials from past, present and future radiobiological research. The STORE platform will consist of a combined "Data Warehouse" and physical repository that will enable the sharing of experimental data sets and materials. STORE will provide a single portal to radiobiological information that is presently distributed over scientific centres worldwide. STORE will provide the necessary Standard Operating Procedures (SOPs) for the evaluation of archived tissue usability. The project will put forward feasible financing models for long-term support of data and bio resources in the radiobiology.

Methods

Within STORE two databases will be developed and maintained. The primary database (Data Warehouse) will form a public repository for radiobiological data and will provide links to other relevant databases. The second one will be a smaller bioresource database containing information about the biological samples in the STORE. Both data bases will be linked to each other.

Data Warehouse

The Data Warehouse will contain a) primary (raw) datasets from legacy experiments and new investigations, input by users or curators, b) summary information and links to datasets from individual projects already submitted to other public databases and c) a portal to other existing databases, such as ERA, the Chernobyl Tissue Bank, and the Northwestern Janus database, mediated through the generation of a BIOMART. BIOMART is an open-source application which takes data tables from distant databases and transforms them into a standard structure to allow queries of the same form to be made across all the databases.

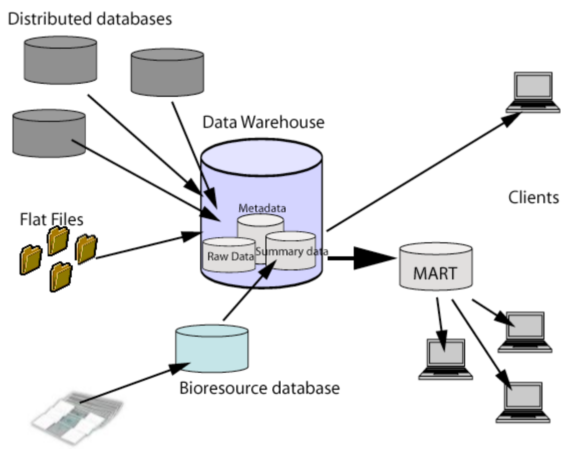

Fig. 2. Scheme of the database.

The Data Warehouse will be a database with the primary data object being the "Study". Key metadata, such as SPECIES, RADIATION QUALITY, ENDPOINT, will be attached to the data and study. Where appropriate, the structure of primary data will be transformed into a standardised form. The data organisation and metadata will be based on the growing group of accepted data structure standards and ontologies for functional genomics and biological and biomedical investigations to enhance interoperability with other databases.

Bioresource database

A second database and curation facility will be established to deal with the physical archiving issues. Current good practice guidelines for biological resource databases have already been described by several agencies, most recently by the NCI (http://biospecimens.cancer.gov/practices/) and within the caBIG project in the USA (http://biospecimens.cancer.gov/practices/cabig_tools/). Such recommendations are a gold standard as they are designed for human clinical material; the degree to which they are implemented in STORE will depend on the results of the investigations on the practice and regulatory issues surrounding tissue retention and international transfer. We suggest that the system developed here will be sample-centric, each sample possessing its own unique identifier corresponding to the individual animal and the study. Interactions with the Data Warehouse to source detailed experimental information on the samples will be accomplished through the individual codes. Where samples have been processed, for example into RNA and DNA, the database will support quality control, aliquoting, bar-coded containers and processes. Tracing and internal audit will be possible so as to identify end users and obtain feedback, and to comply with regulatory requirements.

Regulatory Issues

The regulations concerning archiving and transfer of animal and human tissue across international borders will be a major focus of the project. As we expect that biomaterial will be transported across European but also international boarders during the lifetime of the project, it is one of the main goals to facilitate exchange of samples between remote archives offering researchers advice and support. Based on international regulations on transfer of human and animal biomedical data and biological material a respective set of recommendations will be developed. A particular question important for the radiobiology community is the transport of radioactive material and will be given special attention (see below). To facilitate the comparison of international regulations links to relevant institutions in the US and in Japan have been made.

Sustainability and accessibility of the biological archives

STORE wants to develop operational parameters for a sustainable and accessible radiobiological tissue archive. For that purpose, questions concerning the current status and ownership of biological samples and their documentations have already been investigated within an FP6 project Promotion and Update of the European Radiobiological Archives (ERA-PRO; Tapio et al 2008b) A further task is to prepare a concept for sustainability and accessibility to the biological archive material and documentation in consultation with other international archives. Finally, evaluation of the radiological issues involved in the storage, transport and use of the archive materials is of great importance. Specifically, STORE will give recommendations on how to handle material arising from experiments using long-lived internal emitters. In this case, some radioactivity coming from radionuclides in the tissue has to be taken into consideration when handling the sample.

Establishment of Standard Operation Procedures

The biological material in physical repositories has to be used with greatest care to avoid damage due to its irreplaceable nature.

It has to be borne in mind that most techniques available at the moment were optimised for fresh/frozen tissue. FFPE tissue has recently gained considerable interest as an alternative to fresh/frozen tissue in retrospective biomarker discovery. However, macromolecules such as DNA, RNA and proteins undergo degradation and in the case of proteins also cross-linking during the fixation and aging process, making the applicability of conventional analysis problematic. There is an obvious need for methodological optimisation for FFPE material. Furthermore, as different storing times and conditions and the length of fixation influence the quality of various macromolecules in a different manner, these parameters will be tested using a common tissue model.

Taken together, STORE aims to establish Standard Operating Procedures (SOP) for evaluating quality of radiobiological archive tissue and defining test systems describing the usefulness of such material. Given that successful analysis of biological material isolated from archived tissue is feasible, the procedures performing best in terms of different endpoints compared to the fresh/frozen control tissue, will be defined as SOPs. At the end of the project, the SOPs will be validated by a STORE member not involved in their development.

Discussion

Sharing research data avoids its recollection by unnecessarily repeating animal experiments and enables their reanalysis. The vast amounts of data generated by previous and modern research will be valuable long after the experiments have been finished. It is less clear how data and databases will be maintained in order to guarantee the future access to these resources. The maintenance of databases is particularly at risk of falling victim to the constraints of traditional grant-based funding. We suggest that entirely different criteria have to be applied to judge the value of a database. For example, is it a unique and essential community resource? How are the data curated and validated? How comprehensive, detailed and interconnected are the results?

In many cases, researchers collect ancillary data that extends the primary research outputs: survey data, lab notebooks, spreadsheets, and annotations just to name a few. Much of this ancillary data (and some of the primary data as well) is not currently digitised, e.g. lab notebooks or handwritten specimen labels. Some of this additional data is maintained; much of it is lost, either because it is difficult or impossible to locate, or because it is simply deleted or destroyed. Research data (from old and newly performed experiments) in a digitalised form can be easily transported, worked on with new tools, merged with other data, categorised in new ways and stored in vast volumes. Research data are valuable long-term resources and the way to ensure their potential value is *to share* and *make them accessible*.

There is a need to collect, store, curate and distribute radiobiological data in a standardised form to ensure interoperability within a central database and databases linked to it. Action is urgently required for funding of data and biomaterial repositories on a stable, long-term basis as uncertainty about the future funding and hosting of these resources will be a disadvantage for the whole radiobiological research community.

Malignant blood diseases and tumours in acute radiation sickness survivors following the Chernobyl accident

Belyi, David; Kovalenko, Alexander; Bebeshko, Vladimir
State Institution "Research Center for Radiation Medicine of Ukrainian Academy of Medical Sciences", UKRAINE

Abstract
In the result of Chernobyl accident acute radiation sickness (ARS) developed in 134 patients, including 28 ones who had died in 1986 due to severe radiation damages. At the end of 1986 we started follow-up study on oncological pathology development in 91 ARS survivors (doses up to 7.1 Gy) and 99 patients with doses below 1 Gy. All patients were residents of Ukraine. During 24 post-accidental years malignant diseases of hematopoiesis were observed in 5 patients and solid tumours in 15 ones. Oncohematological pathology consisted of hypoplasia of hematopoiesis (1 case; 1986), acute myelomonoblastic leukaemia (1 case; 1998) and myelodisplastic syndrome (3 cases; 1993, 1995, 1996). All diseases brought patients to death. Patients' mean age was 46.3±7.5 at the moment of irradiation, 54.0±8.1 on disease onset and 55.5±6.8 years at person's death. Leukaemia and myelodisplastic syndromes arose only in ARS survivors. Their latent period was 9.6±2.1 years. The first malignant tumour, sarcoma of hip soft tissues, was diagnosed in 1992. This patient died in 1993. Before 2009 it was revealed as far back as 14 malignant neoplasm of different localization: cancers of colon (3 cases; 1997, 1999, 2001), stomach (2 cases; both in 2004), thyroid gland (2 cases; both in 2000), throat (1 case; 2000), kidney (1 case; 2000), lung (1 case; 2001), prostate gland (1 case 2001), basal cell carcinoma of head (1 case; 2006), urinary bladder (1 case; 2008), and neurinoma of lower jaw that had a malignant transformation (2003). Amongst persons suffered from cancer, 7 patients were successfully treated but the rest ones died. Totally, malignant tumours were diagnosed in 6 ARS survivors (6.6%) and 9 persons from group of comparison (9.1%). At the moment of death from malignant tumors the patients' age was 66.2±9.8 years. The period from irradiation to neoplasm development averaged 15.9±3.1 years.

Introduction
Malignant tumours and leukaemia are considered the stochastic effects of radiation. The majority of radiogenic tumours have no dose threshold (Beebe 1984; WHO 2005) and a risk of cancer development increases with radiation dose. Studying consequences of the Chernobyl accident some researches came to the conclusion of oncological morbidity

rate increase in victims during post-accidental period (Demina 2002; Bespalchuk et al. 2003; Ivanov et al. 2001; Kirillov et al. 2001) and experimental animals as well, who was keeping in Chernobyl zone (Serkiz 1991). Other authors have the opinion that the accident at the Chernobyl nuclear power plant (CNPP) didn't result in essential growth of cancer and mortality from malignant tumours in exposed persons in comparison with the rest population (Buldakov 2002; Ganul et al. 1991; Ivanov et al. 2001; Moysich et al. 2002; Tukov et al. 1998).

Such contradictory results of numerous investigations possibly connected with the fact that CNPP clean-up staff are characterised by wide radiation dose range. The opinion is existed that doses 0.1 Sv and higher are able to cause statistically significant excess risk of cancer incidence (Beebe 1984; Filyushkin et al. 2000; UNSCEAR 2000). This situation makes the study of oncological and oncohematological pathology in persons exposed to irradiation in doses upper 0.1 Sv, especially ARS survivors, are very actual.

Material and methods

After the Chernobyl accident 91 ARS survivors were under follow-up in the hospital of Research Centre for Radiation Medicine (RCRM). From this number 38 patients survived ARS grade 1 (mild), 41 ARS grade 2 (moderate) and 12 ARS grade 3 (severe). As a control group 99 patients with whole-body radiation doses lower 1 Gy (ARS 0 group) were examining during entire post-accidental period (table 1). Patients' groups didn't differ significantly by age

Table 1. Age-specific and dosimetric characteristic of the examined patients

Variables	ARS 0	ARS grade 1	ARS grade 2	ARS grade 3
Number of persons	99	38	41	12
Gender: M / F	89 / 10	36 / 2	40 / 1	12 / 0
Age at exposure, years mean ± SD min - max. 95% confidence interval	 35.9±10.3 18.4-60.3 33.8-38.2	 33.2±8.2 17.6-56.3 30.5-35.8	 40.9±16.5 17.9-79.3 34.1-42.9	 36.6±12.5 20.4-72.6 30.4-51.3
Persons with known dose	15	30	37	11
Dose of irradiation, Gy mean ± SD min – max 95% confidence interval	 0.4±0.3 0.1-1.0 0.2-0.5	 1.0±0.6 0.1-3.3 0.8-1.3	 2.4±0.9 0.5-4.9 2.1-2.7	 4.5±1.4 2.9-7.1 3.6-5.5

All patients had a hospital examination and treatment at the average once per 2 years.

The check-up protocols included full blood count, biochemical tests (basic metabolic panel, chemical pathology and liver function tests), immunological profile (humoral and cellular indicators), thyroid tests (ultrasound and TSH, FT_4), urinalysis, full physical examination, and various instrumental tests as necessary (electrocardiogram (ECG), electroencephalogram, ophthalmological tests, gastro- or colonoscopy, chest x-ray, functional lung test etc. When necessary, patients were consulted by specialists (ophthalmologist, endocrinologist, pulmonologist, cardiologist, gastroenterologist, haematologist, dermatologist, neuropathologist, psychiatrist, urologist or gynaecologist). Further, more complex diagnostic methods were applied as necessary, including CT scans, biopsy, cardio-stress-ECG, serological tests for specific causes, e.g. hepatitis A, B or C viruses, bone marrow tests etc.

Results

The first case of malignant hypoplasia of haematopoiesis was revealed in August 1986 in a patient, who worked several days in the CNPP zone in May and July 1986. His haematological status is characterised by essential leukocytopenia and slight anaemia. The onset of oncohematologic pathology was mistakably estimated as ARS grade 1 manifestation. However the following disease course dispelled any doubts against blood system pathology. The bone marrow aspiration confirmed the oncohematological diagnosis.

Subsequently two ARS grade 3 and one ARS grade 1 survivors developed myelodisplastic syndrome, which had the lethal outcome for all patients (table 2). One more patient, who had survived ARS grade 2, fell ill with acute myelomonoblastic leukaemia after 11.8 years passed from irradiation and died in spite of treatment.

Table 2. Cases of malignant blood disease in ARS survivors and control group

No	Diagnosis	ARS grade	First diagnosed	Age at (years)		Outcome
				diagnosis	death	
1	Hypoplasia of hemopoiesis	0	Aug 1986	48.6	49.3	Died on Apr 1987
2	Myelodisplastic syndrome	1	Sept 1996	45.0	50.7	Died on May 2002
3	Myelodisplastic syndrome	3	Mar 1993	52.1	52.2	Died on Apr 1993
4	Myelodisplastic syndrome	3	Oct 1995	64.6	64.7	Died on Dec 1995
5	Acute myelomonoblastic leukaemia	2	Feb 1998	59.9	60.7	Died on Dec 1998

All patients with malignant blood diseases were male. Their mean age at the exposure was 46.3±7.5 years, at the diagnosis 54.0±8.1 and at death 55.5±6.8 years. The latent period from exposure to first signs of disease was 9.6±2.1 years. Today the relative number of patients, who suffered from oncohematological pathology and died, is 2.9% of 190 persons under follow-up or 4.4% of ARS survivors.

The first case of malignant tumour was revealed in patients of ARS 0 group in 1992 (table 3). During examination of 34 years old man there was found subcutaneous, solid and tender formation on the right hip with dimensions as a pigeon egg. The patient was sent in a city oncological hospital but he refused from examination without clear explanations. When he was admitted in the RCRM hospital next year, it was found several solid subcutaneous nodes. The patients refused from oncological examination again and at the end of 1993 he died. Autopsy proved the supposed diagnosis sarcoma of hip soft tissues.

The second case of oncological pathology as cancer of sigmoid colon was diagnosed in 1997. A patient (ARS grade 1 survivor) only complained on bloody discharges from anus during defecation. The adenocarcinoma in situ was diagnosed after colonoscopy and proved by histological examination.

Table 3. Cases of oncological pathology in ARS survivors and control group

No	Diagnosis	ARS grade	First diagnosed	Age at (years)		Outcome
				diagnosis	death	
1	Sarcoma of hip soft tissues	0	Apr 1992	34.1	34.8	Died in 1993
2	Cancer of colon	1	Mar 1997	54.5		Operated on Jun 1997
3	Leiomyosarcoma of shin Cancer of colon	0	Aug 1998 Jun 1999	72.5 73.4		Operated on Sep 1998 Operated on Jun 1999
4	Cancer of larynx	0	Jul 2000	59.3	59.9	Died on Feb 2001
5	Cancer of thyroid gland	2	Nov 2000	37.6		Operated on Nov 2000
6	Cancer of thyroid gland	2	Dec 2000	42.9		Operated on Jan 2001
7	Cancer of kidney	0	Dec 2000	44.4		Operated on Jan 2001
8	Cancer of colon	0	Nov 2001	63.6	67.5	Died on Oct 2005
9	Cancer of prostate	0	May 2001	71.7	73.3	Died in 2003
10	Cancer of lung	0	Feb 2001	46.1		Operated on Jun 2003
11	Neurinoma of lower jaw	2	Oct 2003	52.7	53.9	Died on Dec 2004
12	Cancer of stomach	0	May 2004	77.5	78.1	Died on Jan 2005
13	Cancer of stomach	0	Jul 2004	65.7	65.9	Died on Sep 2004
14	Basal cell carcinoma of head	1	Nov 2006	51.9		Irradiation
15	Cancer of urinary bladder	2	Jun 2008	66.8	66.9	Died on Aug 2008

It is necessary to note that all subsequent cases of solid tumour either had no clinical symptoms, being a result of causal findings during the routine examination (endoscopy, ultrasound scanning), or coursed with minimum non-specific complaints (so called "the syndrome of minor signs"). In the majority of cases the tumours were revealed owning to physicians having oncologic alarm. However the events took place when patients ignored doctor's opinion and refused informative diagnostic procedure and treatment as well. An operable stomach cancer with clear clinical symptoms and evident endoscopic picture was diagnosed in ARS 0 patient. The patient refused a surgical treatment and died over 3 months.

During 18 years after the first sarcoma diagnosis 14 cancers of different location were revealed: 3 cancers of colon, 2 ones of stomach, 2 thyroid gland, and a cancer of larynx, lung, kidney, urinary bladder, prostate, as well as basal cells carcinoma of head and neurinoma of lower jaw that was undergone malignant transformation. In a patient of ARS 0 group cancer of colon followed leiomyosarcoma of left shin. He was operated with subsequent fractionated X-ray irradiation of shin in total dose of 52 Gy.

Two patients developed cancer of stomach and larynx that had rapid course. The period from diagnosis to lethal outcome was 3 and 6 months, respectively. The first patient was undergone endoscopic procedure in Feb 2004 without any changes of stomach mucous membrane but in July 2004 he was admitted in RCRM hospital with clinical and endoscopic signs of stomach cancer. Cancer of larynx $T_3N_1M_0$ was diagnosed in the second patient during routine follow-up but a year before the patient had no any complaints. Surgical treatment didn't stop metastatic disease with following lethal outcome.

All malignant tumours were diagnosed in male patients. Their mean age at the moment of exposure was 40.9±12.1 years, at the tumour diagnosis 57.9±17.1 and at the moment of death 66.2±9.8 years. The tumours latent period was 15.9±3.9 years. The overall number of patients with oncological pathology is 7.9%, amongst ARS survivors 7.6%, and in ARS 0 group 9.1%.

Statistical analysis showed that tumour incidence and their frequency rate didn't depend on ARS grade and ARS presence or absence (table 4).

Table 2. Relation between cancer incidence and radiation factor

Radiation factor	Spearman's rank correlation		χ2-test	
	r	p	F	p
ARS grade	-0.07	0.36	2.69	0.44
Presence or absence of ARS	-0.083	0.28	1.2	0.27

Discussion

As it was showed above the malignant blood diseases in ARS survivors preceded solid tumours and are not characterised by wide diversity of nosological form (3 myelodisplastic syndromes, acute leukaemia and hypoplasia of haematopoiesis) whereas in A-bombing victims of Hiroshima and Nagasaki from 1950 to 1987 there was diagnosed various form of acute and chronic leukaemia, Hodgkin's and non-Hodgkin's lymphomas, and multiple myelomas (Mabuchi et al. 1995; Preston et al. 1994). The peak of leukaemia incidence fell on 5^{th}-8^{th} year after irradiation (Mabuchi et al. 1995).

Analysing leukaemia incidence in hibakusha and persons, who was exposed to medical irradiation, E. Hall (1989) concluded that leukaemia latent period is 5 year. Other authors considered it shorter, 2-3 years (Rudnev 1992), or longer, 7-10 years (Nenot et al. 1995). The last term is better corresponded our data: all 4 cases of oncohematological pathology, except the first, appeared 7 years later the exposure. Hypoplasia of hematopoiesis in the patient No. 1 (table 2) developed in improbably short term after the initial contact with ionizing radiation. It doesn't enable to consider this case caused by radiation. Most likely the disease set in early but primary clinical symptoms appeared during his work in the CNPP zone.

From 1992 to 2000 myelodisplastic syndrome developed in 112 from 240800 CNPP clean-up workers, including 3 cases in ARS survivors. According to I. Sekine (2003), amongst 93700 A-bomb victims during the 50-year period only 13 cases of myelodisplastic syndrome developed that is absolutely and relatively less than in Chernobyl victims. Both high frequency rate and the latent period of 6-14 years enable to suspect radiation in this disease incidence. To prove this suggestion the additional study has to be set up.

Cancers that developed in CNPP clean-up staff during the first years after the accident, according A. Romanenko et al. (2000), might be the result of existing cancer promotion but not of the new cancer induction. The peak of radioinduced cancer should expect in 15-25 years after irradiation. The first cancer was revealed on 11th year after the exposure in ARS grade 1 survivor. This fact as well as following cases of malignant tumours onset proves the data that minimal latent period for solid tumours has to be 10 years and more (Kato et al. 1995). After this their incidence will increase constantly.

Cancers is a non-threshold radiation effect. After the whole-body short-term radiation exposure with low linear-energy transfer in dose 0.1 Sv the risk of cancer mortality increases on 0.5-1.4% from basal level (Fabrikant 1981) but if the dose 1 Sv it elevates to 9% in men and 13% in women (UNSCEAR 2000). Basing on this data it should expect higher cancer incidence in ARS survivors in comparison with persons exposed to radiation in doses lower 1 Gy. However our study showed that frequency of cancer was higher in control group (9.1%) than in ARS survivors (7.6%) with insignificant difference. There was not found significant difference of cancer incidence between patients with various ARS grades.

Amongst all oncological cases in ARS survivors and persons exposed in doses lower 1 Gy it is impossible to discriminate what tumours are caused by irradiation or developed spontaneously. These cohorts are too small for epidemiological investigations. The data of Japanese survivors showed that amongst 86572 individuals in the Life Span Study cohort there were 7578 deaths from solid tumours during 1950-1990. Of those cancer death, 334 (4.4%) could be attributed to radiation exposure. However this data cannot be extrapolated on relatively small group of ARS survivors or less irradiated persons.

ARS survivors and control group patients more frequently fell ill with cancer of colon (3 cases), stomach (2 cases) and thyroid gland (2 cases). According to results of hibakusha follow-up (1958-1987) their overall tumours included the first two types of cancer for whom the significant excess risks of morbidity and mortality was determined (Ron et al. 1994). The cancer of lung and urinary bladder, which were diagnosed in a patient of control group and ARS grade 2 survivor respectively, also belong to the tumours with the high mortality risk. There was revealed the significant increment of nonmelanoma skin cancer in the incidence data, but not in the mortality series. No significant radiation effect was seen for cancers of the pharynx, rectum, gallbladder, pancreas, nose, larynx, uterus, prostate or kidney in either series.

Sarcomas are the malignant tumours derived from mesenchyme whereas cancers descended from endothelium. No one investigation dedicated to A-bombing Japanese survivors contained data of sarcomas morbidity increase connected with irradiation. Our investigation revealed only 2 sarcoma cases in patients without ARS in anamnesis. This cohort size is not enough for statistical analysis.

WHO concluded (2005, 2008) that several last decades various organs cancer ranks as second having ahead cardiovascular diseases as mortality reasons in European countries including Ukraine. During 24 post-accidental years amongst restricted group of ARS survivors and persons exposed in doses lower 1 Gy 13 persons died due to oncological and oncohematological pathology, 12 ones of cardiovascular diseases and 11 patients of other reasons including traumas and accidents.

The patients' mean age was 56.4±12.4 years when malignant blood diseases and solid tumours were diagnosed. Thus 4 patients belonged to persons of young and mature age (20-44 years), 8 ones to middle age (45-59 years) and 8 patients to elderly and old age (60 and more years). The life span of 13 patients, who died from oncohematological pathology and tumours, was 59.8±11.5 years and didn't reach the average population level that according to WHO data (WHO 2005, 2008) was 62.3 year for male in Ukraine in 2001-2003 but decreased to 61.6 years in 2005. Therefore more than a half of the patients, who died, didn't live till very low average population life span in Ukraine (e.g. in Finland this index was 75.8 years in 2005). This fact enables to consider that the oncohematologic situation in ARS survivors and control group patients is disturbed. The way out of this is the early diagnostic and a radical cure. The localization of neoplasm (blood, digestive tract, thyroid gland, larynx, kidney, lung, prostate, skin) in followed up patients enables to reveal it on the early stage of development by routine and non-invasive diagnostic methods as blood analysis, x-ray examination, ultrasound, endoscopy, examining by otolaryngologist, gynaecologist, urologist, endocrinologist, pulmonologist, haematologist etc.

The second problem, which associates with successful diagnostic, is early patient's visit to physician for medical care. Due to low sanitary and general culture some patients didn't go to physician even if on the background of old complaints a new ones appeared and health changed for the worse. Some patients visited "folk healer" instead of physician or ignored medical recommendations. Therefore the obligatory annual examination of ARS survivors and other Chernobyl victims has to be combined with community health and medical staff oncologic alarm.

Our investigations had showed that malignant tumours appeared in the Chernobyl victims on the background of chronic non-specific diseases of internal organ systems, which didn't threaten patients' life themselves but as any pathological process increased the probability of cell mutagenesis. So a treatment of these chronic diseases is the one more way to decrease the risk of malignant tumours incidence.

Conclusions

During 24 years after the Chernobyl accident malignant blood diseases and tumours ranked as first by mortality reasons in ARS survivors and other exposed persons in doses lower 1Gy. They left behind even cardiovascular diseases. More than 50% of fallen ill with oncological pathology and died of them didn't reach the level of average population life span in Ukraine, which is 20% less the analogous index in economically developed European countries.

Effective treatment of patients depends on both early diagnostic and patients' readiness to follow doctors' recommendations.

Radiation-epidemiological estimation of thyroid pathology risk

Masyakin, Vladimir; Rozhko, Alexander; Nadyrov, Eldar
Republican Research Center for Radiation Medicine and Human Ecology, BELARUS

Abstract

The main source of irradiation of the population after the Chernobyl accident was ^{131}I and its other short-lived isotopes that effected practically the whole population of Belarus. More than 30 % of children aged up to 2 years old received doses over 1 Gy.

The aim of study is the retrospective analysis of clinical data depending on thyroid exposure level among people aged 0–3 at the moment of the Chernobyl accident.

Out of people observed in State registry, we formed 2 groups which are annually examined on thyroid pathology.

1. Basic group including 1004 residents of Gomel oblast aged 0–3 at the moment of the Chernobyl accident who were exposed to short-lived iodine radioisotopes.
2. Control group including 2020 persons born in 1987–1988 in Gomel region and who are observed in State Registry.

As one would expect, the highest estimates of the relative risk were received on thyroid cancer. Even at rather low absorbed thyroid doses, the attributive fraction was more than 94%. In group with high doses, practically all the cases were radiation-induced (AF = 98,5%).

At the same time, the analysis results showed that radiation component was the predominant one at realization of practically all the spectrum of thyroid pathology among subjects irradiated in early childhood. Evident growth of OR was observed in patients with all nodular forms of goiter with increase of thyroid dose. In subjects with thyroid dose above 1 Gy, the attributive fraction of different forms of nodular pathology varied from 60 to 98%.

Statistically significant estimates of relative risk were calculated on all forms of thyroid nodular pathology.

Relative risk of any goiter nodular form in persons affected in early childhood was 3,7 (AF= 71,1%).

These results suggest that considerable part (up to 71%) of goiter nodular form diseases among residents of Gomel region, affected in early childhood, can be referred to thyroid exposure.

Acute myocardial infarction in the cohort of Mayak PA nuclear workers

Abstract
Incidence of and mortality from acute myocardial infarction (AMI) have been studied in a cohort of 12210 workers first employed at one of the main plants of the Mayak nuclear facility during 1948–1958 and followed up to 31 December 2000. Information on external gamma doses was available for virtually all of these workers (99.9%); the mean (± standard deviation, SD) total external gamma dose was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and 0.65±0.75 Gy (99% percentile 2.99 Gy) for women. In contrast, plutonium body burden was measured only for 30% of workers; amongst those monitored, the mean (± SD) absorbed cumulative liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women. 683 disease cases and 338 deaths from AMI were identified in the study cohort. Having adjusted for non-radiation factors, AMI mortality data showed a statistically significantly increasing trend with external dose, excess relative risk per Gy (ERR/Gy) was equal to 0.265 (95% CI 0.004, 0.526), but the evidence for this trend was greatly reduced if adjustment was made for internal liver plutonium dose. In contrast to the mortality findings, there was very little evidence of an association between AMI incidence and external dose, ERR/Gy was equal to 0.029 (95% CI -0.076, 0.134). Among workers with internal liver doses from plutonium exposures, AMI incidence and mortality were raised at 0.1–0.5 Gy relative to lower doses; there was still borderline evidence of such differences after adjusting for external dose. The trends in AMI incidence or mortality with internal dose were not statistically significant. Whilst the data on AMI incidence and mortality were consistent when analysing internal doses, the same was not true when analysing external doses.

Introduction
Acute myocardial infarction (AMI) is one of the most severe forms of the ischemic heart disease with the highest lethality and high percent of complications resulting in long disability, which reduce the quality of life.

The cause of AMI in the overwhelming majority (93-98.5%) of cases is the atherosclerosis of coronary vessels, which is a multifactorial disease, and different endogenous (genetic predisposition, gender, age, hypertension etc.) and exogenous (smoking, emotional stress etc.) factors contribute to its development. Over the last two decades several studies have examined the possible effects of ionizing radiation exposure on circulatory diseases, including AMI. Most of the studies (McGeoghegan et al 2008; Kreuzer et al 2006; Muirhead et al 2009; Shimizu et al 2010; Vrijheid et al 2007) focused on CVD mortality, whereas several studies (Yamada et al 2004; De Bruin et al 2009; Ivanov et al 2006) focused on CVD incidence.

This study was aimed at estimating risks of both AMI incidence and mortality in the cohort of Mayak PA nuclear workers first employed at one of the main plants (reactors, radiochemical, or plutonium) during 1948-1958 in relation to external gamma and internal alpha exposures, taking non-radiation factors into account.

Material and methods

Mayak PA began operations in 1948 as the first and largest nuclear weapons facility in the former Soviet Union and included all the plants necessary for weapon-grade plutonium production, namely, reactors, radiochemical plant, plutonium production plant and auxiliary plants.

From the first days of Mayak PA operation, the special system of personnel medical observation included an obligatory pre-employment medical examination and routine medical examinations of all the workers based on a common standard program. After quitting their job at Mayak, if the former worker stayed in Ozyorsk, he/she was examined at the same specialized medical hospital based on the same standard program. This system of medical observation of Mayak PA personnel health allowed a unique archive of primary medical data to be accumulated and formed the basis for establishment of the unique “Clinic” medical-dosimetry database for the Mayak PA workers cohort (Azizova et al 2008).

The study cohort included 12210 Mayak PA workers, 3552 (29.1%) of whom were women, first employed at one of the main plants from the start of operations through the end of 1958 independently of gender, age, nationality, occupation, and other characteristics. The method of identifying this cohort has been described previously elsewhere (Koshurnikova et al 1988, 1998a, 1998b, 1999).

Vital status as of 31 December 2000 was known for 88.4% of cohort members; of these workers, 52.7% were known to have died and 47.3% were known to be alive as of that time. 53.7% of the 12210 members of the study cohort were known to have left Ozyorsk by 31 December 2000. For persons who continued to be residents of Ozyorsk, vital status was known for all but one person (99.98%). Cause of death was known for 93.5% of deceased cohort members. Morbidity data for the whole period of follow-up were collected for 11597 (95.0%) workers in the study cohort. Only for 5.0% of workers could information not be collected, owing to the loss of their medical documentation. It should be noted that the CVD incidence analysis was restricted to the period of residence in Ozyorsk.

Data on vital status and on dates and causes of death for those workers who migrated from Ozyorsk were provided by the SUBI Epidemiology Laboratory; data on date and causes of death for those Ozyorsk residents whose medical cards and/or case histories had been lost, were provided by the SUBI Occupational Health Laboratory.

Individual dosimetric control of external exposure was performed at Mayak PA from the beginning of operations there. Regular monitoring of internal exposure among those who might have been exposed to plutonium-239 began later, during the 1960s (Vasilenko et al 2007a; Khokhryakov et al 2000). The results of individual monitoring of external and internal exposure were recorded in individual dosimetric cards and journals. The data contained in these documents formed the basis for the establishment of the dosimetric database of Mayak PA workers (Vasilenko et al 2007a, 2007b; Bess et al 2007; Smetanin et al 2007a, 2007b; etc).

Dose estimates from the *Mayak-Doses 2005* dosimetric system were used in this study. Annual doses of external gamma exposure were available practically for all persons in the study cohort (99.9%). The mean (± SD) total gamma dose for the whole period of work at Mayak was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and 0.65±0.75 Gy (99% percentile 2.99 Gy) for women. The range of total gamma doses was very wide, with 32.6% having a total gamma dose greater than 1 Gy.

Plutonium body burden was measured only for 30.0% of workers. Among workers monitored for plutonium exposure, absorbed dose to liver from alpha radiation was used as a surrogate for the dose to muscle; this latter dose is likely to be similar to the dose to blood vessels and the chambers of the heart. Although doses to the liver and muscle would differ, they should be highly correlated with each other. Consequently, the liver dose can be used to look for any *dose–response* relationship between plutonium exposure and circulatory disease. Amongst those who were monitored, the mean (± SD) total liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women.

Data on occupational histories and external gamma exposures for the study cohort were provided by the Mayak PA Radiation Safety Department; data on internal alpha exposure from incorporated plutonium-239 were provided by the SUBI Internal Dosimetry Department.

This study focuses on incidence of and mortality from AMI (ICD-9 codes: 410). Follow-up started on the date of first employment at one of the main plants and continued until the earliest of: date of the first diagnosis of AMI (for the incidence analysis) or the date of death from whatever cause (for both the mortality analysis and the incidence analysis); 31 December 2000 for those known to be alive at that time; the recorded date of departure from Ozyorsk (for the incidence analysis); and the date of "last medical information" in the case of unknown vital status. Comparisons were performed within the Mayak PA workers cohort first employed during 1948–1958.

The analyses included the calculation of relative risks (RRs) for categories of one or more factors, having adjusted for other variables. The relative risks for these categorical analyses were calculated by maximum likelihood, using the AMFIT module of EPICURE (Preston et al 1993). 95% confidence intervals for the RRs and p-values from tests of statistical significance were obtained via likelihood-based methods, using AMFIT. Attention was initially directed to non-radiation factors, following which measures of radiation exposure were analysed with adjustment (through stratification) for non-radiation factors. Analyses of internal radiation exposures were restricted to workers known to have been monitored for possible plutonium exposure.

In addition to the categorical analyses, models for trends in disease rates with level of radiation exposures were also fitted to the data, using Poisson regression methods. These models again were fitted using the AMFIT module in EPICURE. In particular, the excess relative risk (ERR) (ie. the relative risk minus 1) was modeled by a linear trend with external or internal dose, with adjustment for non-radiation factors.

In these main analyses, adjustments were made – through stratification – for gender, attained age, calendar period, period of first employment at the main plants of Mayak PA, plant, smoking and alcohol consumption.

Sensitivity analyses were conducted to examine the impact of: a) modifying the set of non-radiation factors (extra adjustment for hypertension, body mass index, employment duration) for which adjustment was made in the analyses of radiation factors; b) restricting the mortality follow-up (like that of incidence) to Ozyorsk, because some migrants were lost to follow-up and because of lower autopsy rates among those who left the city; c) adjusting for internal dose in analyses of external dose and vice versa; d) using various lag periods for external and internal doses. Furthermore, examination was made of how radiation risks might vary by gender, or between plants at Mayak or by attained age.

To allow for the possibility that radiation might affect stroke risk by modifying levels of blood pressure (Preston et al 2003; Ivanov et al 2001) and body mass index (Telnov 1985), the level of these factors at the time of preliminarily medical examination (before employment at Mayak PA) was considered, in order to avoid systematic errors that might arise through adjusting for values of these factors at later times. In contrast, smoking and alcohol consumption were classified at the time of last information (for the mortality analysis) or at the time of last information prior to the first diagnosis of stroke (for the incidence analysis).

Results

By 31 December 2000, 683 disease cases of AMI were diagnosed during 248030 person-years of follow-up and 338 death cases from stroke were identified during 443350 person-years of follow-up.

Non-radiation factors

Analyses of non-radiation factors revealed statistically significant effects of well-known factors such as gender, age, smoking, hypertension, which were taken into account in the analyses of radiation risks, either in the main analysis or in sensitivity analyses.

Radiation factors

External gamma exposure: Table 1 shows that AMI mortality was statistically significantly higher among workers exposed to external gamma rays in total dose above 1 Gy as compared with workers exposed in doses below 0.5 Gy.

Sensitivity analysis (results not shown) revealed that AMI mortality was statistically significantly higher among workers with a gamma dose above 1.0 Gy relative to workers with a gamma dose below 0.5 Gy, irrespective of lag period used, whether additional adjustment was made for other non-radiation factors and internal exposure. AMI mortality was raised among males and radiochemical plant workers.

There was a statistically significant increasing trend of AMI mortality with increasing external gamma dose (Table 1), but the evidence for this trend was greatly reduced if adjustment was made for internal liver plutonium dose.

In contrast to the mortality findings, there was very little evidence of an association between AMI incidence and external dose.

Table 1. RRs and ERR (95% CI) for AMI incidence and mortality in relation to total dose of external gamma exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.5 Gy)		ERR/Gy
	0.5-1.0 Gy	>1.0 Gy	
Incidence	0.912 (0.710, 1.172)	1.034 (0.823, 1.298)	0.029 (-0.076, 0.134)
Mortality	1.104 (0.766, 1.592)	1.693 (1.229, 2.334)	0.265 (0.004, 0.526)

Internal alpha exposure: Table 2 shows that Both AMI incidence and mortality were statistically significantly raised among workers with cumulative absorbed dose to the liver from plutonium of less than 0.1-0.5 Gy as compared with workers exposed to lower internal liver doses. However, sensitivity analysis (results not shown) revealed that these findings were sensitive once different lag periods were used, whether additional adjustment was made for other non-radiation factors. However, there was still borderline evidence of such differences after adjusting for external dose.

Neither for AMI incidence nor for mortality was there a statistically significant trend in risk with internal dose with or without adjustment for external exposure.

Table 2. RRs and ERR (95% CI) for AMI incidence and mortality in relation to total absorbed liver dose from internal alpha exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.1 Gy)		ERR/Gy
	0.1-0.5 Gy	>0.5 Gy	
Incidence	1.279 (1.026, 1.595)	1.255 (0.878, 1.794)	0.078 (-0.084, 0.241)
Mortality	1.854 (1.216, 2.827)	1.488 (0.743, 2.981)	0.211 (-0.171, 0.594)

Discussion

Our analyses of AMI incidence and mortality revealed, as expected, statistically significant effects of well-known factors such as gender, age, hypertension, smoking, which are consistent with findings of other studies. In contrast, our analyses did not reveal any statistically significant effect of alcohol consumption or body mass index on AMI incidence or mortality, either for males and females.

Having adjusted to non-radiation factors there was statistically significant trend in AMI mortality with increasing external gamma exposure, but the evidence for this trend was greatly reduced if adjustment was made for internal liver plutonium dose. In contrast to the mortality findings, there was very little evidence of an association between AMI incidence and external dose

Among workers with internal liver doses from plutonium exposures, AMI incidence and mortality were raised at 0.1–0.5 Gy relative to lower doses; there was still borderline evidence of such differences after adjusting for external dose. However, trend in AMI incidence and mortality with internal liver dose were not statistically significant.

A complication to interpretation is the lack of knowledge as to those tissues or organs for which radiation exposure might increase the risk of stroke, which is particularly problematic in the case of plutonium intakes. For this analysis, liver dose has been used as a surrogate for the dose to muscle, which is likely to be similar to the dose to blood vessels and the chambers of the heart. Furthermore, the liver and muscle doses should be highly correlated with each other. However, there is uncertainty about which tissue or organ dose is appropriate for this type of analysis. A further complication relates to uncertainties in estimates for internal doses for Mayak workers. It should be noted that – because the dose to the liver from intakes of plutonium would be greater than that to the circulatory system – the ERR/Gy estimated here based on liver dose would be lower than that based on dose to blood vessels and the chambers of the heart. For these reasons, the findings in relation to internal exposure need to be interpreted with caution.

In addition, information is not currently available from other studies of populations exposed to external low-LET radiation or plutonium that would allow comparison of risk estimates for AMI taking non-radiation factors such as smoking or alcohol into account in relation to such exposures.

Conclusions

There was a statistically significantly increasing trend in AMI mortality with external dose, having adjusted for non-radiation factors. Much of the evidence for a raised risk concerned workers with cumulative external gamma doses above 1 Gy. The evidence for this trend was greatly reduced if adjustment was made for internal liver plutonium dose. Among workers with internal liver doses from plutonium exposures, AMI incidence and mortality were raised at 0.1–0.5 Gy relative to lower doses; there was still borderline evidence of such differences after adjusting for external dose. The trends in AMI incidence or mortality with internal dose were not statistically significant. Whilst the data on AMI incidence and mortality were consistent when analysing internal doses, the same was not true when analysing external doses.

This study was conducted with support from the European Commission (EC)'s Euratom Nuclear Fission and Radiation Protection Programme and the Russian Federation's Federal Medico-Biological Agency, through contract №FP6-516478 "Southern Urals Radiation Risk Research" (SOUL).

Abstract

Incidence of and mortality from stroke have been studied in a cohort of 12210 workers first employed at one of the main plants of the Mayak nuclear facility during 1948–1958 and followed up to 31 December 2000. Information on external gamma doses was available for virtually all of these workers (99.9%); the mean (± standard deviation, SD) total external gamma dose was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and 0.65±0.75 Gy (99% percentile 2.99 Gy) for women. In contrast, plutonium body burden was measured only for 30% of workers; amongst those monitored, the mean (± SD) absorbed cumulative liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women. 665 disease cases and 404 deaths from stroke were identified in the study cohort. Having adjusted for non-radiation factors there were no statistically significant trends in either incidence or mortality from stroke with either total external gamma dose or total absorbed internal liver dose; and stroke incidence or mortality rates did not differ significantly between categories for external or internal dose.

Introduction

Cerebrovascular diseases are multifactorial diseases, and different endogenous (genetic predisposition, gender, age, hypertension etc.) and exogenous (smoking, emotional stress etc.) factors contribute to their development. Over the last two decades several studies have examined the possible effects of ionizing radiation exposure on circulatory diseases, including CVD. Most of the studies (McGeoghegan et al 2008; Kreuzer et al 2006; Muirhead et al 2009; Shimizu et al 2010; Vrijheid et al 2007) focused on CVD mortality, whereas several studies (Yamada et al 2004; De Bruin et al 2009; Ivanov et al 2006) focused on CVD incidence.

This study was aimed at estimating risks of both stroke incidence and mortality in the cohort of Mayak PA nuclear workers first employed at one of the main plants (reactors, radiochemical, or plutonium) during 1948-1958 in relation to external gamma and internal alpha exposures, taking non-radiation factors into account.

Material and methods

Mayak PA began operations in 1948 as the first and largest nuclear weapons facility in the former Soviet Union and included all the plants necessary for weapon-grade plutonium production, namely, reactors, radiochemical plant, plutonium production plant and auxiliary plants.

From the first days of Mayak PA operation, the special system of personnel medical observation included an obligatory pre-employment medical examination and routine medical examinations of all the workers based on a common standard program. After quitting their job at Mayak, if the former worker stayed in Ozyorsk, he/she was examined at the same specialized medical hospital based on the same standard program. This system of medical observation of Mayak PA personnel health allowed a unique archive of primary medical data to be accumulated and formed the basis for establishment of the unique “Clinic” medical-dosimetry database for the Mayak PA workers cohort (Azizova et al 2008).

The study cohort included 12210 Mayak PA workers, 3552 (29.1%) of whom were women, first employed at one of the main plants from the start of operations through the end of 1958 independently of gender, age, nationality, occupation, and other characteristics. The method of identifying this cohort has been described previously elsewhere (Koshurnikova et al 1988, 1998a, 1998b, 1999).

Vital status as of 31 December 2000 was known for 88.4% of cohort members; of these workers, 52.7% were known to have died and 47.3% were known to be alive as of that time. 53.7% of the 12210 members of the study cohort were known to have left Ozyorsk by 31 December 2000. For persons who continued to be residents of Ozyorsk, vital status was known for all but one person (99.98%). Cause of death was known for 93.5% of deceased cohort members. Morbidity data for the whole period of follow-up were collected for 11597 (95.0%) workers in the study cohort. Only for 5.0% of workers could information not be collected, owing to the loss of their medical documentation. It should be noted that the CVD incidence analysis was restricted to the period of residence in Ozyorsk.

Data on vital status and on dates and causes of death for those workers who migrated from Ozyorsk were provided by the SUBI Epidemiology Laboratory; data on date and causes of death for those Ozyorsk residents whose medical cards and/or case histories had been lost, were provided by the SUBI Occupational Health Laboratory.

Individual dosimetric control of external exposure was performed at Mayak PA from the beginning of operations there. Regular monitoring of internal exposure among those who might have been exposed to plutonium-239 began later, during the 1960s (Vasilenko et al 2007a; Khokhryakov et al 2000). The results of individual monitoring of external and internal exposure were recorded in individual dosimetric cards and journals. The data contained in these documents formed the basis for the establishment of the dosimetric database of Mayak PA workers (Vasilenko et al 2007a, 2007b; Bess et al 2007; Smetanin et al 2007a, 2007b; etc).

Dose estimates from the *Mayak-Doses 2005* dosimetric system were used in this study. Annual doses of external gamma exposure were available practically for all persons in the study cohort (99.9%). The mean (± SD) total gamma dose for the whole period of work at Mayak was 0.91±0.95 Gy (99% percentile 3.9 Gy) for men and

0.65±0.75 Gy (99% percentile 2.99 Gy) for women. The range of total gamma doses was very wide, with 32.6% having a total gamma dose greater than 1 Gy.

Plutonium body burden was measured only for 30.0% of workers. Among workers monitored for plutonium exposure, absorbed dose to liver from alpha radiation was used as a surrogate for the dose to muscle; this latter dose is likely to be similar to the dose to blood vessels and the chambers of the heart. Although doses to the liver and muscle would differ, they should be highly correlated with each other. Consequently, the liver dose can be used to look for any *dose–response* relationship between plutonium exposure and circulatory disease. Amongst those who were monitored, the mean (± SD) total liver dose was 0.40±1.15 Gy (99% percentile 5.88 Gy) for men and 0.81±4.60 Gy (99% percentile 15.95 Gy) for women.

Data on occupational histories and external gamma exposures for the study cohort were provided by the Mayak PA Radiation Safety Department; data on internal alpha exposure from incorporated plutonium-239 were provided by the SUBI Internal Dosimetry Department.

This study focuses on incidence of and mortality from stroke (ICD-9 codes: 430–432, 434, 436). In the literature, the term "stroke" is sometimes used as a synonym of a wider category of cerebrovascular diseases. In this study the term "stroke" relates to the following group of diseases: subarachnoidal hemorrhage (ICD-9 codes: 430), other and non-specified intracranial hemorrhage (ICD-9 codes: 432), intracerebral hemorrhage (ICD-9 codes: 431), cerebral infarction (ICD-9 codes: 434) and stroke not specified as either cerebral hemorrhage or cerebral infarction (ICD-9 codes: 436). ICD-9 code 435 corresponds to transient cerebral ischemic attack and is not stroke *per se*.

Follow-up started on the date of first employment at one of the main plants and continued until the earliest of: date of the first diagnosis of stroke (for the incidence analysis) or the date of death from whatever cause (for both the mortality analysis and the incidence analysis); 31 December 2000 for those known to be alive at that time; the recorded date of departure from Ozyorsk (for the incidence analysis); and the date of "last medical information" in the case of unknown vital status. Comparisons were performed within the Mayak PA workers cohort first employed during 1948–1958.

The analyses included the calculation of relative risks (RRs) for categories of one or more factors, having adjusted for other variables. The relative risks for these categorical analyses were calculated by maximum likelihood, using the AMFIT module of EPICURE (Preston et al 1993). 95% confidence intervals for the RRs and p-values from tests of statistical significance were obtained via likelihood-based methods, using AMFIT. Attention was initially directed to non-radiation factors, following which measures of radiation exposure were analysed with adjustment (through stratification) for non-radiation factors. Analyses of internal radiation exposures were restricted to workers known to have been monitored for possible plutonium exposure.

In addition to the categorical analyses, models for trends in disease rates with level of radiation exposures were also fitted to the data, using Poisson regression methods. These models again were fitted using the AMFIT module in EPICURE. In particular, the excess relative risk (ERR) (ie. the relative risk minus 1) was modeled by a linear trend with external or internal dose, with adjustment for non-radiation factors.

In these main analyses, adjustments were made – through stratification – for gender, attained age, calendar period, period of first employment at the main plants of Mayak PA, plant, smoking and alcohol consumption.

Sensitivity analyses were conducted to examine the impact of: a) modifying the set of non-radiation factors (extra adjustment for hypertension, body mass index, employment duration) for which adjustment was made in the analyses of radiation factors; b) restricting the mortality follow-up (like that of incidence) to Ozyorsk, because some migrants were lost to follow-up and because of lower autopsy rates among those who left the city; c) adjusting for internal dose in analyses of external dose and vice versa; d) using various lag periods for external and internal doses. Furthermore, examination was made of how radiation risks might vary by gender, or between plants at Mayak or by attained age.

To allow for the possibility that radiation might affect stroke risk by modifying levels of blood pressure (Preston et al 2003; Ivanov et al 2001) and body mass index (Telnov 1985), the level of these factors at the time of preliminarily medical examination (before employment at Mayak PA) was considered, in order to avoid systematic errors that might arise through adjusting for values of these factors at later times. In contrast, smoking and alcohol consumption were classified at the time of last information (for the mortality analysis) or at the time of last information prior to the first diagnosis of stroke (for the incidence analysis).

Results

By 31 December 2000, 665 disease cases of stroke were diagnosed during 249530 person-years of follow-up and 404 death cases from stroke were identified during 443350 person-years of follow-up.

Non-radiation factors

It is known that stroke is a multifactorial disease, therefore analyses of incidence and mortality risks in relation to non-radiation factors were performed first. Our analyses revealed statistically significant effects of well-known factors such as gender, age, hypertension, body mass index, which were taken into account in the analyses of radiation risks, either in the main analysis or in sensitivity analyses.

Radiation factors

<u>External gamma exposure</u>: Table 1 shows that neither for incidence nor for mortality from stroke was there a statistically significant trend in risk with total external gamma dose, nor did incidence or mortality rates differ to a statistically significant extent between categories for external dose. Sensitivity analyses (results not shown) revealed that this finding held irrespective of the lag period used, whether additional adjustment was made for other non-radiation factors and internal exposure, as well as whether analysis was restricted to workers at different plants, or according to gender or attained age.

<u>Internal alpha exposure</u>: Table 2 shows that neither for incidence nor for mortality from stroke was there a statistically significant trend in risk with total internal alpha dose to liver, nor did incidence or mortality rates differ to a statistically significant extent between categories for internal dose. Sensitivity analyses (results not shown) revealed

that this finding held irrespective of the lag period used, whether additional adjustment was made for other non-radiation factors and internal exposure as well as whether analysis was restricted to workers at different plants, or according to gender or attained age.

Table 1. RRs and ERR (95% CI) for stroke incidence and mortality in relation to total dose of external gamma exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.5 Gy)		ERR/Gy
	0.5-1.0 Gy	>1.0 Gy	
Incidence	1.278 (0.999, 1.636)	1.237 (0.977, 1.567)	0.054 (-0.063, 0.170)
Mortality	1.246 (0.911, 1.703)	1.106 (0.816, 1.498)	0.016 (-0.128, 0.160)

Table 2. RRs and ERR (95% CI) for stroke incidence and mortality in relation to total absorbed liver dose from internal alpha exposure (main analysis based on a zero year lag period).

	RRs (vs. <0.1 Gy)		ERR/Gy
	0.1-0.5 Gy	>0.5 Gy	
Incidence	1.001 (0.800, 1.252)	1.080 (0.751, 1.554)	0.017 (-0.097, 0.131)
Mortality	1.401 (1.020, 1.924)	1.047 (0.609, 1.800)	0.120 -0.116, 0.356)

Discussion

Our analyses of stroke incidence and mortality revealed statistically significant effects of well-known factors such as gender, age, hypertension, body mass index, which are consistent with findings of other studies. In contrast, our analyses did not reveal any statistically significant effect of smoking and alcohol consumption on stroke incidence or mortality, either for males and females.

For both incidence and mortality from stroke, there was no evidence for associations with either external or internal radiation in this study.

A complication to interpretation is the lack of knowledge as to those tissues or organs for which radiation exposure might increase the risk of stroke, which is particularly problematic in the case of plutonium intakes. For this analysis, liver dose has been used as a surrogate for the dose to muscle, which is likely to be similar to the dose to blood vessels and the chambers of the heart. Furthermore, the liver and muscle doses should be highly correlated with each other. However, there is uncertainty about which tissue or organ dose is appropriate for this type of analysis. A further complication relates to uncertainties in estimates for internal doses for Mayak workers. It should be noted that – because the dose to the liver from intakes of plutonium would be greater than that to the circulatory system – the ERR/Gy estimated here based on liver dose would be lower than that based on dose to blood vessels and the chambers of the heart. For these reasons, the findings in relation to internal exposure need to be interpreted with caution.

In addition, information is not currently available from other studies of populations exposed to external low-LET radiation or plutonium that would allow comparison of risk estimates for stroke (defined by the ICD-9 codes 430-432, 434, 436) in relation to such exposures.

Conclusions

Having adjusted for non-radiation factors there was no statistically significant trends in both stroke incidence and mortality risk with either total external gamma dose or total absorbed internal liver dose; and stroke incidence or mortality rates did not differ between categories for external or internal dose.

This study was conducted with support from the European Commission (EC)'s Euratom Nuclear Fission and Radiation Protection Programme and the Russian Federation's Federal Medico-Biological Agency, through contract №FP6-516478 "Southern Urals Radiation Risk Research" (SOUL).

Uranium health effects: results from the French cohort of uranium processing workers

Guseva Canu, Irina[1]; Samson, Eric[1]; Caër-Lorho, Sylvaine[1];
Auriol, Bernard[2]; Tirmarche, Margot[1]; Laurier, Dominique[1]
[1] IRSN, FRANCE
[2] AREVA NC, FRANCE

Abstract

A cohort of 2709 male workers (72786 person-years) employed at the AREVA uranium processing plant (1960–2005) in France was constructed to investigate the risk of cancer and non-cancer mortality in relation to occupational exposure to uranium. Cause-specific mortality in the cohort was compared to the national and regional mortality rates (1968–2005) by computing standardized mortality ratios. Exposure to natural and reprocessed uranium compounds, classified by their solubility, was assessed trough the plant-specific job-exposure matrix. Internal comparison between exposed and unexposed subjects was then done to estimate relative risk of mortality in regards of each type of exposure. Cox regression models adjusted for age, calendar period and socioeconomic status were used for analyses. At the end of the follow-up, 15% of the cohort was deceased. From 193 cancer deaths, 48 lung cancers and 18 lympho-hematopoietic cancers, considered as uranium target organs, were observed, as well as 101 deaths from cardiovascular diseases. For none of these causes, mortality among the cohort was significantly increased comparatively to the reference mortality rates. Internal comparison showed an elevated risk of mortality from considered causes among workers exposed to reprocessed uranium-bearing compounds. Mortality risk tended to increase with decreasing solubility of uranium compounds. This cohort study provides original results on cancer and non-cancer mortality related to protracted low-dose uranium exposure. Results suggest that effects on mortality differ by type and solubility of uranium compounds. Availability of data on associated exposure to carcinogenic chemical is another interest of this cohort. The cohort is still young but its further follow-up with extension to other AREVA plants will increase statistical power of the future analyses. Further investigation will focus on cardiovascular risk in dose-response analyses including biological parameters into the models.

Leukaemia risk among European uranium miners in dependence on doses from radon, external gamma, and long lived radionuclides

[5] University of Salzburg, AUSTRIA

Abstract

The study presents recent findings based on leukaemia mortality (69 cases) in three European cohort studies of uranium miners, including 9979 Czech, 3271 French, and 34 994 German miners. The risk is analyzed in relation to cumulated equivalent dose from radon and its progeny, from external gamma radiation, and from inhaled long lived alpha radionuclides. Exposures were estimated from measurements of radon, external gamma, and gross alpha activity in the aerosol. The earlier exposure estimates were based on uranium content in the ore and aerosol measurements in mines. The annual absorbed doses to the red bone marrow from exposure to radon gas, its progeny, long-lived radionuclides, and from exposure to external gamma radiation have been calculated for each miner from the first year of employment to the end of follow-up using the ICRP dosimetric and biokinetic models. The mean cumulated absorbed doses in the entire study are 38 mGy from external gamma, 2.1 mGy from radon and its progeny, and 0.9 mGy from long lived radionuclides. In terms of equivalent dose (using a radiation weighting factor 20 for alpha radiations), about 42% is from radon and its progeny, 39% is due to gamma radiation, and 19% is due to inhalation of uranium and its decay products. The risk coefficients (excess relative risk per sievert) were estimated using Poisson regression analysis. For each separate component, the risk coefficient was significant with p-values: 0.010 (gamma), 0.008 (radon), and 0.020 (long lived radionuclides). The estimated risk coefficient for the combined dose was 3.7 (90%CI: 1.1–8.8). Although the estimated risk is subject to some uncertainty due to small numbers and the dose uncertainty, its magnitude is consistent with estimates from other studies.

The work was supported by the European Commission under FP6 (Contract FI6R 516483) and by the State Office for Nuclear Safety of the Czech Republic (VZ 60022490) and the Czech Ministry of Health (NS 10596-3/2009).

Ionizing radiation and mortality from stomach cancer – Results of the German uranium miners cohort study, 1946–2003

Abstract

Introduction: In the German uranium miners cohort study a 1.15fold statistically significantly increased risk of mortality from stomach cancer compared to the general male population was observed. The aim of the present analyses is to investigate the influence of ionizing radiation.

Methods: The cohort includes 58,987 men who had been employed for at least six months between 1946 and 1990 at the former Wismut uranium mining company in East Germany. By 2003 a total of 20,920 deaths occurred, among them 595 deaths from stomach cancer. Information on exposure to radon progeny in Working Level Months (WLM), external gamma radiation (mSv) and long-lived radionuclides (kBqh/m^3) is based on a detailed job-exposure matrix. Internal Poisson regression models were used to estimate the excess relative risk (ERR) per unit of cumulative exposure and its 95% confidence limits (CI).

Results: There was a statistically significant increase of death from stomach cancer in relation to either cumulative exposure to radon (ERR/100 WLM = 0.022; 95% CI: 0.001–0.043), external gamma radiation (ERR/Sv=1.83; 95% CI: 0.41–3.25) or long-lived radionuclides (ERR/kBqh/m^3=0.018; 95% CI: 0.0044–0.032), respectively. A statistically significantly increased relative risk was observed at exposure categories above 1,500 WLM (RR=1.74; 95% CI: 1.06–1.43) and above 300 mSv external gamma radiation (RR=2.22: 95% CI: 1.07–3.37).

Conclusion: The present preliminary analyses suggest that occupational exposure to ionizing radiation may increase the risk for stomach cancer among uranium miners. In a next step stomach doses based on dosimetric models will be calculated and the corresponding risk estimates presented. Moreover, potential confounder like exposure to arsenic, fine or quartz fine dust will be considered.

Case-control study of lung cancer incidence under combine occupational and domestic radon exposure

Abstract
Case-control study of lung cancer incidence for the population of Lermontov city (Caucasus, Russia) was performed. Near the territory of Lermontov city the uranium mining was conducted from 1947 to 1990. The considerable part of male population of the city worked in uranium mining. In the Lermontov city three main districts with different kinds of houses exist: multi-storey buildings constructed after 1970; one – three storey buildings constructed before 1970; one-storey rural type houses. The average indoor radon concentrations in these districts are 170, 540 and 910 Bq/m^3 respectively. The lung cancer rate considerably above the average regional level was observed for the population of Lermontov city. The indoor radon concentrations and occupation radon exposure levels in the group of 121 lung cancer cases and in control group composed of 196 peoples were analyzed. Both archive and contemporary indoor radon measurements in combination with the retrospective detectors were used for reconstruction of domestic exposure. The temperature normalization approach was used for assessment of average annual radon concentration in dwellings from the results of radon measurements by charcoal absorbers. The average radon exposure reconstruction period was 38 years for case group and 34 years for control group. The occupation expose information was obtained from medical-sanitary department of former uranium mining facility. It was shown that in average 32% of total radon exposure for uranium miners was due to domestic indoor exposure. It means that in epidemiological studies of uranium miners the domestic radon exposure also should be taken into account. The excess relative risk of lung cancer incidence in case of combine occupational and domestic radon exposure was ERR=0.011 (– 0.003 ÷ 0.029) WLM^{-1}. After the excluding of uranium miners from analysis (46 men from case group and 9 from control group) the excess relative risk value was estimated as ERR=0.0040 (– 0.003 ÷ 0.034) WLM^{-1}.

Introduction

To estimate the influence of radon exposure on lung cancer incidence the case-control studies on uranium miner cohorts were conducted in various countries (Lubin et.al. 1994, Tomasek 2002, Grosche et.al. 2006). The results of these studies were used for estimation radon exposure hazards both for occupational and indoor exposure (BEIR VI 1999). Unfortunately in the analysis of dose-effect response in uranium miners studies the contribution of domestic indoor exposure was not taken into account. As a result the considerable uncertainties in radiation risk assessment can take place because of the indoor radon exposure in uranium rich regions can be comparable with the occupational exposure.

To estimate the radiation risk under the combine occupation and domestic indoor radon exposure the case-control study for the population of Lermontov city (Caucasus, Russia) was performed. Near the territory of Lermontov city the uranium mining was conducted from 1947 to 1991. The considerable part of male population of the city worked on uranium mining facility.

Material and methods

The main cohort in the study was formed from the peoples diagnosed as lung cancer patients from 1995 to 2004. The diagnoses were verified by instrumental and morphological methods. Practically all diagnosed lung cancer patients were included in the case group. The control group was formed from the Lermontov city inhabitants by random approach. The control group corresponded to the gender, age and professional distribution of the adult population of the Lermontov city. The size of case group was 121 and control group – 196 peoples.

The radon exposure estimation was made by the combination of the archive results of the measurements conducted by Regional Department of Federal Medical Biological Agency from 1992 and the measurements conducted by the nuclear track detectors during the our studies. The measurements made by the Regional Department in general were performed by charcoal absorbers sometimes in the combination with the nuclear track detectors. The average charcoal absorber exposure duration has been 4.7 days. More than 3200 archive results of radon measurements were used during the analysis. In the Lermontov city three main districts with different kinds of houses exist: multi-storey buildings constructed after 1970; one – three storey buildings constructed before 1970; one-storey rural type houses. The average indoor radon concentrations in these districts are 170, 540 and 910 Bq/m^3 respectively.

To estimate the average annual radon concentrations in the dwellings of the case and control groups the archive measurement data were analyzed using the temperature normalization approach. The archive meteorological data on the outdoor temperature on the period 1992 – 2004 were used for analysis. For the different kinds of dwellings in which the multiply measurements were carried out the typical dependence of radon concentration relative change on outdoor temperature was obtained. The example of such dependence for one-storey rural type houses is presented on Fig. 1.

For some flats the direct measurements of radon concentrations were not conducted. In this case the results of the measurements performed in the neighbouring flat in the same house were used. In some cases the coefficient connecting the radon concentration between the ground and upper floors was applied (Fig. 2).

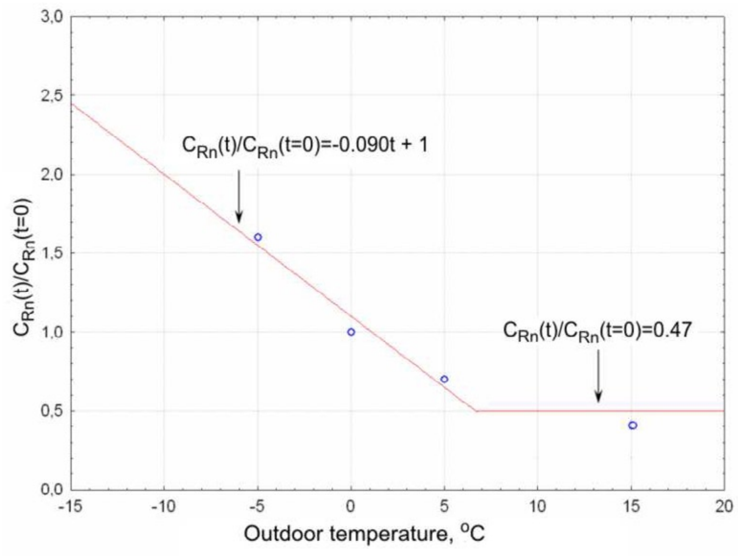

Fig. 1. The dependence of radon concentration on outdoor temperature for one-storey rural type houses in Lermontov city.

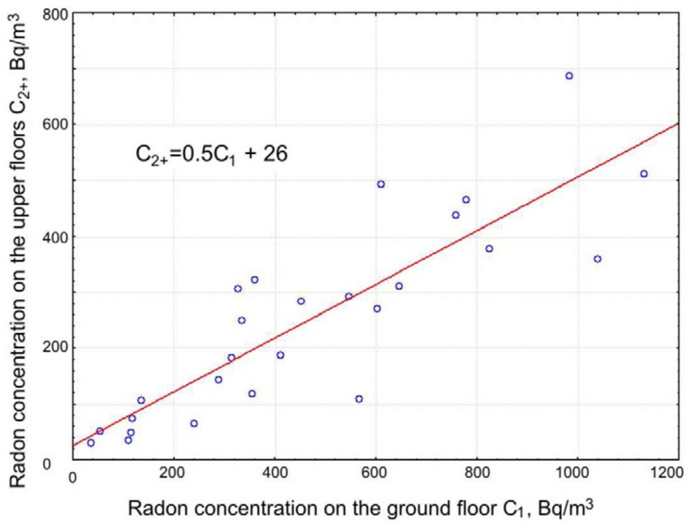

Fig. 2. The dependence of radon concentration between the ground and upper floors for multi-storey houses in Lermontov city.

The correctness of temperature normalization approach for the radon exposure assessment was verified by the use of retrospective surface trap radon detectors. The multilayer LR-115 track detectors designed in our laboratory (Bastrikov, Zhukovsky 2004, Bastrikov et.al. 2006) were placed in the dwellings on the mirrors or furniture glasses. Such comparative measurements have been conducted in 27 dwellings. The age of the objects used for retrospective measurements of radon concentrations was in the range from 13 to 68 years (31 year in average). The good correlation has been found between the values of the average radon concentrations measured by retrospective surface trap detectors and calculated by the temperature normalization approach with the use of archive results of charcoal absorber radon measurements (Fig. 3).

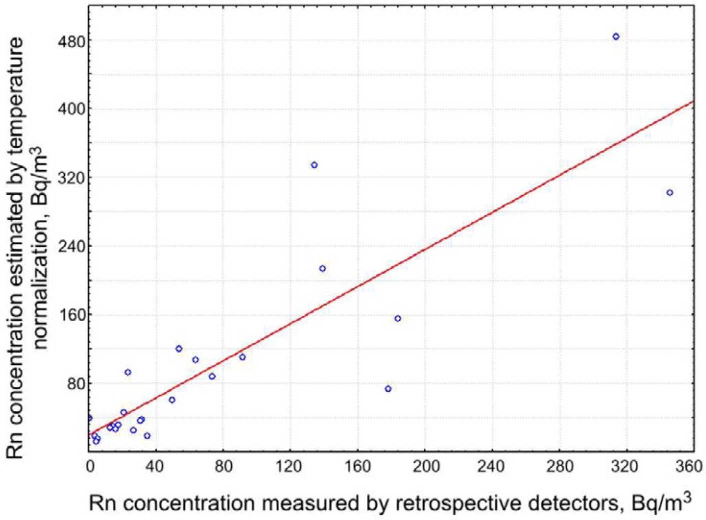

Fig. 3. Correlation between the values of the average radon concentrations measured by retrospective surface trap detectors and calculated by the temperature normalization approach.

Results

The radon concentration distribution parameters for the case and control groups in Lermontov city are presented in the Table 1. For each member of investigated groups the levels of domestic radon exposure have been calculated taking into account the radon levels in the dwellings, duration of the living in the last and in the previous dwellings and the average value of equilibrium factor F=0.44 estimated for the Lermontov city by the direct measurements of equilibrium shift between radon decay products. The average radon exposure reconstruction period was 38 years for case group and 34 years for control group. The last five years before the lung cancer diagnosing or including into control group were not considered during cumulative radon exposure calculations. The parameters of domestic radon exposure distributions are presented in the Table 2.

Table 1. Radon concentration distribution parameters for case and control groups in Lermontov city.

Group	Arithmetic mean, Bq/m^3	Geometric mean, Bq/m^3	σ_{LN}
Case	277	64	1.12
Control	243	73	0.89
All groups	257	70	0.99

Table 2. Parameters of domestic cumulative radon exposure distributions.

Group	Geometric mean, WLM	Minimum, WLM	Maximum, WLM	σ_{LN}
Case	23	0.7	499	1.19
Control	21	0.3	281	1.19
All groups	22	0.3	499	1.19

On the next step of our work the levels of occupational radon exposure were reconstructed. In one of uranium mine near Lermontov city the average radon concentrations decreased from 278 in 1947 to 3.0 kBq/m^3 in 1975. In other uranium mine radon levels decreased from 7.0 to 1.5 kBq/m^3 in period from 1960 to 1991. After 1991 the uranium mining in Lermontov city has been ceased. The levels of individual occupational exposure were reconstructed on the base of monitoring data and information about duration of work in the mines or on the territory of facility logged in workbooks. The occupational exposure was calculated for 60 members of case group and 31 members of control group. Among the professionally exposed peoples 48 miners worked directly in underground mines. The parameters of occupational radon cumulative exposure distributions are presented in the Table 3. The parameters of total radon exposure distribution are given in the Table 4. It was found that for uranium miners in average 32% of total radon exposure was due to domestic indoor exposure. It means that in epidemiological studies for uranium miners the domestic indoor exposure should be taken into account as well as occupation radon exposure.

Table 3. Parameters of occupational cumulative radon exposure distributions.

Group	Geometric mean, WLM	Minimum, WLM	Maximum, WLM	σ_{LN}
Case	42	3	603	1.56
Control	26	3	1352	1.78
All groups	35	3	1352	1.65

Table 4. Parameters of total cumulative radon exposure distributions.

Group	Geometric mean, WLM	Minimum, WLM	Maximum, WLM	σ_{LN}
Case	41	0.7	628	1.34
Control	24	0.3	1388	1.34
All groups	30	0.3	1388	1.36

For radiation risk assessment the odds ratios of lung cancer incidence for combined occupational and domestic radon exposure were calculated. The results are presented in the Table 5.

Table 5. Odds ratio of lung cancer incidence for combined occupational and domestic radon exposure.

Range of Rn exposure, WLM	Peoples in case group	Peoples in control group	Odds ratio	90% confidence interval
0 – 5	8	23	1.00	-
5 – 40	47	102	1.32	0.64 – 2.76
40-140	43	56	2.21	1.04 – 4.68
> 140	23	15	4.41	1.85 – 10.5

The dose-effect dependence can be described by the equation:

$$OR(P_{tot}) = 0.011(P_{tot} - P_0) + 1 , \qquad (1)$$

where P_{tot} – cumulative total (occupational and domestic) radon progeny exposure, WLM; P_0=2 WLM – radon progeny exposure for which the OR=1 assumed. The 90 % confidential interval of the slope factor is in the range from – 0.003 to 0.029 WLM^{-1}.

Odds ratios were also calculated only for situation of domestic indoor exposure. The uranium miners were excluding from analysis (46 men from case group and 9 from control group). The odds ratios for reduced groups exposed only indoors presented in the Table 6.

Table 5. Odds ratio of lung cancer incidence for domestic radon exposure.

Range of Rn exposure, WLM	Peoples in case group	Peoples in control group	Odds ratio	90% confidence interval
0 – 3	4	13	1.00	-
3 – 30	39	100	1.27	0.47 – 3.40
30 – 140	29	68	1.39	0.51 – 3.79
> 140	3	6	1.63	0.37 – 7.22

The dose-effect dependence for domestic radon progeny exposure can be described by the equation:

$$OR(P_{ind}) = 0.004(P_{ind} - P_0) + 1 , \qquad (2)$$

where P_{ind} – cumulative domestic radon progeny exposure, WLM; P_0=5 WLM – radon progeny exposure for which the OR=1 assumed. The 90 % confidential interval of the slope factor is in the range from – 0.003 to 0.034 WLM^{-1}.

Discussion

The most detailed studies of radon-induced lung cancer for uranium miners were presented in the works (BEIR VI 1999, Grosche et.al. 2006). The excess relative risk of lung cancer estimated in these works was 0.0076 (0.0041 – 0.014) WLM^{-1} (BEIR VI 1999) and 0.0021 (0.0018 – 0.0024) WLM^{-1} (Grosche et.al. 2006) respectively. The values of the slope factors obtained in our paper 0.011 (– 0.003 ÷ 0.029) WLM^{-1} for combine exposure and 0.004 (– 0.003 ÷ 0.034) WLM^{-1} for domestic exposure in general are in good agreement with the published data. The differences in the risk assessment for combine occupational and domestic exposure and for indoor exposure in dwellings can be explained by different kinds of uncertainties in occupational and indoor exposure assessments and not very high statistical power of this epidemiological study.

Conclusions

The case-control study is conducted in the Lermontov city (Caucasus, Russia) to establish the connection between lung cancer incidence and combine occupational and domestic radon exposure. The temperature normalization approach has been developed to estimate the cumulative indoor radon exposure on the base of archive radon measurements by charcoal absorbers and track detectors. The good correlation has been found between the values of the average radon concentrations measured by retrospective surface trap detectors and calculated by the temperature normalization approach. The levels of individual occupational exposure were reconstructed on the base of monitoring data and information about duration of work in the mines or on the territory of facility. It was found that for uranium miners in average 32% of total radon exposure is due to domestic indoor exposure. The excess relative risk of lung cancer incidence in case of combine occupational and domestic radon exposure is 0.011 (– 0.003 ÷ 0.029) WLM^{-1}. After the excluding of uranium miners from analysis (46 men from case group and 9 from control group) the excess relative risk value was estimated as 0.0040 (– 0.003 ÷ 0.034) WLM^{-1}. The obtained results are in good agreement with BEIR VI data.

Abstract

The influence of the polluted environment on health of the population has been studied for a decades in industrial countries. It is established that polluted environment can cause great variety of diseases in all categories of inhabitants. Most vulnerable groups are children and pregnant women because of possible genetic or teratogenic defects in the newborns. To prevent this situation, control of the environment is established. Besides the usual industrial pollutions, during the NATO air strikes on Serbia in 1999, many industrial facilities were destroyed and harmful, toxic substances were released in concentrations even ten thousand times higher than maximum permissible. Additionally, depleted uranium ammunitions were deployed in south of Serbia. In the years after, health surveillance of the soldiers who served in DU contaminated regions in Kosovo were organized and increased cancer incidence is noticed as well as non-specific diseases (cardiovascular, rheumatic) and psychological disturbances, including PTSP, alcohol abuse and social problems. According to EUROCAT protocol their children born after the strikes were followed-up too, and higher rate of congenital (skeletal, cardio-vascular) and chromosomal anomalies, immunological disorders and endocrine diseases were noticed. Similar results were found in the inhabitants of the most polluted regions.

Mortality due to gastrointestinal cancers in northern part of East-Ural Radioactive Trace

Yarmoshenko, Ilia; Seleznev, Andrian; Konshina Lidia
Institute of Industrial Ecology, RUSSIA

Abstract
The objective of the study was to evaluate the register of causes of death, created using deaths certificates issued by rural municipalities at northern part of EURT, as a source of information for analysis of mortality caused by radiation induced gastrointestinal cancers. In the register the case (6158) and control (4844) groups were formed according to assessments of initial contamination of municipalities by Sr-90 – above and bellow 0.1 Ci per square kilometer respectively. Average colon dose 0.07 Gy and 440 gastrointestinal cancer deaths was observed in case group. The analysis included comparison of gastrointestinal cancers contribution to total number of deaths in the groups and estimation of excess number of deaths for sex, age and time since accident categories. To assess years of life lost (YLL) due to excess cancer cases the life durations were compared. By results of estimation total number of excess cancer deaths is 57±39 (with 90% CI) and total YLL is 893±279 for period from 1967 to 2000.

Introduction
Accidental explosion of waste storage tank at former Soviet Union plutonium production plant “Mayak” in 1957 had released considerable radioactivity to atmosphere and caused contamination of the environment (East-Ural Radioactive Trace, EURT). Available data on the radioactive contamination allowed the assessment of post-accident population radiation exposure. For analysis of radiation induced health effects the rural population of Kamensky rajon (Sverdlovsk oblast, Russia) was evaluated. That administrative district is situated in northern part of EURT, as far as 80-130 km from “Mayak” plant. The radioactive trace crossed territory of Kamensky rajon and caused contamination by ^{90}Sr up to 190 kBq/m^2.

Rural population of the district (more than 30 000 peoples in 1957) was chosen for analysis because its homogeneity in relation to social and environmental factors other than accidental radiation exposure. Radiation exposure of rural population directly associates with the levels of initial contamination of residential area and agricultural lands. Due to consumption of contaminated food and milk gastrointestinal tract received higher doses. This presentation describes the results of analysis of case of deaths related to cancers of gastrointestinal organs (esophagus, stomach, liver and colon) in rural population of northern part of EURT.

Material and methods

The primary source of information on causes of deaths of EURT population from Kamensky rajon was the archive of Sverdlovsk oblast civilian registry office. The death certificates issued by rural municipalities, which stored in the archive, contain the information as follow: unique identification of death certificate, sex, date of death, date of birth, place of birth, last place of residence, duration of life at last place of residence and the cause of death. Totally data on 15,685 cases of death for period 1954-2000 were obtained from the archuve. Obtained data were used to create Register of causes of deaths of rural population of Kamensky rajon (Register).

Cumulated doses absorbed due to radioactive contamination were estimated according to Guidelines "Reconstruction of doses accumulated by residents of the Techa river basin and the area affected by the accident at the "Mayak" plant in 1957" approved by Ministry of Health of Russia in 1995 (Guideline 2.6.1.024-95). The main factors contributed to radiation doses are consumption of contaminated crops, vegetables and milk, external exposure from contaminated soil and inhalation as well as external exposure during transfer of radioactive cloud. The Guideline suggests intake rates of radionuclides due to inhalation and ingestion and external exposure rates standardized per unit contamination by ^{90}Sr.

Case and control groups of the study were formed by dividing the Register due to level of initial contamination. Control group was formed from the residents of settlements with initial contamination level equal or bellow 0.1 Ci/km^2 and case group – from residents of settlements with initial contamination higher than 0.1 Ci/km^2. Thus control and case groups include residents of the same administrative territory.

Relative contribution of gastrointestinal cancers to the total mortality in the control group was estimated as ratio of number of deaths from gastrointestinal cancers (n) to total number of deaths (N). Estimated relative contribution was then applied to total number of deaths in case group (M) to assess expected number of deaths from gastrointestinal cancers in case group (E):

$$E = M\frac{n}{N}. \qquad (1)$$

Comparing the expected and observed numbers of deaths the excess number of deaths O-E and observed to expected ratio O/E were estimated. The variances of O and E were assessed accepting Poison distribution for n and O.

For each case of death at age A the years of expected life lost ($L(A)$), was accepted using data of demographic statistics for region. Then observed and expected total years of life lost (TYLL) for cases of gastrointestinal cancer deaths in case group were estimated using equations:

$$ObsTYLL = \sum_{\substack{Case\\Group}} L(A) \qquad (2)$$

$$ExpTYLL = \frac{M}{N}\sum_{\substack{Control\\Group}} L(A) \qquad (3)$$

Estimated expected and observed values were applied to assess excess TYLL of life lost $\boldsymbol{ObsTYLL - ExpTYLL}$ and relative value $\dfrac{\boldsymbol{ObsTYLL}}{\boldsymbol{ExpTYLL}}$.

To estimate the variance of TYLL the variance of expected life lost was accepted as follows:

$$\mathrm{Var}\left(\sum_{i=1}^{K} L_i\right) = \mathrm{Var}(L_0) + \ldots + \mathrm{Var}(L_i) + \ldots + \mathrm{Var}(L_K) \approx K \cdot \mathrm{Var}(L), \qquad (4)$$

To adjust assessments for sex and age at exposure factors the estimations were performed in subgroups formed according to categories of the factors (for age in 1957 five years categories were considered). Then the estimations were summarized to draw the final results.

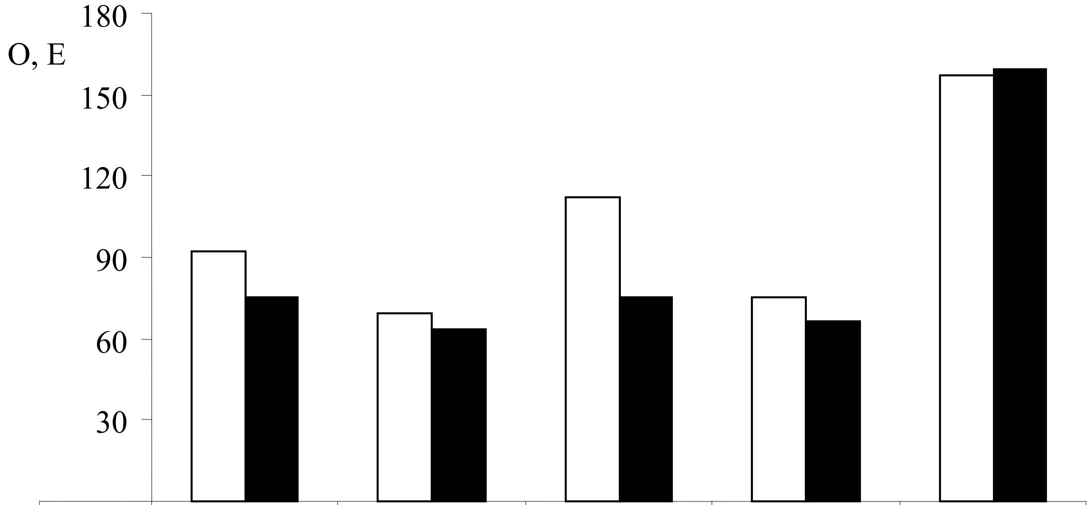
Results

General characteristics of case and control groups are presented in Table 1. Dependence of total observed and expected cases of gastrointestinal cancers in case group on calendar year is presented on Fig. 1. For periods before 1967 the difference between expected and observed values is insignificant. Significant difference ($p<0.05$) is obtained for period 1967-1977, for periods after 1977 the difference demonstrates a tendency of decreasing ($p>0.05$). Values of excess cancer deaths in case group are also presented on Fig. 1. After summarizing for period 1967-2000 estimated number of excess gastrointestinal cancer cases is equal to 57±39 (with 90% confidence interval). Estimated related excess TYLL in case group is 870±280 years, which is equivalent to about 15 years of life lost per excess case of cancer. For cancers other than gastrointestinal estimated number of excess cases (6±49) and excess TYLL (-222±410) in case group are insignificant.

Values of O-E and ObsTYLL-ExpTYLL in case group for period 1967-2000 in dependence on age in 1957 were tested (Table 2). For age at exposure interval 35-65 total value O-E = 54±39 (with 90% confidence interval). For age younger 35 in 1957 insignificant value of O-E is obtained. Significant values of excess TYLL in case group are observed for each ten years category in interval 35-65, where total value is 797±129 (with 90% confidence interval). For younger and elder ages at exposure the values of excess TYLL are insignificant.

Table 1. General characteristics of case and control groups

Characteristic	Case group	Control group
Number of entries	6 158	4 844
Male/female ratio	0.486/0.514	0.482/0.518
Total years of life after 1957	120 877	107 238
Mean colon dose, mGy	70	4.5
Number of gastrointestinal cancer deaths	440	278



Year	1954-1961	1962-1966	1967-1976	1977-1986	1987-2000
O-E	17±26	5.6±22	37±25	8.7±21	-2.3±32

Fig. 1. Observed (white boxes) and expected (black boxes) number and excess cases (O-E) of gastrointestinal cancer deaths in case group.

Table 2. Estimated number of excess of gastrointestinal cancer deaths and related excess TYLL in case group.

Age in 1957	O-E	ObsTYLL-ExpTYLL
<35	3.5±16	13±167
35-45	15±17	292±170
45-55	20±19	270±98
55-65	18±21	235±78
65-75	5.5±13	12±39
>70	-5.1±5	-

To compare risk of gastrointestinal cancers in case and control groups by age at exposure categories the relative risk parameters O/E and ObsTYLL/ExpTYLL were estimated. Two approaches yielded matching results though uncertainty of estimation by excess TYLL is in general lower than by excess cancer cases estimation. The parameter ObsTYLL/ExpTYLL demonstrates a tendency to decreasing with age at exposure from 1.5 (1.2-2.1 with 90% confidence interval) at age 35-45 to 1.0 (0.97-1.1 with 90% confidence interval) at age 65-75 in 1957.

Discussion

The crucial issue of the analysis is association of obtained excess cases of gastrointestinal cancer deaths and excess TYLL with accidental radiation exposure. In general the correlation of excess values with radiation exposure can be considered as reasonable evidence. However, the created Register is not sufficient to search such correlation. Nevertheless, we believe that the reasons such as follow support conclusion on relationship between estimated excess gastrointestinal cancer mortality in the case group of Register and the exposure. The case and control groups of studied rural population live within the same administrative and geographical territory and are homogeneous considering the social and demographic factors. It can be quite certainly supposed that the groups differ only by the factor of accidental radiation exposure. Considerable decreasing of gastrointestinal cancer mortality appeared within the period 10-20 years after accidental exposure, which can be related to the period of latency of the gastrointestinal cancers. There are no excess cases in the elderly population. Absence of excess cases deaths due to cancers other than gastrointestinal is in agreement with estimated nonuniform radiation exposure of organs and tissues.

Conclusions

Analysis of the register of causes of death of population live within northern part of EURT revealed increase of mortality due to gastrointestinal cancers, which can be associated with radiation exposure after accident at Mayak nuclear plant in 1957.

Abstract

Childhood leukaemia near nuclear installations has been investigated widely in the past decades, but the results have been inconclusive. Radiation exposure for the population appears negligible.

We investigated leukaemia incidence in children living near the two Finnish nuclear power plants (NPPs) using both cohort and case-control analysis.

The residential cohorts defined by censuses in 1980 and 1990 showed no increased risk of childhood leukaemia in the population residing within a 15-km zone from the NPPs compared to the 15–50-km zone.

In the case-control analysis with individual residential histories for 16 children with leukaemia and their 64 matched controls, residential distance from the NPP was not associated with leukaemia.

The results of the cohort and case-control analyses were consistent and neither of them indicated an increased risk of leukaemia. Even though the small sample size and lack of population residing within the 5-km radius limit the strength of the conclusions, the findings are reassuring from the public health perspective.

Introduction

Since 1983, childhood leukaemia near nuclear installations has been investigated widely but the results have been inconclusive so far (Laurier et al. 2008). The positive findings have been mainly limited to reprocessing sites while studies covering more than 100 nuclear power plants (NPPs) have shown little indication of increased risks. An exception was the recent German study reporting an increased risk of leukaemia among young children (aged <5 years) but not older ones living within a 5-km range around NPPs (Kaatsch et al. 2008). This finding raised public health concern and the need for information in Finland where a new NPP is being built but no published study has been available on childhood leukaemia and nuclear power.

We investigated leukaemia incidence near Finnish NPPs in children (aged <15 years) using cohort and case-control analyses which included information on residential history (Heinävaara et al. 2010).

Material and methods

Finland has four nuclear power reactors located in two nuclear sites, both having two reactors. Loviisa has been in commercial production since May 1977 and Olkiluoto since October 1979. Both sites are located at the seashore (Fig 1, large graph). The fifth nuclear power reactor is currently under construction in Olkiluoto.

Municipalities with any area within 15 km from the NPP were defined as being situated near to an NPP. According to this definition seven municipalities situate near to NPPs (Fig 1, small graphs).

In the cohort analysis, cohorts of people living near NPPs were formed based on census data at the end of 1980 and 1990. The coordinates of residence were obtained for these cohorts at the end of 1980 and 1990 from the Population Register Centre. Leukaemia cases diagnosed during the follow-up of the cohorts until the end of 2000 were obtained from the Finnish Cancer Registry. Leukaemia cases and data population counts were aggregated into 2 km * 2 km squares based on the coordinates of residence in the beginning of the follow-up. Leukaemia incidence in cohorts living within a 15-km zone around the NPPs was compared to that in reference cohorts living in the 15–50-km zone (Fig 1, small graphs). We calculated the indirectly standardized risk ratios (RRs) adjusting for age and socioeconomic status.

In the case-control analysis, the association between the residential distance from the nearest NPP and leukaemia was studied. Cases diagnosed with leukaemia between January 1, 1977 and December 31, 2004 and living in the municipalities near an NPP were identified from the Finnish Cancer Registry. Four controls were randomly chosen from the Population Registry Centre and matched to cases with respect to sex, age, and the municipality of residence at index date (i.e., date of diagnosis of the corresponding date). Residential histories of all cases and controls were obtained from the Population Register Centre. Case-control analysis included 16 children, 11 boys and 5 girls, with their 64 matched controls. All cases had acute lymphocytic leukaemia.

In the case-control analysis, residential history was taken into account from the date of production of the nearest NPP until the index date. The distances from the nearest NPP to each residence and the corresponding durations were calculated for each subject. Average distance was calculated as the sum of distances weighted by their relative durations. Categorized average distance was used as a primary measure for residential distance. Categorized distance at diagnosis and minimum distance were used as secondary measures for residential distance. Minimum distance was the shortest distance from any of the subjects' residence to the NPPs. The association between leukaemia and the residential distance measures was assessed with odds ratios (ORs).

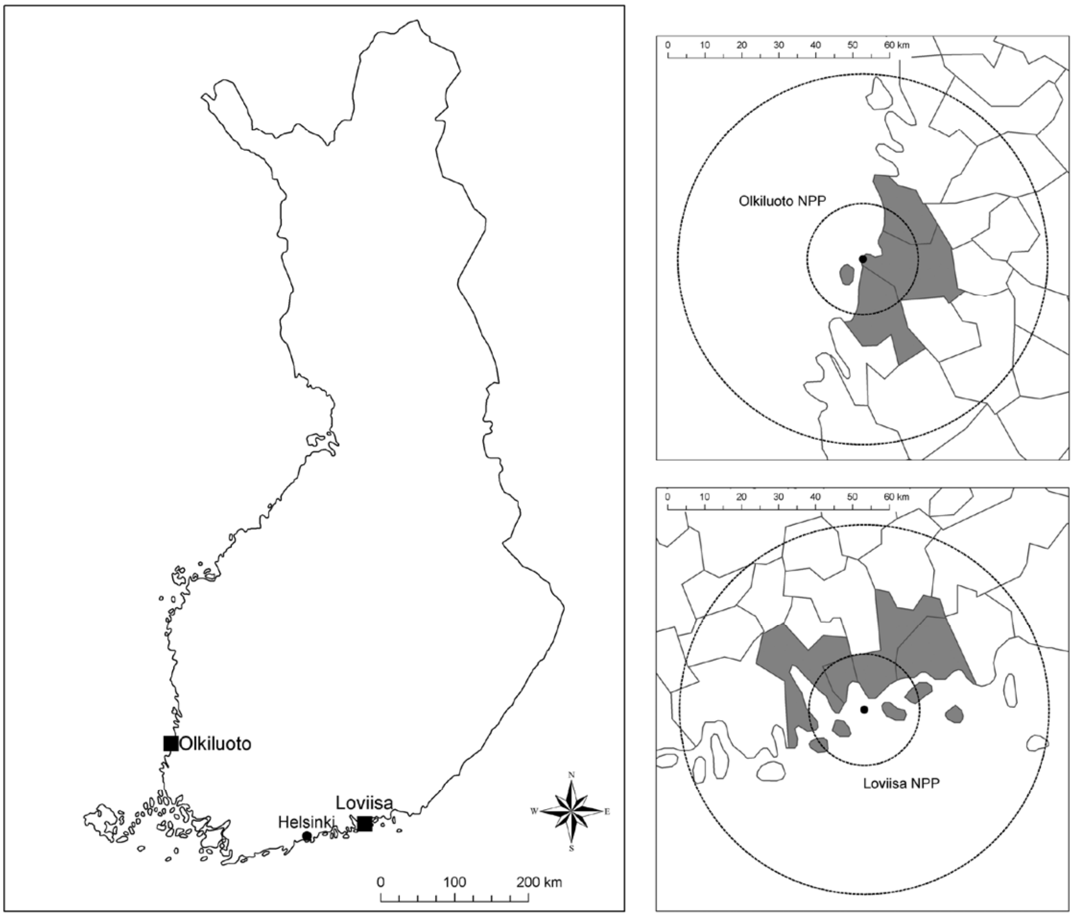

Fig. 1. Nuclear power sites Loviisa and Olkiluoto are located at seashore in the Southern and Western Finland, respectively (large graph). Municipalities near Olkiluoto site are Eurajoki, Luvia and Rauma whereas Loviisa, Ruotsinpyhtää, Pernaja and Pyhtää are near Loviisa site. Case-control analysis cover grey area. Small and large circles illustrate residential zones of 0-15 km and 15-50 km around the NPPs used in cohort analysis (small graphs). ***Source:*** **Municipal boundaries © National Land Survey of Finland, licence 53/MML/10.**

Results

In the cohort analysis, the rate ratios (RRs) of childhood leukaemia for the cohort living within the 15-km zone from an NPP were 1.0 (95% CI 0.3, 2.6) for the 1980 residential cohort and 0.9 (95% CI 0.2, 2.7) for the cohorts of 1990. For both cohorts, incidence of childhood leukaemia within the 15-km zone from the NPPs was comparable to that in the 15-50-km zone (Table 1).

Table 1. Observed leukaemia cases (Obs) within the 15-km zone from the NPPs and rate ratios (RRs) with 95% confidence intervals (95% CI). Expected incidence within the 15-50-km zone from the NPPs was used as a reference.

	Boys			Girls		
Childhood leukaemia	**Obs**	**RR**	**95% CI**	**Obs**	**RR**	**95% CI**
Residential cohort of 1980	3	1.1	0.2, 3.3	1	0.8	0.0, 4.5
Residential cohort of 1990	2	1.2	0.2, 4.5	1	0.6	0.0, 3.3

In the case-control analysis, the mean (maximum) of average distance was 18.4 km (59.7 km) km for leukaemia cases and 19.3 km (86.4 km) for controls. None of the children lived within the 5-km zone around the NPPs (Table 2). The odds ratio (OR) of leukaemia in the closest category (5-9 km) was 0.7 (95% CI 0.1, 10.4) compared to the reference, ≥30 km zone. None of the ORs related to categorized average distance differed significantly from the unity (Table 2). The result was the same for categorized distance at diagnosis and minimum distance.

Table 2. Odd ratios (ORs) with 95% confidence intervals (95% CI) of childhood leukaemia related to categorized average distance in the municipalities near the NPPs.

Average distance	Cases	Controls	OR	95% CI
0-4 km	0	0	-	
5-9 km	1	5	0.7	0.1, 10.4
10-19 km	11	41	0.9	0.2, 4.4
20-29 km	1	9	0.3	0.0, 3.6
≥30 km	3	9	1.0	

The results showed no heterogeneity between nuclear power sites, sexes, 5-year age groups and 10-year calendar period in cohort or case-control analysis.

Discussion

We assessed the risk of childhood leukaemia in populations living near the Finnish nuclear power plants. The results of the cohort and case-control analysis were consistent and did not indicate an excess of leukaemia.

The strengths of the study include comprehensive individual residential histories for all subjects in the case-control study. The nationwide, population-based cancer registry allowed identification of the complete roster of leukaemia cases in the study population. Combining two approaches in the study allowed a thorough evaluation of the leukaemia risk.

A key limitation of the analyses was the small number of cases. Therefore more detailed analyses, such as childhood leukaemia in young children aged less than 5 years living within a 5-km zone around the NPPs (corresponding to the findings of the German KiKK study), could not be assessed. As in other studies on the issue, exposure assessment was challenging as the monitoring of exposures indicates practically zero doses from the power plant exposures. If there is any excess radiation exposure to the population residing close to the power plants, it would have to be from internal exposure, which is more difficult to measure than external radiation. Yet, the concentrations of radionuclides are very low and calculated maximal dose contribution negligible.

Conclusions

This study showed no evidence of increased risk of leukaemia in children living close to the nuclear power plants in Finland.

Abstract

People in the Arctic regions can be heavily exposed from the global radioactive fallout due to their diet rich in reindeer meat in which radionuclides accumulate. The primary aim of this study was to assess whether the estimated lifetime cumulative radiation doses for the Arctic population from atomic bomb testing have had detectable effects on the incidence of cancer. A cohort of the Arctic population in Finland (n = 34,653) was identified through the Population Register Center with grouping by reindeer herding status, ethnicity and radiation exposure. Annual average radiation doses, based on ^{137}Cs whole-body measurements, were assigned by birth-year, gender and reindeer herder status. Cancer cases of radiation-related cancer types (cancers of the bladder, female breast, colon, esophagus, liver, lung, ovary, stomach, brain and nervous system, bone and thyroid, non-melanoma of the skin, basal cell carcinoma of the skin, and leukemia) during 1971-2005 were identified from the Finnish Cancer Registry. A total of 1,580 cancer cases were observed versus 1,948 expected on the basis of incidence rates in Northern Finland [standardized incidence ratio (SIR) was 0.81 with 95% confidence interval (CI) of 0.77-0.85]. For the reindeer herders SIR was 0.72 (95% CI 0.60-0.85) and for the Sami people SIR was even lower, 0.47 (95% CI 0.37-0.60). No association between the lifetime cumulative radiation exposure from global radioactive fallout and cancer incidence in the Arctic population was found. Potential underestimation and misclassification of the radiation dose may affect the results and the findings should be interpreted with caution.

Introduction

Most of the atmospheric testing of nuclear weapons was performed during 1945-1963 and the highest global fallout from these tests occurred in the early 1960s (UNSCEAR 2000). ^{137}Cs is the most important component of human radiation exposure from the fallout. Its persistence in the environment is enhanced by a slow turnover in the northern ecosystems. After the A-bomb testing period further exposure resulted from the Chernobyl nuclear power plant accident in 1986. However, the ^{137}Cs deposition in Northern Finland was only a fraction of that received from atomic bomb testing. The route of exposure among Arctic population is mainly through the intake of food with elevated radioactivity, resulting in protracted internal exposure (Rahola and Suomela 1998). For human exposure, the lichen-reindeer-human pathway is important, because ^{137}Cs is enriched in the food chain (Golikov et al. 2004; Miettinen and Häsänen 1967). The diet of Arctic people in Lapland is rich in reindeer meat and they have several-fold higher ^{137}Cs body burdens from the global test fallout than other populations of the Nordic countries (Rahola and Muikku 2004; Rahola and Suomela 1998).

The Sami people are the indigenous population of the Northern Scandinavia and the Kola Peninsula, and are genetically distinct from other Northern European people (Lahermo et al. 1996). In all published epidemiological studies, the Sami populations have had a cancer incidence below the national and regional average (Haldorsen and Tynes 2005; Hassler et al. 2004; Hassler et al. 2005; Hassler et al. 2008; Soininen et al. 2002; Wiklund et al. 1990; Wiklund et al. 1991). The lower cancer risk of the Sami has been suggested to reflect lifestyle and/or genetic factors. However, the non-Sami population in the Arctic areas has not been investigated. Even though the radiation exposure has been the motivation for several studies on cancer risk among the Nordic indigenous populations, no information on radiation doses has been available in earlier studies.

Material and methods

The baseline cohort consisted of all 36,461 Finnish residents identifiable from the Population Register Center born in the northernmost municipalities of Finland (Figure 1). These areas were chosen because they have the highest numbers of reindeer herders and people of Sami ethnicity. Subjects in the baseline cohort were born between years 1860 and 2001.

People registered as reindeer herders in the censuses carried out in the end of 1970, 1975, 1980, 1985, 1990, or 1995 were identified from Statistics Finland. Persons resident in Finland on 1 January 1971 or later were included in the final study cohort (n = 34,653). Persons whose own mother tongue or that of both parents was any of the three Sami languages were defined as ethnic *Sami* (Table 1).

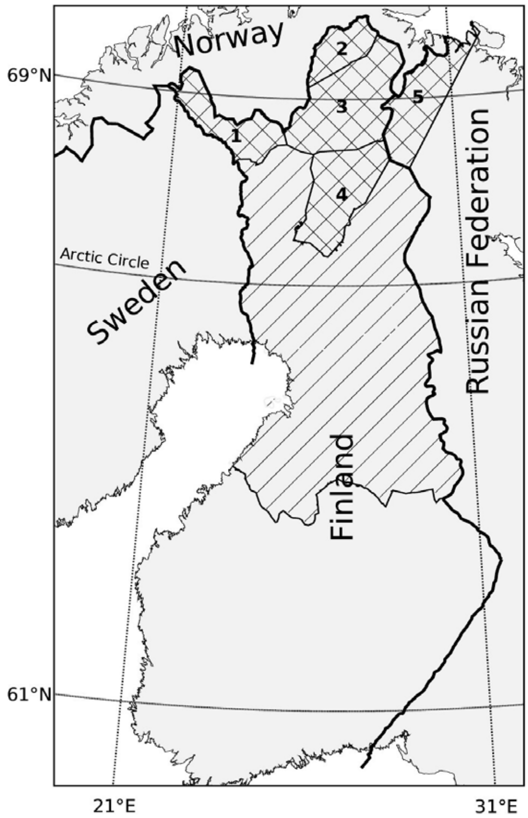

Figure 1. Birth municipalities of the study cohort members: 1 = Enontekiö; 2 = Utsjoki; 3 = Inari; 4 = Sodankylä; 5 =Petsamo (in Russia). The reference region for defining the expected numbers of cases (Cancer Care Responsibility Region of the Oulu University Hospital) is illustrated with a raster without a number.

Mean doses were assigned to groups defined by birth-year, gender, and reindeer herding status. Radiation dose assessment was primarily based on the ^{137}Cs body burden among the reindeer herders and other people in Lapland during 1961-2003. The ^{137}Cs body burden estimates from the whole-body measurements were available from surveys carried out by the Department of Radiochemistry, University of Helsinki in 1961-1977 and by STUK in 1986-2003 (Rahola and Muikku 2004). Annual doses were estimated for reindeer herders and non-reindeer herders according to gender (Figure 2). The cumulative whole-body dose was calculated as the sum of the assigned calendar-year-specific annual doses, taking into account the reindeer herding status. If a subject had a reindeer herding occupation in the earliest available census or if either parent of a child was a reindeer herder, the beginning of the reindeer-related exposure was assumed to start at three years of age. For spouses of reindeer herders, the beginning of the reindeer-related exposure was assumed to be the wedding year. Parents of a reindeer herder whose own occupation was unknown were assumed to have been reindeer herders, and calculation of reindeer-related exposure for them was assigned to start at three years of age. Subjects classified as reindeer herders remained in that exposure category regardless of subsequent changes in occupation or place of residence (assuming that their consumption of reindeer meat remained high).

Table 1. Description of the study population. Number of subjects (N) and person-years during 1971-2005.

		Total	
		N	Person-years
All		34,653	874,391
	Men	17,262	429,433
	Women	17,391	444,958
Reindeer herder		2,786	70,287
	Non-Sami	716,154	46,225
	Sami	917	24,063
Non reindeer herder		31,867	804,104
	Non-Sami	30,747	774,869
	Sami	1,120	29,236
Estimated cumulative radiation dose[a] (mGy)			
	0-0.9	13,523	172,293
	1-4.9	9,916	192,209
	5-9.9	19,665	376,65
	>10	6,612	133,24

[a] Based on ^{137}Cs whole body measurements. A person may change exposure category during the follow-up period and therefore contribute to numbers of more than one category

The cumulative dose (D) was assigned as a function of follow-up

$$D = \sum_{t_o}^{t_1} d_{ijk}$$

where t_0 is the start of exposure and t_1 is the time of observation. The annual dose, d, depends on: gender (i), calendar year (j), and reindeer herding status (k).

Incident cancer cases occurring in 1971–2005 were identified from the Finnish Cancer Registry. Results are given for *a priori* selected radiation-related cancer sites. The category of "*radiation-related cancer sites*" is defined to consist of cancers consistently associated with radiation in previous studies, i.e., cancers of the urinary bladder, female breast, colon, esophagus, liver, lung, ovary, stomach, bone, basal cell carcinoma of the skin, brain and nervous system and thyroid, as well as leukemia.

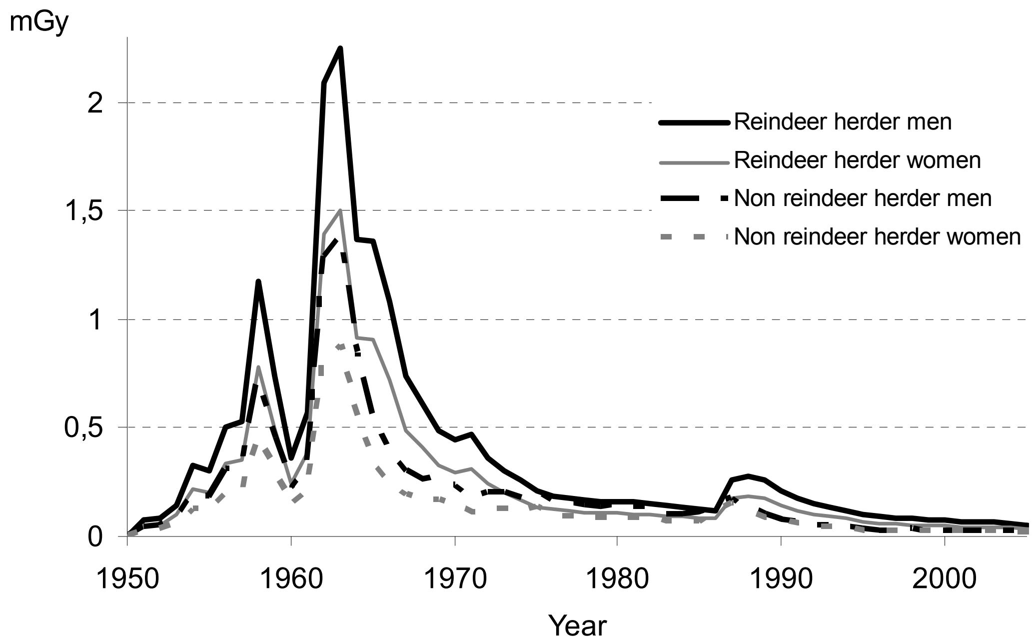

Figure 2. Average annual internal doses (mGy) from the ^{137}Cs for reindeer herders and other persons in Lapland.

The observed numbers of cancer cases and person-years at risk in the study cohort were counted according to sex and five-year age groups, separately for five calendar periods. The person-years were calculated until date of cancer diagnosis, death, emigration or the end of 2005, whichever came first. Follow-up in a given dose category was started when the cumulative dose reached the threshold level of the category with lagging by the induction period (latency). A latency of two years was allowed for leukemia, five years for thyroid cancer and ten years for other cancers. The expected numbers of cancer cases were calculated by multiplying the number of person-years in each stratum by the corresponding average cancer incidence in Northern Finland (Figure 1). The standardized incidence ratio (SIR) was defined as the ratio of observed to expected number of cases. The exact 95% confidence interval (95% CI) for each SIR was estimated on the presumption that the number of observed cases followed the Poisson distribution.

An ethical review of the study protocol was conducted by the Radiation Protection Advisory Board. The Population Register Centre gave the permission to use the population database for identifying the study population. The permission to use the census data on occupation was obtained from Statistics Finland. The National Research and Development Centre for Welfare and Health gave permission to use Finnish Cancer Registry data.

Results

A total of 1,580 cases of radiation-related cancer were observed versus 1,948 expected in the study population, indicating lower cancer risk in the study area than in the entire Northern Finland. The cancer incidence among the Sami was lower than in the rest of the study cohort, independent of the reindeer herding status. Reindeer herders had a slightly lower cancer incidence than non-reindeer herders (Table 2). The SIR for radiation-related cancers was not associated with the estimated cumulative radiation dose (Table 3).

Table 2. Observed (Obs) and expected (Exp) number of cancer cases and standardized incidence ratios (SIR) and 95% confidence intervals (95% CI) of radiation-related cancer sites by the reindeer herding status and ethnicity in the Arctic population in Finland.

	Sami		Non-Sami		All	
	Obs/Exp	SIR (95% CI)	Obs/Exp	SIR (95% CI)	Obs/Exp	SIR (95% CI)

All	68/144	0.47 (0.37-0.60)	1,512/1,804	0.84 (0.80-0.88)	1,580/1,948	0.81 (0.77-0.85)

Table 3. Observed (Obs) and expected (Exp) number of radiation-related cancer cases and standardized incidence ratios (SIR) and 95% confidence intervals (95% CI) of the Arctic population in Finland by estimated radiation dose based on ^{137}Cs whole body measurements during 1971-2005.

Dose	Obs/Exp	SIR (95% CI)
0-0.9 mGy	137/191	0.72 (0.60-0.85)
1-4.9 mGy	33/44	0.76 (0.52-1.06)
5-9.9 mGy	811/966	0.84 (0.85-0.97)
>10mGy	307/378	0.81 (0.72-0.91)

Discussion

We evaluated cancer risks associated with estimated cumulative radiation doses, based on ^{137}Cs whole-body measurements, among the population in northernmost Finland. The cancer incidence for several primary sites was lower than among the other inhabitants of Northern Finland. No association was found between the cumulative radiation dose and radiation-related cancer sites.

The dose estimation of the current study is prone to underestimation and misclassification, mainly because reindeer meat is also rich in natural polonium, while only dose from ^{137}Cs was considered. The estimated group-level radiation doses have significant individual uncertainty. Due to uncertainties in the quantitative dose estimation quantitative risk estimation was not performed in the current paper. Northern people have a relatively high intake of smoked and salted food and a low intake of fresh vegetables and fruit, but on the other hand, a high consumption of berries. These etiologic factors constitute potential confounders that we were unable to control. Interaction between radiation and dietary risk factors is also a possibility.

Conclusions

The overall cancer incidence in Arctic population cohort was lower than in the general population in Northern Finland. Ethnic Sami people had a lower cancer incidence than the rest of the cohort. No association was observed between the lifetime cumulative radiation exposure from global radioactive fallout and radiation-related cancer risk.

Abstract

Work involving the preparation and assay of radiopharmaceuticals is associated with the highest occupational medical staff exposure from gamma emitters (^{99m}Tc, ^{131}I).

Our health status surveillance, a 5 years follow-up, of 16 subjects (18.11±13.76 years exposure length, 31,3 % easy-smokers) included mandatory national recommendations effect indices: clinical, haematological, cytogenetic micronuclei-MN in peripheral blood. Moreover we performed MN in sputum, oral exfoliated cells, oxidative stress indices (whole blood superoxide dismutase activity – SOD, serum lipoperoxides - Lpox).

During follow-up, 18.7% subjects over 12 years ^{131}I exposure were monitored for occupational thyroidal pathology, other 12.5% for dermic papillose, 56.3% for cardiovascular disorders or allergic rhinitis. Lymphocytes decreased level correlated inversely with exposure length in 31.2% cases. HGB, HCT modifications were associated with reticulocytes response in 12.5% subjects, but inverse correlated with years of exposure (r= -0.42). In 56.3% cases were neutrophil modifications with a 3 years tendency of normal values return at 28.1%. For 6.3% were found numerical and structural blood MN disorders due to workload or no radioprotection rules used. In 36.4% cases MN high level in oral mucous epithelial cells were indirect correlated with exposure length but direct correlated with smoking habit (r=0.58). Sputum type II cytology showed 16.7% ferruginous bodies over 20 years exposure, no correlation with smoking habit. Despite of allowable external exposure limits recorded, chronic exposure increased the SOD activity (148.8±106.6 U/ml) in 12.5% cases and Lpox level (2.4±1.9 µmol/l) at 18.7%, having no correlation with tobacco use.

We emphasized that continuously clinical and bioassay monitoring in nuclear medicine practices can reveal early changes of radiation induced effects. New proposals on national legislation for improving health surveillance of medical staff will be made.

Introduction

Nuclear medicine practices have a greater contribution to the exposure of medical staff involved as compared to other medical uses of radiation. While effective doses for radiologists in diagnostic radiology are at average of 1 mSv/year with increased values for interventional radiology, for medical personnel from diagnostic or therapeutic nuclear medicine is associated with high exposure average doses of 1-2 mSv/year from gamma emitters (^{99m}Tc, ^{131}I), low-linear-energy-transfer (LET) radiation (UNSCEAR 2000, 2006).

Occupational exposure control is usually made for both workplaces– external exposure (dose rate and radioactive contamination) and individual monitoring– individual dose estimation (dosimetry).

Internal dose assessment can be quantified by radioactive measurements (whole body counting, activity excreted in body fluids or in the breathing zone).

Health status assessment of medical staff with ionizing radiation exposure is annually performed by occupational medicine physicians with radio-pathology empowerment and based on national recommendations for effect indices in nuclear medicine exposure (clinical, haematological, cytogenetic micronuclei-MN-in peripheral blood, psychological test, thyroidal hormone determinations) (MPH 2007).

Material and methods

In a 5 years surveillance study of 16 subjects (81.2% females, 31.3% easy smokers, 18.11±13.76 years mean exposure length) we investigated effects indices, mandatory in Romanian national recommendations (MPH 2007): complete physical examination, haematological tests (blood count and blood cells` morphology: HGB, HCT, RBCs, RBC indices, WBC, platelets, reticulocytes, lymphocytes), cytogenetic test – unstable aberrations - number of cells with micronuclei (MN)/ 1000 counted cells in peripheral blood lymphocytes cultures (Popescu 2006) and specialty exams (endocrinology - T_3 triiodothyronine and T_4 thyroxine blood level, ophthalmology, psychology examinations).

Moreover we performed blood oxidative markers as whole blood superoxide dismutase activity (SOD), serum lipoperoxides (Lpox) and MN in sputum and oral exfoliated cells- by mucous cell brushing - a non invasive, not expensive method useful as screening technique.

In the final interpretation, clinical and biodosimetry results were correlated with individual exposure recorded by individual film and electronic dosimeters. Analytical methods used in this study were: t-Student, correlation and descriptive statistics by EXCEL functions.

Results

During follow-up, 18.7% subjects over 12 years ^{131}I exposure were monitored for occupational thyroidal pathology (polinodular goitre) with T_4 levels inversely correlated with exposure length.

Other clinical findings were pigmentation and skin papillose (12.5%), cardiovascular disorders (18.7%) as hypertension and respiratory arithmia, allergic rhinitis (18.7%) or musculoskeletal diseases (12.5%) and minor epileptic strokes (6.2%).

Severe anaemia ($2.98*10^6$ RBC, HGB 8.8 g/dl, HCT 26.8%) were found in one case with 40 years of ionizing radiation exposure.

As haematological marrow cells are the most affected even after short time of exposure, we found the lymphocytes decreased level correlated inversely with exposure length in 31.2% cases.

Trombocytes and neutrophil granulocytes modifications found in 56.3% cases. HGB, HCT and erythrocytes modifications were associated with reticulocytes response in 12.5% subjects, but indirect correlated with years of exposure (r= -0.42).

Genomic instability such as micronucleation were found for 6.3% of subjects, both numerical and structural blood MN disorders related to workload or no radioprotection rules used. In 36.4% cases MN high levels in oral cells were indirect correlated with exposure length but strongly direct correlated with smoking habit (r=0.58). The modifications trend had maintained during 5 years follow up.

Sputum type II cytology in 36.4% of subjects (Babes-Papanicolau classification) showed 16.7% ferruginous bodies over 20 years exposure, but with no correlation with smoking habit.

Despite of allowable external exposure limits recorded, chronic exposure increased the stress oxidative markers such as SOD activity (148.8±106.6) in 18.8% cases and Lpox level (2.4±1.9) at 31.3%, also in our study, having no correlation with smoking.

Discussion

Doses control in nuclear medicine practices implies radioprotection regarding inhalation or ingestion during preparation or injection the radiopharmaceuticals.

In ^{99m}Tc handling the external exposure is important, with high annual dose rates up to 500 mSv especially at hands and fingers, while the average annual effective dose to monitored medical workers averaged over five - years period can vary between 1.04 mSv and2 mSv. (UNSCEAR 2000, 2006).

In our follow-up study for effective dose estimation due to external exposure were monthly recorded the individual dose equivalent Hp (10) which did not exceeded 170 µSv, admitted value for occupational exposure for occupational ionizing radiation exposed personnel. (NCNAC 1996, BSS 1996, ICRP 2007).

There were rare cases of slight exceeding of Hp (10) limit (180µSv/month) in 5.8% of subjects. The cumulative film badge, dose for medical staff were under 24 mSv/year.

Gamma ionizing radiation-induced health effects are not specific and the targeted damages are observed as deterministic effects in hematopoetic system, lungs, thyroid, skin, eye, gonads, embrio/faetus and as stochastic effects by direct DNA damage or delayed effects – carcinogenesis (Little 2000), potential for biological effects expressed within one or two cell generation radiation risk (Morgan et al.1996, Little 2000, Ward 1999, 2002).

We focused to monitor in hematopoetic system the number of lymphocytes, with knowing tendency of decreasing immediately after exposure. In 32.1% cases the decrease of lymphocytes number (95% CI: 29.56-37.68) % were inverse correlated with exposure length (r=-0.35) (fig.1).

Platelets number had no significant changes in all years of monitoring period (fig. 2).

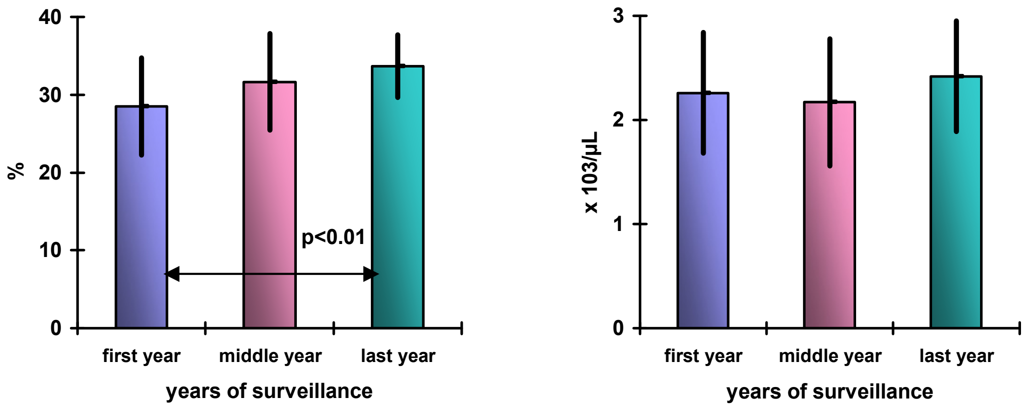

Fig. 1. Lymphocytes mean values in surveillance period.

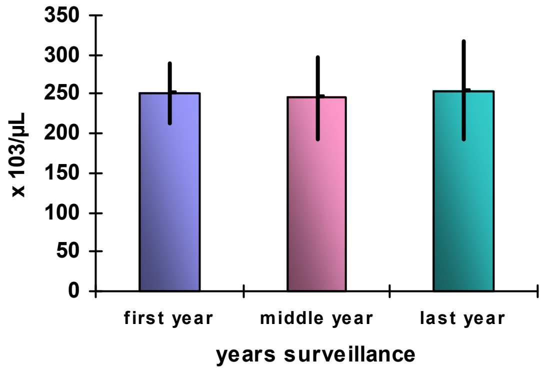

Fig. 2. Platelets mean values in surveillance period.

Numerical modifications (95%CI: 49.60-61.22) % - neutrophil granulocytes immunostimulation / immunosuppressed were found in 56.3% cases correlated inversely with occupational length (r=-0.31) and smoking habit for easy smokers: Brinkmann index under 200 (r=-0.28), statistically non-significant (p>0.05). We noticed at 28.1% subjects the trend to normal values recovery after 3 years of ionizing radiation exposure (fig. 3).

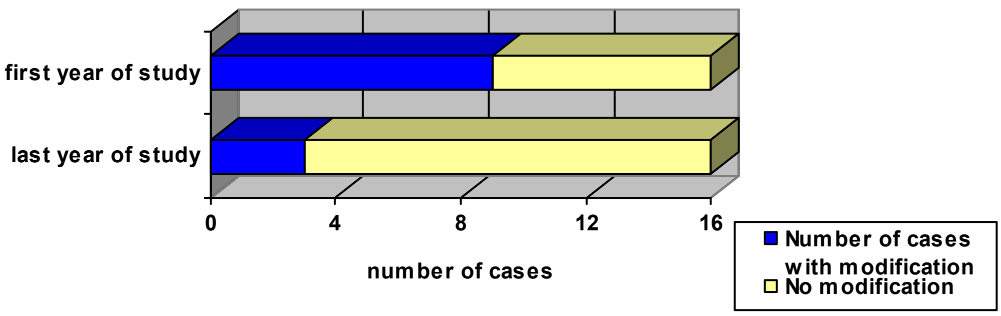

Fig. 3. Number of neutrophil granulocytes distribution in surveillance period.

Erythrocytes, which smoothly decrease after weeks of exposure (UNSCEAR 2000, 2006), in our study this trend was maintained in same values with no significant variations (fig. 4).

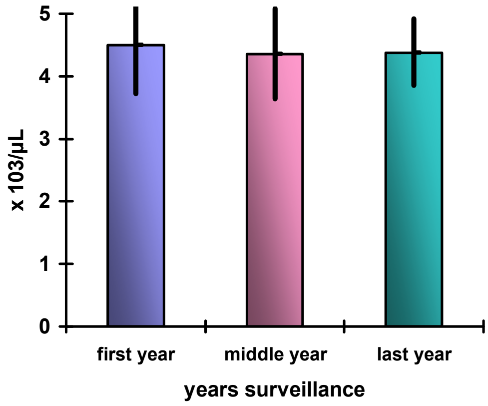

Fig. 4. Erythrocytes mean values in surveillance period.

Also HCT (95% CI: 34.42, 42.74) % correlated inversely with exposure length (r=-0.42), anaemic syndrome being observed in 12.5% of cases, one severe type. HGB (95% CI: 11.43, 14.59) g%, HCT and erythrocytes modifications were associated with reticulocytes response (95% CI: 6.06, 22.96) ‰ in 12.5% subjects, but significantly inverse correlated with years of exposure (r= -0.42).

Eosinophils granulocytes (95% CI: 0.62, 5.56) % in 12.5% of cases had a constantly numerical increasing trend over a 5 years-surveillance but had significantly positive correlation only with cigarette smoking for moderate smokers: Brinkmann index over 220 (r=0.79, p<0.01).

At subjects over 12 years ^{131}I exposure were monitored, clinical and therapeutic, an occupational multinodular goitre with hyperthyroidism, T_3 and T_4 levels trend were inverse correlated with exposure length. (r=-0.47).

Non targeted effects, like bystander effects (Yier 2000, Belyakov 2001), genomic instability (Emerit 1994, Morgan 1996, Wright 1998, 2000), adaptive response (Wolf 1998) are specific significant at low doses and this evidence is a new model for classical theory of radiation biology (Baverstock 2005).

We performed cytogenetic tests based on the assay of unstable aberrations such as MN in peripheral lymphocytes, sputum and oral exfoliated cells, visible in cellular cytoplasm at the first post-irradiation mitosis (Muller 1996).

These methods available at present for our study seemed useful to estimate the individual effects in moderate – low LET radiation doses. For 6.3% subjects were found numerical and structural blood MN disorders due to workload, meaning an acute recent exposure. Blood MN changes had no correlation with smoking habit but had an inverse correlation with occupational exposure length (fig. 5).

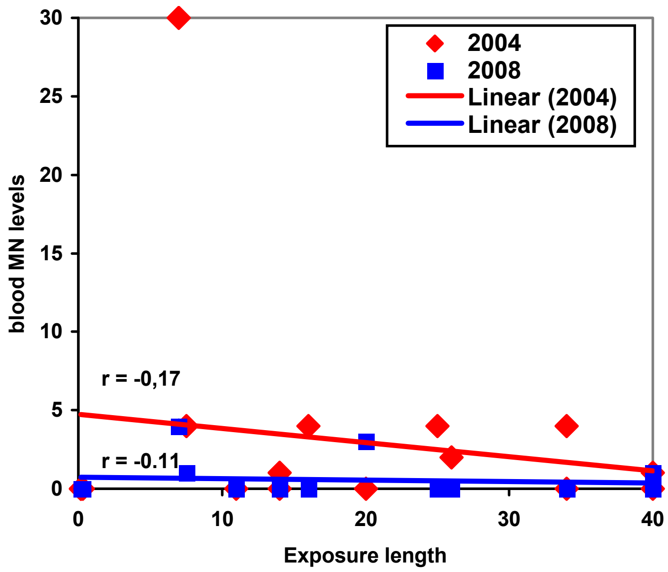

Fig. 5. Correlation between blood MN and exposure length during study surveillance.

Also, we observed a direct correlation of cases with blood/oral MN level modifications during 5 years surveillance (r=0.44). In 36.4% cases MN high numerical level in oral cells were inverse correlated with exposure length (r=-0.44) but significantly positive with smoking habit (r=0.58) (fig. 6).

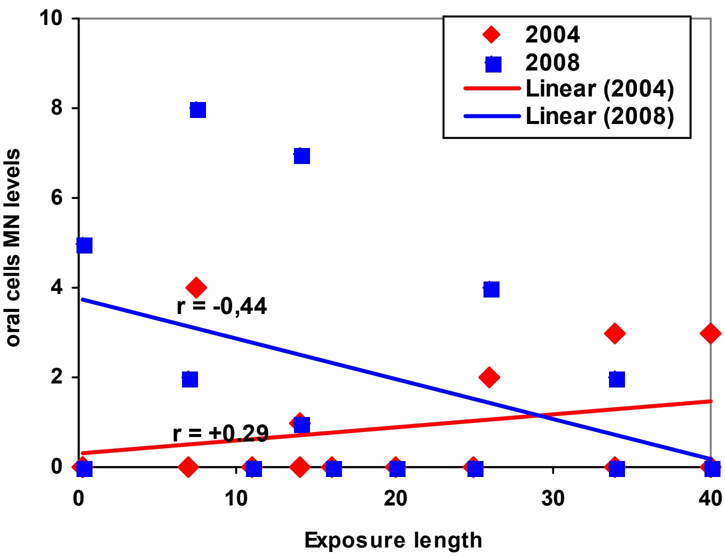

Fig. 6. Correlation between oral cells MN and exposure length during study surveillance.

Sputum type II cytology in 36.4% of subjects showed also 16.7% ferruginous bodies over 20 years exposure, but with no correlation with smoking habit. It seems that non-uniform/not constantly medical staff monthly exposure (for gamma generators) and adaptive mechanisms are responsible for the indirect correlation between length of exposure and MN alterations either in sputum or oral cells. Recently it was demonstrated that chromosome instability in cells can develop specific cell variants more resistant to radiation exposure (Limoli 2001).

The bystander effect is cell type dependent and energy metabolism or reactive oxygen species (ROS) (Mothersill 2000) are involved in mediation of this kind of response. (Emerit 1994, Pollycove 1998, 1999, Lyng 2001). Antioxidant enzymes SOD/Lpox annihilate ROS, stress oxidative markers disturbances indicating a continuously oxidative processes and cellular stress aggression of health status caused by ionizing radiation exposure (Kłucinski et al. 2008).

For medical personnel involved in our study SOD activity (95% CI: 42.25-255.51) U/ml had increased levels in 12.5% of cases with no correlation with exposure length or tobacco use (Kłucinski et al. 2008). Lpox varied (95% CI: 0.4-4.38) µmol/l from 18.7% high levels directly with occupational exposure, to 6.2% decreased level after 7 years of occupational exposure at smoker personnel (fig. 7).

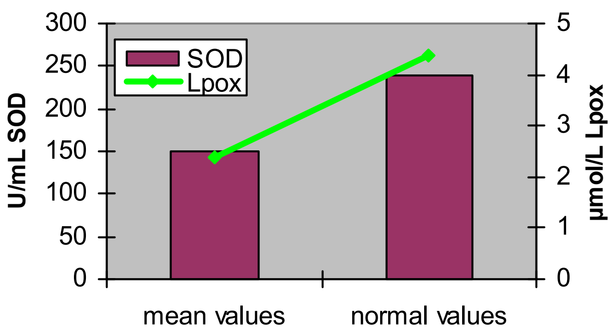

Fig. 7. Comparison trend of SOD and Lpox mean values in study surveillance.

An accurate assessment of oxidative stress in biological system is hard to perform, because a comprehensive surveillance must include measurements of all antioxidants, but that would be expensive, long time processing and technically difficult (Olisekodiaka MJ et al. 2009).

Conclusions

We emphasized that continuously clinical and bioassay monitoring in nuclear medicine practices – haematological, cytogenetic and oxidative stress status - can reveal early changes of radiation-induced effects.

Long term exposure to gamma-rays changes the antioxidant response of medical staff, having no correlation with cigarette smoking.

New proposals (such as MN in oral mucous epithelial cells) on national legislation for improving health surveillance of health care staff will be made.

Abstract

Radon and its progenies can be inhaled and deposited in the airways. Many of the decay products of the radioactive radon isotopes are short lived alpha, beta and gamma active atoms interacting with the epithelial tissue after their deposition and decay in the lung. Some of the radon and thoron decay products are short lived alpha-emitters and can transmit large amount of localized energies to the surrounding cells causing cellular and tissue damages. Since these interactions take place at a microscopic scale, the averaging of radiation dose to the whole body or the whole lung seems not to be fully appropriate for the quantification of the health effects. The aim of this study was to reveal the exact spatial correlations of different microdosimetric quantities and biological endpoints in the epithelium following the deposition and decay of short lived radon progenies. For this purpose complex numerical methods were developed. Air and particle transports in reconstructed three-dimensional airways were simulated. Particle deposition coordinates were recorded and alpha tracks generated. The cell nucleus architecture of the epithelium was reconstructed and interactions of alpha tracks with the nuclei were modelled. Our results demonstrate that in some clusters of nuclei the probabilities of single and even multiple hits are high even at low levels of macroscopic exposure. For the cells located in the deposition hot spots the probability of cell killing and transformation is more than one order of magnitude higher than the corresponding values assuming uniform surface activities.

Introduction

Radiation protection directives and regulations are based on our knowledge about health effects of radiations. Although by the accumulating experience, development of experimental and computational techniques and the emergence of new, multidisciplinary approaches a series of questions have been answered, some others are still to be clarified. One of these challenging tasks regards the biological response triggered by low dose densely ionising radiations. Densely ionizing radiation produces a unique type of damage in which multiple lesions are encountered within close spatial proximity. The degree of damage clusterization can be further accentuated by the nonuniform radiation source distributions. Such a nonuniform surface activity distribution is produced by the inhaled radionuclides deposited within the airways. The site specificity of radioaerosol deposition in the lungs has been demonstrated both experimentally and by computational methods. However, the consequences of the inhomogeneous radionuclide deposition at cellular and tissue level are not fully explored to date. Although a comprehensive experimental study on the effect of spatial distribution of hit cells on different biological endpoints is still missing, it is clear from the existing experimental results that the spatial distribution of activity and related cellular alpha hit distributions are essential for the induced biological damage.

This study proposes to quantify the spatial distribution of the cell nucleus hits and the related biological endpoints, such as cell killing and cell transformation. Knowledge of distances between hit, killed and transformed nuclei instead of providing only their number distribution or simply assuming that they are uniformly distributed may be an important step towards a qualitatively better risk assessment. Elucidation of spatial correlations is essential especially for low doses, where neither epidemiology nor the experiments could establish a statistically convincing plausible dose-effect relationship.

Methods

Based on detailed histopathological studies (e.g. Saccomanno et al. 1996) the radon induced carcinomas arise preferentially in the upper lobes, especially in the right upper lobe. Therefore, in the present study a representative central airway segment consisting of a single bronchial bifurcation was considered (Figure 1). The 3D geometry model was constructed based on the numerical technique described by Hegedűs et al. (2004). To get the expected locations of the depositing radioactive particles it is necessary to track them within the airways. Since particle trajectories are strongly influenced by the airstreams, only a coupled (particle-air) approach can yield appropriate results. Air- and particle transport within the model airway bifurcation was simulated by the FLUENT CFD (computational fluid dynamics) code (FLUENT User's Guide 2001). Breathing parameters characteristic of light physical activity were selected. Radiation exposure conditions were characteristic of the former Czech uranium mines derived from Tomasek et al. (2008) publication. Inhaled particles were tracked until they deposited in the model airway or left the geometry. Deposition coordinates were recorded for further processing. Inhomogeneity of the deposition pattern was quantified by the help of activity maps. Activity maps were constructed by scanning the surface of the airway bifurcation by a regular triangle shaped surface element (surface area = 0.43 mm^2) and assigning to each patch a relative activity density value. Activity density is given by the sum of the activities provided by the individual radionuclides deposited on a patch divided by the area of the patch (computational cell). The ratio of the local activity density to the average activity density yields the relative activity density.

In order to model the interaction of the radiation with the radiosensitive epithelial cell nuclei, alpha tracks were generated and a three-dimensional bronchial epithelium was constructed (see also Szőke et al. 2008). Alpha-tracks were simulated as straight lines with randomly selected directions. Their lengths (ranges) were derived based on the initial kinetic energies of alpha particles and published stopping power functions for air and tissue (ICRU 1993). Near wall and far wall alpha tracks were distinguished based on their direction to the nearest surface element. By definition, tracks entering directly into the tissue are near wall alpha tracks, whereas tracks first entering the airway lumen then penetrating into the epithelium are far wall alpha tracks. The reconstruction of the three-dimensional bronchial cell nucleus structures is based on the histological data of Mercer et al. 1991. In this work, basal, indeterminate, ciliated, preciliated, goblet and other secretory cell nuclei types were distinguished. Hit probabilities and cell killing probabilities were computed for each type of cells, including both proliferative and terminally differentiated cells. However, transformation probabilities were computed only for the radiosensitive basal and goblet cells (see Figure 1). For the simulation of cell killing and cell transformation, results of the *in vitro* cell irradiation experiments from the open literature were used.

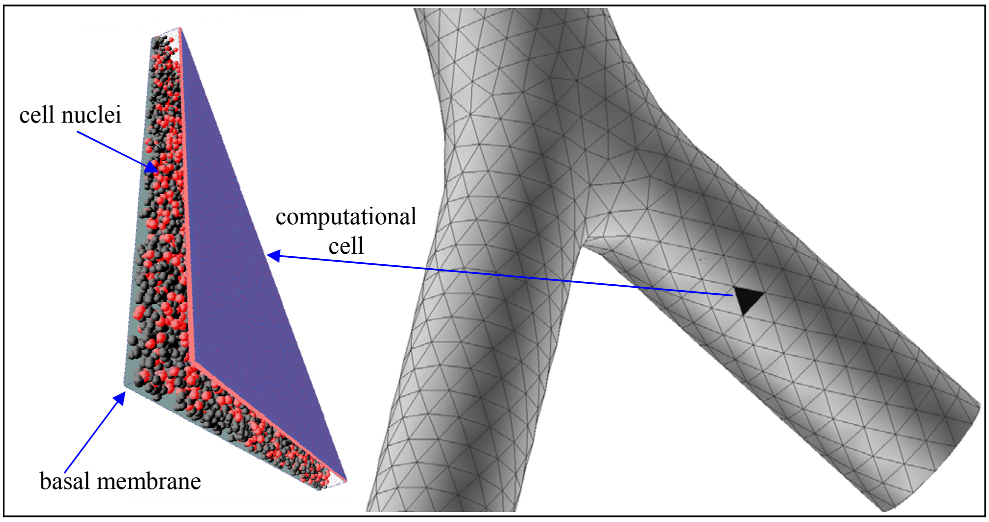

Fig. 1. Discretized (meshed) model airway bifurcation geometry and reconstructed epithelial cell nuclei.

Results and discussion

Figure 2 depicts the deposition patterns of attached (red dots) and unattached (blue dots) radon decay products corresponding to 0.01 WLM. As expected, particles deposited nonuniformly along the airway bifurcation, with the dividing spur as a preferential deposition site. The deposition efficiency, defined as the ratio of the number of deposited to the number of entering particles, was 0.46 % and 16.2% for the attached and unattached radon daughters, respectively (tracheal airflow rate was 50 l/min). Furthermore, the left panel of Fgure 2 demonstrates that the deposition of the molecular (unattached) radon progenies is less inhomogeneous than that of the attached ones. Quantification of the inhomogeneity of deposition distribution is demonstrated in the right panel. In the most exposed patch, the activity is roughly 40 times higher than the activity averaged over the whole bifurcation geometry. This suggests that cells located within this patch can be at considerable risk even if the average activity is not so high. To verify this, hit probability distributions were computed. The scanning technique presented at the description of activity maps (Methods section) was used to count the number of hits for each computational cell, then the distribution of hit numbers per patch was plotted for the 0.25 WLM exposure level (Figure 3, left panel). To highlight the importance of considering realistic deposition distributions, the hit number per patch distribution in case of uniform activity distribution is also presented for the same exposure level (Figure 3, right panel).

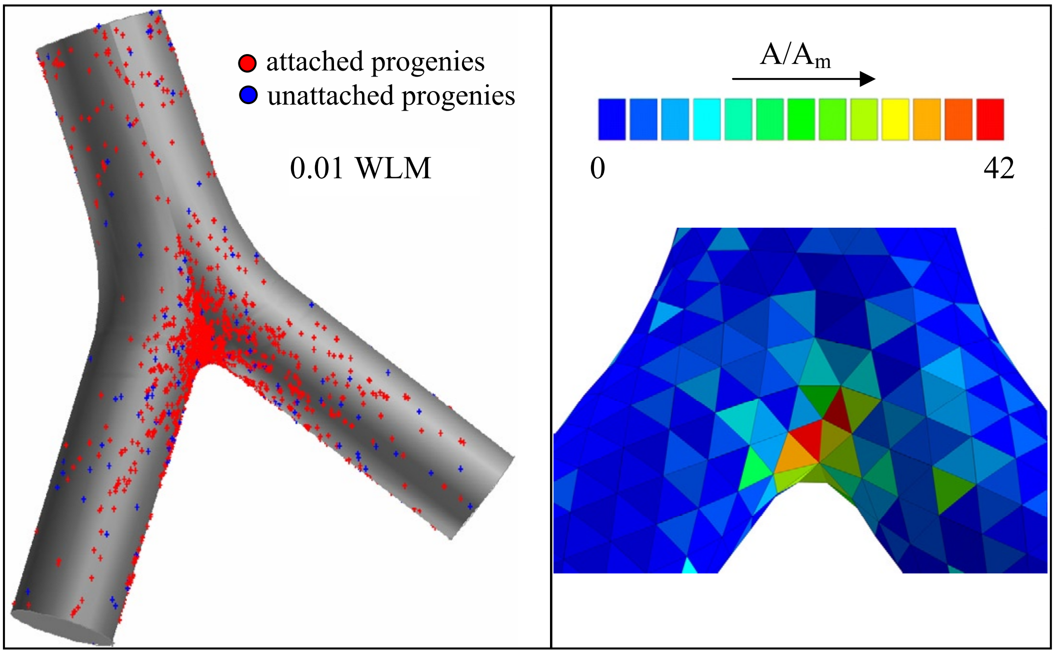

Fig. 2. Deposition pattern of attached and unattached radon progenies assuming an exposure level of 0.01 WLM (left panel) and activity density map in the vicinity of the carinal ridge normalized to the mean activity density (right panel).

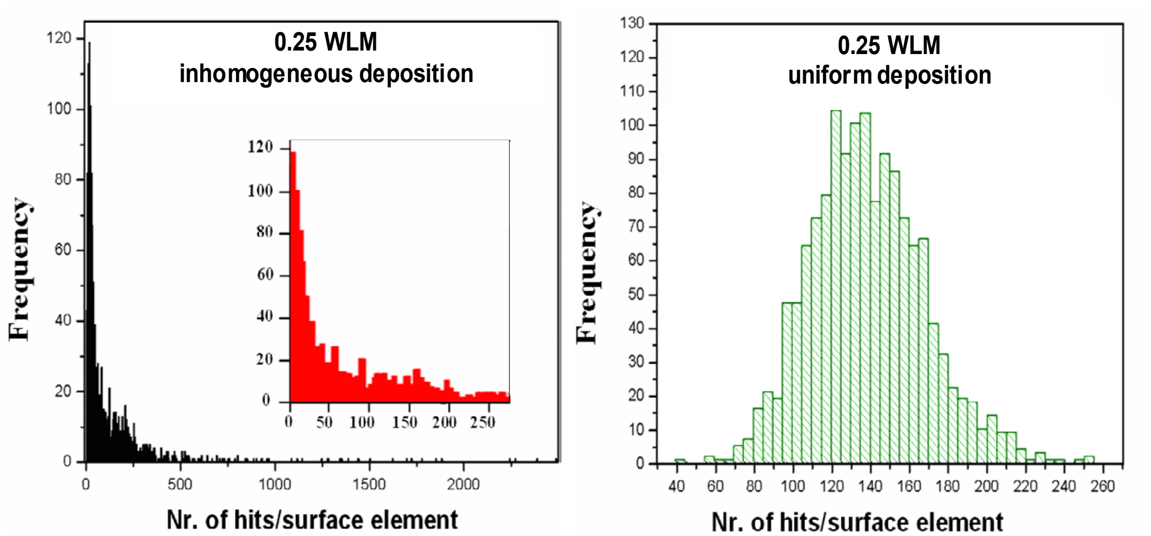

Fig. 3. Distribution of the number of hit cell nuclei located in a pre-specified surface element assuming inhomogeneous (left panel) and uniform (right panel) radioaerosol deposition distributions corresponding to 0.25 WLM radiation exposure.

Figure 3 reveals that the two hit distributions are quite different. Considering realistic deposition distribution while most of the patches receive no hit or only a small number of hits, a few patches receive hundreds and even thousands of hits. In contrast assuming uniform deposition, like most of the current models, the number of hits per patch is closely distributed around a mean value of about 130. This means that for the same exposure the degree of clusterization of the hit cells is much higher in case of inhomogeneous deposition compared to the case of uniform deposition. To check whether this observation is valid for other exposure levels, as well, the mean and maximum number of hits per patch were plotted as a function of WLM. Figure 4 demonstrates that the inhomogeneity in the distribution of hit cell nuclei per patch is present at any exposure level in the low dose range. This result suggests that although the proportion of cell nuclei receiving hits is quite low in the low dose range, there are areas, where the number of hit nuclei is very high and thus the most exposed cells are close to each other. The above fact is usually neglected by current risk models, which operate with average hit numbers.

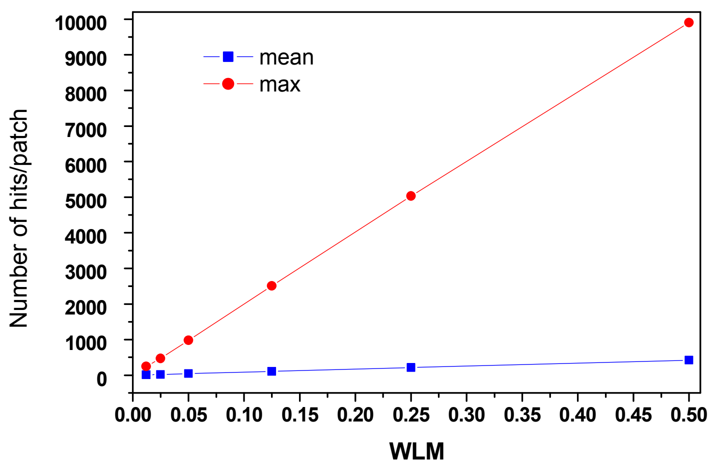

Fig. 4. Average and maximum number of cell nucleus alpha hits per patch (computational cell) as a function of working level.

It is worth mentioning that computations related to Figures 3 and 4 do not account for multiple hits. Taking into account the multiple hits the inhomogeneity becomes even more accentuated. Location of the cell nuclei receiving multiple hits are illustrated in Figure 5. The figure demonstrates that assuming realistic particle deposition patterns, the probability that a cell nucleus located in the carinal ridge of the airway bifurcation receives multiple hits is much higher than it is for a nucleus from the cylindrical parts of the bifurcation. In addition, the mean value of the distances of cell nuclei receiving multiple hits to their multiple hit neighbours (d_m) is also significantly lower than the same parameter characteristic of uniform deposition, indicating that cells at direct risk are closer to each other when assuming realistic deposition scenarios. To verify whether the finding holds for other exposure levels, as well, the probability that a cell nucleus receives at least one and at least two hits was calculated for a range of WLM values (see Figure 6). Although assuming uniform radionuclide deposition, in the considered working level interval, the probability of at least one and at least two hits increases linearly with the increase of the exposure level, there is little chance for a nucleus to receive at least one hit below 6 WLM and the probability of more than two hits is almost zero. In contrast, in the hot spot of the inhomogeneous deposition, the curves are nonlinear and the probability of at least one and at least two hits can be high even at low exposure levels, suggesting that for these regions of the tissue the “low dose problem” is actually a” high dose problem”.

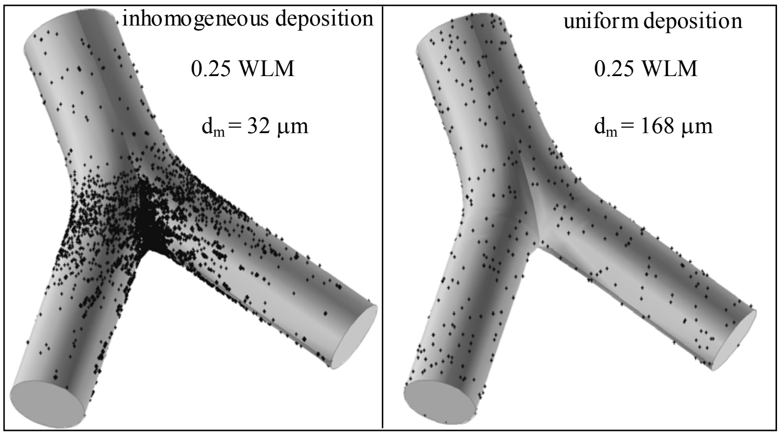

Fig. 5 Locations of cell nuclei receiving multiple hits in case of realistic nonuniform (left panel) and uniform (right panel) radionuclide surface distributions. d_m denotes the mean value of the distances between the nuclei receiving multiple hits and their nearest neighbours receiving multiple hits.

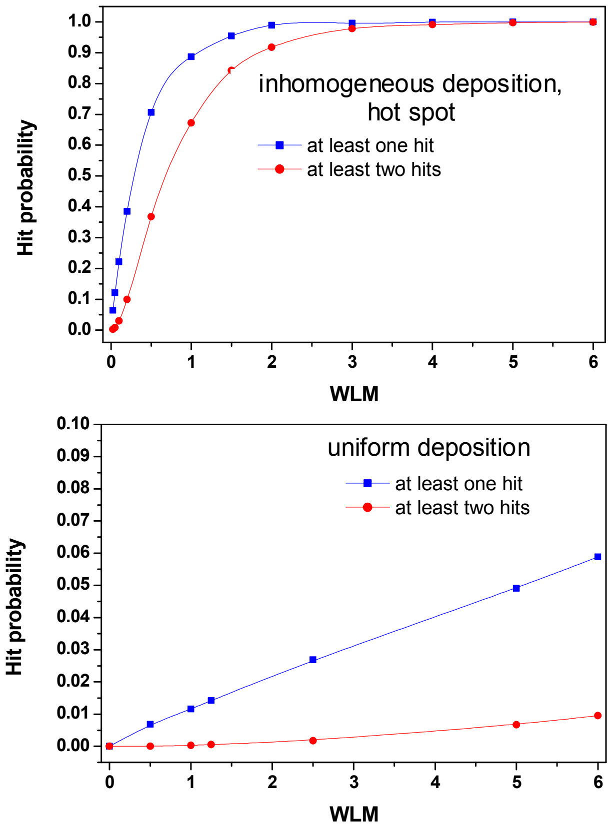

Fig. 6. Probability that a cell nucleus is hit at least once or twice as a function of WLM. The upper panel refers to nuclei in the deposition hot spot of the inhomogeneous deposition pattern, whereas the bottom panel presents the case of uniform deposition.

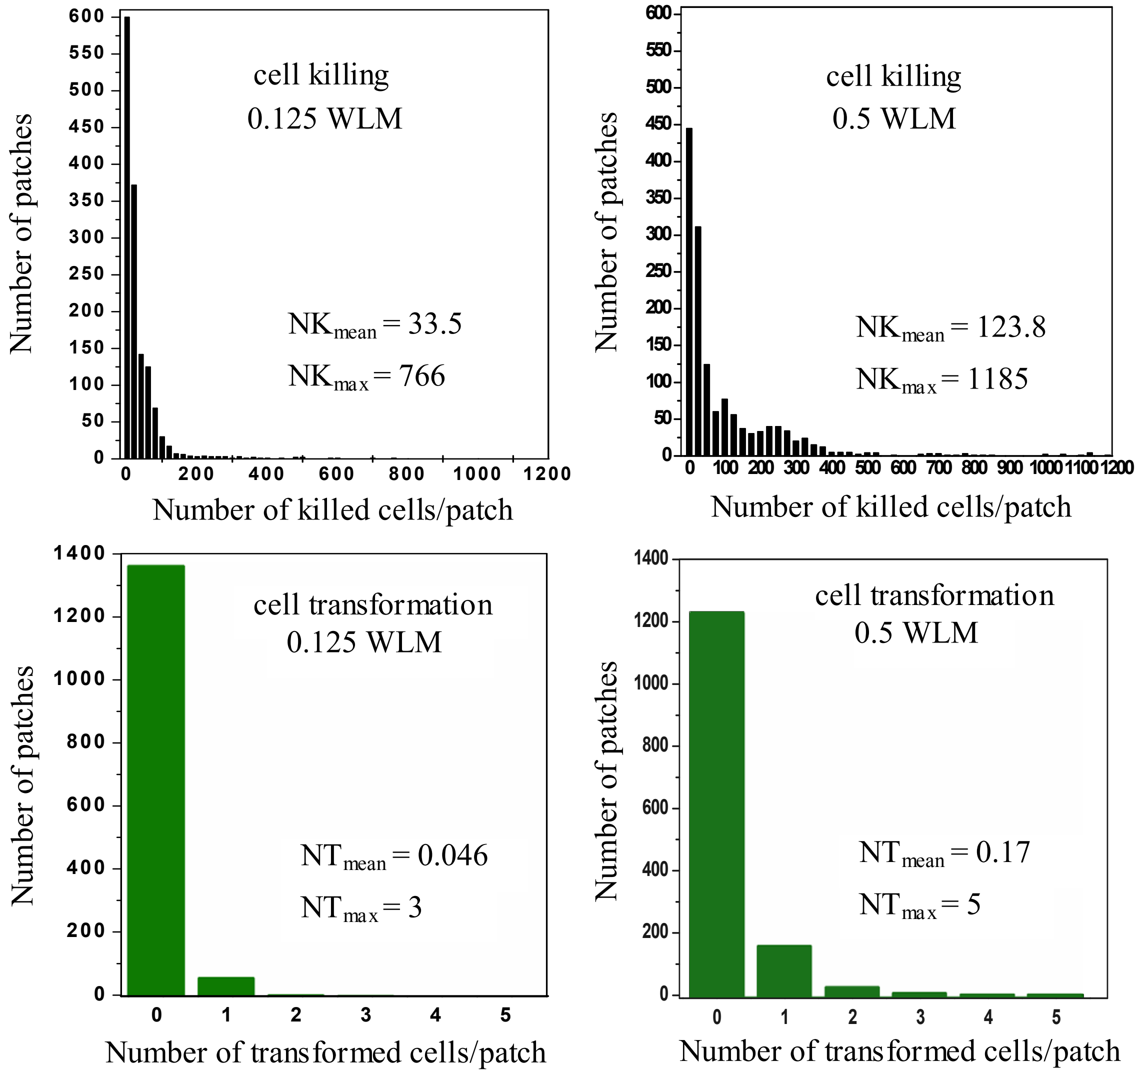

Fig. 7. Distribution of the number of killed (upper panels) and transformed (bottom panels) cells per patch at 0.125 WLM (left panels) and 0.5 WLM (right panels) exposures, assuming inhomogeneous deposition patterns. NK_{mean} – mean number of dead cells per patch; NK_{max} – maximum number of dead cells per patch; NT_{mean} – mean number of transformed cells per patch; NT_{max} – maximum number of transformed cells per patch.

To reveal the cell biological consequences of the nonuniform deposition, cell death and cell transformation distributions were computed. The results of these simulations are presented in Figure 7. The figure reveals that following the tendencies concerning the microdosimetric parameters illustrated in Figs. 3-6, spatial distribution of the biological endpoints is also heterogeneous. While the average number of inactivated cells in a patch is 33.5 at 0.125 WLM, it reaches 766 in the hot spot. The corresponding values for 0.5 WLM are 123.8 and 1185, respectively. It has been demonstrated by different experiments that the transformation frequency due to ionising radiation is extremely low in the low dose range (e.g. Sawant et al. 2001). For instance, according to Miller's microbeam irradiation experiments performed on CH310T1/2 cells (Miller et al. 1999) only one cell out of ten thousand surviving cells receiving exactly one hit will be transformed. Applying the computational schemes described in the methods section, the average number of transformed cells on a patch is 0.046 at 0.125 WLM and 0.17 at 0.5 WLM. However, our computations demonstrated that even at low exposures and hence low average transformation probabilities, there were three transformed cells at 0.125 WLM and 5 at 0.5 WLM in the hot spots. It is worth mentioning that one patch corresponds to about 10^4 cells (or nuclei). The existence of significant number of cell death and cell transformation events in restricted areas suggests that, extended detrimental effects might occur even in the low or intermediate dose range.

Conclusions

In this study, spatio-temporal distributions of microdosimetric parameters and related biological endpoints were determined in the central bronchial airways by complex computational methods. As expected, the deposition patterns of the inhaled attached and unattached radon progenies are nonuniform within an airway bifurcation with primary activity hot spots located at the dividing spur (carinal ridge). Cell nucleus hits of radon progeny alpha particles were also heterogeneous in space, although to a slightly lower extent than the distribution of the deposited radionuclides. The probabilities of single and multiple hits were quite high in the deposition hot spot even at low doses and increased in a nonlinear manner with increasing exposure level. The mean distances between hit nuclei were significantly reduced for hot spots compared to the corresponding mean distances in case of uniform deposition. Our computations revealed high cell killing rates in the deposition hot spots at low macroscopic doses. Oncogenic transformation probabilities are also significantly higher at the carinal ridges where transformed cells are closer to each other. Present results may help in the elucidation of different aspects concerning the biological consequences of radio-aerosol inhalation and may serve as inputs for future risk assessment models.

Abstract

Introduction: There are considerable uncertainties concerning health effects of low doses of ionising radiation on heart. The Life Span Study of the Japanese atomic bomb survivors shows excess radiation-associated risk for cardiac disease even at doses of 0.5 Gy.

Aim: We have used both a human endothelial cell line and a mouse model to study proteomic alterations after low-dose irradiation.

Methods: The human endothelial cell line Ea.hy926 was irradiated with 0.2 Gy gamma rays with two different dose rates and the cells were harvested 4h and 24h after the irradiation. The proteome changes were analysed using 2 DE-DIGE techniques. Using a C57/Bl6 mouse model functional and proteomic alterations in mitochondria isolated from irradiated and sham-irradiated murine hearts 4 weeks after heart-focussed irradiation (0.2 Gy, 2 Gy X ray) were analysed.

Findings: In the endothelial cell line, out of more than fifty protein spots that showed significant alterations in their expression 22 proteins were identified. Among the pathways affected by the low-dose ionising radiation are Ran and Rho/Rock pathways, stress response and glycolysis. In the mouse model, no differences between sham- and irradiated cardiac mitochondria were found in swelling, respiratory coupling and production of ATP. However, we could identify significantly increased ROS formation in cardiac mitochondria 4 weeks after the exposure to 2 Gy ionising radiation.

Conclusions: The immediate response to low-dose ionising radiation in the human endothelial cell line includes alterations in the expression of small GTPases (or their regulators) such as Ran and RhoA, the expression of which is known to be regulated by the production of reactive oxygen species (ROS). Similarly, we find in the long-term response of irradiated murine heart mitochondria an increased production of endogenous ROS. We conclude that changes in the oxidative stress may be an important factor in the development of radiation-induced cardiac disease.

Modelling and experimental studies on adaptive response

Abstract

The ability of a low "priming" radiation dose to decrease the cell response to a subsequent higher "challenging" dose is termed adaptive response (AR). The main proposed mechanisms to explain AR are: increased efficiency of DNA repair, induction of anti-oxidant enzymes, alteration of cell cycle progression, changes in chromatin conformation. The model proposed by Curtis in 1986 that considers a modulation of the efficiency of DNA repair activity and of the level of anti-oxidant enzymes, starting from the framework of lethal-potentially lethal (LPL) model, was extended with the inclusion of the dynamical variables representing the efficiency of repair, the levels of radiation induced radicals and of anti-oxidant enzymes. In the simulation code particular attention was devoted to the induction of anti-oxidant enzymes as adaptive response mechanism, even if the more relevant mechanism remains the modulation of the repair efficiency, by which the cells processes the initial radiation damage. Furthermore, in order to describe different radiation qualities, the weight of the two factors (i) production of direct damage and (ii) production of free radicals have been made variable in the model. Our model is able to describe the protective effect of a priming dose. Moreover, in agreement with the literature data, the simulations show that the AR happens in a given priming dose and priming dose rate ranges only, and requires at least 4 hours to develop. In order to get more insights on the role of cell-cell communication as factors affecting the AR, experimental studies have been performed using sparse or confluent AG1522 cell monolayer. The results obtained after gamma-irradiation suggest that cell density is a crucial factor for observing an AR. The possibility of an AR induced as bystander effects and as a function of radiation quality is under study.

The α-particle irradiator at the ISS: a useful tool for low dose/dose rate studies

Esposito, Giuseppe; Antonelli, Francesca; Belli, Mauro; Campa, Alessandro; Simone, Giustina; Sorrentino, Eugenio; Tabocchini, Maria Antonella

Abstract

An α-particle irradiator has been developed for radiobiological studies at the Istituto Superiore di Sanità (ISS), Rome, Italy. It consists in a 200 mm diameter stainless steel chamber that can be equipped with alpha sources of different activities, allowing modulation of dose and dose-rate.

In the present configuration the irradiator, equipped with ^{244}Cm or ^{241}Am sources, provides a useful facility for irradiation of cultured mammalian cells with α-particles at dose rate in the range of 1-100 mGy/min, with spatial variations of less then ± 7%. Moreover, for both sources the photon doses calculated at the cell entrance are negligible compared to the α–particle dose. A further important feature of the irradiator is that the seal necessary to keep the helium gas inside the chamber is provided by the Mylar® base of the sample holder. This solution decreases energy degradation and eliminates the problems related to the estimation of the air layer between the exit window and the sample holder. Mylar®-based Petri dishes with different irradiation area were designed that can house permeable membrane inserts, mimicking the same geometry of commercial cell culture insert companion plates. Due to the limited residual range of α-particles, this feature is particularly valuable for co-culture experiments aimed at investigating bystander effects.

The small size allows the irradiator to be easily positioned into a standard CO2 incubator, avoiding use of "*ad hoc*" and separate devices for temperature control and for keeping the cells in the proper air/CO_2 mixture. This important feature makes it possible to carry out long term irradiation and/or post-irradiation incubation of cells in physiological conditions.

The irradiator has been already successfully used to continuously irradiate confluent primary human fibroblasts for up to 14 days as well as to investigate cellular and molecular end points in directly hit and in bystander primary human fibroblasts.

Using of radioprotectors and antidotes during the external radiation exposure and radionuclide incorporation

Zhorova, Elena; Kalistratova, Valentina; Nisimov, Petr; Belyaev, Igor; Korzinkin, Mikhail
A.I.Burnasyan Federal medical biophysical center, RUSSIAN FEDERATION

Abstract

We have studied experimentally on mice the compatibility of radioportectors (indralin and riboxin) and antidote drugs (potassium iodide and ferrocin) during the external gamma ray exposure and incorporation of ^{131}I and ^{137}Cs. We have shown that during combined action of both external and internal radiation factor radioprotectors and antidotes do not affect the efficiency of each other. In the absence of antidotes the radioprotectors alternates the exchange kinetics of the radionucildes. Application of the indralin alone increases the concentration of ^{131}I in the thyroid and kidneys and ^{137}Cs in the liver. Application of riboxin alone decreases the concentration of ^{137}Cs in organs and tissues at early times. The accumulation rate and concentration values for radioniclides in different organs depends on the time of radioprotector application.

Low-dose irradiation delays neuronal differentiation during early embryonic brain development

Abstract
Recent interest into the effects of low-dose ionizing irradiation on the human brain has been rather limited partly due to the fact that the adult brain (postmitotic neurons) is very insensitive to radiation damage. However, epidemiological studies on individuals who were exposed to ionizing radiation *in utero* after the atomic bombings in Hiroshima and Nagasaki, showed an increased incidence of mental retardation and behavioural defects. These defects were most outspoken when the irradiation occurred between weeks 8 and 15 of gestation, which is a critical time for human embryonic neuronal development. This suggests a higher sensitivity of neurons during their early differentiation.

Initial experiments in our laboratory showed that young adult mice that had been irradiated with doses (1 Gy) *in utero* at day 12 of gestation (E12) and at lesser extent with lower doses (0.2 Gy) at day 11 of gestation (E11) suffered from memory and learning defects as assessed by Morris Water Maze testing. In order to identify possible pathways involved in neurogenesis that could be affected by low-dose irradiation during early neuronal development, we irradiated pregnant mice at day 10 (E10) and 11 of gestation at 0, 0.1 or 0.2 Gy. Three hours after irradiation, embryonic brains were isolated for total RNA extraction and subsequent microarray analysis using the MoGene 1.0 ST Arrays (Affymetrix, USA).

In line with earlier observations, our analysis revealed upregulation of several genes involved in p53-responsive pathways in a dose-dependent way in both E10 and E11 irradiated embryos, indicating that these pathways are important for the response of the embryonic brain to low doses of irradiation. Furthermore, we observed that low doses of irradiation attenuate many functions of the normal physiological changes in gene expression, and in particular functions related to neurogenesis and synaptogenesis. This suggests that normal neuronal development may be delayed by low-dose irradiation. A significant amount of the affected genes involved in neurogenesis were predicted targets of the neuronal gene silencer RE-1 silencing transcription factor (REST) of which the expression in the embryonic brain decreases during differentiation. Interestingly, expression of REST was increased when E11 brains were

irradiated both at 0.1 and 0.2 Gy, while the expression of the REST target genes dose-dependently declined.

Together, our data indicate that the cognitive defects observed in young adult mice that had been irradiated *in utero* may be related to delayed neuronal differentiation due to a repression of neuronal genes following increased expression of the neuronal silencer REST. The exact mechanism behind the radiation-induced stimulation of REST remains to be elucidated.

Abstract

Thyroid cancer is one of the malignancies that are induced by radiation exposure as supported by epidemiological studies of different radiation-exposed groups such as: the survivors of atomic bombing in Japan, Marshall islanders exposed to nuclear test fall out and children undergoing head or neck radiotherapy or accidentally exposed to radiation like in Chernobyl accident. In these two last groups, the age was an important determinant of the radiation-exposure outcome.

Besides the age at the time of exposure, genetic susceptibility is one of the factors that can interfere in the development of thyroid cancer. The aim of the FP6 EU GENRISK-T project is to define the genetic component influencing the risk of developing thyroid cancer after exposures to low dose radiation as there is currently no accurate model of the dose response curve for thyroid cancer at low doses. To shed light on the cause-effect relationship between low radiation exposure, thyroid cancer and genetic background we used a mouse model with low sporadic rate of developing thyroid cancers. Such studies of genetic susceptibility would be impossible to conduct in humans due to the significant incidence of sporadic thyroid cancers and to the presence of "confounding" non-radiation induced tumours.

Balb/c mice were irradiated at 12 weeks of age with either low (25cGy, 50cGy, 100cGy) or high (4Gy) X-ray doses and sacrificed 4 hours, 9 or 18 months post-irradiation. Thyroid cancer was assessed via histopathology examinations to detect any morphological alteration in the thyroid tissue structure. In addition, we used immunohistochemistry to detect the level of some proliferation markers (PCNA and Cyclin-D1) that would be indicative of the proliferation status of the thyroid tissue.

Based on histopathology examinations of thyroid tissue sections from the 9 month mouse group, we found that no mice had developed thyroid tumors even at the highest doses. However, at a dose of 1 Gy, we found two specific cases, one of microfollicular hyperplasia and the other one of acute infiltrate with granulocyte. Regarding the immunolabeling with Cyclin-D1 and PCNA, we found a dose-dependent increase of these molecules significant from 25cGy onwards compared to the controls. Examination of thyroid tissue sections from the remaining mouse groups (4 hours and 18 months) is currently under progress. In parallel, high-throughput microarray technology is currently performed.

This work is financially supported by the EU Euratom programme (GENRISK-T : contract FP6-36495).

Identification of health risks in workers staying and working on the terrains contaminated with depleted uranium

Abstract

Objectives: This study investigated health risks in workers permanently or occasionally residing in the contaminated terrains by low ionizing radiation doses originated from ammunition containing depleted uranium (DU).

Methods: The studied population had been composed of two test groups (T-I, T-II) occasionally .exposed to DU, and two referent (R-I, R-II) groups not exposed at any time to DU. All of them had been evaluated for the following: complete clinical examination and blood count, presence of immature forms and blasts, leukocyte alkaline phosphatase activity and cytogenetic tests (lymphocyte karyotype and chromosomal aberrations). The probability of onset of the characteristic complete biomarkers – chromosomal aberrations, had been specially analyzed using logarithmic function of the Poisson regression.

Results: The difference between the groups was found in potential exposure to DU, which was not found in the reference group R-I and R-II being probable in the test group T-I and T-II. Estimated function of density of probabilities of Poisson distribution of the chromosomal aberrations in the test group T-II was drastically different from the corresponding distribution of the referent group R-I and to the somewhat lesser extent from the group R-II; Wilcoxon test exactly confirms presence of significant difference between the reference group R-II and test group T-II, $p<0.05$.

Conclusion: Damages of chromosomes and cells, had been used for the relative radiation risk assessment, were highest in the test group T-II of workers additionally occupatioanlly exposed to DU. Group of workers T-I, had been exposed to DU working on contaminated terrain, have had certain risks of cell and chromosome damages, and that risk was not greater than the risk to the referent group R-II of workers occupationally exposed to ionizing radiation.

Introduction

The research studies directly related to depleted uranium (DU) and its utilisation for military purposes are relatively rare in comparison to the studies related to the natural uranium.[1] Natural uranium is normal component of the lithosphere (in the region of Serbia, averagely ranging between 0.5–5g/1 ton of the soil) and it is composed of 3 mutually balanced isotopes: 234, 235 and 238 (depleted).[2 3]

Utilization of ammunition containing depleted uranium (DU) has resulted in contamination of the terrains after the bombing and continuous exposure of the living world to small ionizing radiation doses,[4 - 6] in addition to the already existing natural (e.g., uranium) and artificial (e.g., radio cesium) radionuclides. Local human population living and working in the contaminated environment has been also exposed to continuously increased radioactivity to DU.[7 8]

Two ways of DU transfer from the contaminated environment to humans are possible. Ingestion is the predominant form of DU contamination transfer from the environment to the human bodies in the post-conflict period. DU containing in the soil finds its different ways to be included in the food chain. Through contamination of underground and ground water, radionuclide comes into the plants and animals, to be finally consumed by human population.

The mechanism of internal contamination through inhalation is also possible. The aerosol forms are deposited in the soil, to be thereafter returned to the aerosol forms under the influence of wind or human activities, thus coming into the human body through inhalation.[3]

The study is aimed at identification of health risks in workers permanently or occasionally residing in the contaminated territory associated with contamination of the terrain by low ionizing radiation doses resulting from utilization of ammunition containing DU.

Methods

According to the health consequences monitoring program on the contaminated terrain proposed by the World Health Organization in 1996,[9] the studied population was evaluated for the following:

- Complete clinical examination;
- Complete blood count;
- Leukocyte formula and leukocyte/lymphocyte ratio;
- Microscopically observed morphological changes; presence of immature forms and blasts;
- Leukocyte alkaline phosphatase (L-ALP) activity;
- Cytogenetic tests (lymphocyte karyotype and chromosomal aberrations).

The method had been limited to analysis of the peripheral blood cells and cytogenetic analysis of lymphocyte karyotype as the most sensitive parameters of low dose influence, due to short time period (5 years after initial contamination) for clinical presentation of the possible diseases. Nevertheless this is sufficiently long time of period to expect positive findings of DU blood and urine values, regardless of the previous presence of absence of contamination.

Identification of environmental radionuclide presence effects on the body was performed indirectly, using analysis of blood count parameters: total count of red blood cells, haemoglobin concentration, mean corpuscular volume (MCV), platelets, white blood cells, leukocyte formula. Particular attention had been given to lymphocyte/leukocyte ratio, leukocyte alkaline phosphatase (L-ALP) activity, chromosomal aberration and lesion frequency, probability of onset of chromosomal aberrations.[8 10 - 12]

The venous blood was used for the blood cells count. An automatic counter counted erythrocytes, reticulocytes, platelets and leukocytes.

Blood smears stained with May-Grunewald-Gyms were studied through the optical microscope with immersion for the differences the white cell components, presence of morphologically altered blood cells, young precursors, immature forms and blasts.

Percentages of the white cell components of the blood (specific leukocyte shapes) were used to determine the absolute number of lymphocytes.

The capillary blood smears were stained for alkaline phosphatase using a modified Kaplow's method.[8] The colourless cytoplasm was marked 0, the mildly stained 1, the clearly stained 2, that with numerous granules 3, the intensely stained 4. Every hundred of counted cells was multiplied by the stain intensity index. The sum of these products makes the L-ALP score, i.e. the value of enzyme activity. Score of enzyme activity was presented as the international units (IU).

Chromosomes were observed in peripheral blood lymphocytes. Moorhead's method and conventional cytogenetic techniques were used for preparation of lymphocytes.[10 12] The cells in metaphase were microscopically examined in stained (2% M.G. Gyms) smears under immersion (magnification 100x16). The karyotypes of 200 prepared metaphase lymphocytes were analyzed, when the chromosomes were arranged in equatorial plane. The most characteristic aberrations were dicentric chromosomes. Ring chromosomes and acentric fragments were considered the equivalent to dicentric (chromosome aberrations – ca). Chromatid and chromosomal breaks and chromatid exchanges were designated as chromosomal lesions – cl. Lymphocytes having karyotype damages were marked as damaged cells – dc.[12]

The final studies were performed during 2004, five years after the initial contamination caused by DU radioactive ammunition used in 1999, and the whole five-year period had been taken into account.

Environmental follow-up measurements were performed on several occasions (2001, 2002 and 2004) applying the well known methods, according to which, the initial contamination of the terrain was determined.[5 6] The above evidenced chronically increased population exposure due to DU transfer into the biosphere.[8]

Measurement of the total drinking water alpha-activity resulting from both and DU (DU) from different sources (the total of 18 points) in the contaminated region revealed the values below 1 Bq/l, i.e., averagely 10mBq/l.

The specific DU activity in water samples ranges between 0.03 and 0.21Bq/l.

The total alpha-activity in the samples that are indicators of biosphere contamination (animals – rabbit; and plants – vegetation moss and lichen) ranges between 1340± 200 and 1740 ±260 (rabbit); moss 1370±210 and lichen 1860±280 Becquerel at the average.

The specific activity of the DU in meat (rabbit) was 2.3Bq/kg., while in plants it was 16-48 Bq/kg, averagely: 23± 5Bq/kg.

Cesium 137gamma activity as the indicator of radioactive contamination (even before the conflict) was lower, 0.16 ±0.05Bq/kg (rabbit) and 2.0± 0.1(vegetation).

Statistical analysis included two groups of subjects (table 1): reference group (without potential risk of exposure to DU) and test group (with potential risk of exposure to DU).

Reference group was designed to include two characteristic samples. The first reference sample was obtained from the population considered to be exposed one to natural phone without occupational exposure to ionizing radiation, physical or chemical mutagens. The group comprised young workers employed at the Federal Customs Administration, averagely aged 36.6 years, exclusively males with average 7.6 years of service and zero duration of exposure (group R-I).

As opposed of the above group, another reference group (R-II) was introduced composed of workers employed at the Institute of Oncology in Belgrade, who had been occupationally exposed to ionizing radiation effects. They were constantly subjected to dosimetric and medical control. Dosimetric control included monitoring doses by personnel dosimeters. The absorbed external doses of ionizing radiation to the bodies were measured by personnel thermo luminescent dosimeters (TLD) for the duration of occupational exposure (DOE). The TLD measurements were expressed in mSv, as equivalent doses. Average annual doses for the observed five-year period (1999-2004) have been presented (table 1).

Medical control included periodic check-ups based on the program proposed by the Ionizing radiation protection law,[11] incorporating ICRP recommendations, in order to get the insight into general health status, symptoms and clinical signs (complete clinical evaluation).

The group was averagely aged 42.7 years, with 28.6% of males, 15.6 years of service at the average and 23.8 years of occupational exposure at the average.

Test group comprised two specific samples. The first sample (T-I) included the workers employed at the Radio Television of Serbia from Belgrade, who had stayed, during the North Atlantic Treaty Organization (NATO) bombing of Federal Republic of Yugoslavia (FRY), on several locations including Pljačkovica hill near Vranje, the town in south Serbia ,in order to repair malfunctions on the TV antenna hit by DU ammunition. The group was not occupationally exposed to ionizing radiation before that. However, due to the nature of their occupation, the test group was exposed to increased electromagnetic radiation present on TV antenna. Their average age was 53.7 years, 95% of them were males with 28.7 years of service and 0 years of occupational exposure.

The second test group (T-II) included health care workers from Vranje, who were occupationally exposed to ionizing radiation since they have lived and worked in vicinity of the terrain contaminated with DU.

The workers have been constantly subjected to dosimetric and medical check-ups, similarly to R-II group.

The average age of the second test group (T-II) was 43.3 years, 59.6 % of them were males with 14.8 years of service and 11.1 years of occupational exposure.

Statistical methods

The samples were compared based on the observed parameters using the estimated Poisson distribution and the significance of the difference was tested using Wilcoxon rank sum test with 95% confidence interval and significance threshold at the level of 0.05. The probability of onset of the characteristic complete biomarkers was specially analyzed using logarithmic function of the Poisson regression and it was quantified by lambda parameter (λ).

Linear regression correlation analysis and Student's t-test comparison at the probability level of 0.05 were used.

Results

Measurements performed at the working sites confirmed that the exposure doses absorbed by the occupationally exposed medical professionals in Belgrade (group R-II) and Vranje (group T-II) were admissible and low. The readings were performed in the reference group II using thermo luminescent dosimeters (TLD) and the equivalent doses ranged between 1.00 mSv and 2.04 mSv (1.34mSv/year, at the average). As for the test group II, the mean annual dose was 2.08 mSv, with minimal and maximal values being 0.9 mSv and 4.98 mSv, respectively (Table 1).

The obtained results were tabularly presented in the context of the comparative pair analysis (table 1), both with negative clinical finding of the diseases associated with low ionizing dose radiation effects:

1. Referent group I (R-I) and test group I (T-I);
2. Referent group II (R-II) and test group II (T-II).

Table 1. Statistical parameters of reference and test groups with average annual dose.

Statistical parameters		Groups

(year)	σ	0	9.3	0	9.2
α_ci = 0.05	ci_lower	0	10.9	0	8.6
	ci_upper	0	16.7	0	13.7

TLD - term luminescence dosimeter
DOE - duration of occupationally exposure
μ – mean value – central tendency measure
σ – standard deviation
α_ci = 0.05; ci_ lower, and ci_ upper = confidence interval and deviation below and above it

The R-I/T-I pair differs with respect to average age and average years of service, in absence of any differences related to sex and years of exposure which has had zero value in both groups. The difference in sample size may be considered negligible. The difference was found in potential exposure to ionizing radiation – it was not found in the group R-I, being probable in group T-I because of exposure to DU.

As for the pair R-II/T-II, i.e., health professionals employed in the ionizing radiation zones in two cities (Belgrade and Vranje) in Serbia, no differences were found related to age, years of service, years of exposure, occupation (approximately the same level of qualification). However, the difference was found with respect to their age, mean value (1.34mSv/2.08mSv) and range of annual equivalent ionizing radiation dose over the observed five-year period (1.0-2.04 mSv/0.9-4.98mSv). The equivalent dose of ionizing radiation in T-II was by 55% higher from the dose in R-II as a consequence of the working site conditions. Workers from the test group II have head higher work load (greater number of radiological procedures per single shift). The difference between the groups was also found in potential exposure to DU, which was not found in R-II being probable in the T-II.

The analysis included blood count elements (Tables 2 and 3).

Table 2. Statistical parameters of reference and test groups of blood count.

Mean erythrocyte values were not statistically significant for probability threshold condition α=0.05 for the subject pair R-I/T-I (table 2). The subjects from the both groups were within the standard range for the erythrocytes. Mean haemoglobin values were also within standard range in the both groups. The difference was not found with respect to the criterion of falling of the measured haemoglobin values out of the standard interval. However, mean haemoglobin values were statistically different with respect to the probability threshold condition α=0.05.

The parameter of the erythrocyte volume (mean corpuscular volume -MCV) indicating haemoglobin content in the erythrocytes and cellular size and shape relevant for its function, was not statistically significant, likewise reticulocyte number. No significant difference was found between the subject pair R-I/T-I with respect to red blood cell line parameters (table 2).

Mean platelet values were not statistically different. All the subjects from both groups were within standard range for platelets (table 2).

As for the subject pair R-II/T-II (table 2) mean red blood cell values ranged within standard limits and the difference found between them cannot be considered statistically significant with respect to the probability threshold condition α=0.05. The difference was found with respect to the criterion of falling of the measured values out of the standard interval for erythrocytes. However, it cannot be considered statistically significant.

As for the test group (T-II) the total number of subjects found to be out of the standard range was 5 (11,9%) being in the reference group (R-II) 5 or 9,5%, with their deviation ratio of 1,2. Mean haemoglobin values were within standard limits and the difference between them cannot be considered to be statistically significant for the condition of probability threshold α=0.05. The difference was found with respect to the criterion of falling out of the measured values out of the standard interval for haemoglobin, MCV and reticulocytes and it must be considered statistically significant.

As for the test group T-II, there was significantly higher number of subjects who were out of the standard interval for haemoglobin when compared to the reference group, while the number of subjects out of the standard interval for MCV was significantly lower when compared to the reference group R-II (table 2). Therefore, red blood cell line generally cannot be considered significant in this pair as well with respect to the ionizing radiation influence. As it may be seen in table 2, no differences in platelet line were found for the test pair R-II/T-II. The mean values do not differ significantly while deviations from the standard interval are approximately the same in the both groups.

As for the pair comprising reference and test group R-I/T-I (table 3) mean values of white blood cells were within standard limits and they were not statistically different for α=0.05 (confidence 95%). Additionally, no difference was found with respect to falling out of the borderline values of the standard while blood cell interval, while deviation above the upper limits was almost the same in the both groups. No significant difference was found in number of lymphocytes. The average distribution in the leukocyte formula was 0.32% vs. 0.29% (table 3), while mean values of the absolute number of lymphocytes were 2.1± 0.5 vs.1.8±0.5. The difference was found with respect to the criterion of deviation of the measures values from the standard interval for lymphocytes. As for the reference group I, the number of subject falling out of the standard interval was significantly lower (12%) in comparison to the test group I (45%).

As for the R-II/T-II pair, no difference was found in white blood cell count, being 16.7% for the reference group and 17% for the test group, meaning that this difference in deviation was not significant. Significant difference was not found with respect to other elements of the leukocyte formula. Basophiles were not evidenced. Moreover, no immature cells or blasts were observed.

Although the comparison between the groups revealed no statistical difference, deviation from the standard intervals for white blood cells and lymphocytes was still present, however it was approximately the same in the both groups (reference II and test II), which included health care professionals.

In comparison to the reference group I (free of ionizing radiation risk) the deviations are prominent (tables 2 and 3).

It has been known that, in addition to alteration of white blood count, ionizing radiation **also** influences leukocyte alkaline phosphatase activity changes as well as the changes of the natural proportions of the leukocytes formula (table 3). As for the L-ALP activity, the changes were characterized by increased activity and they cannot be considered statistically significant, particularly owing to the fact that they follow the increase in white blood count, which is normal phenomenon.

Due to specific lymphocyte sensitivity, lymphocyte-related changes are also particularly characteristic with respect to their number and correlation with white blood cells as well as with respect to chromosomal aberrations in their nuclei.

The correlation analysis of leukocyte and lymphocyte relation was performed for all subjects from the reference and test groups. The analysis of linear regression of the relation between leukocytes and lymphocytes gave regression coefficient for the reference and test groups R-I, R-II, T-I and T-II: 0.76, 0.83, 0.90 and 0.78, respectively. The results of comparison of the linear regression parameters using parametric Student's t-test with significance threshold of 0.05 did not show any difference. In none of the cases statistical difference of white blood cells and lymphocyte proportions was identified for the probability level of 0.05.

Presence of chromosomal aberrations was analyzed in the reference and test groups (Tables 4 and 5).

alfa=0.05 - Confidence 95%; probability (p) at 0.05

Observation of the first pair from the groups R-I and T-I evidenced presence of chromosomal aberrations (table 4.) in the both group. Poisson distribution parameter λ differs, however the corresponding confidence intervals are crossed over for the significance threshold α=0.05, which indicates that the difference is not statistically significant. The former is confirmed by Wilcoxon test of matching of the estimated parameters of the Poisson distribution. The former indicates the presence of tendency toward chromosomal aberrations (higher risk of their onset) in the group T-I in comparison to the comparative reference group R-I. However, the difference in incidence of chromosomal aberrations is not significant, at the average (tables 4 and 5), although the frequency of chromosomal aberrations (table 4) is higher in the group T-I (0.21% vs. 0.08%) in comparison to the reference one.

The equivalent analysis for the test pair R-II and T-II shows similar tendencies, however they are more prominent and exceed the limits of statistic tolerance in testing of differences (do not belong to the same set - tables 4 and 5). Estimated function of density of probabilities of Poisson distribution of the chromosomal aberrations in the test group T-II is drastically different from the corresponding distribution of the reference group R-I and to the somewhat lesser extent from the group R-II; Wilcoxon test exactly confirms presence of significant difference between the reference group R-II and test group T-II, $p<0.05$ (tables 4 and 5).

The difference in chromosomal aberrations is observed between the reference groups R-I and R-II which is expected since the groups are mutually different with respect to the occupational exposure to low ionizing radiation doses (table 4). Reference group II has significantly higher incidence of the unspecific chromosomal lesions ($p=0.0012$) in comparison to R-I group, as well as significantly higher number of the damaged lymphocytes for that reason (damaged cells – dc, p=0,0054 Frequency of chromosomal aberrations characteristic for radiation is increased (0.17% vs. 0.08%) however the increase is non-significant ($p=0.13$, Wilcoxon test). Poisson distribution parameter λ is higher (0.33 vs. 0.16) in the group R-II. This indicates that the probability for onset of chromosomal aberrations is higher in R-II in comparison to R-I group (tables 4).

The results of the chromosomal aberration analysis indicate that the test group I, which has been temporarily occupationally exposed to the effects of low environmental ionizing radiation doses as well as to non-ionizing radiation, had been different from the groups R-I and T- II being at the same time the most similar with the results of the health-related risk analyzes to the referent group R-II, which was chronically occupationally exposed to ionizing radiation.

Group T-I has been significance low chromatid lesions than R-II ($p=0.0022$, table 5). Frequency of chromosomal aberrations characteristic for radiation is increased (0.21%) and Poisson distribution parameter λ is higher than in referent groups (λ=0,42), but they are no significant.

Test group II, despite test group I, had been significantly different (confidence 95%; table 5) from the both of referent groups (R-I and R-II) taking into consideration chromosomal aberrations in lymphocytes ($p<0.01$) and damaged cells ($p<0.05$).

Accordance to logarithmic function Poisson regression, complete biomarkers (chromosomal aberration – ca) showed that relative risk (RR) in group T-II was 4; in group T-I is 2 and in group R-II it was 3, while in group R-I exposed only nature radiation, relative risk had been 1.

Discussion

Identification of field contamination resulting from application of radioactive ammunition risks on the health on individuals living and working on the contaminated territory is significant for studying of the admissible levels of absorbed radiation of different population groups, particularly individuals occupationally exposed to the ionizing radiation as well as their patients and general population.

The obtained results indicate the presence of the objective risk if exposure of workers living and working on the known contaminated terrain on the south of Serbia as a result of DU originating from the military conflicts that took place on the terrain in 1999.

DU ammunition has become a source of environmental contamination.[4 5 6] On one hand, it is superimposed to the natural phone, while on the other, it penetrates to the soil and ground water to come thereby into the biosphere. Thus, DU becomes a residual radiological risk for human life in the course of their life on the affected terrain.[13] As for the non-occupationally exposed population, each dose above 1mSv/1year is conspired to be a significant dose. Low environmental doses are cumulated during the stay in such regions and within five-year period, if they are above 1 mSv per year, they may reach 6mSv, which represents the upper limit for the occupationally exposed individuals in the category B zone.[11] For this reason, the individuals working and living on the contaminated territories are subjected to health monitoring.[3 6 9]

The analysis included blood count elements, as the most sensitive parameters associated with the reaction of the organism to ionizing radiation effects, which may be monitored and point out to the early signs of the diseases using simple techniques. Blood element differences were observed between the studies groups, however they were insufficiently specific or statistically significant, and thus the analyses were not sufficient for risk assessment.

Lack of specificity of the blood count elements as health indicators for assessment of ionizing radiation risk points out to the need of analysis of chromosomal aberration presence.[12 - 14]

As for the workers living in a wider region with verified contaminated zones who are occupationally exposed to low doses of ionizing radiation, statistical differences were identified upon their comparison with the referent group of the occupationally equivalent subjects, particularly with respect to onset of the chromosomal aberrations. For that reason, the number of damages lymphocytes is higher, which is essential for their organism defence role.

No statistically significant difference was found with respect to unspecific, single-stranded chromatid changes (lesions), which do not form chromosomal figures (dicentrics). Most probably, they are also the result of other causes, in addition to radiation (chemical metal toxicity, habits, smoking etc.) and they may influence karyotype instability.[12]

Additionally, it has also been evidenced that onset of these lesions on DNA is accompanied by the same number of the stable aberrations (deletion, inversion and translocation), which indirectly suggests the probability of onset of mutations (due to stable aberrations fixed in the cell division).

Test group II (workers in the radiation zone in the contaminated region in the southern Serbia) had been composed of two groups of subjects. The first one was composed of individuals at risk of uniform low-dose irradiation on their working sites, while the second one comprised the individuals at risk of contamination with DU. For this reason, the radiation risk was the highest in this group and it has been quantified by the highest probability of onset of chromosomal aberrations and the highest frequency of chromosomal aberrations and damaged lymphocytes. Damaged lymphocytes lost function because since 50% of them tend to disappear after the initial divisions, and before division ten, all the remaining damages ones also disappear.[8 10 12 14]

Only referent group I was free of any of the 2 above mentioned risks – radiation at the working site or radiation at the contaminated terrain. Therefore, it is clear why the referent groups are also mutually different, since the referent group II had been composed with the individuals chronically exposed to low ionizing radiation doses at their work sites. Nevertheless, the difference was found between the reference groups I and II with respect to chromosomal lesions, i.e., higher risk expressed as probability of onset of lesions was found in the referent group II composed of the occupationally exposed health care professionals from Belgrade. The group was also proved to have higher frequency of unspecific lesions in comparison to the test group I, in which occupational exposure was not continuous but only occasional during repair works on the TV antenna on the contaminated terrain. This group was not exposed to increased radiation and did not have relative risk due to exposure to DU. It was not significantly different from other referent groups with respect to other parameters, however if was different from the test group II composed of subjects continuously staying in the vicinity of the contaminated region.

Accordingly, statistically significant differences related in comparison with the referent group had not been observed, although changes values of certain parameters were evidenced in workers who had lived out of the contaminated regions but who were occupationally exposed for some time due to their stay in the contaminated zone performing their professional tasks.

Therefore, life in the contaminated region is associated with higher radiological risk, particularly for those who work in the ionizing radiation zone and probability of potential occupational diseases may be higher and thus workers rights related to occupational diseases, treatment and assessment of their working abilities should be considered. Additionally, the criteria for recognition of radiation-induced occupational diseases must be also reconsidered in the new circumstances associated with increased risk of environmental contamination as well.

The above fact points out need for further investigations of the association between occupational exposure to the ionizing radiation effects and effects of the underlying environmental contaminants, particularly within the context of the increased relative risk that way quantitatively verified in this study. Accordingly, the aspect of legal regulations in the fields of occupational protection should be also reconsidered, since the situation is new and uncovered by the current regulations. This is particularly important for the health risks of medical professionals in the ionizing radiation zone in southern Serbia, having in mind the fact that their work load is higher due to higher morbidity rate among the population in the underdeveloped region.[9 15]

Conclusions

For all the above, the latent period before onset of the disease is prolonged, and thus the consequences of the DU effects are yet to be expected. The former points out to the need of reassessment of the admissible level of radiation in case of occupational exposure. Decrease of occupational exposure (admissible dose level) may suppress the influence of the environmental doses, since natural phon is increase by superimposed contamination with DU.

Increased health risk of the workers exposed to ionizing radiation caused by profession and additionally by contamination from the contaminated environment by DU, has become because of cumulative radiobiology effects of small doses over the continual exposition and it depends to the time of period of exposure duration.

Current challenges for radiation protection in medical X-ray and molecular imaging

Mattsson, Sören
Lund university at Malmö, Medical radiation physics, Malmö, SWEDEN

Abstract
The increasing radiation exposure from medical diagnostic procedures is becoming a subject of concern and social interest and is given increased attention by health professionals, authorities and manufacturers. Also patients are now more and more concerned about their exposure situation. New imaging technologies that use x-rays or radioactive materials are continuously developed. These include faster CT-scanners, new interventional techniques, increased use of positron emission tomography (PET), and digital imaging techniques. The techniques are often combined into a single investigation, such as PET/CT and SPECT/CT. As the availability and quality of radiological imaging methods has continued to grow, increases in image quality rather than a reduction in patient dose continues to characterise modern practice. The benefits of the new techniques are so rewarding that a tendency to overuse the technology has occurred. The aim of the presentation is to inform about developing technologies and clinical techniques, and their associated potential radiation risks to patients and staff. The presentation also includes a discussion on tools for optimising investigations and improved dose management, and most importantly, ways to create greater awareness of the physicians prescribing the examinations. It is important that the advances in imaging technology also provide increased medical benefits to large numbers of patients, while maintaining the efforts to keep unnecessary exposure to a minimum. Therefore, persons educated and trained in radiation protection have to be fully involved in planning, dose measurement and optimisation and have to initiate necessary radiation safety training for the medical staff, including those who refer the patients for an investigation. Strict guidelines need to be developed so that referring physicians carefully weigh the benefits against the potential risks and base their decisions on medically relevant data.

Justification of medical exposure in diagnostic imaging – a way forward

Abstract

The network of Heads of European Radiation Control Authorities (HERCA) has appointed a working group (WG6) to test the feasibility of the European Commission guidance on estimating population doses from medical x-ray procedures, Radiation Protection Report No 154. Fourteen European countries have collected frequency and/or dose information for at least the "TOP 20" examinations that in RP154 were identified as most contributing to the total collective effective dose. The national surveys were aimed to establish updated national information on doses representative for current apparatus and scan techniques. Around 2002, the collective effective dose for the "TOP 20" examinations ranged from 303 to 1421 mSv per 1000 population in Europe. In 2008 the figures still range from 331 to 1521 mSv per 1000 population. However, the contribution to the "TOP20" from conventional radiography examinations has decreased, while the contribution from CT now is in the range 46 – 81%. The challenges and uncertainties in estimating frequency and dose recognised in RP154 were still present. A need to update the "TOP 20" list was recognised.

Introduction

The use of ionizing radiation in diagnostic radiology makes a major contribution to population dose. The introduction of new modalities such as multi-detector computed tomography has tended to increase the doses; it is therefore of concern for the radiation protection authorities to follow trends in the medical use of radiation. An EU-funded project called DOSE DATAMED (2004 - 2007) was set up to develop harmonized methods for future surveys of population exposure from medical x-rays. The project group was recruited from radiation control authorities or expertise institutes in ten European countries. The guidance was published in 2008 by the European Commission as report No 154 in the Radiation Protection Series [1]. Since then, the network of Heads of European Radiation Control Authorities (HERCA) has appointed a working group (WG6) to test the feasibility of RP154 for ongoing European surveys. Some of the countries are performing full national surveys based on the identification and frequency counting of 225 specific x-ray examinations or 70 broader categories of examinations. Others are testing the methodology based on the set of 20 examinations identified as the ones contributing most significantly to collective effective dose. Pitfalls and challenges associated with the different approaches will be identified. All countries are collecting dose values for at least the “TOP 20” examination types, to establish updated national information on doses representative for current apparatus and scan techniques. Around the turn of the century, the collective effective dose for the “TOP 20” examinations ranged from 303 to 1421 mSv per 1000 population in Europe. Comparison of the collective effective dose averaged over the population based on the frequency in 2006-2008 and updated dose information from the “TOP 20” examinations will be presented, looking for trends and information from more European countries.

Material and methods

How to count the “TOP20” examination types” in 2008

Detailed descriptions of the 20 types of examination that were consistently found to be amongst the highest contributors to the collective effective dose in the ten DOSE DATAMED countries, the ‘Top 20 Exams’, are provided in RP154 Appendix 1 Table A1 [1]. They are sorted according to imaging modality:

- PLAIN RADIOGRAPHY (without contrast media): 1. Chest/lung, 2. Cervical spine, 3. Thoracic spine, 4. Lumbar spine, 5. Mammography, 6. Abdomen and 7. Pelvis & hip
- RADIOGRAPHY/FLUOROSCOPY (mostly involving use of contrast media): 8. Barium meal, 9. Barium enema, 10. Barium follow, 11. IVU (Intravenous Urography) and 12. Cardiac angiography
- COMPUTED TOMOGRAPHY (CT): 13. CT head, 14. CT neck, 15. CT chest, 16. CT spine, 17. CT abdomen, 18. CT pelvis and 19. CT trunk
- INTERVENTIONAL PROCEDURES: 20. Coronary angioplasty (PTCA)

The recommended definition of an x-ray examination is [1]: ‘*An x-ray examination or interventional procedure is defined as one or a series of x-ray exposures of one anatomical region/organ/organ system, using a single imaging modality (i.e. radiography/fluoroscopy or CT), needed to answer a specific diagnostic problem or clinical question, during one visit to the radiology department, hospital or clinic*’.

Table 1. Overview of the national frequency survey methods.

Country	National source of information	No of hospitals and entities in the survey (%)
Belgium	National Health Insurance Institution code system (RIZIV / INAMI): about 130 (double - quadruple coded) types of diagnostic and/or interventional X-ray procedures (dental X-ray excluded)	All (7 university hospitals, 61 public hospitals & 135 private hospitals), medical institutes, and practices (100%)
Denmark	Part of "Sundhedsvæsenets Klassifikationssystem" (SKS) www.medinfo.dk/sks. 206 x-ray codes	All public hospitals report examinations to SKS (100%)
Estonia	Estonian Health Insurance Fund code system: 73 types of diagnostic and interventional X-ray procedures, including CT and dental X-ray	All
Finland	The national code system; About 800 codes	Covered about 97%
France	CCAM, 224 codes (including radiography, CT and diagnostic IR)	
Germany	Health insurance companies (codes designed to meet the German system of reimbursement)	10% of hospitals, 100% of practices (tot.:70% of *exams*)
Iceland	The codes are based on old Swedish codes which have been modified over the years.	All
Lithuania	The Lithuanian Health Information Centre provides only total numbers. For radiography/fluoroscopy the distribution in UNSCEAR 2000 (Table 30) was used to establish the TOP 20 numbers, while the CT numbers were gathered from hospitals.	
Netherland	Radiological code system (CTG)	All (university hospitals, regular hospitals, private clinics, screening)
Norway	Radiological code system (NORAKO), The Norwegian association of radiologists, version 2008 178 codes for X-ray based exams (302 in total)	ALL (100%): 50 hospitals, 25 private X-ray institutes, 10 private hospitals & screening
Sweden	Classification of radiological procedures from the National board of Health and Welfare (SoS 1991) No of codes: 299	20 entities (hospitals, health care centres) corresponding to 20 % of the whole country
Switzerland		Small pilot, survey runs now
UK	National Standard Representation of Clinical Imaging Procedures. No of procedures: 3220	

Most countries used a kind of radiological code system to collect frequency data (Table 1). These coding systems are in many countries also used for reimbursement purposes, and are not directly reflecting the number of examinations in the way they are defined in RP154. Each country had to develop a method for the translation of code frequencies into actual numbers of examinations. Some countries collected information from only a part of the activities and scaled up to reflect the whole country, while other countries collected frequency data from all hospitals and x-ray institutes. Lithuania had only the total number of radiography/fluoroscopy available but used the distribution between various types of examinations provided by UNSCEAR [2]. Switzerland is running a national survey now; the data are preliminary scaled up from a small sample, also considering the distribution in the Swiss 2002 data. Estonia and Luxembourg are also currently running their surveys and may provide more data in near future.

The dose survey methods

The majority of the dose figures were collected from 2006 – 2008, while some countries have used dose data from 2000 – 2006. The dose data were in most countries collected from calibrated x-ray equipment by appointed professionals in the hospitals and sent in to the authority. In most countries the dose data were collected in terms of the “practical dose quantities” as identified in RP154; the dose-area product (DAP) for radiography and fluoroscopy, mean glandular dose (MGD) for mammography, and dose-length product (DLP) for CT examinations, i.e. in these countries the national dose figures were based on the same data material as used for the establishment of national diagnostic reference levels. Here, the conversion coefficients from the practical dose quantities to effective dose, based on the ICRP 60 definition and tissue weighting factors [3] were used. On the other hand, some countries (Finland, France, Switzerland) based their national dose figures on the use of various kinds of software that calculate the effective dose based on exposure and scan parameters. In Finland for example, they used PCXMC (STUK, Finland) to calculate the effective dose for plain radiography, both according to ICRP 60 [3] and ICRP 103 [4].

Results

Trends in frequency in X-ray based radiological examinations during the last six years

The frequency for the sum of the “TOP20” examinations in 2008 is presented in Table 2 with comparison to 2002 for the countries that contributed to RP154 [1].

Table 2. No exams/y/1000 population in 2008 compared to 2002 for the “TOP 20” [1].

Participating country	2002	2008	Change (%)
Belgium	790	690	– 13 %
Denmark	279	327	+ 17 %
Estonia	n.a.	354	
Finland	n.a.	432	
France	503	572	+ 14 %
Germany	723	612	– 15 %
Iceland	n.a.	481	
Lithuania	n.a.	761	
Luxembourg	572	n.a.	
Netherland	335	341	+ 2 %
Norway	507	464	– 9 %
Sweden	355	382	+ 8 %
Switzerland	444	570	+ 28 %
UK	305	335	+ 10 %
Average (min – max)	481 (279 – 790)	487 (327 – 761)	

On average, the “TOP20” examination frequency has been quite stable during the last six years, and it can be noticed that Belgium and Germany that counted for the highest frequencies in 2002 have lower frequencies now. The frequency for each of the “TOP 20” examination types for the countries in the survey is presented in Table 3. Typically, there is only a factor 2 – 9 between the highest and lowest frequency among the countries in the use of plain radiography, while there are huge differences in the use of fluoroscopic examinations; some countries have almost stopped using those procedures. There are also huge differences in the use of CT.

Table 3. The range in examination frequency normalised to per 1000 population for the “TOP 20” examination types as defined in RP154 [1] in fourteen European countries anno 2008.

TOP 20 Exam type	Specific exams included in ‘Exam type’	Average frequency	lowest frequency	highest frequency
1. Chest/lung	Lungs & ribs, Thoracic inlet	182.7	104.7	428.1
2. Cervical spine	Cervical spine	16.3	6.5	45.3
3. Thoracic spine	Thoracic spine	10.5	4.4	20.6
4. Lumbar spine	Lumbar spine Lumbo-sacral joint Sacro-iliac joints Sacrum & coccyx	33.8	14.9	59.5
5. Mammography	Symptomatic & Screening	61.3	21.7	85.0
6. Abdomen	Abdomen (plain film)	22.3	0.7	56.0
7. Pelvis & hip	Pelvis (one or both hips)	53.7	38.2	89.9
8. Ba meal	Ba meal (stomach & duodenum)	2.0	0.04	7.1
9. Ba enema	Ba enema (colon)	2.4	0.2	12.5
10. Ba follow	Ba follow (small intestine) Small bowel enema	0.8	0.1	1.8
11. IVU (Intravenous Urography)	IVU (kidneys, ureter and bladder)	2.4	0.1	11.4
12. Cardiac angiography	Coronary angiography Left or right ventriculography	5.2	1.7	15.0
13. CT head	Head, brain, facial bones	32.6	18.7	58.0
14. CT neck	Soft tissue in neck, cervical spine	6.9	0.8	34.4
15. CT chest	Chest/thorax	18.8	4.8	32.6
16. CT spine	CT of lumbosacral spine	9.0	0.9	33.7
17. CT abdomen	Abdominal organs	23.9	3.6	44.8
18. CT pelvis	Pelvic bone &/or organs	4.8	0.6	24.5
19. CT trunk	CT of chest, abdomen & pelvis. CT of thoracic/ abdominal aorta	19.1	0.5	106.0
20. Coronary angioplasty (PTCA)	PTCA	2.3	1.3	5.8

Trends in radiation doses per patient examination during the last decade

Effective dose values for each of the “TOP 20” examination types is presented in Table 4, all referring to ICRP 60 tissue weighting factors [3]. There are huge variations in average dose figures between reporting countries also in 2008. The factor between the highest and lowest country average dose figures are in the range 2 – 68. The variations in CT doses seem to be somewhat lower, a factor 2 - 5 between the countries which have submitted data recently. There are also considerable variations in doses regarding angio- and interventional procedures, cardiac angiography and PTCA.

The effective dose for all plain radiography examinations seems to have decreased during the last six years. This tendency also applies to the fluoroscopy examinations (except barium enema). On the other hand, the effective doses in CT seem to have been quite stable, even though a slight decrease in dose is seen for CT of chest and abdomen.

Table 4. The range in national average effective dose values for the “TOP 20” examination types in 2008 compared to similar values reported in 2002 [1].

TOP 20 Exam type	Effective dose 2002 (mSv)	Range (min – max)	Effective dose 2008 (mSv)	Range (min – max)
1. Chest/lung	0.12	(0.02 – 0.30)	0.09	(0.01 – 0.29)
2. Cervical spine	0.27	(0.02 – 1.10)	0.23	(0.02 – 1.10)
3. Thoracic spine	1.01	(0.30 – 3.50)	0.81	(0.30 – 3.50)
4. Lumbar spine	1.86	(0.40 – 4.10)	1.32	(0.40 – 4.10)
5. Mammography	0.33	(0.10 – 0.60)	0.20	(0.03 – 0.42)
6. Abdomen	1.53	(0.40 – 3.60)	1.19	(0.40 – 2.93)
7. Pelvis & hip	0.89	(0.40 – 2.00)	0.70	(0.25 – 2.00)
8. Ba meal	7.71	(2.30 – 18.50)	6.38	(2.00 – 18.50)
9. Ba enema	8.60	(5.40 – 15.90)	9.83	(2.60 – 25.73)
10. Ba follow	10.48	(2.20 – 42.30)	9.08	(0.63 – 42.30)
11. IVU (Intravenous Urography)	4.03	(2.10 – 7.90)	2.91	(2.10 – 4.25)
12. Cardiac angiography	9.12	(4.30 – 12.00)	7.15	(1.20 – 14.40)
13. CT head	2.07	(1.20 – 2.60)	1.95	(1.20 – 3.05)
14. CT neck	2.53	(1.30 – 3.40)	2.70	(1.10 – 5.00)
15. CT chest	8.29	(4.10 – 11.50)	5.35	(3.50 – 7.37)
16. CT spine	5.47	(2.90 – 9.10)	7.04	(3.10 – 11.81)
17. CT abdomen	12.54	(8.40 – 18.60)	10.28	(5.30 – 17.90)
18. CT pelvis	8.73	(7.00 – 10.60)	7.65	(0.80 [i] – 14.48)
19. CT trunk	13.54	(7.90 – 24.40)	15.80	(8.40 – 33.40)
20. Coronary angioplasty (PTCA)	14.05	(9.00 – 23.0)	15.04	(2.84 – 23.00)

[i] The lowest dose value is due to that CT pelvis was interpreted as CT pelvimetry

Trends in collective effective doses per 1000 population (limited to the TOP20 exams)

The collective effective dose per 1000 population from the list of "TOP20" examinations has on average been increasing from 744 to 864 mSv for the group of countries participating in the two surveys around 2002 and 2008. Furthermore, there are still major differences in 2008 in the total collective effective dose per 1000 population between the countries, the variations being about the same as in the previous survey; 331 – 1521 mSv per 1000 population. France, Netherland and Switzerland are countries where the collective effective dose seems to have increased significantly, more than expected from the increase in frequency (Table 2).

Table 5. Trends in the collective effective dose per 1000 population in 12 European countries in the last decade, based on twenty identified examination types most contributing to S around the year 2000 [1].

Example of table	**DOSE DATAMED [1]**		**New surveys based on the year 2006/08**	
Participating country	**S/y/1000 pop [mSv] for the "TOP 20" i)**	**Year of survey data ii)**	**S/y/1000 pop [mSv] for the "TOP 20" iii)**	**Trend in S from previous survey to current situation (%)**
Belgium			1387.7	
Denmark	351	1995	454.9	+ 30%
Finland	500 iv)	1995	346.1	
France	597	2002	1110.1	+ 86%
Germany	1421	2000	1521.5	+ 7%
Iceland			1276.1	
Lithuania			466.6	
Luxembourg	1388.5	2002	n.a.	
Netherland	303.3	2002	477.0	+ 57%
Norway	942.2	2002	942.9	0
Sweden	550	1995	591.1	+ 7%
Switzerland	831	1998	1366	+ 64%
UK	312.8	2001	331.2	+ 6 %
In average	**744**		**856**	**+ 12 %**
Range in TOP20	**[303 – 1421]**		**[331 – 1521]**	

i) From APPENDIX 3 to ANNEX 1 – DD Report 1 in Radiation protection N° 154 [1], In the table, data in square "TOTAL 1-20 (excl. 'All' groups)" was selected

ii) The year when the frequency of the examination was counted in last survey. The dose data could be older in some countries.

iii) Current surveys done according to European guidance RP No 154 [1] based on frequency from 2008 (except German data from 2006 and French from 2007) and updated national dose figures.

iv) The data includes all examinations and is therefore not directly comparable to the "TOP 20"

Contribution of examination types to the collective effective dose in 2008

The contribution to the collective effective dose from the “TOP 20” examination types sorted according to the imaging modality is presented in Figure 1. We do not yet have the values of total collective effective dose from all countries in the survey, and cannot assume that the distributions of the modalities within “TOP20” are representative for all examinations. It is still interesting to notice that CT examinations now account for 46 – 81% of the “TOP20” collective effective dose, while the corresponding numbers in 2002 were 33 – 72%, i.e. the contributions from CT are higher now. On the other hand, the collective effective dose from plain radiography and radiography/fluoroscopy contributed 17 – 51% to the “TOP20” total in 2008, while the corresponding numbers from 2002 were 16 – 47% for the different countries (same range even though average has changed).

The only interventional procedure included in “TOP20” is PTCA. Obviously many other interventional procedures contribute to the total collective effective dose. The collective effective dose from PTCA ranged from 6.8 to 55.5 mSv per 1000 population between countries in 2008. The reported figures also represent a major increase from 2002 to 2008 in some countries. This might be due to some kind of underreporting of frequency (Table 3) or misinterpretation of the dose (Table 4).

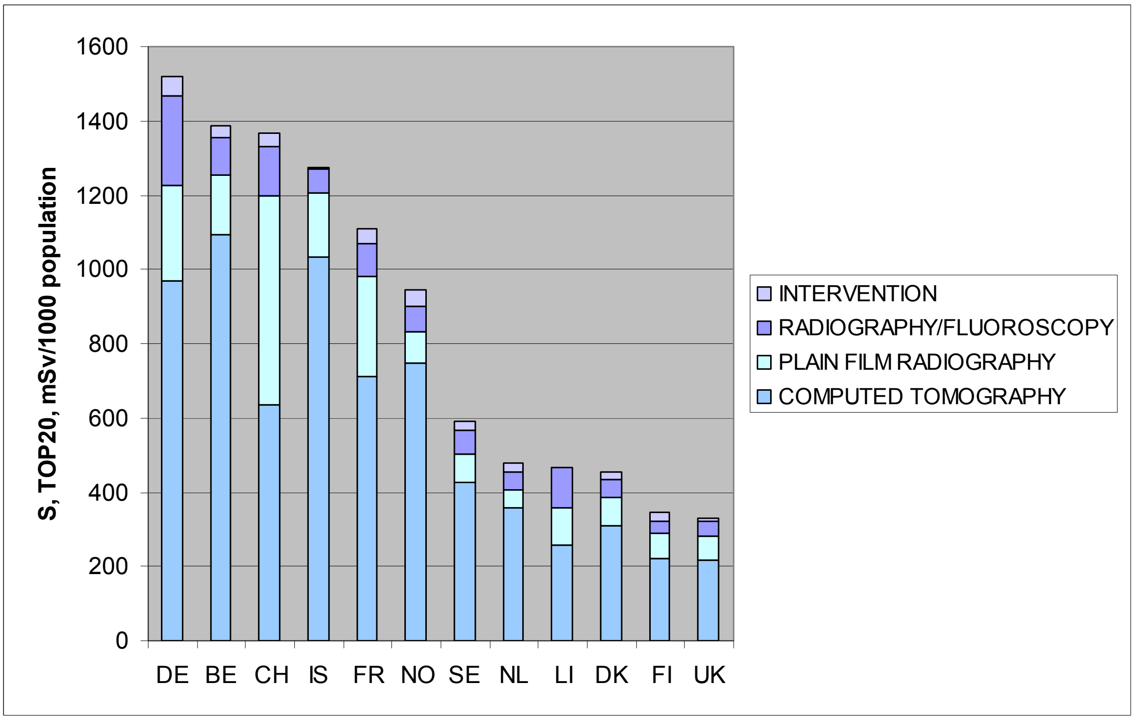

Fig. 1. Contribution of collective effective doses from different imaging modalities to the total from all “TOP20” examinations for twelve European countries anno 2008.

Discussion

All the participating countries tried to collect data as reliably as possible paying attention to the recommendations given in RP154 [1]. However, the conditions for collecting data differ between countries, and this was also foreseen in ref [1] where alternative procedures with different levels of ambition are presented. Of course that means that the uncertainties will vary with the methodology applied. There are a number of problems and pitfalls in the process of assessing the data required which are not always recognised or could not be avoided.

In the estimation of frequencies e.g. the following difficulties have to be coped with: The identification of all examinations belonging to the TOP20 categories is not straight forward. The coding system sometimes comprises the evaluation of an already performed examination, there can be local variations, there is not specified how examinations of pairs of organs are counted (one or two examinations). These problems can be overcome by checking all the details in the files with examinations and e.g. eliminate the merely administrative codes, but this can be very time-consuming.

The source from which data are retrieved has also impact on the quality of data. The majority of the participating radiation safety authorities are entitled to request data on frequency and dose from the health care sector. With the RIS/PACS rather complete data can be retrieved, but there is the risk for missing those examinations not connected to the normal RIS. This could be e.g. mammography or PTCA performed outside the x-ray department. Others have received data from the insurance companies. There the coding system usually is not well adapted to the needs for this collection of data and the registers will normally cover only a special selection of all patients.

The dose assessment could be even more cumbersome. Mostly the average dose assessed in a country for a particular examination is based on just a few measurements in some x-ray departments. Surveys have shown that the average patient dose for a specific examination can vary with a factor of 10 and more between different x-ray rooms, and taking the figures for just a few rooms will not necessarily reflect the average for the whole country.

Each of the TOP 20 categories may comprise several types of examinations, with different radiological techniques and different typical doses. However, mostly one type will constitute the vast majority of examinations within one category and using the same dose in the estimates for the remaining examinations as for the dominant one will only introduce a small error.

Despite all these possible pitfalls the data are reliable, certainly more than the data for 2002 with which comparison is done. It takes time and experience to learn how to deal with the problems of e.g. a coding system with ambiguities or assessing examinations to the TOP 20 categories. This can be achieved (and was in this study) by checking the retrieved data in detail and i.e. correct for wrong affiliation or searching alternative pathways to get the missing data.

To the results, both the examination frequency and the collective effective dose for the “TOP 20” examinations have slightly increased during the last six years. We can however not conclude with respect to the total for all x-ray based examinations. Some of the survey countries have collected information from the whole range of examinations; it has to be analyzed further how new procedures like CT colonoscopy, CT urography and CT angiography affect the total frequency and collective dose in a country. The material should be analysed in more detail, also with respect to single examinations and groups of examinations. It is for example recognised that the frequency of CT examinations has increased significantly during the last six years, but this trend has been offset by the decrease in plain film and fluoroscopy examinations. The trends in CT doses will also be analysed further, for a better understanding of how the technological development influence the doses.

Conclusions

The HERCA WG6 network consists of countries with certain traditions of population dose surveys. The radiological systems used to categorize imaging procedures in the fourteen countries have many similarities, but are very different in detailing level. The problems and uncertainties in using them for the estimates of examination frequency are recognised. Still, all participating countries managed to apply the RP154 methodology for estimating the frequency for the twenty examinations identified as the "TOP 20". Most countries also have running programs to collect doses from the radiological departments in terms of RP154 "practical dose quantities", i.e. it was possible to establish country mean values for the effective dose for the "TOP 20" examinations by means of the provided conversion coefficients and assess collective effective doses from those "TOP 20" examinations, or alternatively pick values from RP154. The list works well for comparison purposes, huge differences both in frequency and doses are identified between European countries, which should be analyzed further. However, new imaging procedures have been introduced since 2002, thus it is not possible to estimate the total collective dose based on the old "TOP 20" list. The significant efforts needed to perform a high quality population dose survey should not be underestimated.

Medical exposure of the French population in 2007

Etard, Cécile[1]; Aubert, Bernard[1] ; Sinno-Tellier, Sandra[2]
[1] Institut de Radioprotection et de Sûreté Nucléaire, FRANCE
[2] Institut de Veille Sanitaire, FRANCE

Introduction

The Institute for Radiation protection and Nuclear Safety (IRSN) and the National Institute for Public Health Surveillance (InVS) have been collaborating since 2003 to provide updated data on medical exposure of the French population, as requested in the European Directive 97/43/Euratom. The first report published in 2006 was based on 2002 dataset.

This study is related to 2007 dataset. It only includes ***diagnostic*** procedures from the following imaging modalities: conventional radiology including dental radiology, computed tomography (CT), nuclear medicine and interventional radiology restricted to diagnostic procedures. The objective of the study is to characterise the exposure of the French population in 2007 according to these imaging modalities, to anatomical areas and to age and sex of the patient. The part of the population really exposed for diagnostic purposes has also been estimated.

Material and methods

To characterise the diagnostic medical exposure of the population, it is necessary to estimate:

- the number of each type of examination,
- the distribution of these examinations by age and sex,
- the mean effective dose associated to each type of examination.

According to the EC 154 report, the dosimetric quantities used in this study are the “collective effective dose” and the “annual average effective dose per inhabitant”.

Each type of examination is defined by a unique code in the French Common Classification for Medical Care (CCAM). For the four imaging modalities listed above 376 codes have been studied.

For private practice, a continuous and representative sample of about 1% of the population (about 500 000 persons) has been followed by the National Health Insurance since 2006. All cares performed to people of this sample by private practitioners are registered. The 2007 data related to the 376 codes of examination studied have been analysed according to the type of examination, age and sex of the patient.

For public practice, as no global registration was available, two national surveys have been specifically conducted:

- one survey within 50 representative radiological departments in public hospitals: the total activity of each department in 2007 and dosimetric information for each examination (DAP or DLP) have been collected and analysed according to the type of examination, the sex and the age of the patient,
- one questionnaire sent to all the 127 nuclear medicine departments in public hospitals: the total 2007 activity and dosimetric information for each examination (radiopharmaceutical and administered activity) have been collected and analysed according to the type of examination.

A mean effective dose has been associated to each type of examination, using the national guidelines in radiology or in nuclear medicine, data collected to update the French Diagnostic Reference Levels, recent French and European studies and dosimetric information collected through the two national surveys.

Results

Medical exposure

74.6 million examinations have been performed in 2007. The conventional radiology represents 63% of them, dental radiology 24.7%, computed tomography 10.1% and nuclear medicine 1.6% (fig. 1).

The annual average effective dose per inhabitant has been estimated to 1.3 mSv/year/inhabitant in 2007. Computed tomography contributes to 58%, conventional radiology to 26% and nuclear medicine to about 10% of the annual dose (fig.1).

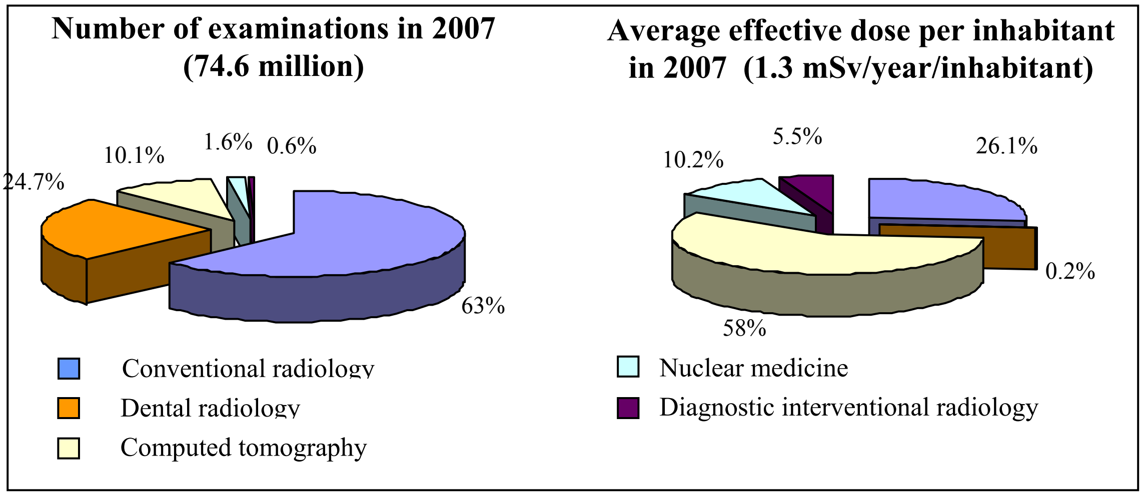

Fig. 1. Distribution of examinations and associated effective dose according to imaging modalities in 2007.

Following the recommendations of the EC Radiation Protection report n°154, the contribution of the “TOP 20 exams” has been estimated. These “TOP 20 exams” have been defined as the 20 examination types that contribute most to the collective effective dose (excluding nuclear medicine). Figure 2 shows the annual number of the “TOP 20 exams” and the associated contributions to the effective dose, per inhabitant, in 2007.

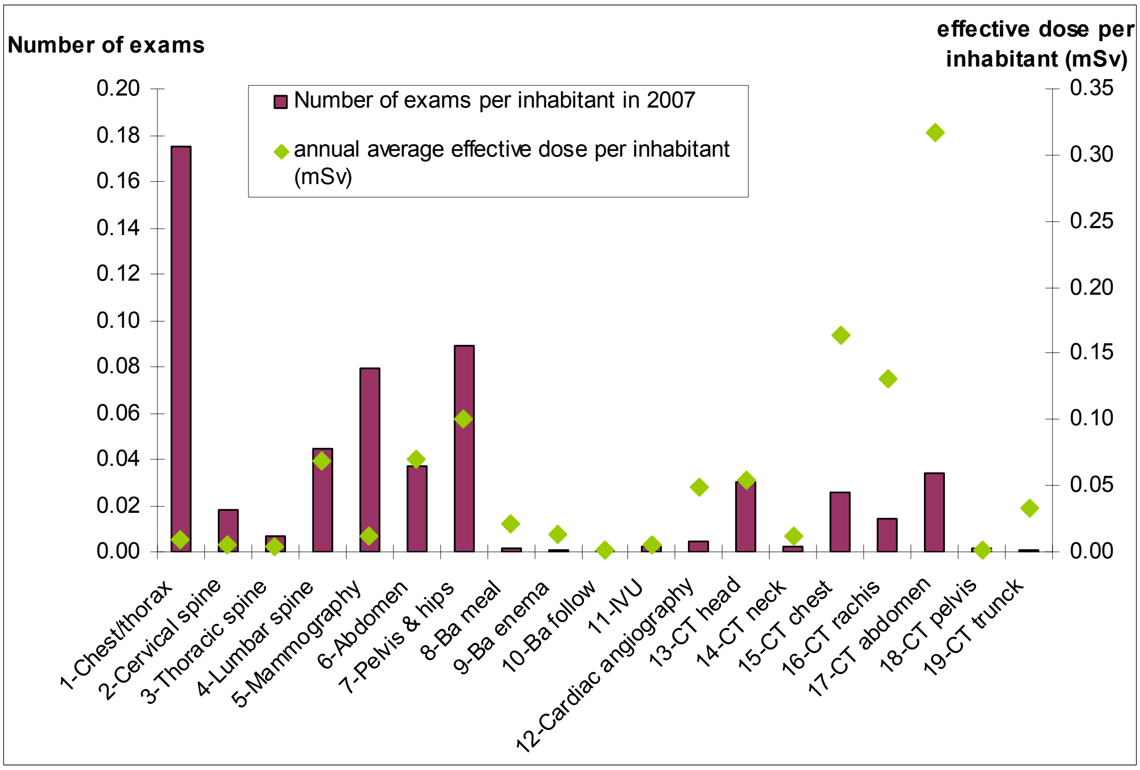

Fig. 2. Number of examinations per inhabitant in 2007 and associated contributions to the effective dose per inhabitant, for « TOP 20 exams » defined in the EC Radiation Protection report n°154.

Analysis to age and sex of the patient

For conventional radiology and computed tomography the information on sex and age of the patient was available. It was possible to study the age and sex distributions of x-ray procedures and associated effective dose (fig. 3 and 4).

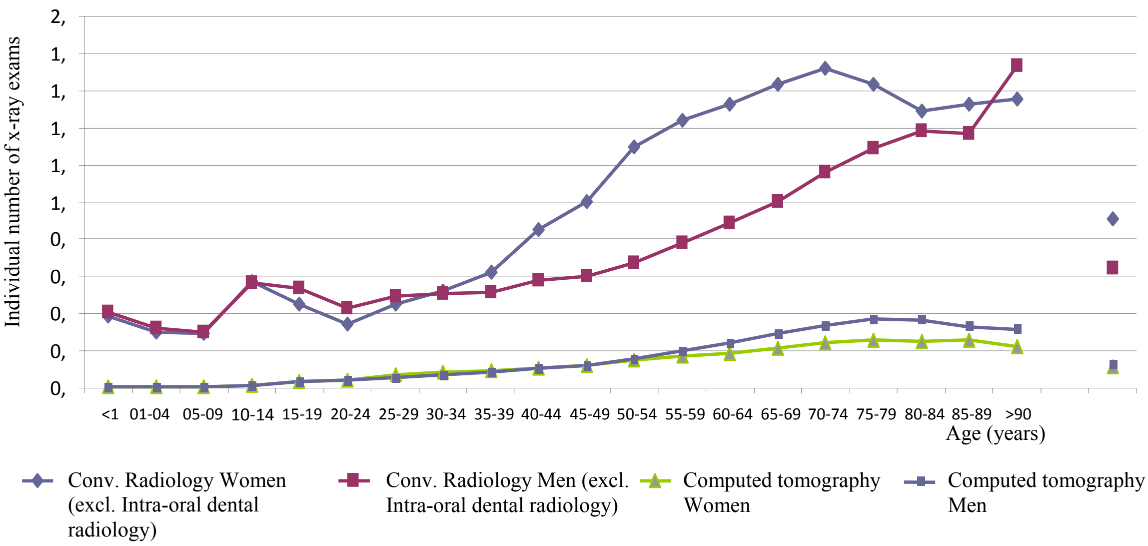

Fig. 3. Age and sex distribution of the annual number of x-ray examinations per inhabitant in 2007.

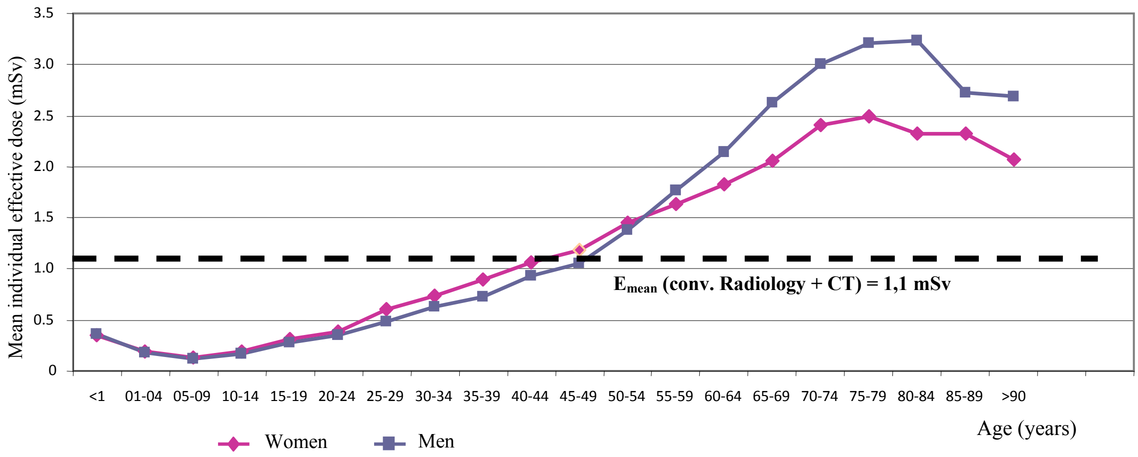

Fig. 4. Age and sex distribution of the annual average effective dose per inhabitant in 2007.

Part of the population really exposed to ionizing radiation for medical purpose

The average effective dose per inhabitant has been estimated to 1.3 mSv/year/inhabitant in 2007. Nevertheless it is obvious that this mean value does not reflect the real situation: people who did not perform any examination received no dose in 2007; other people received much more than 1.3 mSv per year because of numerous examinations. It was therefore interesting to estimate and to characterise the population really exposed.

The data to achieve this objective was only available for private practice. In 2007, the part of the French population exposed to at least one examination in the private sector has been estimated to 27.7% (radiology, CT or nuclear medicine). In terms of effective dose:

- 72.3% received no dose,
- 17.9% received less than 1 mSv,
- 6% received between 1 and 5 mSv,
- 3.8% received more than 5 mSv.

The average individual effective dose received by the 27.7% of the population exposed for medical purpose has been estimated to 2.5 mSv per year.

Discussion

The annual average effective dose per inhabitant due to medical exposure increased by a factor of 1.6 between 2002 and 2007 (0.83 vs 1.3 mSv/year/inhabitant). The main reasons to explain this large increase in dose in that period are:

- a better knowledge of the examination frequency due to the CCAM classification,
- a large increase of the number of CT and nuclear medicine examinations (+ 26% and +38 % respectively),
- a more important part in 2007 of CT exams that exposed chest, abdomen and/or pelvis, organs that highly contribute to the effective dose,
- a large increase of PETSCAN examinations.

Conclusions

The annual average effective dose per inhabitant has been estimated to 1.3 mSv/year/inhabitant in 2007 in France. This value is lower than the one of the Unites States (3 mSv per inhabitant in 2006) and in the range of the European values published: from 0.4 mSv in the UK to 2 mSv in Belgium (EC radiation protection report n°154). The method developed in this study ensures reproducibility and accuracy of assessment of medical exposure. Finally, it could contribute to assess patients' protection policy.

All these results have been published in March 2010 and the report can be downloaded: www.irsn.org or www.invs.sante.fr.

Feasibility study of a simplified method to determine population doses from medical x-ray imaging

Frank, Anders; Almén, Anja; Leitz, Wolfram
Swedish Radiation Safety Authority, 171 16 Stockholm, SWEDEN

Abstract

Medical X-ray imaging has been the largest man made source of population doses for many years, and is rapidly increasing due to an increased use of computed tomography. It is important to obtain information about the contribution from different examinations to these doses in order to select appropriate radiation protection actions. Guidance for assessing population doses is provided in a publication of the European commission with amongst others a simplified method where the collection of data is restricted to a sample of representative hospitals for those 20 x-ray examination categories contributing mostly to the population dose. The purpose of this study was to check the feasibility of this approach.

The national coding system was used to identify the 20 categories. From a sample of hospitals (around 20 % of the country) frequency data was collected from the radiological information system (RIS). Problems envisaged were differences in the code system between hospitals and that one category could include several codes. This was solved by editing the data manually. The frequencies were scaled up to represent the whole country using information from a complete assessment from 2005. Dose values were collected from national dose surveys and when not available from tabulated values in the guidance.

The population dose was calculated to 5700 manSv. The contribution to the population dose from examinations not included in this figure was estimated to be less than 10 %. The total uncertainty of the population dose was expected to be relatively low. This could be achieved with a modest workload, using a rather small sample. However, due attention has to be paid to the ambiguities in the coding systems, to the selection of the sample of hospitals and to the methods of extrapolation to a national value.

Estimation of exposure from medical exposure

The importance of estimating exposure to the populations from different sources has been emphasized in the radiation protection community, among others by UNSCEAR [1]. UNSCEAR has evaluated the exposure of the population on a global level. There it is shown that a large part of the radiation dose from artificial radiation sources comes from medical exposures. This figure has increased significantly in some countries [2]. Evaluating level and trends of these doses from medical exposures is thus an important issue that can help to set priorities for radiation protection activities.

The EU directive MED [3] requires that the member states must assess the distribution of radiation doses from medical exposure for the population and for relevant reference groups, without specifying in more details how this should be carried out, e.g. what quantity to be used and which relevant reference groups were envisaged. To use collective effective dose [4] is one option. This quantity has been introduced in order to describe the radiation to a group of persons. Collective effective dose has been used to compare the radiation dose incurred by different sources, often on a national level. However, the quantity has to be used with care, the group of persons included could be exposed very unevenly when most of the radiation dose is received by only a few people. The collective effective dose alone does not say anything about the dose distribution within the group. Therefore this figure has to be complemented with other information in order to be useful. The results of an assessment of collective doses may be dependent on the methodology.

In order to calculate the collective effective dose from medical exposures the numbers of examinations have to be known together with the effective doses. The ideal method would be to assess the effective dose for every patient for all single examinations and to sum up these figures. However, this is not feasible; the amount of data to be handled must be reduced. One method that has been proposed is to restrict the dose estimate to those examinations that contribute most to the collective effective dose. This method has been developed in a European project, called DOSE DATAMED, aiming at proposing unified methods that can be used in Europe [5]. One of the methods proposed there is called TOP 20. In this method, 20 examination categories contributing most to the collective effective dose are identified and the assessment of the total collective effective dose is restricted to these 20 categories. The frequency of these categories of examinations performed in the country has to be assessed and the average effective dose for each of them be estimated. More details about this method are found in [5].

The TOP 20 method was applied in Sweden. This presentation addresses some key issues: the importance of specifying and categorizing the examinations, difficulties and pitfalls encountered in data collection and uncertainties concerning effective dose and frequency.

Material and methods

Description of categorization

In 1991 the National Board of Health and Welfare in Sweden issued a coding system (KRÅ) for all radiological examinations that were performed at that time [6]. The classification was intended to be used for registration of radiological examinations e.g. in the radiological information system (RIS). The first task was to identify which codes in the Swedish KRÅ are corresponding to each of the TOP 20 examination categories in [5], listed in table 1. This task was performed by an experienced radiologist.

Table 1. The TOP 20 list as defined in the [5].

TOP 20 categories		
Radiography 1 chest/Thorax 2 Cervical spine 3 Thoracic spine 4 Lumbar spine 5 Mammography 6 Abdomen 7 Pelvis & hip	**Flouroscopy** 8 Barium meal 9 Barium enema 10 Barium Follow 11 Intravenous Urography (IVU) 12 Cardiac angiography	**Computer tomography (CT)** 13 CT head 14 CT neck 15 CT chest 16 CT spine 17 CT abdomen 18 CT pelvis 19 CT trunk **Interventional Radiology** 20 Cardiac dilatation/stenting (PTCA)

Frequency collection

Frequency data from all radiological examinations during 2008 were collected from a sample of hospitals in Sweden. From each hospital, data was retrieved from the local RIS comprising local RIS codes, examination description and number of examinations. Most, but not all local RIS codes corresponded to the KRÅ codes. Non-matching codes could be identified by manually checking the description of examination given together with the code. With this time consuming procedure a rather complete estimate of the frequencies for the TOP 20 examinations could be performed. However, some data are missing in the reporting, for those examinations that are not always registered in the normal RIS, e.g. screening with mammography and PTCA outside the radiological department. Frequency data from the sample was scaled up to represent the whole country by using information from a national survey from 2005 [7], which included all examinations and hospitals in Sweden. The scaling factor was determined by taken the data from 2005 and calculate the ratio between the number of examinations from the sample of hospitals and the total number of examinations from the whole country.

Unlike in the data collection from the sample in 2008 the national survey in 2005 did provide reliable figures for the frequency of mammography examination. Therefore the frequency data from the 2005 survey was taken for the year 2008. For comparison frequency data from the 2005 survey was used to create a corresponding TOP20 list for 2005. Also for PTCA and cardiac angiography a national reporting system for these procedures exists [8] including frequencies and doses, expected to be more reliable than the data from the sample.

Doses

The radiation safety authority has established diagnostic reference levels for 12 examinations [9]. Both in 2005 [10] and in 2008 [11] all Swedish hospitals reported the patient doses for these 12 radiological examinations, as the average for approximately 20 normal sized patients for every examination room. These examinations correspond to 11 of the TOP 20 categories and hence the average of the radiation doses reported was taken as the national dose value for the respective examination. For the remaining 9 categories, tabulated dose values from the guidelines [5] were used. The effective dose was derived by multiplying each dose figure with the corresponding conversion factor in table 14 in the report. [5].

Results

Categorization

In total 84 KRÅ codes were found to correspond to the TOP 20 categories. The number of codes in one category varied between 1 and 16. The KRÅ system did not contain any code for CT-trunk, the category number 19 of the TOP 20. However, some hospitals reported local RIS codes for complex examinations, i.e. multitrauma which were added to the CT – trunk category.

Frequency

Data from 20 hospitals were collected. These hospitals represent 4 out of 5 hospital categories available in Sweden, table 2. In the 2005 survey, these hospitals performed 18 % of the radiography/radioscopy, and 21 % of the CT examinations in Sweden.

Table 2. Total numbers of different categories of health care entities in Sweden and the numbers used for the sample.

Hospital category	Number collected	Total number in Sweden
University Hospitals	1	8
Central (county) Hospitals	4	18
Small Hospitals	4	55
Health Centers (small radiological units)	0	28
Private radiological units	11	26

The data for all the TOP 20 categories from 2005 and 2008 showed that the total number of examinations increased with 3% during this time period. However, this figure varies considerably between the different radiological techniques. Plain radiography examinations and fluoroscopic decreased with 1% and 32%, respectively. On the other hand CT and PTCA increased with 28% and 8% respectively. In total, approximately 3.5 million TOP 20 examinations have been performed in Sweden during 2008. Approximately 74% of these were plain radiography examinations, 3% were fluoroscopy, 22% were computed tomography (CT) and 1% coronary angioplasty. In the 2005 survey, the TOP20 examinations represent 71% of the total number of examinations. Table 3 shows the frequencies for the different modalities for 2005 and 2008.

Table 3. Number of TOP20 examinations performed with different modalities in 2005 and 2008.

Frequencies			
TOP 20	**2005**	**2008**	**Difference (%)**
Plain radiography	2627120	2611702	-1
Fluoroscopy	173238	117749	-32
CT	600650	765998	28
PTCA	17671	19120	8
Total	3418679	3514569	3

Collective effective dose

For approximately 90% of the total collective dose national data was used and for the remaining 10% tabulated data was used from the guidelines [5]. A comparison between the reported data from 2005 and 2008, show that the collective doses for plain radiography and fluoroscopy have decreased with 19% and 36%, respectively. This is due to a decrease of the number of examinations and a decrease of the mean dose values (see table 4). The collective dose for CT and PTCA has increased during these three years with 30% and 8%, respectively, mainly because of the increased number of examinations. The mean dose values for CT have decreased slightly (see table 4). The dose data for PTCA was available for 2008 in [8], the same value was taken for 2005.

For all examinations the dose per examination has decreased or remained unchanged, but the total collective dose increased with 8% from 2005 to 2008. This can mainly be attributed to the increased number of CT examinations.

The total collective dose for the TOP 20 examinations in 2008 is approximately 5700 manSv, and 11% of the total collective dose is caused by plain radiographic examinations, 12% by fluoroscopy, 72 % by CT examinations and 5% by PTCA. CT of the abdomen is the single examination contributing most to the total dose, to 40% of the total collective dose. The collective dose from the TOP 20 examinations is estimated to represent 90% of the total collective dose from all examinations in Sweden.

The details of the distribution of the collective doses and how they have changed since 2005 are shown in table 4. The changes in dose are presented as those resulting from change in frequencies (Δfreq) alone (column 3 & 4), from change of dose (Δdose) per examination alone (column 5 & 6) and from both of them (column 7 & 8).

Table 4. Collective doses from 2005 and 2008 including separate contribution from changes in frequency and DSD.

Collective dose (manSv)							
Exams	**2005**	**2008 due to ∆freq**	**Diff (%)**	**2008 due to ∆dose**	**Diff (%)**	**2008 due to ∆freq and ∆dose**	**Diff (%)**
Plain radiography	863	835	-3	730	-15	699	-19
Fluoroscopy	1023	833	-19	812	-21	658	-36
CT	3142	4261	36	3020	-4	4093	30
PTCA	247	268	8	247	0	268	8
Total	5274	6197	17	4809	-9	5718	8

Uncertainties

It was easy to get reliable data for those examinations that were stored in the local RIS. It took some effort to stratify the data, i.e. to decide which examinations belong to which TOP 20 category and to eliminate codes for administrative measures. For those examinations the uncertainty is expected to be low. It was obvious after the collection of data that figures for mammography were missing. For mammography the values from the 2005 survey were used also for 2008, because there are no indications that the frequency of examinations should have changed considerably in this time period, no screening activities have been stopped and no have been added. For coronary angiography and PTCA the collected frequency data from a national quality system were used. This system comprises all examinations/procedures performed in the country resulting in low uncertainties. The scaling of the sample to the whole country is inevitably introducing uncertainties. Collected values for CT trunk are unreliably since there are no national codes for complex examinations. Some hospitals have introduced local codes.

Some of the uncertainties in dose estimation are due to the fact that 10% of the collective dose is assessed using the dose figures listed in [5], which might or might not be representative for the Swedish practices. In addition, the national doses do not cover all KRÅ codes for the various TOP 20 categories.

Feasibility of the TOP 20 approach

This study has been performed with confined resources, where data from a limited number of hospitals was analyzed and an extrapolation to the national level was performed. The uncertainties from the assessment of the frequencies originate from: The uncertainty of the reported frequencies in the sample and the uncertainty arising from the scaling to the entire country. For the majority of the TOP 20 categories the reported values are accurate. However, as pointed out above, the data had to be checked in detail in order to be able to remove e.g. administrative codes not representing the conduct of an examination. There are also large uncertainties for the category “CT trunk” for which no national code exist. The problem with underreporting of data for mammography, coronary angiography and PTCA has been overcome by using other sources. For example the PTCA frequencies would otherwise have been underestimated by 28%.

We believe that this study was performed with relatively low uncertainties. Due to the earlier performed nation wide survey a small sample could be used for the study without introducing considerable uncertainties. A nation wide survey including all examinations and all hospitals should be performed in regular intervals, 5 to 7 years. That not only enables facilitates study as the present one but can also be used for a revision of the TOP 20 list which is, as shown in this study, not static at all

Although a national code is used specifying different examinations it is not unambiguous what to include to the TOP 20 list of examinations, this interpretation will contribute to the overall uncertainties in the suggested method. Even though the national coding system is rather logical, different hospital within Sweden used the codes differently. When standardized evaluation method, e.g. a computer reading of the data is used, systematic errors in the frequency data can be introduced. Thus it is important to both manually check the data and actually enquire how the hospital has used the national coding system. The example of coronary angiography and PTCA showed that there could be other sources for data on frequencies and doses than those commonly used. It could be worth while to look for similar national data bases that might exist for special procedures.

The confidence in and uncertainties of the result heavily depend on available dose data. In this study, the dose data from national dose surveys was used for examinations contributing to 90% of the total collective effective dose from the TOP 20. These dose surveys reveal a large range of average doses between hospitals. That implies that there is a large uncertainty when the doses from only a few hospitals are used as the dose for calculating the collective effective dose. The same argument holds for the use of tabulated dose values that will also introduce a large uncertainty.

This study shows that the simplified “TOP 20” method can give reliable results. Of great help for this achievement was the availability of an earlier nation wide survey and that national dose data exist for the most important examination.

Conclusions and future work

In this study we show that the total examination frequency remained almost constant and the collective dose increased with about 8 %. This is due to that the decrease of both frequency and dose for conventional x-ray examinations is counterbalanced by the increase of the frequency of CT examinations. The TOP 20 method proved to be adequate for providing the data needed with sufficient accuracy,

In the future such surveys could be made easier by using the data at the hospitals more efficiently. The data system in the hospitals already contains all information needed, but in slightly different technical platforms. Some hospitals make use of this information internally already for there own planning and optimization work. It could be useful for the estimation of collective effective dose to have a common system with validated radiation dose data and frequency of well defines examinations.

Paediatric computed tomography (CT) exposure and radiation induced cancer risk: setting up of a French cohort study

Bernier, Marie-Odile[1]; Rehel, Jean-Luc[2]; Brisse, Hervé[3]; Caër-Lorho, Sylvaine[1]; Aubert, Bernard[2]; Laurier, Dominique[1]

[1] Institut de Radioprotection et de Sûreté Nucléaire, Epidemiology Department, FRANCE

[2] Institut de Radioprotection et de Sûreté Nucléaire, Medical Radiation Protection Expertise Unit, FRANCE

[3] Institut Curie, Radiology Department, FRANCE

Abstract

Introduction: The increasing use of computed tomography (CT) scans for paediatric population raises the question of a possible impact of such ionising radiation (IR) exposure on the occurrence of secondary leukaemia and other cancers. We describe the preliminary results of an ongoing large-scale cohort study of cancer risks among children exposed to CT scan in France, performed in collaboration with the "Société Francophone d'Imagerie Pédiatrique et Prénatale" (SFIPP). This study will be included in a trans-national collaborative cohort study for long term follow-up.

Material and methods: In 18 paediatric radiology departments, demographic and IR exposure information concerning children less than 5 years, who underwent at least one CT scan between 2000 and 2006, are under collection. Absorbed organ doses are calculated with the "CT-expo" software.

Results: Until now, 28,190 children free of cancer or leukaemia at the first CT scan examination have been included. Age at first CT scan exposure was less than 1 year for 42%, 1 to 2 years for 19%, and 13% per year of age up to 4 years old. The mean number of CT examination per child was 1.5 (min 1, max 30) and concerned head in 66% of the cases, thorax in 22%, abdomen and pelvis in 10% and other localisations in 2%. Highest cumulated organ doses were observed for brain and lens during head exposure and mean absorbed doses were 27 mGy (range: 2.8 – 478 mGy) and 30 mGy (0.5–620 mGy), respectively.

Conclusion: This cohort allows to better characterizing organ doses associated with CT scan exposure in childhood. Relatively high doses to radiosensitive organs (lenses, ovaries, breast, etc...) have been observed, as well as quite large dose ranges according to the protocols used. This underlies the need for optimization of paediatric CT protocols, or even standardization. The follow-up of the cohort will be first based on cancer incidence up to age 15, and on mortality afterward to quantify a possible excess cancer risk.

Variing CT settings to decrease patient dose in PET/CT studies without degradation in attenuation correction

Neuwirth, Johannes[1]; Staudenherz, Anton[2]; Hefner, Alfred[1]
[1] Seibersdorf Labor GmbH, Austria
[2] Univ. Clinic of Nuclear Medicine, Austria

Abstract
PET/CT hybrid devices are using CT for attenuation correction as well as for anatomic or/and diagnostic purposes. To gain optimal images, the companies install fixed protocols for PET/CT which is not optimized in every case.

This pose the question, how CT parameters can be varied, particularly voltage and current, with the aim to lower patient dose but preserving useful attenuation correction.

To measure the effects of different CT parameter settings on the PET image we used a self constructed "Attenuation Phantom". This phantom consists on eight hollow acrylic cylinders with different diameters and several bones (two femoral, a spine with rips and a pelvic bone). The Scanner we used was a Siemens Biograph PET/CT.

First, the phantom was filled with 18F, whereas the cylinders, due to NEMA conditions - received eight times more 18F than the remaining phantom volume. A PET-scan was performed with and without attenuation correction based on a CT-scan. Following CT parameters were used, whereas the first four settings were carried out with care dose and the last four settings with minimum current-time-product (mAs):

140 kV/138 mAs; 120 kV/138 mAs, 100 kV/138 mAs, 80 kV/138 mAs, 140 kV/30 mAs; 120 kV/27 mAs, 100 kV/13 mAs, 80 kV/8 mAs.

The results demonstrate that the setting parameters have little to no effect on the qualitative and quantitative output of the attenuation correction, hence the calculated activity concentration. Therefore a reduction of both current-time-product and voltage are justified for the sake of lowering the effective dose to the patient for medical examinations where a high-quality diagnostic CT is not necessary.

Introduction
The simultaneous imaging of anatomic features and metabolic activities with Positron tomography (PET) and Computer tomography (CT) in one device is state-of-the-art for numerous medical examinations. One of the properties of the CT is the attenuation correction, a quantitative technique to correct images for the effects of attenuation. Older PET-scanner used line sources (e.g. 68Ge), which rotated around the analyzed volume. Today this expensive and time-consuming method is replaced by the CT.

PET/CT devices mostly rely on the setting parameters of the CT for high-quality resolution which on the other side is not justified by using CT just for attenuation correction.

This work aims to establish guidelines relating to parameters at PET/CT-scanners for attenuation correction with the objective to limit unnecessary exposure of the patient. This is done by applying different setting parameters to the CT and their subsequent use for the attenuation correction.

Material and methods

Attenuation coefficients of analyzed areas of a human body have to be simulated with a special phantom. In practice, the CT measures attenuation coefficients which are used for the correction of the activity concentration at the PET. Therefore a phantom for body simulations at PET/CT-devices should have both scatter characteristics like the human body as well as contrast elements with strong different attenuation coefficients, such as lung equivalent and compact bone.

Existing phantoms in nuclear medicine were designed for quality assurance and are just partial suitable for the purpose of this work. The NEMA PET-Body – phantom [1], [2] comes close to these requirements, but has to be modified. It consists of six hollow spheres of acrylic glass and a cylinder filled with polystyrene-balls which simulate the lung. For testing attenuation correction over the complete phantom volume, the spheres are replaced by hollow acrylic cylinders in different diameters (10 mm; 15 mm; 25 mm and 38 mm), so that the respective volumes span the entire phantom's height . For the measurements these cylinders and the remaining phantom volume are filled with 18F, the concentration in the cylinders being eight times as high as for the remaining phantom volume due to NEMA conditions. To simulate bone density three backbone segments from a pig are placed in the centre of the phantom with a 10 mm acrylic hollow cylinder in its midst. At the edge of the phantom two pig's thigh bones with pelvic bones are situated (Fig.1).

The cylinders were filled with an activity concentration of 51 kBq/cm^3 whereas the remaining phantom volume contains 5.9 kBq/cm^3 at the time of measurement (concentration ratio: 8.6:1). The measurements included three series where each run started with a Topogram (overview screen) followed with four CT-expositions with respectively fixed voltage and four different currents and ended with a PET-scan. Afterwards the evaluation of the PET-scan was carried out with and without attenuation correction.

A Siemens Biograph 64 PET/CT Hybrid device was used for the measurements. 16 different setting parameters of the CT were chosen, including the standard setting for attenuation correction (140 kV; 30 mAs) which is referred to as the "Care dose" (Table 1).

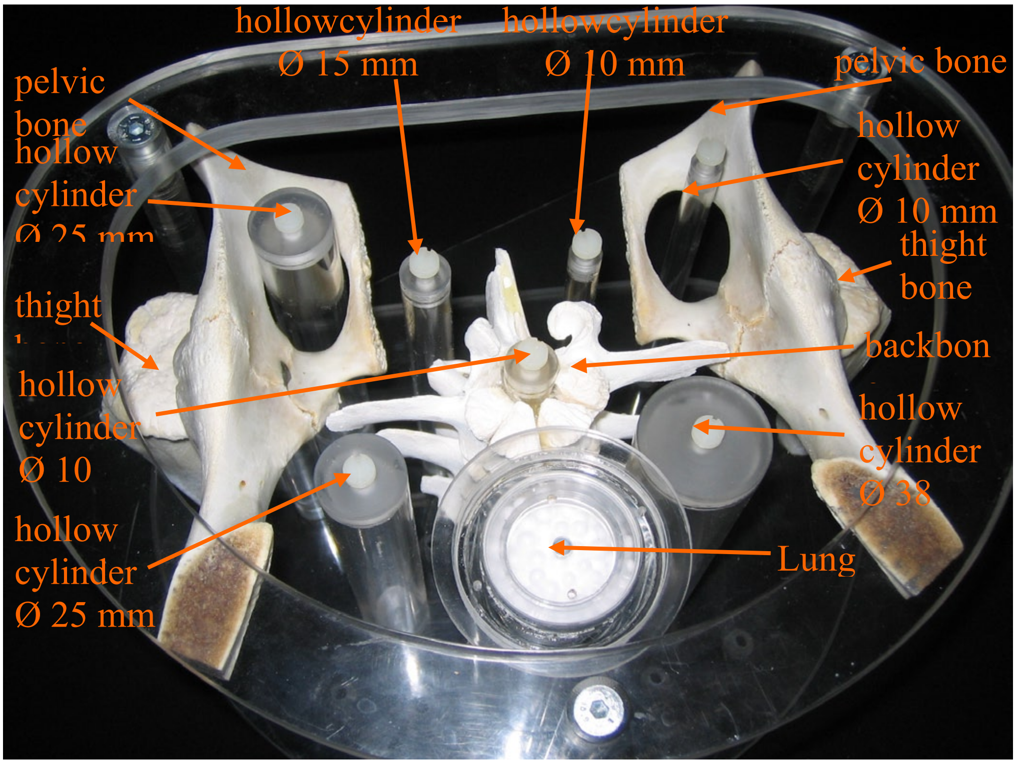

Fig. 1. Phantom with hollow acrylic cylinders, the lunge-equivalent, the three backbone segments in the middle and the two thighbones with pelvic bones at the edge.

Table 1. Setting parameters of the different CT-serials.

	Voltage	Current	Pitch
1.	140 kV	138 mAs	1,5
2.	140 kV	100 mAs	1,5
3.	140 kV	65 mAs	1,5
4.	140 kV	30 mAs	1,5
5.	120 kV	138 mAs	1,5
6.	120 kV	95 mAs	1,5
7.	120 kV	51 mAs	1,5
8.	120 kV	27 mAs	1,5
5.	100 kV	138 mAs	1,5
6.	100 kV	95 mAs	1,5
7.	100 kV	51 mAs	1,5
8.	100 kV	13 mAs	1,5
9.	80 kV	138 mAs	1,5
10.	80 kV	95 mAs	1,5
11.	80 kV	51 mAs	1,5
12.	80 kV	8 mAs	1,5

The analyses of the PET measurements were carried out with Imagej (Vers. 1.41c). In every slice inside the cylinders as well as in the remaining phantom volume a ROI (Region Of Interest) was constructed, so that fringe effects can be avoided. Inside the constructed areas the means and standard deviations of the activity concentration were calculated.

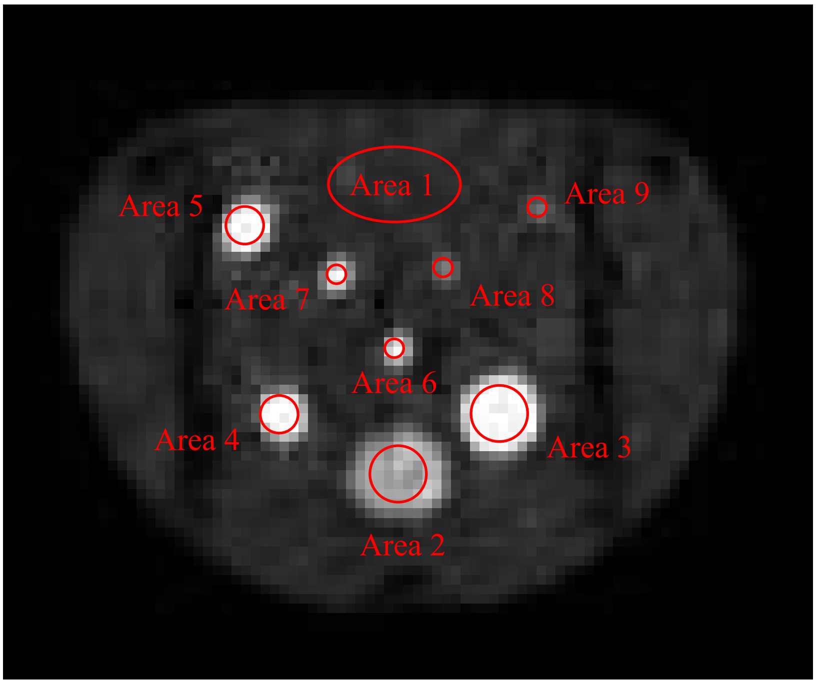

Fig. 2. Attenuation corrected PET-pictures (140 kV; 30 mAs, Slice 48) with ROI`s for calculating the respective means and standard deviations of the activity concentration. Area 2-9 are the selected ROI`s of the cylinders and Area 1 represents the remaining phantom volume. The two dark lines origin from the pelvic bones due to the zero 18F accumulation of the bones.

Results

Surrounding tissue of a radioactive source, especial high density tissue, can falsifies the true activity concentration of an area and even the form of the area them self. The optimum attenuation correction is given by exact reconstruction of the form of the area and the activity concentration in it. A first analysis of the results shows that a smaller cylinder, filled with ^{18}F, correlates with a worsening of the attenuation correction. This effect gets even worse with bone structured surrounded areas. Fig. 3 displays this effect, where area 8 and area 9 with Ø 10 mm are reconstructed with very little activity concentration according to area 3 with Ø 38 mm. Area 1,3,4 and 5 are also relatively homogenous over the entire scan length in comparison to Area 6,7,8 and 9. This is due to the insufficient attenuation correction of the cylinder areas with small diameters (< 15 mm) and the partial-volume-effect, wherein different tissue types are mixed within a pixel (resolution of the PET-scanner: 4 mm per pixel). However the setting parameters of the CT cannot be accounted for this effect as seen in Fig. 4 where the attenuation corrected images are shown with the highest and the lowest setting parameters. There the maximum deviation of displayed activity concentration in the same ROI and the same slice is less then 6 %!

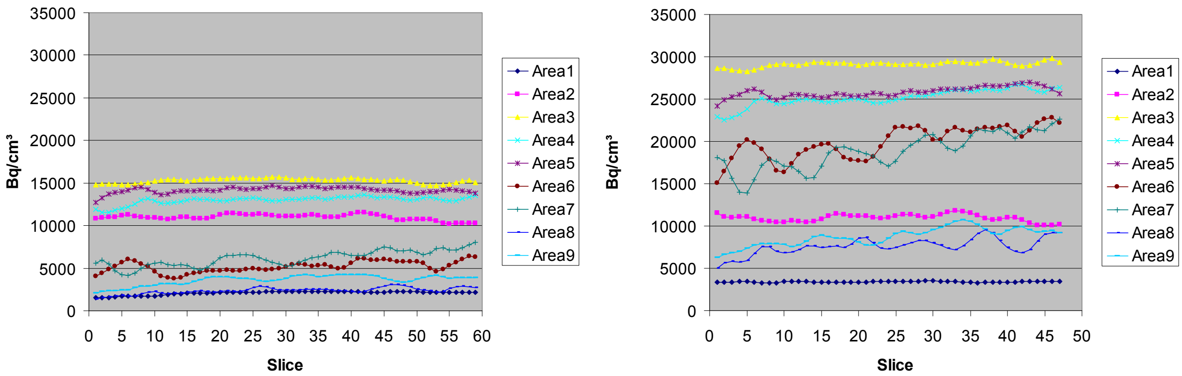

Fig. 3. Left: uncorrected PET-image. Right: PET-Image left attenuation corrected (140 kV; 30 mAs). This Image consists of fewer Slices due to the interpolation algorithm.

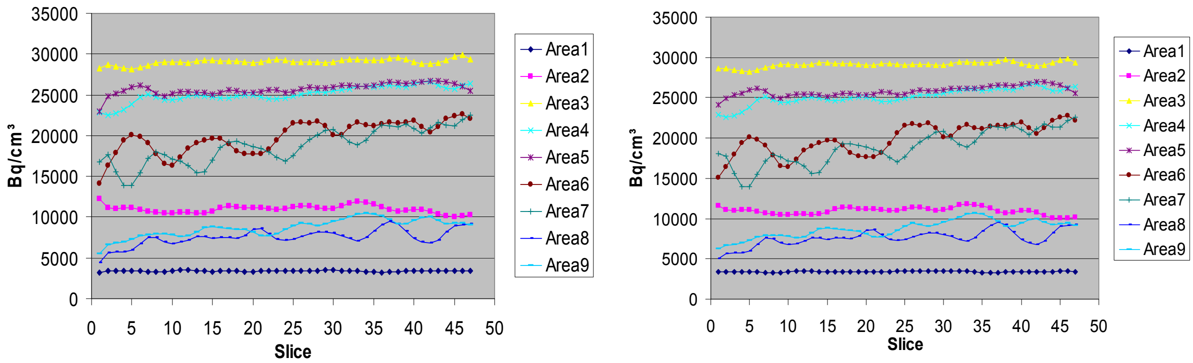

Fig. 4. Left: attenuation corrected PET-image (140 kV; 138 mAs). Right: attenuation corrected PET-Image (80 kV; 8 mAs).

On the basis of the computed tomography dose index (CTDI) which is given by the respective CT software for every setting parameter it is possible to estimate the effective dose of a patient 0,0. 0 illustrates the relation between voltage, current-time-product and the resulting effective dose for pelvic CT images of a male patient. One can clearly see the linear ascent of the effective dose as a function of the current-time-product with voltage determining the steepness.

So in order to reduce patient dose i.e. lower the effective dose to a value less than the one which corresponds to setting parameter of the "Care Dose" (140 kV and 30 mAs) one has to stick to the setting parameters displayed in Tabble 2. For example, at a voltage of 140 kV the current-time-product has to be adjusted to ≤ 30mAs.

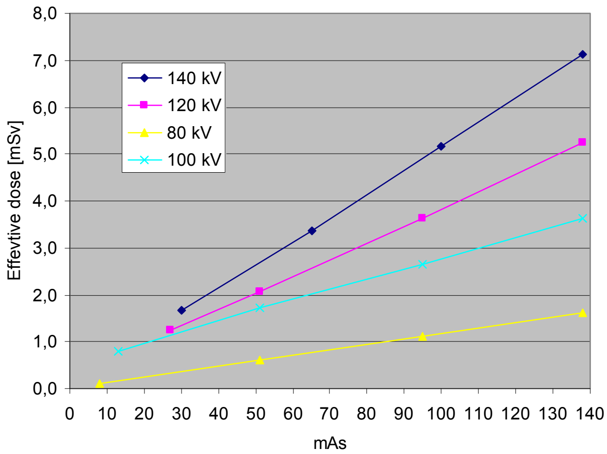

Fig. 5. Estimated effective dose of a female patient for pelvic CT images with different setting parameters. Each line represents a different voltage.

Table 2. Setting parameters to reduce patient dose at Siemens Biograph 64 PET/CT hybrid device.

Voltage	Current-time-product
140 kV	≤ 30 mAs
120 kV	≤ 39 mAs
100 kV	≤ 48 mAs
80 kV	≤ 139 mAs

When selecting the lowest possible voltage and current-time-product a decrease of the effective dose of 92 % can be achieved. In the case of a pelvic exposure of a male patient at a Siemens Biograph 64 PET/CT Hybrid device this corresponds to a reduction of the effective dose from 0,7 mSv to 0,1 mSv. However it should be noted that the effective dose strongly depends on the exposed body region, sex, age, weight and other factors., Nonetheless its reduction as suggested above is independent of these parameters. Finally it also must be mentioned that a PET/CT hybrid device also can be used for anatomical imaging and therefore changing the setting parameters can yield unworkable images.

Discussion

This project demonstrated that the reduction of patient dose is possible by decreasing setting parameters of the CT for attenuation correction purposes using a Siemens Biograph 64 PET/CT hybrid device. The variation of the setting parameters has proofed to have very little effect on the quantitative outcome of the attenuation correction.

Trigger Levels to prevent tissue reaction in interventional radiology procedures

Trianni, Annalisa[1]; Gasparini, Daniele[2]; Padovani, Renato[1]

Abstract
It is well known that the large use of fluoroscopy in interventional radiology procedures may induce unintended patients' skin injuries. For that reason assessment of skin dose for these procedures is getting more and more important.

Aim of the study is to investigate the role of cumulative air kerma (CK) as on-line dose indicator and to evaluate the pos-sibility to define a local CK trigger level which can help opera-tors to identify situations with high probability to exceed a peak skin dose of 2 Gy, the threshold dose for transient skin erythema. Cerebral angiography, aneurysm embolisation and chemoembolisation of liver cancer have been identified as the interventional procedures where high skin doses could be delivered.

Dosimetric data (CK, air kerma area product (KAP) and fluoroscopy time) have been collected in a sample of procedures and peak skin dose (PSD) have been measured from dose distributions measured with large area radiochromic films (Gafchromic, IPS, USA) located between table top and patient.

PSD varied in very wide range and in a few cases were close to the threshold for main erythema and epilation (6 Gy). The correlations between PSD and CK have been successfully assessed for each procedure type and a trigger level for CK has been derived to alert the interventionalist on the probability to have reached a PSD of 2 Gy.

In our center local trigger levels of 5200 mGy and 2500 mGy has been established for brain aneurysm embolisation and chemoembolisation procedures respectively.

As suggested by ICRP in the publication No. 85, a follow-up for patients whose estimated peak skin dose was 3 Gy or greater has been implemented as a routine practice.

Introduction
The extensive use of fluoroscopy in interventional radiology procedures may induce unintended patients' skin injuries varying from erythema to necrosis. Some cases have been described in a review paper by Koenig et al.

As stated by the European regulation 97/43/Euratom patient dose should be periodically evaluated to guarantee optimisation and justification of the practice.

Moreover the ICRP (International Commission on Radiological Protection) recommends to provide an adequate follow-up and eventual treatment of these injuries, for patients whose skin dose has been 3 Gy or greater.

Maximum skin dose (MSD) could be directly measured using film or thermoluminescent dosimeters (TLDs). In this way the operator doesn't have an immediate knowledge on the amount of dose received by patient. It is important to perform an "on-line" evaluation (e.g.: during the procedure) of patient's skin dose to individuate those procedure in which it could be greater than threshold for deterministic effects. Therefore dosimetric indicators for estimating and monitoring patient skin dose in routinely practice should be individuated.

For interventional radiology procedures kerma-air product (KAP) and cumulative air kerma (CK) at the interventional reference point (IRP) could be used as dosimetric indicators for skin dose.

Aim of this work is investigating the correlation between these parameters and the skin dose directly measured in a sample of procedure.

The dosimetric indicator that better correlate with the MSD could then be used to define trigger levels that indicate the overcoming of threshold for deterministic effects and necessity of medical follow-up for possible radiation injuries, respectively.

Material and methods

In the period October 2007 – October 2008 data from procedures, both diagnostic and interventional, performed in two interventional rooms in Udine University Hospital (Udine, Italy) have been collected.

The procedures were performed with two angiographic system equipped with a digital flat panel detector by four experienced radiologists.

The peak skin dose (PSD) has been measured with radiochromic films (Gafchromic XR-typeR, IPS, USA), placed between patient and couch in a sample of 61 procedures. Radiochromic films have been calibrated under an angiographic beam for comparison with an ionisation chamber (Radcal, Model 2026C 6cc ion chamber).

Films were read with a flatbed scanner (Epson 1680pro) in reflective mode. Images obtained were evaluated in terms of dose with a Matlab home-made routine.
The correlations between PSD and KAP and PSD and CK have been investigated for each procedure type.

Results

Data collected are summarized in Table 1, in which are reported: type of procedure, number of patients, mean values of fluoroscopy time (FT), kerma-area product (KAP) and cumulative air kerma (CK) at IRP.

Table 1. Mean and SD fluoroscopy time (FT), air kerma-area product (KAP) and cumulative air kerma (CK) for a sample of interventional procedure performed at Udine University Hospital in the period October 2007- October 2008.

Procedure	No	FT (min)	KAP ($Gycm^2$)	CK (mGy)
Cerebral Angiography	197	6.1 ± 8.2	71.1 ± 49.2	770.9 ± 887.4
Aneurysm Embolization	76	26.6 ± 13.5	135.4 ± 60.8	2153.7 ± 1345.3

Lower limb angioplasty	44	15.6 ± 9.9	24.7 ± 37.6	149.0 ± 237.6
Carotid angioplasty	73	9.4 ± 5.5	53.7 ± 26.0	247.3 ± 135.7
Iliac angioplasty	45	11.4 ± 9.8	80.5 ± 89.5	401.9 ± 293.8
Below-knee angioplasty	27	17.9 ± 10.4	8.9 ± 14.3	101.8 ± 326.0
Renal angioplasty	12	7.7 ± 3.5	48.8 ± 54.8	308.6 ± 270.3
AAA/AAT	13	11.6 ± 5.1	87.6 ± 50.3	495.7 ± 248.6
Brachyteraphy	9	22.6 ± 19.8	16.4 ± 14.6	104.1 ± 94.5
Cavography	7	7.5 ± 6.5	66.1 ± 53.8	273.3 ± 216.4
Fibrinolysis	10	19.9 ± 11.0	28.1 ± 29.6	113.2 ± 102.9
Caval Filter	10	7.0 ± 7.3	64.1 ± 98.3	236.7 ± 282.7
Fistolography	10	4.6 ± 4.0	4.5 ± 14.6	28.4 ± 109.2
Flebography	26	6.5 ± 16.1	28.4 ± 58.9	300.2 ± 803.9
HVPG measurement	10	9.1 ± 7.1	29.2 ± 18.1	167.0 ± 100.1
TIPS	13	20.5 ± 13.3	117.3 ± 74.1	827.5 ± 609.5
Epiaortic trunk angiography	13	3.6 ± 3.3	40.9 ± 30.5	221.3 ± 150.4
Vertebroplasty	13	13.0 ± 16.1	51.4 ± 26.0	392.7 ± 157.3

Mean values of FT, KAP and CK indicate that cerebral angiography, aneurysm embolisation and chemoembolisation of liver cancer are procedure where high skin doses could be delivered. PSD has been measured in a sample of these procedures: results are summarised in Table 2.

Table 2. Peak skin dose (PSD) (mean values, SD and range) for a sample of selected interventional procedures.

Procedure	No	PSD (mGy)	Range (mGy)
Cerebral Angiography	25	352.4 ± 145.4	98.8 ¸ 561.9
Aneurysm Embolization	18	1072.5 ± 1085.2	332.2 ± 4941.9
Chemo-embolization	38	1343.8 ± 915.7	343.4 ± 4135.5

The correlation between PSD and KAP and CK was investigated. Results for cerebral angiography are represented in figures 1 and 2 for KAP and CK respectively.

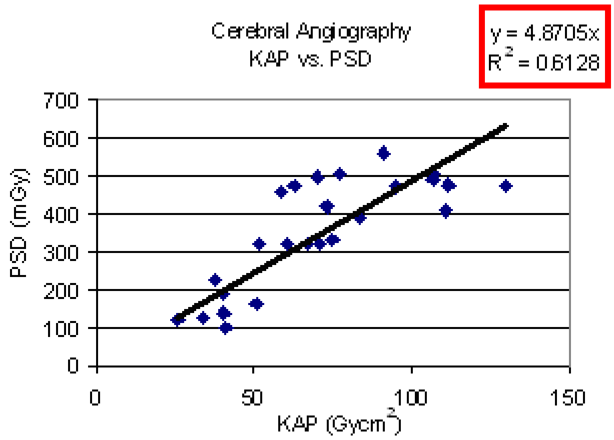

Fig. 1. Correlation between KAP and PSD for cerebral angiography.

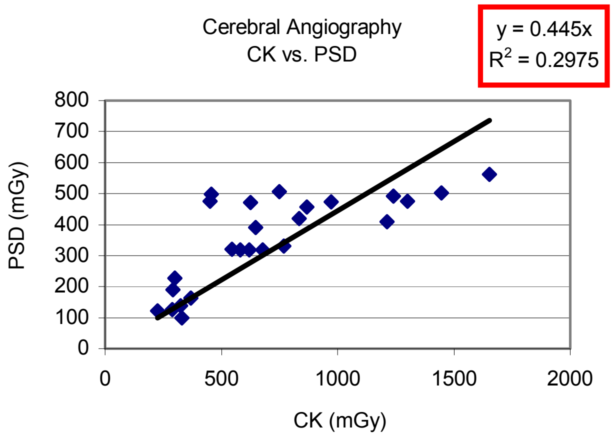

Fig. 2. Correlation between CK and PSD for cerebral angiography.

Results for aneurysm embolisation are reported in figures 3 and 4 for KAP and CK respectively.

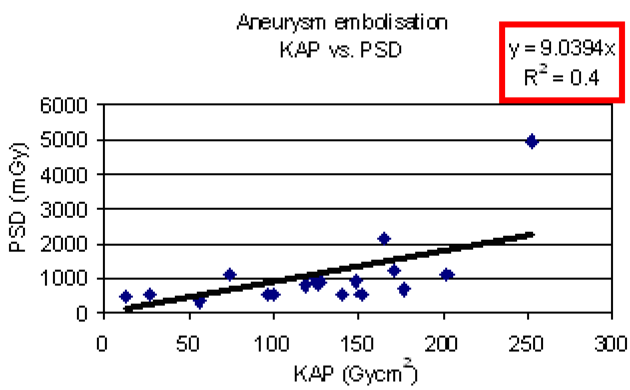

Fig. 3. Correlation between KAP and PSD for aneurysm embolisation.

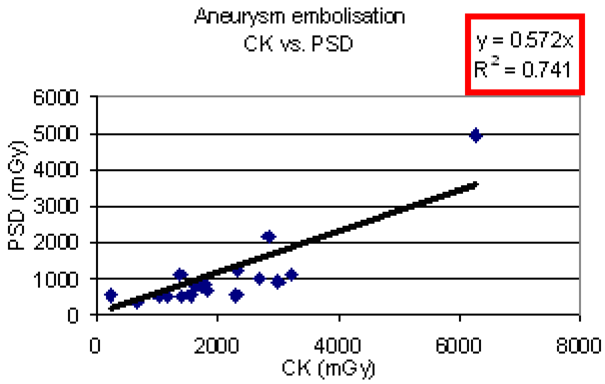

Fig. 4. Correlation between KAP and PSD for aneurysm embolisation.

Results for chemoembolisation are reported in figures 5 and 6 for KAP and CK respectively.

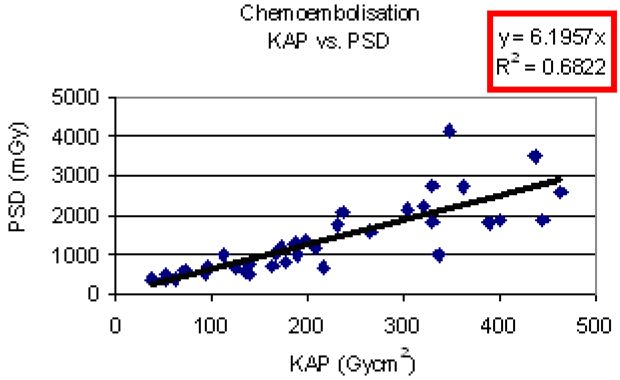

Fig. 6. Correlation between KAP and PSD for chemoembolisation.

Discussion

Registered values of KAP, CD and FT are high and suggest high doses to patient' skin, in particular for cerebral angiography, aneurysm embolisation and chemoembolisation for liver cancer.

Therefore it's important to understand the meaning of these values in terms of skin dose. Moreover it's important to allow the operator to have an immediate knowledge of the amount of dose received by patient and to recognize those procedures in which the dose could be greater than the threshold for deterministic effects.

For that reasons the correlation between dosimetric indicators as KAP and CK given by the equipment and PSD directly measured has been assessed and the possibility to establish trigger levels to be used in routinely practice has been investigated for cerebral angiography, aneurysm embolisation and chemoembolisation.

A. *Cerebral angiography*

For cerebral angiography procedures, correlation between PSD and both dosimetric indicators is weak (R2=0.61 and R2=0.3 respectively for KAP and CK). This is probably due to the high number the projections at different angles used in these procedures.

As a consequence the definition of a trigger level wasn't possible.

However doses measured in the sample are quite low (maximum value of 561.9 mGy).

A comparison between FT, KAP and CK of the sample in which PSD has been measured and the values of the entire database October 2007-October 2008 was performed: mean values were not statistically different.

This allow to assert that doses delivered in this type of procedure are generally not high and the definition of trigger levels in this case is not relevant.

B. ***Aneurysm** embolisation*

For aneurysm embolisation procedures, correlation be-tween PSD and KAP is weak (R2 = 0.4), instead correlation between PSD and CK is quite strong (R2 = 0.74), as reported in figures 3 and 4.

A retrospective analysis on the entire database was done using the linear coefficient to estimate PSD from CK. Estimated PSD exceeded the threshold for transient erythema (2 Gy) 10 times (13% of procedures) and 2 times the threshold for temporary epilation (3 Gy).

Therefore it's necessary in this case define a trigger level that indicate the possible overcoming of 3 Gy for PSD.

The value established in terms of CK for that type of procedure in our centre is 5200 mGy.

C. *Chemoembolisation **for** liver cancer*

For chemoembolisation procedures, correlation of PSD resulted good (R2 = 0.68) with KAP and very strong with CK (R2 = 0.93).

For these procedures, a retrospective analysis on the entire database, using the linear coefficient between PSD and CK found, was done as well. PSD exceeded the threshold for transient erythema (2 Gy) in 25 procedures (17% of the total number) and in one procedure PSD was estimated to be higher than 5 Gy.

Therefore, also in his case, it's necessary to define a trigger level that indicate the possible overcoming of 3 Gy for PSD.

Conclusions

Doses delivered to patient' skin during some interventional procedures could be very high and overcome the threshold for tissue reactions.

For procedures at highest doses it's opportune to define trigger levels based on cumulative air kerma values (CK) measured by the equipment to inform the operators that the dose delivered in a procedure could be higher than the threshold for skin damage.

Skin doses measured for cerebral angioplasty were well below the threshold for deterministic effects and no trigger level has been established.

For aneurysm embolisation and chemoembolisation PSD measured were quite high. For that reason trigger levels have been established in terms of CK. In our centre these levels are 5200 mGy and 2500 mGy, respectively for aneurysm embolisation and chemoebolsation.

As suggested by ICRP in the publication No. 85, a follow-up for patients whose estimated peak skin dose was 3 Gy or greater has been implemented as a routine practice.

Abstract
Within the Information System on Occupational Exposure in Medicine, Industry and Research (ISEMIR), a new IAEA initiative, a working group on interventional cardiology (WGIC) aims to assess staff radiation protection levels and to propose an international database of occupational exposures.

A survey of regulatory bodies (RB) has provided information at the country level on radiation protection practice on IC. Concerning requirements for wearing personal dosimeters, only 57% of RB specify the number and position of dosimeters for staff monitoring.

Less than 40% of RB could provide occupational doses. Reported annual median effective dose values (often <0.5 mSv) were lower than expected considering validated data from facility-specific studies, indicating that compliance with continuous individual monitoring is often not achieved in IC. A true assessment of annual personnel doses in IC will never be realized unless knowledge of monitoring compliance is incorporated into the analysis.

Introduction
The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) has the mandate within the United Nations system to assess and report the levels, effects and risks of exposure to ionizing radiation from all sources, including the collection of dose data on occupational, public and patient radiation exposure. Complementary to the work of UNSCEAR, in 2009 the International Atomic Energy Agency (IAEA) initiated the Information System on Occupational Exposure in Medicine, Industry and Research, referred to as the ISEMIR project. ISEMIR is now undergoing a three-year test period.

The ISEMIR project was established to help to improve occupational radiation protection practice in targeted areas of medicine, research and industry, where non-trivial occupational exposures occur. Within each area, its main objectives are to identify good practices and deficiencies, define actions and key issues that need to be addressed, and disseminate information and knowledge so as to contribute to the reduction of risk of radiation exposure and facilitate the implementation of internationally agreed upon radiation protection practices. A final goal is to make proposals for establishing an international database for the regular collection of occupational dose data in targeted areas of radiation use in medicine, industry and research.

Within ISEMIR, the first Working Group on Interventional Cardiology (WGIC) was set up to assess radiation protection practice and occupational exposure to workers (cardiologists, electrophysiologists and other staff members) involved in IC. Its main objectives are to gain a worldwide overview of the current situation in this field, identify good practices and deficiencies, and define actions to be implemented to improve occupational radiation protection practice in IC. The working group intends to come up with recommendations for harmonizing worldwide monitoring procedures and set up a system for regular collection of occupational doses in IC.

This paper reports the results of an international survey of national regulatory bodies on requirements for staff dosimetry and on dose data availability at the country level.

Material and methods

In its first year (2009) the WGIC performed an international survey on requirements for staff dosimetry and on dose data availability for IC at the country level, using the following questions addressed to the radiation protection (RP) regulatory body:

1. Number of workers (total number, physicians, other professionals) with personal dosimetry involved in IC procedures in 2008.
2. Values of occupational doses (effective dose) in the national authority's database (or database accessible by the national authority) - median and 3rd quartile for each year (2006, 2007, 2008) and each occupational grouping (physicians, other professionals, and all).
3. Does the RP Regulatory Body define the number and position of dosimeters for staff monitoring in IC?
4. Does the RP Regulatory Body require a person to have specific RP training to perform fluoroscopy in IC?
5. Does the RP Regulatory Body require a person to have a specific license or certification in RP to perform fluoroscopy in IC?

Questionnaires were distributed by the IAEA to RP regulatory bodies. The questionnaire was emailed to 191 RP regulatory bodies in 136 countries, reaching, finally, about 180 regulatory bodies. Some Member States have a federal system of government, with the radiation protection regulations covering the use of X-rays being administered at the state level. State regulatory bodies were contacted for such countries where contact information was available.

Results

Responses were received from 81 regulatory bodies (56 national regulatory bodies and 25 state regulatory bodies), giving an overall country response rate of 40% (Table 1). The responding regulatory bodies have jurisdiction over countries and states whose summed population is about one-quarter of the world's total population. Few responses were received from the regulatory bodies of countries with large populations.

Table 1. Numbers of regulatory bodies (RBs) contacted, numbers and percentages (in parentheses) of responses received and portion of the world population represented.

Region	Countries contacted	Countries responded	RBs contacted	RB responses	Total regional population, 10^6	Total population of responding countries, 10^6
Africa	35	10	35	10 (29)*	1000	212 (21)
Asia Pacific	29	14	37	17 (46)	3879	815 (21)
Europe	49	26	49	26 (53)	731	222 (30)
Latin America	21	5	21	5 (24)	679	151 (22)
North America	2	2	49	23 (47)	341	212 (62)
Global	136	57	191	81 (42)	6630	1612 (24)

* Values in parentheses are percentages of the corresponding total.

Questions 1 and 2 asked about the number of monitored workers involved in IC in 2008 and the values of occupational doses registered for physicians, other workers and all workers. Averaged results suggest that monitored physicians in IC represent about 40% of all persons in IC being individually monitored.

About 50% of regulatory bodies provided some occupational dose data (question 2). Of these there was a wide variety of responses, ranging from detailed, accurate dose values to data that were inconsistent and/or ambiguous. It was often necessary to write back to regulatory bodies to obtain more detailed information about their responses.

About half the regulatory bodies stated that they were not able to provide occupational dose data for IC, citing the following reasons:

- no central dose register in the country;
- no easy access to the central dose register by the regulatory body;
- regulatory body only has records of doses if they exceed some particular threshold (e.g. investigation or action level);
- no specific classification for interventional cardiologists, or other persons in IC in the database.

Some of the dose data supplied were not suitable for further analysis for the following reasons:

- reported dose data were "contaminated" with doses from other occupational classes and functions, such as interventional radiology;
- corrected and uncorrected doses were mixed – e.g. doses were corrected for wearing position only if they exceeded some threshold, and these corrected values were then entered back into the original database of raw doses;

- reported doses were from a database that contained only doses above some action level.

After excluding dose data for the above reasons, occupational dose data from 29 countries were analyzed giving the following results:

- For those regulatory bodies reporting data for IC physicians as a group, in 2008 the average median effective dose was 0.73±0.62 mSv per year, and the average 3rd quartile effective dose was 1.09±0.69 mSv per year. The 2008 results are based on reported monitoring results from 23 countries, for a total of 1432 interventional cardiology physicians. Data were analysed on a per country basis.
- For 2006 and 2007 the average median effective doses for IC physicians were 0.67±0.64 and 0.78±0.60 mSv/year respectively, and the average 3rd quartile effective doses were 1.80±2.54 and 1.35±1.25 mSv/year respectively.
- For those regulatory bodies reporting data for other professionals in IC as a group, in 2008 the average median effective dose was 0.76±0.68 mSv per year, and the average 3rd quartile effective dose was 1.10±1.09 mSv per year. The 2008 results are based on reported monitoring results from 17 countries, for a total of 825 other professionals working in IC. Data were analyzed on a per country basis.
- For 2006 and 2007 the average median effective doses for other professionals were 0.42±0.38 and 1.07±1.17 mSv per year respectively, and the average 3rd quartile effective doses were 1.28±1.06 and 1.46±1.12 mSv per year respectively.
- For those regulatory bodies reporting data only for all persons in IC combined, in 2008 the average median effective dose was 0.56±0.47 mSv per year, and the average 3rd quartile effective dose was 1.68±0.21 mSv per year. The 2008 results are based on reported monitoring results from only 4 countries, for a total of 391 persons working in IC. Data were analysed on a per country basis.
- For 2006 and 2007 the average median effective doses for all persons in IC combined were 0.59±0.34 and 0.76±0.39 mSv per year respectively.

Distributions of median and third quartile annual effective doses from the regulatory bodies' reported data for interventional cardiologists, for the years 2006 to 2008, are given in Figure 1.

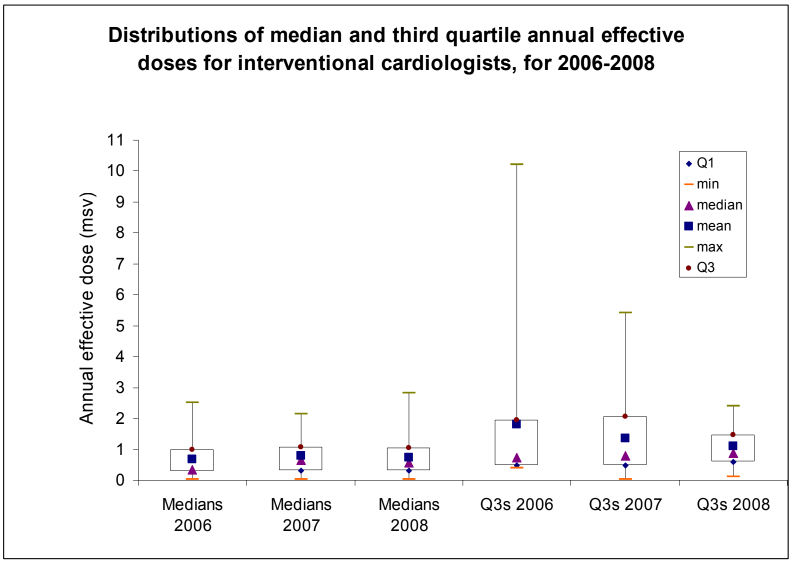

Figure 1. Distributions of median and third quartile annual effective doses from the regulatory bodies' reported data for interventional cardiologists, for the years 2006 to 2008.

The similarity in the values of doses reported for the IC physicians as a group and for the other professionals as a group deserves comment. Emphasis has traditionally been placed on the IC physician as being the person with the most potential for being occupationally exposed. Radiation protection training promotes the use of additional radiation protection tools, such as the ceiling suspended screen, to bring about a lower level of occupational exposure for the physician. The other professionals, such as the theatre nurse may not be afforded the same access to these additional radiation protection tools, having to then rely on the protective apron and distance as the main means of protection. Attention may need to be given to providing additional protective tools for these other professionals if occupational radiation protection in IC is to be truly optimized.

In all cases, annual effective doses remain well below the 20 mSv occupational dose limit, recommended by the ICRP. Specific dose values for extremities and eyes were not requested. It may be useful to obtain these in the future.

Despite some vetting of the dose data provided, other issues remain. Often personnel who have moved into more administrative duties remain on the monitored list, thus lowering average doses for that occupational group in the facility. It is very difficult to keep track of the doses for interventional cardiologists who may work in more than one facility, and reported doses may not be total doses across all workplaces. The treatment of doses at the limit of detection may differ from one regulatory body to another – a zero dose may be assigned, or a nominal minimum reporting dose or even some other nominal value. This may affect the statistical analysis, especially the mean.

But the largest potential shortcoming of the reported results is whether the dosimeters were actually being worn by the interventional cardiologists whenever they were performing IC procedures. The reported annual median effective dose values were lower than expected considering validated data from facility-specific studies, indicating that compliance with continuous individual monitoring is often not achieved in IC. Reasons for non-compliance with monitoring range from simple negligence to deliberate avoidance because of the fear of exceeding some dose threshold that leads to regulatory or administrative investigation (often as a result of an above-the-apron dose value being used as a surrogate for effective dose with no correction). All of these reasons would indicate that the results reported above are likely to be an under-estimate of the real situation.

Table 2. Number of regulatory bodies that mandate the number and position of personal dosimeters for monitoring in IC.

Region	Numberof responding RBs	Number and position mandated by the RB?		
		Yes	No	Not answered
Africa	10	3 (30)*	4 (40)	3 (30)
Asia Pacific	16	8 (50)	8 (50)	0 (0)
Europe	26	19 (73)	7 (27)	0 (0)
Latin America	5	2 (40)	2 (40)	1 (20)
North America	22	13 (59)	8 (36)	1 (5)
Global	79	45 (57)	29 (37)	5 (6)

* Values in parentheses are percentages of the corresponding total.

Concerning requirements for wearing dosimeters, 57% of regulatory bodies define the number and position of dosimeters for staff monitoring in IC (Tables 2 - 4).

Among those regulatory bodies defining the number and position of the dosimeter(s):

- 40% require the use of one dosimeter, worn above the apron (80%), and at the collar level above the apron (50%);
- 20% of regulatory bodies require the use of two dosimeters, worn beneath and above the apron in almost all cases,, except where the second dosimeter was to be used for extremity monitoring;
- 2% of regulatory bodies require the use of three dosimeters, one above and one beneath the apron, and a third finger type dosimeter;
- 38% did not specify their defined wearing position.

Table 3. Number of personal dosimeters mandated by regulatory bodies for IC.

Region	No of RBs mandating the number of dosimeters	Number of dosimeters required:			
		1	2	3	Not specified
Africa	3	1	1	0	1
Asia Pacific	8	0	2	0	6
Europe	19	10	2	1	6
Latin America	2	0	1	0	1
North America	13	7	3	0	3
Global	45	18 (40*)	9 (20)	1 (2)	17 (38)

* Values in parentheses are percentages of the corresponding total.

Table 4. Mandated location of personal dosimeters in IC when one dosimeter was mandated.

Region	No of RBs mandating only 1 dosimeter	Mandated wearing position:					
		Worn above the apron:			Worn below the apron:		
		Chest or trunk	Collar or shoulder	Unspecified	Chest or trunk	Collar or shoulder	Unspecified
Africa	1				1		
Asia Pacific	0						
Europe	10	4	2	2	2		
Latin America	0						
North America	7		7				
Global	18	4	9	2	3	0	0

Analysis of the responses on radiation protection training requirements showed that just over one half (55%) of regulatory bodies mandated RP training for personnel in order to be able to perform IC procedures. Clearly there is a need for many countries to strengthen the regulatory framework for occupational RP in IC.

The question on licensing or certification requirements for persons to be able to perform fluoroscopy in interventional cardiology unfortunately yielded ambiguous results. Analysis of responses and accompanying comments indicated that there was confusion about who needed to be licensed (e.g. the physician or the radiographer), what the licence was for (e.g. use of radiation or practice of medicine), and who issued the licence (e.g. radiation protection regulatory body or medical registration body or similar). No meaning results could be concluded, except that there was a spectrum of (radiation protection) licensing systems in use throughout the world, ranging from the physician not needing to have a licence to use radiation in interventional cardiology through to the physician needing such a licence.

Conclusions

This study presents the results of about eighty responses from regulatory bodies on staff exposure in IC practice. The results are helping the WGIC of ISEMIR formulate recommendations to improve monitoring methods and facilitate more adequate collection of data at the country level.

Obtaining reliable data on occupational exposures in IC from RP regulatory bodies proved to be difficult. Many regulatory bodies have limited access to these data, and, even if they do have access, the data are often not detailed enough to provide the required information. A further complicating factor is that recorded doses may underestimate true occupational exposure because compliance of IC personnel can be poor, and because an individual's exposures from different IC facilities may not be summed. Alternative strategies for the collection of IC occupational dose data will need to be utilized if a worldwide database of such information is to be established under the ISEMIR project.

Radiation-induced cancer risk from recurrent CT scanning

Dijkstra, Hildebrand; Groen, Jaap; Bongaerts, Fons; Van der Jagt, Eric; Greuter, Marcel
University Medical Center Groningen, University of Groningen, Department of Radiology, PO Box 30.001, 9700 RB Groningen, THE NETHERLANDS

Abstract

Radiation induced carcinogenesis is a well known potential risk of diagnostic radiology. Especially the use of relatively high dose CT and exposure at a young age may lead to increased risk. Therefore the purpose of our study was to estimate the radiation-induced cancer risk from recurrent computed tomography scanning and associated lifetime attributable risk.

The cohort comprised 11,968 patients who underwent two or more diagnostic CT's from January 2005 to January 2009. In total 44,449 CT examinations were performed. Associated risk was estimated using the BEIRVII methodology on the basis of sex, age at each exposure and estimated mean dose. Each patient's cumulative risk was estimated by combining the LAR for each individual CT.

In the cohort, the youngest patient was 2 days old, the oldest 108 years old. The average age was 55.0±17.5 years with a median of 58 years. On patients of ten years or younger 593 (1.3%) examinations were performed. Ten or more CT examinations were performed on 551 (4.6%) patients, and between 15 and a maximum of 44 CT examinations were performed on 155 (1.3%) patients. An estimated cumulative effective dose of more than 100 mSv was received by 312 (2.6%) patients, and an estimated cumulative effective dose between 150 and a maximum of 314 mSv was received by 107 (0.90%) patients. Of the patients receiving more than 100 mSv, associated LAR had mean and maximum values of 0.87% and 5.6% for cancer incidence and 0.12% and 1.2% for cancer mortality, respectively. 120 (1.0%) patients of the cohort had an estimated LAR for cancer incidence greater than 1%, of which 29 (24%) patients had no cancer history. Recurrent CT scanning in this cohort may be responsible for 16 radiation-induced cancers and 10 cancer deaths in further life.

Recurrent CT scanning added to a significant increase in cancer risk in our cohort which may be a serious problem in long term follow-up of non-cancerous patients or patients who survived their (previous) cancer.

Introduction

The use of diagnostic radiology has shown a rapid growth in recent years [1]. Especially the use of computed tomography as a 3D technique contributed to this growth [1,2]. CT usage over the past quarter of a century has risen approximately 12-fold in the UK and 20-fold in the US [2]. It has been estimated that more than 62 million CT scans per year are obtained in the US, including at least 4 million children [1]. However, radiation induced carcinogenesis is a well known potential risk of diagnostic radiology. Moreover, especially the use of relatively high dose computed tomography (CT) and recurrent exposure at young age may lead to increased tumor risk and radiation-induced mortality [3,4,5]. It has been estimated that 29,000 future cancers could be related to CT scans performed in the US in 2007 [5]. Because some patient groups with chronic diseases or for the long term follow-up of cancer are repeatedly exposed to CT and sometimes a relatively young ages, it is very important to estimate the associated lifetime attributable risk (LAR) of these exposures. Therefore, the purpose of our study was to estimate the radiation-induced cancer risk from recurrent computed tomography scanning and associated lifetime attributable risk.

Material and methods

This retrospective study was performed at a main university medical center in The Netherlands with more than 1,300 beds and 190,000 radiologic examinations in 2009. From the database of the Radiology Information System (Radi, Hiscom, Leiden, The Netherlands) all patients were extracted that underwent two or more diagnostic CT scans from January 2005 to January 2009. Re-assessment of CT scans performed in other hospitals was excluded. In addition, sex, date of birth, examination type and examination date were extracted. From the examination date and date of birth, the age of the patients at the time of exposure was calculated. From the Hospital Information System (ZIS, Hiscom, Leiden, The Netherlands) the patient history and pathology was extracted.

From the Biological Effects of Ionizing Radiation (BEIR) VII report (fig 1), the associated LAR was estimated on base of sex and age at the time of exposure in terms of the probability of tumor induction and tumor death [6]. The total radiation induced tumor probability LAR_{tot} for each patient was calculated by using the LAR at each exposure:

$$LAR_{tot} = 1 - \prod_{i=1}^{N} (1 - LAR_i) \qquad (1)$$

where LAR_i is the lifetime attributable risk at exposure i and i runs over all N exposures. The probability of radiation induced tumor death was calculated in an analogue way.

Each examination was assigned an effective dose. In table 1 a summary of the effective doses is given for the anatomical regions. The effective doses were assigned on base of typical adult doses and are within range of common published estimates. The effective dose of the individual patient, as well as the scanner type and date of examination were not taken into account. Blank and contrast scans were assigned the same effective dose and two phase contrast scans were assigned twice the effective dose.

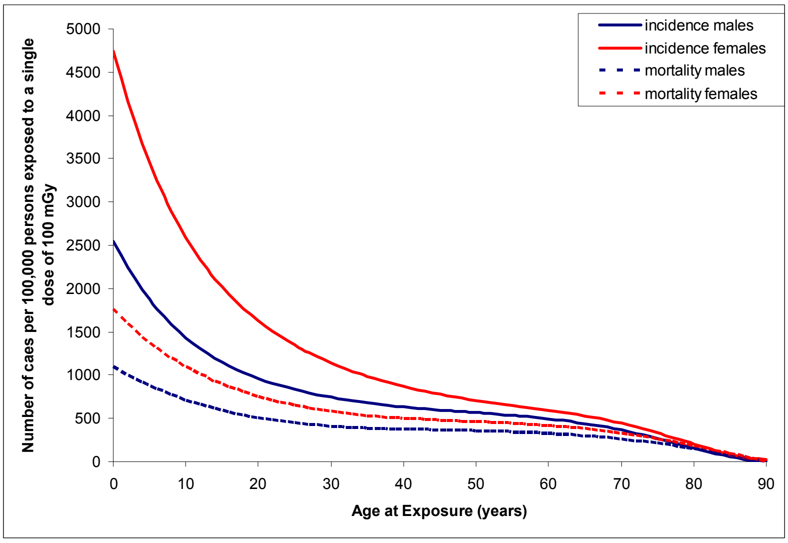

Fig. 1. Estimation of the number of radiation induced tumors (solid lines) and radiation induced mortality (dashed lines) as a function of age at exposure for males (blue) and females (red) according to BEIR VII.

Table 1. Estimated Effective dose per anatomical region in mSv.

Anatomical region	Scan	Blank [mSv]	Contrast [mSv]	Two phases [mSv]
Head	Skull	1.1	1.1	2.2
	Sinus	0.2	0.2	0.4
	Mastoid	0.3	0.3	0.6
	Mandibula	0.8	0.8	1.6
	Face	0.9	0.9	1.8
Neck	Neck, CWK	1.5	1.5	3.0
Thorax	Thorax	4.0	4.0	8.0
	TWK	5.0	5.0	10.0
	Shoulder	1.0	1.0	2.0
Abdomen	Abdomen, kidneys	10.0	10.0	20.0
	LWK, sacrum	8.0	8.0	16.0
Extremities	Upper leg	1.0	1.0	2.0
	Other	0.3	0.3	0.6

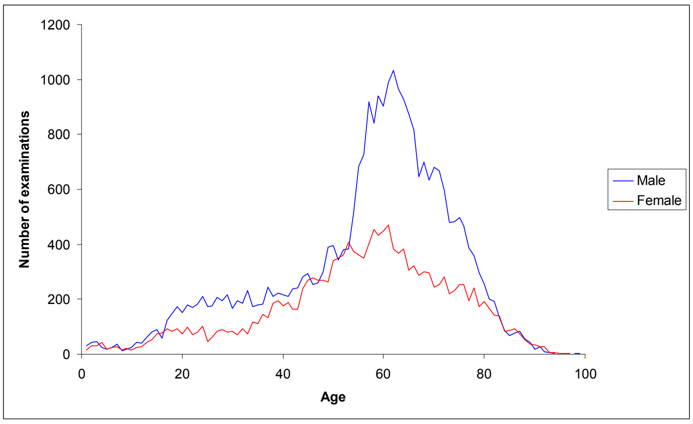
Results

The cohort comprised 11,884 patients (63.5% male). In the cohort, the youngest patient was 2 days old, the oldest patient was 108 years old. The average age was 55.0±17.5 years with a median of 58 years (table 2).

Table 2. Patient demographics.

sex	No of patients	Minimum age [y]	Maximum age [y]	Mean age [y]	Standard deviation [y]	Median age [y]
Male	7,595 (63.5%)	0	108	55.4	17.2	59
Female	4,373 (36.5%)	0	97	54.3	18.0	56
All	11,968 (100%)	0	108	55.0	17.5	58

In total 44,449 CT examinations were performed. 2,426 (5.5%) examinations were performed on patients of 20 years or younger of which 593 patients (1.3%) were 10 years or younger (fig 2). More than 70% of the examinations where performed in the thorax and abdomen region (fig 3).



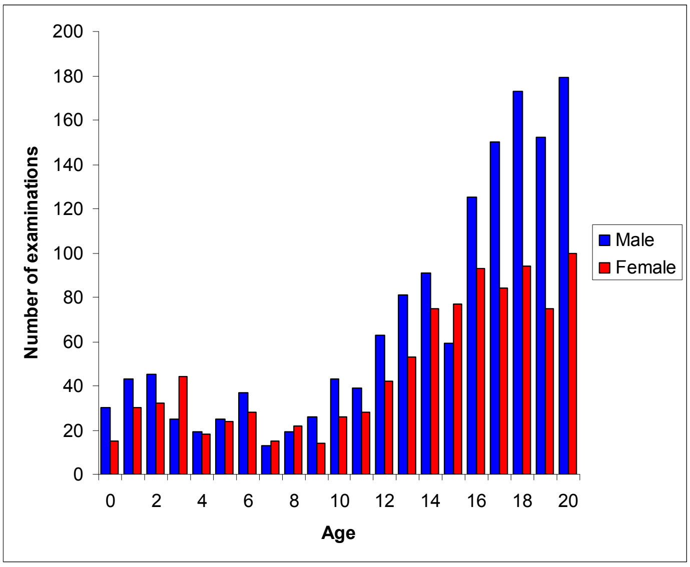


Fig. 2. Distribution of age at examination for males and females.

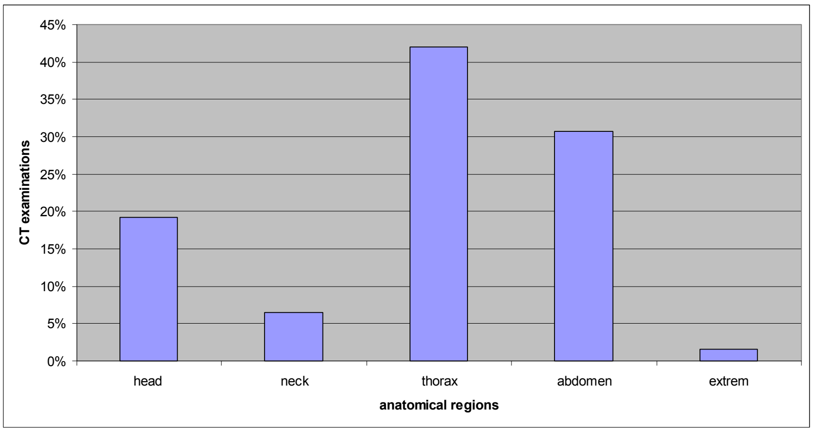

Fig. 3. Distribution over the anatomical regions for in total 44,449 CT examinations.

2,575 (22%) patients underwent 5 or more CT examinations, 551 (4.6%) patients underwent 10 or more CT examinations, and 163 (1.4%) patients underwent between 15 and a maximum of 44 CT examinations (fig 4).

312 (2.6%) patients received an estimated cumulative effective dose of more than 100 mSv, and 107 (0.90%) patients received between 150 and 314 mSv (fig 5).

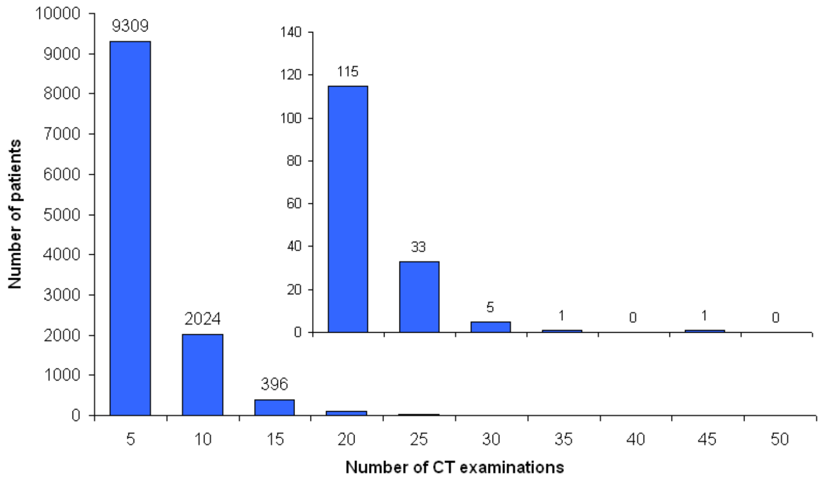

Fig. 4. Histogram of the number of CT examinations per patient.

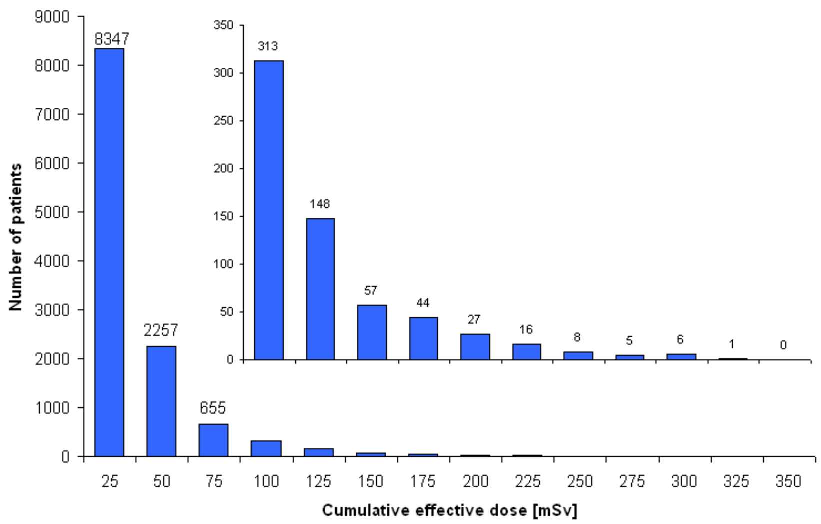

Fig. 5. Cumulative effective dose per patient.

Of the patients receiving more than 100 mSv, associated LAR had mean and maximum values of 0.87% and 5.6% for cancer incidence and 0.12% and 1.2% for cancer mortality respectively (fig 6, 7). 120 (1.0%) patients of the cohort had an estimated LAR for cancer incidence greater than 1%, of which 29 (24%) patients had no cancer history (table 3). These values imply that recurrent CT scanning in this cohort may be responsible for 16 radiation-induced cancers and 10 cancer deaths in further life.

Discussion

We have shown that recurrent CT scanning added to a significant increase in radiation induced cancer risk in our cohort. 1.0% of our patient had an estimated LAR for radiation induced cancer incidence larger than 1%. However, of these patients as much as 24% had no cancer history. These figures might cause a serious problem in the long term follow-up of non-cancerous patients or patients who survived their (previous) cancer.

Recently Sodickson et al. concluded also that recurrent CT and associated cumulative CT radiation exposure added incrementally to baseline cancer risk [7]. The cohort they studied was taken from 22 years of CT examinations from a tertiary academic medical center. Therefore, the number of patients in their cohort was much larger and the number of examinations was much larger also. In addition, they observed that 15% of their patients had a cumulative effective dose of more than 100 mSv, whereas we observed that only 2.6% of our patients had a cumulative effective dose of more than 100 mSv. As a consequence, the maximum LAR they estimated was 12% and 6.8% for tumor induction and tumor death respectively, whereas we estimated a maximum LAR which was much smaller, i.e. 5.6% and 1.2% respectively. Also the fraction of their cohort with a LAR larger than 1% was much larger than in our study, 7% versus 1%. Finally they observed that 40% of this fraction had no history of cancer, whereas we observed that only 24% of this fraction has no history of cancer. The relatively larger LAR observed by Sodickson et al. can be partly explained by the larger fraction of women in their cohort and the relatively larger fraction of thorax examinations. In addition the maximum cumulative effective dose in their cohort was much larger, 1375 mSv versus 314 mSv and also the maximum number of recurrent CT scans in their cohort was much larger, 132 versus 44. This might also partly explain the relatively larger LAR observed in their study. However, because we used larger dose values for two phase examinations and we also included patients under the age of 11 in our cohort, this would increase the LAR in our study. Recently Griffey et al. reported a maximum estimated LAR for cancer incidence of 5.6% in emergency department patients undergoing multiple CT which corresponds very well with the maximum estimated LAR for cancer incidence of 5.9% in our study [8].

In our cohort, 5.5% of the CT examinations were conducted on patients of 20 years and younger and 1.3% on patients of 10 years and younger. A study from the US showed much more patients in the same age groups, with 18% of the CT scans conducted on patients up to 20 years and 6% of the CT scans conducted on patients up to 10 years [9]. Furthermore, their dose was slightly higher for CT-head (1.5 mSv) and CT-chest (5.4 mSv) compared to the maximum effective doses applied in our study (1.1 mSv and 5.0 mSv respectively). These figures indicate that for young patients in the US the LAR from recurrent CT scanning might be even higher than the estimated LAR values for young patients in our study. In addition, it was recently shown that as much as 30 percent of all CT examinations conducted on patients younger than 35 years were unjustified and could have been replaced by magnetic resonance imaging or would not have been needed [10]. When we apply these numbers to our population then about 2041 CT examinations conducted on our patients younger than 35 years may have led to an unjustified risk of cancer incidence.

It is well known that the individual effective dose of a patient depends on the scanner type, the specific protocol used and varies with specific patient parameters [11]. We did not adjust the effective dose estimates for these effects but used average effective dose estimates per anatomical region. This approach has several limitations, and we plan to extend our study for individual patient effective dose estimates. In addition, patients with a single CT scan were not included in our study. However, because of the relative low effective dose of one single CT scan with respect to the cumulative effective dose of multiple recurrent CT scans, we estimate that the influence of including single CT scans in our cohort is relatively small. Finally, also interventional CT procedures were included in our cohort. Because the effective dose in an interventional CT procedure depends strongly on the total scan time, an average effective dose estimate would only provide a crude estimate of the patient’s individual dose. However, because the number of interventional CT procedures in our database is relatively small and we estimate that this would not change our results. Finally, the errors in the cancer risk model as presented in the BEIR VII report are estimated at a factor of 2 [6]. Therefore, the error in the cancer risk model is thought to be dominant over the other limitations listed above.

Conclusions

Recurrent CT scanning added to a significant increase in cancer risk in our cohort which may be a serious problem in long term follow-up of non-cancerous patients or patients who survived their (previous) cancer.

Abstract

According to the EC directive 97/43/EURATOM the Member States are required to implement clinical audits for medical radiological practices in accordance with national procedures. Correspondingly, the Finnish legislation requires that the radiological units have to implement self-assessments and external clinical audits of their practices. To ensure the quality and consistency of clinical auditing, an Advisory Committee for the coordination, development and follow-up of the clinical audits was established in 2004 by the Ministry of Social Affairs and Health. The committee is a multi-disciplinary group of clinical experts, independent of any auditing organizations. Its tasks include, among other things, evaluating the suitability and coverage of the criteria used in clinical audits and collecting summaries and reviews of the results.

The Advisory Committee has issued four recommendations dealing with the competence, experience and independence of the auditors, developments for the second audit round, how to take into consideration the accreditations of nuclear medicine units and the ten points of interest given for clinical audits in the legislation. Two more recommendations are being prepared concerning audit reports and how to take into consideration the new European guideline on clinical audit. Current other activities include efforts to encourage the national scientific and/or professional societies to contribute to the development of the criteria of good practice, and a review of clinical audits in some other countries in order to propose improvements of the Finnish implementation. The Committee has also conducted a survey of the results of the complete first round of audits in Finland and organized a particular seminar on clinical audits. Further information (in Finnish) is available from “www.clinicalaudit.net”. In this paper, the achievements and experiences of the national coordination efforts are discussed in detail.

Introduction

The EC directive 97/43/EURATOM (MED-directive) introduced the concept of Clinical Audit for the assessment of medical radiological practices and the Member States are required to implement clinical audits in accordance with national procedures. The directive has been transposed to the Finnish legislation with a requirement that the radiological units have to implement self-assessments and external clinical audits for their radiological practices. The practical methods of the external clinical audits are not specified in detail in the legislation, and in particular, no particular organization is designed to carry out the audits. Therefore, more than one approach for the practical implementation had been expected and a national coordination of efforts for the quality and consistency of auditing has been considered necessary.

In 2004, a national steering group, or an Advisory Committee for Clinical Audit, for the development and follow-up of the clinical audits in Finland was established by the Ministry of Social Affairs and Health. This Committee is a multi-disciplinary group of clinical experts, independent of any auditing organizations. It has representatives of all three disciplines (diagnostic radiology, nuclear medicine and radiotherapy) and of all major professional groups (physicians, medical physicists and radiographers), and in addition, a representative of Finnish Accreditation Service (FINAS) and the Radiation and Nuclear Safety Authority (STUK). The Committee has been established in three years' terms.

Objectives

The objectives of the Advisory Committee are:

- To co-ordinate and develope clinical audits for the medical use of radiation
- To promote good quality and the consistency of criteria for good practices in clinical audits

The detailed tasks of the Advisory Committee have been specified as follows:

- To follow-up the implementation of clinical audits in Finland and to prepare national summaries
- To advice on the competence and training requirements for auditing organizations and auditors
- To assess the relevance and adequacy of audit criteria in different sectors (diagnostic radiology, nuclear medicine and radiotherapy)
- To advice on examination and treatment specific audit criteria and objectives and to promote their implementation
- To evaluate the importance of other quality audits in medical practice (such as audits for accreditation or for the certification of quality systems) for clinical audits, and give recommendations on their exploitation in clinical audits
- To follow-up international developments in clinical audits and in order to develop the Finnish practice of clinical audits

Actions

One of the main actions of the Advisory Committee in order to achieve its objectives has been to prepare and issue recommendations. By now, the Advisory Committee has issued six recommendations:

- Requirements of competence, experience and independence of the auditors (Recommendation 1, 2005).
- Development of clinical audits: Recommendations by the Advisory Committee for the second audit round (Recommendation 2, 2006)
- Taking into consideration of accreditations in the clinical audits of nuclear medicine (NM) units (Recommendation 3, 2006)
- Taking into consideration of the ten points of interest given in the Degree (423/2000) in clinical audits (Recommendation 4, 2008).
- Recommendation on the audit reports (Recommendation 5, 2009)
- Recommendation on how to take into consideration the new European guideline on clinical audit (Recommendation 6, 2009).

The first recommendation specifies for example that the auditors are required to have practical clinical experience in the field to be audited, the lead auditors must have at least one week specific training on the audit techniques, and the composition of the audit team must generally include a physician (e.g., radiologist, oncologist, or nuclear medicine expert and a radiation technologist, and in certain cases (e.g. for radiotherapy), also a physicist.

The second recommendation set out the priorities for the next audit round, recommending specific topics of interest in the three fields (diagnostic radiology, nuclear medicine and radiotherapy) including more detailed “in depth” assessments of selected examinations and treatments. It also gave references to some recommended criteria of good practices. The third recommendation describes specific considerations to be taken into account in clinical audits of NM units which have been accredited, in order to avoid unnecessary overlap with the audits carried out for the accreditation. The fourth recommendation considers in detail the contents of the ten points of interest set out in the Degree (423/2000) and specifies the sub-items of each point where clinical audit should have the highest weight. The purpose of this recommendation is to unify auditor’s interpretations of these ten points of interest and to avoid unnecessary overlap of clinical audits with regulatory inspections.

The fifth recommendations gives some particular guidance on clinical audit reports, e.g. that the reports must be stored for at least 12 years. The sixth report deals with the EC Guidelines of Clinical audit [1] raising some key points of the Guidance to ensure its implementation in the Finnish practice of clinical audits.

Besides giving recommendations, the Advisory Committee has conducted a survey of the results of the complete first round of audits in Finland (2000-2006). The summary of this survey has been published (in Finnish) in the Committee web-site and is briefly reviewed below. In 2006, at the end of its first term of operation, the Advisory Committee organized a half-day seminar on clinical audits, where the recommendations of the Committee and the summaries and future development of the clinical audits, on point of view of auditing organizations and authorities, were presented and discussed. In the beginning of 2010, after the end of its second term of operation, the Advisory

Committee organized another half-day seminar on clinical audits, where the new recommendations of the Committee and the EC Guidance on clinical audits were introduced and the future development of the clinical audits (criteria of good practices, audit methods) were discussed.

Besides the published recommendations and presentations in the above two seminars, the Committee has given several lectures on clinical audit at national meetings and training events, and replied and given comment or statements on several questions by the auditing companies, auditors or individual persons from audited organizations. The Committee has also participated in two meetings between the auditing organizations and the authority (STUK), where the possible overlap of clinical audits and regulatory inspections has been discussed.

The Committee has also actively followed and participated in the international developments of clinical audits. The Committee has participated and provided scientific support on organizing of an international Symposium (2003) and an international Workshop on clinical audits (2008) in Tampere, Finland. An EC project leading to the publication of the EC Guidance on clinical audits was lead by the Secretary of the Committee, and also Committee's chairman and one other member participated in this project. Committee's members have given several presentations and published several papers on the topic of clinical audits (see the list of publications and presentations below).

Currently, the Committee is addressing the national scientific and/or professional societies in order to encourage the societies to contribute to the development of the criteria of good practice. Further, the Committee has reviewed the development of clinical audits in some other countries in order to propose improvements of the national implementation of clinical audits. The future working plan includes also the development of guidance for self-assessment of practices.

From the beginning of its establishment the Advisory Committee has maintained a dedicated web-site "www.clinicalaudit.net", where all recommendations, proceedings of the seminars and all other documents and information on the Committee have been published. The wed-site also publishes information and maintains links to the international activities where the Advisory Committee has been a contributor (e.g. the EC Guidance on Clinical Audits).

Summary of clinical audits

After the first five years period of auditing (2000-2006), the National Advisory Committee conducted a survey of the results of the audits by reviewing the audit reports, altogether 346 reports, with the permission of the audited health care units. The following gives a brief summary if this survey.

All of the first clinical audits have been carried out by the same organization, employing a total of 38 auditors from volunteered health care professionals. The audits have typically been carried out by a team consisting of a medical expert (physician) and a radiographer, in several cases (e.g. for radio-therapy, nuclear medicine and large units of diagnostic radiology) also a physicist. The duration of the audit has varied between 0,5 and 4 days depending on the size of the unit, being most typically 1-2 days. The audits have been based on the guidance and check lists developed by the auditing organization. The criteria of good practices have been derived partly from the legislative requirements, partly from existing recommendations for good clinical practices (e.g. referral guidelines, image quality criteria), while the audits to a great extent have also relied on the professional judgement of the auditors. Besides interviews and reviews of documents and data, the audits have included assessment of the image quality for a sample of patient images.

A significant number of recommendations to improve the practices have been issued in the audits, on the average 4-7 recommendations per health care unit. An example of the main topics of recommendations for diagnostic radiology units is shown in Fig. 1. The results have also suggested that the criteria of good practices, now mainly based on legislative requirements, should be supplemented by more clinical criteria in order to avoid unnecessary overlap with regulatory inspections.

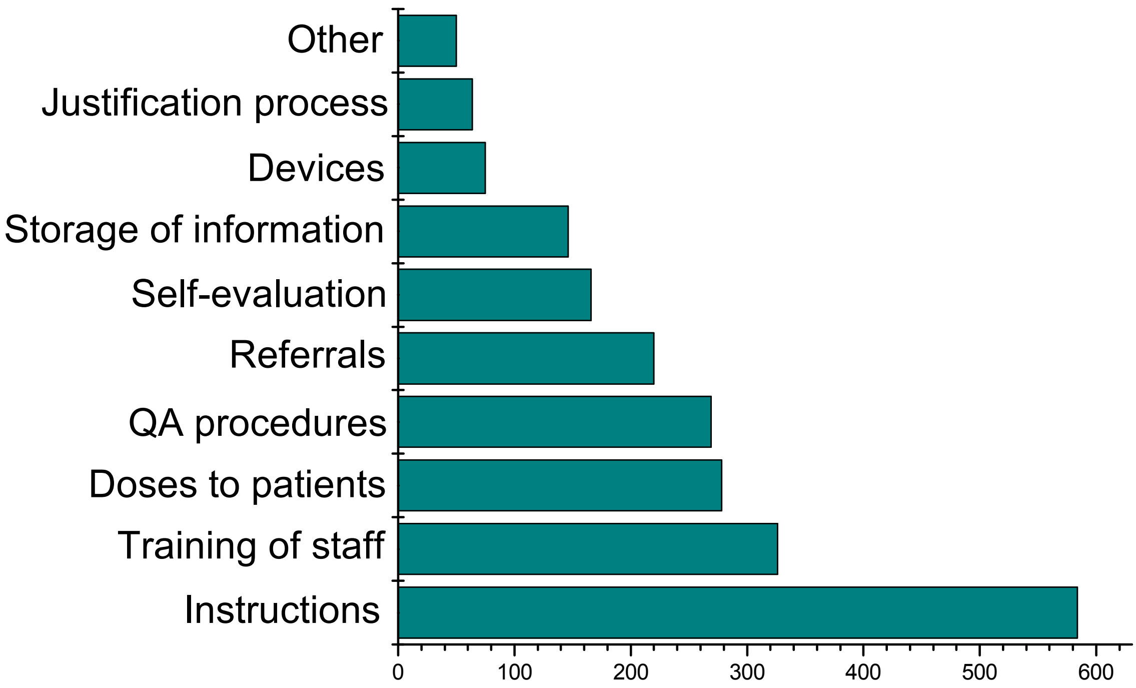

Fig.1. The total number of recommendations given at the first external clinical audits of diagnostic radiology units, classified according to the points of interest from Decree 423/2000.

Conclusions

The organization and criteria for external clinical audits in Finland have provided the radiological units with easy access to such audits. The role of the National Advisory Committee, in collaboration with the Radiation and Nuclear Safety Authority (STUK), has proved to be important for overall co-ordination, review and development of the national efforts as well as maintaining good quality and consistent methods of the audits.

Publications and presentations

Radiation protection of patients in medical radiology: proposal for a worldwide action plan

Lacoste, A. C.; Bourguignon, M.; Godet, J. L.
ASN, FRANCE

The highest doses of ionizing radiations of artificial origin delivered to the population result from medical exposures of patients (UNSCEAR data). In developed countries such as USA and Japan, they are the first source of exposure to radiations of the population, before natural exposure. Medical exposures represent an average of 1 mSv per capita per year worldwide. By averaging the data over the whole population when only about 10% of it is exposed annually, the average value of 1 mSv underestimates the real average dose effectively received by the persons medically exposed.

Exposures of the populations to ionizing radiations from medical origin are constantly increasing worldwide. The trend in dose increase in diagnostic radiology and nuclear medicine seems unavoidable and is due to a combination of factors :

- There is a clear increase worldwide in the number of medical equipments which deliver the highest doses, i.e., CT and PET, because they are the most useful;
- There is an increase in the number of examinations which deliver the highest doses : whole body scanning, virtual colonoscopy, CT coroscanning … Whole body CT may deliver in one single examination almost the maximum effective dose that a worker can receive in one year, i.e., 20 mSv;
- Radiologic imaging results in a net health benefit for the patients :
    - Medical imaging is a decisive tool in combination with laboratory dosages for making the diagnosis of diseases ;
    - Medical imaging is also an efficient non effractive tool to treat patients. Interventional radiology as a subspecialty of radiology is also a growing field because it provides minimally invasive ways of diagnosis and therapy under image guidance. It is widely used to replace surgery whenever possible for treating heart, brain, kidney … vascular diseases or tumours ;
    - Finally, medical imaging is decisive to drive the therapeutic strategy and to follow up the efficacy of patients' treatments.

Recurrent publications advocate an excess of cancers due to medical ionizing radiations. Hypothetical numbers of cancer in excess are calculated on the basis of the ICRP risk estimates for low doses of ionizing radiations.

However, attention needs to be paid to limit the medical doses delivered since they may reach in some patients in whom examinations are repeated the level of the upper limit of the so called "low doses", i.e., about 50 mSv in children and 100 mSv in adults, above which statistically significant increase of cancers has been established. Thus if medical exposure of patients continue to grow, time will come in few decades where an excess of cancers will be demonstrated by epidemiology studies.

Thus time has come for a worldwide action plan to limit the growth of medical exposure to ionizing radiations.

Action plan

Since medical exposures to ionizing radiations are the highest of all exposures, and since the trend in the increase of dose due to medical imaging seems unavoidable, the radiation protection authorities, the international organizations in radiation protection and the medical professionals could slow the rate of increase through the following actions :

1. Radiation protection principles to be revisited and enforced :
   - Justification of new radiology procedures, e.g., whole body CT, CT coroscanning, CT virtual colonoscopy,… Request to the medical professionals to identify the real indications/non indications of these new techniques and to complete the referral criteria for imaging guides. Support of the recent WHO initiative for the development of an international referral criteria for imaging guide;
   - Optimization of CT and interventional radiology. Request to the medical professionals to revisit the guides of procedures in the sense of their optimisation;
   - Support of the IAEA initiatives in radiation protection of patients;
   - Dedicated attention to children and young adults.

2. Substitution by other medical imaging modalities (MRI and ultrasound) to be encouraged :
   - Request to the professionals to revisit the referral criteria for imaging guide by highlighting when MRI and ultrasound must be preferred to radiology and nuclear medicine procedures when the results are equivalent ;
   - Request to medical policy makers to favour the installations of MRI equipments at an appropriate level to be determined on the basis of the delay of appointment for an examination.

3. Optimisation of CT and digital imaging equipments :
   - Request to industry to optimise, lower the doses delivered by the equipments, e.g., pulsed radiology for interventional radiology, and develop the corresponding standards in relation with standardisation organisations;
   - Request to industry to provide the radiologists with in line dosimetric parameters for optimisation, to include these data in the headers (DICOM) and to provide software for the statistical use of these data as an experience feedback;
   - Continuous development of quality assurance, especially regarding the new digital equipments;
   - Support of the recent HERCA initiative.

4. Specific training of all medical radiology professionals
   - Enforcement of a continuous training in radiation protection. Modules of training to be developed and distributed;
   - Development of peer training regarding new technologies, especially in interventional radiology.

5. Development of concerted actions for the audit of radiology practices, especially for the procedures delivering the highest doses, i.e., CT, interventional radiology and PET;
   - Elaboration of guidelines for peer review of medical practice. Support of the European Commission initiative (RP n°159);
   - coordination with the authorities, if any, responsible for the control of medical device safety as a whole (e.g., AFSSAPS in France).

6. Organization of periodic scientific meetings to make the point on all radiation protection issues in medicine

7. Information and education of patients regarding the risks of ionizing radiations

TLD postal dose audit of radiotherapy beams calibration: creation of national quality assurance system in Ukraine

Pylypenko, Mykola[1]; Stadnyk, Larysa[2]; Shalyopa, Olga[2]
[1] Grigorev Institute for Medical Radiology, Chief of Institute, Scientific Chief, UKRAINE
[2] Grigorev Institute for Medical Radiology, Central Laboratory of Radiation Hygiene of Medical, UKRAINE

Abstract

According to IAEA/ICRU requirements for effective radiotherapy and prevention of radiation effects the discrepancy between stated and delivered absorbed dose in tumor should not exceed ±5 %. In Ukraine the metrological control of radiation parameters of radiotherapy units in hospitals are carried out once per 2 years. In hospitals a control of radiation beam calibration are carried out by medical physics using own clinical dosimeters once per quarter or year. But it is necessary to organize the independent control of calibration quality. In 1969 IAEA with WHO established the TLD postal programme to verify the calibration of radiotherapy beams in developing countries. The main purpose of the programme is to provide an independent quality audit of dose delivered by radiotherapy units using TL-dosimetry. Ukraine was included to IAEA programme since 1998. During 1998 – 2008 there were 152 radiation beam checks of 76 radiotherapy units. Although the participation in IAEA/WHO TLD-audit was voluntary and confidential some hospitals (about 25%) never took part in this programme. IAEA/WHO TLD dose audit shows that only 47 – 75% of radiation beams in different years (average value – 64,5%) were within the acceptance limits of ±5 % at first stage of TLD-audit, moreover about 10 – 15.5% of radiotherapy beams had errors of calibration outside ± 10%. After two stages only 69.6 – 89.5% (average value – 77,6 %) of radiotherapy beams were in the acceptance limits of ± 5%. The main reasons of such results were outdated state of radiotherapy units and clinical dosimeters in hospitals, absence of qualified medical physics and using old methodology of absorbed dose estimation in tissues. Thanks to technical and methodological support of IAEA, Ukraine has a possibility to create national system of TLD postal dose audit and provide the control of quality calibration of radiotherapy beams for all hospitals on regular and obligatory basis that will assist in improving quality of radiotherapy.

Making the best use of the radiation in diagnostic radiology – improvement is needed

Almén, Anja; Leitz, Wolfram; Richter, Sven
Swedish Radiation Safety Authority, SWEDEN

Abstract
In the radiological protection community there is an increasing concern about justification. This is partly, due to the remarkable increase in the number of CT examinations in the last 10 years in Europe and in the US, and partly because it is recognized that there is a large potential for averted dose if a substantial part of the examinations is unnecessary. Because of this concern a study was conducted in Sweden in order to investigate the level of unjustified examinations. The study included all patients, in all departments, from large university hospitals to small health care units, examined with a CT scanner during one specific day. There were patients without known disease, patients before, during and after treatment of disease. The evaluation was performed by a group of radiologists and physicians. Some findings; a substantial part of the examinations were unjustified, about 20 %. Certain types of examinations had a higher and some a lower level of justification compared to the average number. Examinations of younger patients had a slightly lower level of justification. But as anticipated the observers were not always unanimously in the grading. The first conclusion is obviously, that justification is important and there is a need for the radiation protection community to take active part in the work. Furthermore, it is not fruitful to compare the data in this study with others because the result depends on the methodology and the examinations included. The study also indicates that it is necessary to improve the situation for specific types of examinations. In order to improve the situation much work is needed. One key issue is to develop a system for assessing the cost and the benefit of the procedures. It should be emphasized that risk comprises not only radiation risk. In order to succeed a joint effort involving different professionals is required. This is a challenging task but is essential when striving for making the best us of the radiation.

Concern has been raised
Diagnostic radiology is used in different situations and for different purposes, e.g. to verify disease or in planning treatment. Thus, there are different reasons for performing examinations. Which type of equipment is available differs, conventional radiology, computer tomography, magnetic resonance imaging or ultra sound examinations can be chosen, sometimes for the same purpose. Different methods might be applied with

specific equipment and new equipment, techniques and applications is introduced. One important question is how these complex situations can be managed in the health care sector, so that the diagnostic procedures have positive impact on the health of the individual patient.

The consumption of radiology differs between countries, e.g. the number of examinations per capita differs between the European countries [1]. One example, the total number of x-ray examinations per 1000 inhabitants and year differ with a factor of 4 between the UK and Germany. The reasons for such differences are not obvious, it might be due to differences in the availability of health care, diagnostic equipment, medical doctors, radiology specialists, or to factors such as reimbursement systems. No clear answers have been given, and most remarkable a medicine based reason has not been presented yet.

Common to all countries the rapidly increasing number of computer tomography (CT) examinations [2]. Serious concerns for this development have been expressed. Some are concerned about the health care costs and some about insufficient competence for performing complex examinations, and others are concerned about the increased radiation dose. The increased number of examinations might, at least partly, be explained by an increasing number of unjustified examinations. The present study was designed to cover this aspect.

Finding a method to assessed justification

The assessment of justification is not an easy task. On a more generalised level the outcome of different diagnostic procedures has to be evaluated systematically, which gives evidence on what impact the diagnostic procedure has on the handling of specific group of patients. Unfortunately, for many of the procedures evidence on this level is not available [3]. Therefore evidence on a lower level has to be accepted in the guidelines for the use of diagnostic procedures that have been worked out [4]. There are also hazards, including radiation, that have to be addressed in order to truly evaluate a diagnostic procedure. Thus this is a complex situation.

For the individual patient it has to be investigated whether a certain diagnostic procedure will give a positive impact on that particular person's health. A complete thorough analysis has to be performed for every patient, including the outcome of the investigation and the impact on health. This requires large resources and the involvement of different professionals. The studies available use simpler methods of estimating the justification level [5, 6, 7], as did the Swedish study which was based on the evaluation of referrals [8].

The Swedish study design and results

The referrals for all CT-examinations that were conducted in Sweden during one day were requested, which resulted in a total of 2435 CT-examinations. Eighteen physicians were engaged as evaluators of the justification of the examinations. Predominantly each examination was evaluated by two physicians, one clinician and one radiologist. A CT-examination was regarded as justified when the examination was judged as accurate for this patient.

In addition to patient data, information was available on the organisation as well as health care region the prescriber belonged to and on the anatomical region examined. About 20 % of the examinations were found to be not justified. Further analysis is required.

Making use of the results from the assessments

Three aspects will be discussed here; differences found for different types of examination, examinations performed in different health care regions and for different prescribers.

Different health care regions

Due to the fact that the study involved the whole country results for different health care regions can be derived, figure 1.

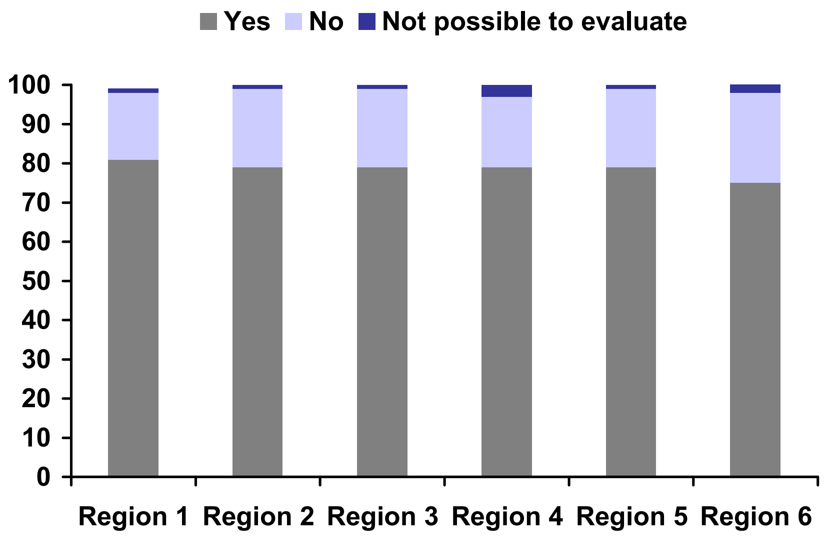

Fig 1. Level of justification (%) in different regions, all examinations.

No difference can be found between the health care regions. However, the data comprise all types of examinations, referred to for various reasons. These highly aggregated data could very well hide important findings.

Different types of examinations

In figure 2 the level of justification for different types of examinations is shown.

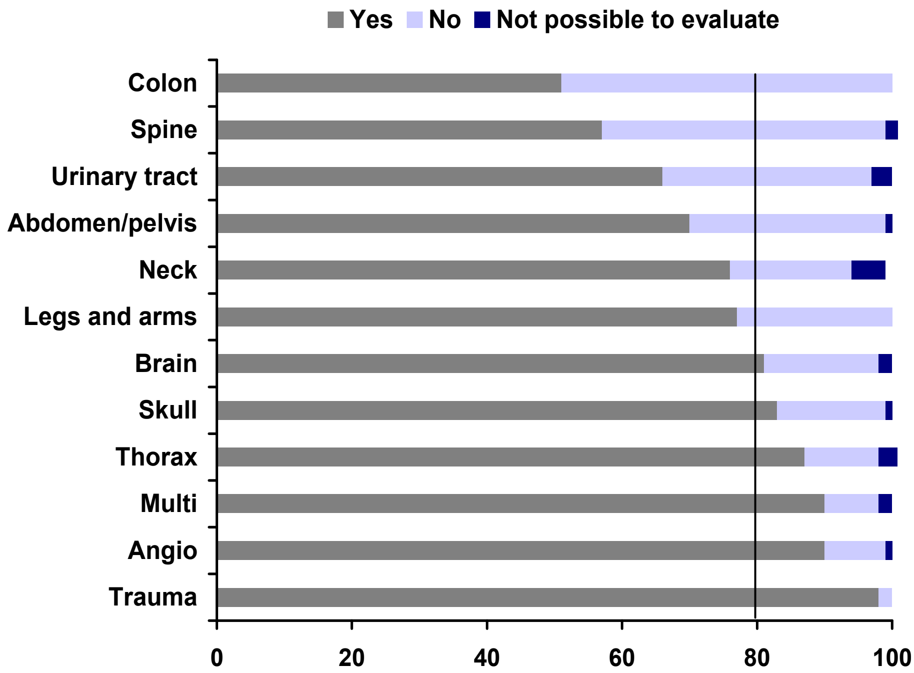

Fig 2. Level of justification (%) for different types of examinations.

The level of justification is different for different types of examinations. For example, more than 45 % of the colon and spine examinations were unjustified. On the other hand, for the trauma and angiographic examinations the figure was less than 10%.

Different health care regions and different types of examinations

Large differences between health care regions were found when going into more detail in the analysis. Figure 3 gives fraction of those spine examinations (in %) in the various regions which that should have been replaced by a MR or ultrasound examination according to the opinion of the evaluators.

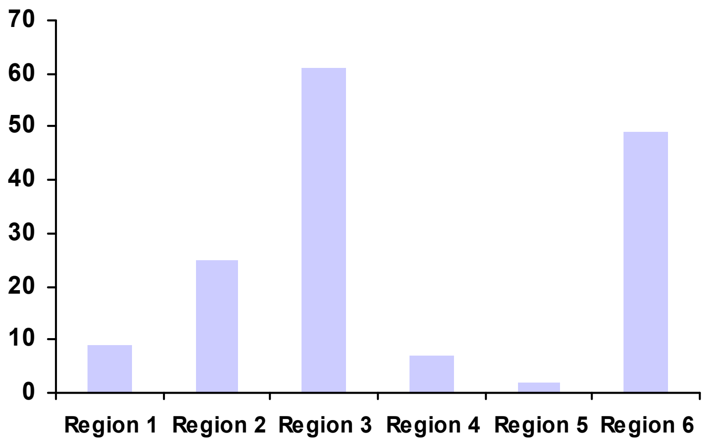

Fig 3. The fraction of spine examination that should have been replaced by a MR or ultrasound examination.

For region 3 and 6 more than 50 % of the CT examinations should have been replaced by MR or ultrasound examinations according to the opinion of the evaluators. For the regions 1, 4 and 5 this figure was less than 10 %. No obvious reason for these differences was found.

Prescribers from hospitals and health care centres

It is also interesting to study the significance of the prescriber's place of work. The results for examinations referred from hospitals and from health care centres respectively, are shown in figure 4.

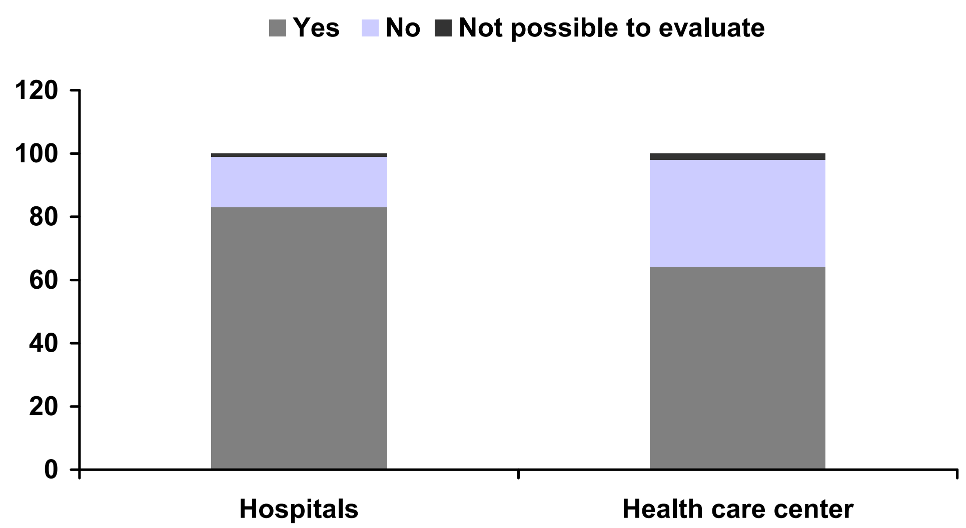

Fig 4. The level of justification (%) for examinations from hospitals and health care centres.

Clearly a difference exists. A larger fraction of examinations referred from health care centres were unjustified. In this context, it should not be forgotten that the radiology departments did agree to perform the examinations.

Experiences from the study

The study showed that assessment of justification is not an easy task, and unambiguous results cannot be expected. As could be predicted the evaluators did not always agree on what was justified since consensus not exists when to perform what type of examination. The need for more elaborated guidelines and discussions about these guidelines is evident.

The methodology differs between different studies; therefore when comparing the results it is important to consider the design of the studies. Our study gave an overall figure of 20 % unjustified CT examinations, however, when looking at specific examinations this figure varies between 2 and 50 %. Other studies have shown figures for unjustified examinations varying between 4 to 40 %. This is an indication that unjustified examinations are a considerable problem that must be dealt with [5, 6, 7].

Addressing radiation risk

In the Swedish study we have not specifically addressed radiation risk, apart from the fact that CT is a relatively high radiation dose examination. The risk, any risk, is difficult to assess for one individual in advance. The concept of effective dose and risk calculations is not directly applicable for an individual [9]. Thus, the risk assessment, any risk assessment, has to be performed for a group of individuals. Therefore the radiation risk has to be accounted for in the evaluation of different types of examinations, on the more generalised level.

Conclusion - more multidisciplinary work is needed

This study is an assessment of justification, but it is not a full evaluation of diagnostic procedures. That will include evaluating diagnostic performance, diagnostic impact, hazards (including radiation), costs and impact on health taken into account. It is also important not to forget that a prerequisite for a justified examination is a high quality (optimised) examination and a qualified evaluation of the examination. In order to improve the situation a multidisciplinary approach is needed.

This study shows that there are disagreements between different professionals. Much work has to be done on a national and sometimes international level in order to minimise these differences. The subjects that could be addressed are; what to expect (and not to expect) from the diagnostic procedure, when to perform (and not to perform) a certain diagnostic procedure and how (and how not) to perform the diagnostic procedure. This should include a true evaluation to what extent the diagnostic procedure is indicated and contributes to good health. For the radiation protection community a well-known example of assessing justification is mammography screening for early detection of breast cancer. Here the evaluation included the cost, the radiation risk, the diagnostic performance, the ability to treat disease, preparedness for handling false positive findings and the acceptance of false negative results [10, 11]. This example shows that there are interdisciplinary issues so complex that collaboration on a European level would be recommended.

For the individual patient a robust system including guidelines, sufficient clinical indicators, communication with the patient and between professional and competent experienced judgments remains a prerequisite making the best use of diagnostic radiology. In the development of guidelines the radiation risk and optimisation of examinations are important issues to deal with and this is not possible without involving the radiation protection community.

On the patient dose recording and reporting

Coroianu, Anton[1]; Ghilea, Simion[2]; Rosca Fartat, Gabriela
[1] SC MB TELECOM Ltd, SC Hiperdia SA, ROMANIA
[2] Nuclear Training Center, ROMANIA

Abstract
Romanian authorities built a regulatory framework for implementing the radiation protection requirements in the field of medical exposures. In this regard, among other actions, it was issued a legal binding document that requires a system for recording and reporting, at national level, the patient doses for each X-ray generator or irradiation source used in diagnostic or treatment. The responsibility for recording the data belongs to the practitioner, and the correctness check is radiological safety officer's duty. Moreover, in case of diagnostic radiology, the patient shall be informed in a written form about the dose he received during the procedure. The aim of this paper is to make an analyse on the appropriateness of parameters required by regulation and on the patient radiation protection benefits and costs in the context of a recognised need for harmonisation of quantities, terminology and procedures for dosimetry in diagnostic.

Introduction
The Article 12 of Council Directive 97/43/EURATOM requires Member States to ensure that the distribution of individual dose estimates from medical exposure is determined for the population and for relevant reference groups of the population in Member States. Following the request regarding the implementation of Directive's requirements the necessary regulations and administrative provisions brought into force by the Romanian health authorities by issuing the Order no.1542/2006 of the Ministry of Health. The provisions of this regulation establish a mechanism to collect and to report the patient's doses at the national level, involving in this process all the diagnostic radiology, nuclear medicine and radiotherapy departments within the country. In order to harmonize at the national level the reporting system, the Order no. 1003/2008 of the Ministry of Health has been published. Among the other information, the effective dose of all patients shall be reported. The regulations seem to be burdensome and difficult to be respected because the provisions have no regard to ICRP recommendations and there are no adequate procedures and available resources.

Regulation on recording and reporting the dose of the patients
The objective of the current regulation is to build a system for recording and reporting of the data regarding the medical exposure to ionizing radiation of the population. In this regard, for each X-ray generator or irradiation source used for medical purposes, it

is required to be ensured an individual recording system either electronically or on the paper for monitoring the data results from medical exposures to ionizing radiation of the population.

According to the legally binding provisions, the recording system shall include at least the following information:

1. Patient data:
   a) name and surname;
   b) date of birth;
   c) personal identification number;
   d) gender;
   e) height;
   f) weight;
   g) in cases of females of childbearing potential it shall be mentioned the possibility of pregnancy and during pregnancy, if necessary;

2. data on individual exposure parameters used, as appropriate:

Diagnostic radiology	Nuclear Medicine	Radiotherapy
a) Projection (examination)	a) Examination or treatment type	a) Procedure type
b) Source-patient distance (cm)	b) Radiopharmaceutic/radionuclide	b) Source-patient distance (cm)
c) Field (cm x cm)	c) Administrated activity (Bq)	c) Field (cm^2)
d) kV		d) Target volume (cm^3)
e) mA		e) The dose/session (Gy)
f) mAs		
g) timp (s)		
h) DAP(mGy x cm^2)		

3. data for patient dose assessment, as appropriate:

Diagnostic radiology	Nuclear Medicine	Radiotherapy
a) DAP indication (mGy x cm2)	The effective dose estimated	a) Number of sesions
b)Skin absorbed dose (mGy)		b)The total dose in target volume
c) Absorbed dose rate at the intensifier screen surface (mGy)		
d) CTDI (mGy)		

The responsibility for recording the above data is assigned by the regulation to the practitioner and the responsibility for checking the accuracy belongs to the radiation protection officer. The license holder shall centralize the data at the institution level according to the information system of the Ministry of Public Health. Moreover, the patient shall be notified in writing regarding the result of the examination and the dose received due to the medical exposure to ionizing radiation. The data registered could be controlled by the competent authorities and shall be archived for a minimum 5 years period. The centralized data shall be reported quarterly by the license holder to the ionizing radiation hygiene laboratory based on territorial assignation. The Ionizing Radiation Hygiene Laboratory forwards the centralized data to the county public health authorities and Bucharest, up to the end of the next month of the reporting month. Counties and Bucharest public health authorities shall annually report to the Ministry of Public Health the centralized data on the medical exposure of the population in the counties and in Bucharest. The Institute of Public Health centralizes the collected data reported by counties and Bucharest, issues an annually report and informs the Commission of Radiology, Medical Imaging and Nuclear Medicine which belongs to the Ministry of Health. The Commission of Radiology, Medical Imaging and Nuclear Medicine review the report provided by the health authorities and proposes an action plan for optimizing the radiological procedures. The annual report data on medical exposure of the population and the plan for optimizing radiological procedures are subject to approval by Minister of Public Health and shall be forwarded to the National Commission Nuclear Activities Control, and international institutions concerned, as appropriate. Violating the provisions of this Order shall be punished administrative, disciplinary, or criminal contravention, as appropriate, under the law. In order to detail the requirements of the Order 1542/2006 on recording and reporting the patients' dose and to establish a unitary system for recording and reporting, Ministry of Public Health issued the Order no. 1003 of May 19, 2008 for approving the use of forms for registration and reporting data on medical exposures to ionizing radiation. The provisions of this regulation establish the forms for registration of the individual parameters of exposure in diagnostic radiology, in nuclear medicine and in radiotherapy, for recording data on individual medical exposure to ionizing radiation and for the centralized reporting data on medical exposure to ionizing radiation by the hospitals that provide radiology, nuclear medicine and radiotherapy. In order to be in accordance with these requirements the hospitals should report, among other information, the number of examination/type of procedure for different age/sex distribution and the corresponding dose, mean dose, and effective dose, including for the X-ray dental examinations and for nuclear medicine.

Discussion

Actually, the issued regulations require a national study without having the necessary resources to perform it properly because guidance on the effective dose assessment methodologies and medical physicists with particular expertise in diagnostic radiology dosimetry are available neither in hospitals nor in the Ionizing Radiation Hygiene Laboratories. Moreover, the mandatory requirements focus only on the dose patient and do not take into account the image quality indicator and the fact that there are large uncertainties in the coefficients used to convert dose measurements to effective dose. According to the ICRP recommendations, the main uses of effective dose are the prospective dose assessment for planning and optimization in radiological protection, and demonstration of compliance with dose limits for a regulatory purpose which is not the case of medical exposures. Nevertheless, the effective dose is useful as a comparator for relative magnitudes of doses for different types of examination, but it must not attribute to this more certainty than is justified. The use of effective dose for assessing the exposure of patients has severe limitations that must be considered when quantifying medical exposure. Effective dose can be of value for comparing doses from different diagnostic procedures and for comparing the use of similar technologies and procedures in different hospitals and countries as well as the use of different technologies for the same medical examination. However, for planning the exposure of patients and risk-benefit assessments, the equivalent dose or the absorbed dose to irradiated tissues is the relevant quantity. Moreover, the regulations do not take into account that for the examinations where particular radiosensitive organs receive significant doses, it is recommended to give estimates of doses to these organs in the assessment, rather than effective dose. Also, it is recognized that for complex examinations, detailed analyses of dose for each projection should be undertaken. This could allow an indication of effective dose to be obtained for particular examinations. However, this level of detail requires a significant effort to provide information that is of limited value and involve an unjustified cost and very limited benefit for the patient. Therefore, the absence of a certain level of strictness will determine a high level of inaccuracy that may negatively influence the results and conclusions despite of workload spent and obtaining no significant benefits for the patients.

Conclusions

A national study performed according to Radiation Protection no.154 - European Guidance on Estimating Population Doses from Medical X-Ray should replace the regulations for the estimation of population doses as required by the Article 12 of the EC Medical Exposure Directive. It is recognized that the collection of data on medical exposures is important to provide a large national data bank of doses for the specific range of hospitals, but this goal could be achieved without burning regulations and unacceptable costs. It should be considered the suitability of the involvement of the medical radiology professional societies, in order to establish the priorities, methods, quantities, cost effectiveness and for the assessment of the results. Moreover, in order to decrease the workload and to increase the accuracy of the collected data for future population dose estimates it should be established electronic information systems in hospitals as input to the national database. In addition, the approach that includes the dental X-ray examinations in the scope of the medical exposure data collection of the population should be reconsidered.

Abstract

The introduction of new and more beneficial diagnostic procedures combining CT and PET or SPECT is related to a rapid growth of medical exposures. The European collaborative project MADEIRA (Minimizing Activity and Dose with Enhanced Image Quality by Radiopharmaceutical Administration) within the 7th EURATOM FP aims to improve 3D nuclear medical imaging in terms of increase of spatial and temporal resolution and also of reduction of the radiation exposure. The project is organized in 5 work packages, which are identified as:WP1 assessment of clinical data, WP2 PET magnifier probe development, WP3 physics-based image processing; WP4 biokinetic and dosimetric modelling; WP5 training and dissemination activities. In particular in WP1 quantitative biokinetic data were collected in patients after administration of 18F-choline and those data were used to develop detailed compartmental models and to evaluate the internal dose to the patient. Moreover, the biokinetic models were used as a basis to define more efficient protocols for data collection (WP4). The collected tomographic images were used to test different reconstruction algorithms (WP3) including some newly developed ones for which a patent is pending. In addition a special phantom for checking image quality in nuclear medicine imaging was designed and also for this a patent is pending. WP2 deals with the construction of a PET insert probe. The different modules of the probe have been developed and their performances monitored, and the probe prototype is going to be tested in clinical conditions with the use of the developed reconstruction methods. Finally, training and dissemination activities include the organization of two training courses (Milan, November 2008; Malmö November 2009), and the Malmö Conf. on Medical Imaging (June 2009) as well as the tutoring of graduate and doctoral students and young post-doctoral researchers.

A study for the application of prospective approaches for safety assessment in new radiotherapy techniques

Abstract

Modern and advanced planning and delivery technologies and techniques, recently introduced in radiation therapy for improving the treatment outcome, call for new challenges in terms of radiological protection of the patient and risk management of potential accidental exposure. The increased complexity related to these technological and process changes, places indeed new demands on quality assurance programmes and new attitudes and approaches of safety culture. In particular, prospective techniques for risk assessment in modern radiotherapy practices are recommended. A research project aimed to study these aspects and to sensitize the Italian scientific community in the use of prospective approaches has been recently launched by a working group of the Italian Association for Medical Physics (AIFM). In the first phase of the project intraoperative radiation therapy (IORT) practices carried out with mobile electron linear accelerators are considered. Process flow diagrams describing the activities, the instruments and the adopted procedures are properly developed in view of the identification of possible failure modes and the assessment and management of the associated risk. The methods and the analyses performed during this first phase are presented in this work. In a second phase, similar approaches will be considered and applyed for the risk assessment in other modern radiation therapy techniques, including hadrontherapy.

Introduction

Radiotherapy technologies and methodologies to plan and accurately deliver the dose to the target volume significantly improved in the recent years. Intensity modulated radiation therapy (IMRT) is becoming the standard technique in most of the developed countries, and, since the start-up marketing, more than 200 tomotherapy machines are operating throughout the world. Similarly, other modern radiation therapy techniques like intensity modulated arc therapy (IMAT), image guided radiotherapy (IGRT), stereotactic body radiotherapy (SBRT) are gradually gaining ground in many radiation therapy departments. Also the number of patients treated with intraoperative radiation therapy (IORT) is increased as effect of the recent development and rapid growth of dedicated treatment units. Finally, centres and facilities devoted to hadrontherapy are spreading in various countries.

The increased complexity related with the technological and process changes, places new demands on quality assurance (QA) programmes and new attitudes and approaches of safety culture. In fact, traditional instruments and procedures for QA, for the characterisation of radiation beams, and for the verification of the delivered dose may be no more adequate and effective for the modern radiotherapy techniques.

A number of accidents in conventional external radiotherapy have been extensively investigated and the lessons learned from events with major consequences have been reported and disseminated with the aim to prevent reoccurrence, following the so called “retrospective approaches” (IAEA 2000; ICRP 2000). Some general lessons learned from accidents occurred with conventional radiotherapy can be applicable also to new technologies. In particular, the presence of well-trained staff with necessary education background and specialised training; the draw up of written and comprehensive procedures and the identification of responsibilities are key-elements for a successful treatments, independently of the techniques used (Ortiz Lopez 2009).

However, in order to assess and manage the new risks deriving from the use of innovative radiotherapy methodologies, retrospective approches are not enought adequate since they have the intrinsic limitation of being confined to reported experience, thus unreported events or other latent risks remains unaddressed. Therefore, prospective approaches have to be implemented with the aim to find out all the elements that could go wrong and to identify, *a-priori*, all the potential hazards that might occur during a radiotherapy treatment. Prospective approaches are widely applied in high-risk industries, such as the nuclear, aviation, and chemical industries to assess and manage risk. Recently, the interest in using these methodologies for safety assessment in complex medical practices, like radiotherapy is gaining importance, and literature on this topic is rapidly increasing (Ekaette et al. 2006; Ekaette et al. 2007; Ford et al. 2009; Huq et al. 2008; Ramirez 2009; Thomadsen et al. 2003; Vilarguit et al. 2008).

On the basis of this new needs, at the beginning of 2010, a multidisciplinary working group (WG) involving experts from the European Institute of Oncology (IEO), from the National Centre for Oncological Hadrontherapy (CNAO) and from the Physics Department of the State University of Milan has been established in the frame of the Italian Association for Medical Physics (AIFM) with the aim to sensitize the Italian scientific community in the use of prospective approaches in radiotherapy practices. The components of the working group have skills and experience in various areas including radiation therapy, oncology, health physics, dosimetry, radiation protection, statistics, computer science and modelling complex systems. Considering the experience on IORT gained by the components of the WG, it was decided to start to become familiar with prospective techniques using this irradiation methodology.

Intraoperative radiation therapy (IORT) using electron beams is a special treatment modality involving the delivery of a single-fraction large radiation dose to the exposed tumour or tumour bed at the time of surgery. Due to its multi-disciplinary nature, this procedure needs a well-coordinate team approach by anaesthesia, surgery, radiation oncology and medical physics staffs. For many years, IORT has been commonly performed using a conventional linear accelerator located in a radiotherapy treatment vault or, only in a few cases, in a dedicated and shielded operating room (OR) (Palta et al. 1995; Beddar et al. 2006, ISS 2003). The recent development and rapid growth of dedicated treatment units, namely mobile linear accelerators, have changed the scenario in a relevant way, allowing a larger number of patients to undergo normal surgical procedure and immediate irradiation without the need of transportation outside the operating theatre.

Mobile linear accelerators are quite compact and only operate in electron mode up to 10-12 MeV for radiation protection restrictions, thus offering the great advantage that they can work in almost any conventional OR.

At the European Institute of Oncology (IEO) in Milano (Italy), since 1999 more than five thousands patients have been treated with IORT, using two dedicated mobile linear accelerators installed in different ORs: a Novac7 (NRT, Italy) and a LIAC (Sordina, Italy). At IEO, IORT is mainly used in the conservative treatment of early-stage breast cancer (figure 1), either exclusively for partial breast irradiation at the dose of 21 Gy or as an anticipated tumour-bed boost at 12 Gy (Orecchia et al. 2003; Veronesi et al. 2005; Ciocca et al. 2003, 2006, 2009; Ivaldi et al. 2008).

In terms of the risk of accidental radiation exposures to the patient, the main critical aspect in IORT seems to consist in its single-shot nature itself, unlike conventional radiation treatment modalities, where daily dose fractionation can somehow permit dose compensation if a systematic error in the whole treatment process is detected. Furthermore, in IORT up to now no image-based treatment planning is normally performed prior to the dose delivery, treatment parameters (like field size, beam energy, blocks or surface bolus) being defined in the minutes immediately before the irradiation and Monitor Units consequently calculated by the medical physicist.

The aim of this work was to present the preliminary results of the application of the failure mode and effects analysis (FMEA) prospective approach to IORT, starting from the definition of both process and fault trees, then through the assignment of a score for each potential failure mode using the risk probability number (RPN) and finally suggesting additional safety measures for process improvement.

Material and methods

IORT process tree

Following the guidelines recently proposed by the WHO (Who 2008), the whole radiotherapy treatment process can be divided into ten stages: 1) assessment of patient, 2) decision to treat, 3) treatment protocol prescription, 4) positioning and immobilization, 5) simulation, imaging and volume determination, 6) planning, 7) treatment information transfer, 8) patient set-up, 9) treatment delivery, 10) treatment verification and monitoring. Nonetheless, the strong specificity of IORT using electron beams, implying single-fraction dose delivery, makes steps from n. 4 to 8 not applicable. The state-of-art of IORT assumes the lack of a pre- or peri-operative simulation and CT-based treatment planning, while future improvements will necessarily require the availability of dedicated imaging devices with volumetric capability (CT or cone-beam CT modality) located directly inside the OR. The first three steps were not included in this study, since they are part of the medical decision making process and they will need to be analysed at a different level of the work. The successful performing of the tasks of commissioning, calibrations and maintenance of the equipment was taken as a base for the scope of this analysis. Thus, the IORT process tree was restricted to one phase, including treatment delivery and verification, and sub-processes were identified.

Failure mode and effects analysis (FMEA) for IORT

Failure mode and effect analysis is an established pro-active method, widely used in industry, that helps to identify and counter weak points occurring in a complex process. This technique has been also suggested by the Task group 100 of the American Association of Physicists in Medicine (AAPM) as a powerful tool for the implementation of suitable QA programs in modern radiotherapy. Consequently, it has been recently applied for safety evaluation in radiation oncology (Ford et al 2009), including IMRT (Huq et al. 2008).

FMEA focuses on the sub-processes, trying to identify what could go wrong (the failure mode), the potential causes of failure and the potential related effects. Since the goal of FMEA is to rank the failure modes in order of importance, for each failure three attributes are assigned: the occurrence rating (O); the severity rating (S), and the detection rating (D). Conventionally, a 10-point scale is used for scoring each of these categories, with 10 being the most severe, most frequent, or least detectable. The product of these three indices gives the risk probability number (RPN=S x O x D). The failure modes that have the highest RPN indicate the areas of greatest concern where corrective actions should be implemented in order to reduce the overall risk of accident.

Results and discussion

Within the stage of treatment delivery and verification, the identified sub-processes in IORT using a mobile electron linear accelerator are reported in table 1.

Nine potential failure modes were identified and for each of them potential causes and effects were investigated (table 2). Following the FMEA approach and on the basis of the authors' experience, a risk probability number will be assigned to each failure mode and presented. Among the nine identified failure modes, the undetected linac malfunctioning, wrong MU calculation and misalignment of internal shield appeared as the most critical. The former two failures modes are strictly connected to the specificity of IORT technique, where the treatment machine in the OR is usually switched on few minutes before each patient irradiation, then switched off, unlike conventional stationary linacs in the Radiotherapy Department, which are always kept in the operational mode during all the working day; moreover, in IORT the treatment parameters cannot be chosen in large advance and consequently MU calculation has to be rapidly performed. Concerning the internal shield, it is commonly used for breast irradiation to protect underlying normal tissues, such as the lung, heart, ribs, pectoral muscles, so potential misalignment, combined with the use of high beam energy, could result in undesired acute and late toxicity.

The following additional safety measures to be implemented aiming at the IORT process improvement in terms of patient safety were identified: a) implementation and extensive use of in-vivo dosimetry procedures, using real-time suitable detectors, like MOSFET sensors, allowing immediate action levels to be applied in case of detected dose discrepancies; b) independent, double-checking of MU calculation and data entry to be stated as mandatory, together with the implementation of an automatic system for MU calculation; c) identification of a dedicated radiotherapy staff, composed by the radiation oncologist, therapist (also in view of safe manoeuvring of the mobile linac, especially critical when close to the patient) and medical physicist, adequately trained to IORT procedures.

Conclusion

The FMEA method as a prospective approach to avoid accidental exposures has been applied to IORT using mobile and dedicated electron linear accelerators directly operating in the operating room. Potential failure modes, causes and effects of failures have been investigated, as well as three additional safety measures for process quality improvement proposed. Prospectively, further investigation will be oriented to the application of more complex prospective methods, such as probabilistic safety assessment (PSA) to IORT and other newer radiation therapy technologies, like hadrontherapy.

Figure 1. Example of an IORT procedure in the operating room at IEO, Milan, for a patient affected by early-stage breast cancer, using a mobile electron linear accelerator.

Table 1. Sub-processes of the stage "Treatment delivery and verification" in IORT. Legend of abbreviations: CTV=clinical target volume; RO= radiation oncologist; RT=radiation therapist; MP=medical physicist; OR=operating room; MU=monitor units.

Sub-processes of the stage "Treatment delivery and verification" in IORT.
• Machine start-up
• Preparation of surgical bed (for optimal exposure of CTV to radiation beam)
• Normal tissue protection (mechanical displacement, internal shielding)
• Selection of applicator (size and bevel angle)
• Selection of beam modifiers (bolus, blocks)
• Evaluation of target thickness
• Confirmation of dose prescription
• Beam modifier placement
• In-vivo dosimeter placement
• Applicator placement
• Treatment volume documentation (photographs, clips, x-rays)
• Beam stopper placement (below surgical table)
• Applicator docking to the linac
• Temporary vertical shielding placement (around surgical table)
• OR evacuation (all personnel)
• Selection of beam energy
• MU calculation
• Dosimetry sheet compilation and signing (MP)
• Data entry (treatment parameters) on treatment console
• Physical delivery of radiation dose (start button pressed)
• Confirmation of dose delivery using dosimeters
• Applicator-to-linac undocking
• Removal of all IORT devices and dosimeters
• Linac switch-off
• Treatment recording, reporting (in pt chart or medical record) and signing (RO/RT/MP)

Table 2. Application of failure mode and effects analysis (FMEA) in IORT, for the stage "Treatment delivery and verification".

Step	Potential failure mode	Potential causes of failure	Potential effects of failure
Normal tissue protection; applicator placement	Misalignment of internal shielding	Shielding displacement, wrong applicator placement	Unintended normal tissue irradiation
Selection of the applicator	Inadequate safety margins	Underestimation of CTV extension, inadequate selection of the applicator	CTV underdose
Evaluation of target thickness; selection of beam energy	Inadequate energy selection	Human error in the measurement of target thickness or consultation of dosimetry atlas, failure in the communication between operators	CTV underdose or viceversa unintended normal tissue irradiation
Applicator placement	Inadequate preparation of the area to be treated or inaccurate placement of the applicator base	Biologic fluid accumulation, tissue protrusion inside the applicator, air gap presence	Wrong dose distribution
Applicator placement	Geographic miss of the CTV	Inadequate localization of the CTV; applicator displacement due to physiological movements	CTV underdose; unintended normal tissue irradiation
Applicator docking to the linac	Inaccurate docking (for soft-docking systems)	Malfunctioning and tolerances of the alignment optical system	Wrong dose distribution
MU calculation	Wrong MU calculation	Human error in the calculation, failure in the communication between operators	Wrong dose delivery
Data entry at the treatment console	Incorrect data entry at the treatment console (beam energy, MU, field size)	Human error in manual data entry, failure in the communication between operators	Wrong dose distribution
Physical delivery of radiation dose	Undetected failure of the linac	Linac malfunctioning, linac operated in physics rather than clinical mode, linac start-up procedures not correctly followed	Wrong dose delivery and/or distribution

Abstract

Introduction: Computer Tomography revolutionized radiological diagnosis, the number of CT examinations growing quickly. Due to its nature, computer tomography implies higher radiation doses than those in classical radiology. An increased number of examinations, if justified, must be regarded as a benefit for the patient. Monitoring the patients' trend in CT is of particular importance as technology evolves rapidly towards extremely efficient equipments capable of acquiring 4, 8, 16, and 64 slices per rotation. At the same time, reducing examination time led to increasing CT usage as a diagnosis means.

Material and method: The present study refers to four departments of radiology, three of them being private. The data regarding the number and type of performed examinations as well as the examination protocols come from the registers of these departments. One of the equipments is single-slice (SSCT) and the others are multi-slice (MSCT), all of them having instruments to compute and display the dose length product (DLP) and the dose index (CTDI), according to the protocol in use. We estimated the effective dose and compared them with the reference values in other studies.

Results: The skull and abdomen examinations represented a large majority. The effective dose average varied from one department to another. In comparison to other studies, the average abdominal effective doses were below the values in other studies for SSCT (5.90 mSv compared to 12 mSv), while for MSCT were above them (7.29 mSv compared to 6.59 mSv).

Conclusions: The variation of the patients' dose for a particular type of procedure represents a premise for improving the optimisation process of protecting the CT examined patients. In order to diminish doses, it is very important to adjust some parameters such as the multi-amperage or the number of examined sections depending on the clinical requirements, without compromising the image quality.

The risk of medical exposure to ionizing radiations in pediatrics

Dadulescu, Elena[1]; Mossang, Daniela[1]; Sorop, Ioana[1]; Bodari, Dan[2]; Pera, Corina[3]

[3] County Emergency Hospital Resita, Romania

Abstract
Radiological examination of children is extremely significant since it stands for the safe and most accurate investigation method. However, one shouldn't neglect the risk of cancer induction that is up to three times higher for children than for adults. This risk is given by the children's anatomic features and their longer life expectation. A special attention is paid to premature children and to those showing clinical complications leading to longer hospitalization periods, thus increasing the number of radiological examinations.

The study has been conducted in the New Born and Pediatrics Clinics of Dolj County Hospital, Romania, between 2007 and 2008. The focus was on the frequency of radiological examinations and the entrance surface doses within the most relevant radiological procedures. The measurements have been carried out using the multi-functional device for testing the quality of radiological systems RMI-242.

The lung X– ray is the most frequently used type of examination, the measured doses being up to four times higher than the reference levels in the literature.

The utilized radiological equipment is not especially designed for the purpose of pediatric radiology, making thus impossible to choose the specific parameters which lead to smaller doses without altering the quality of the radiological image.

What's worrying is not the dose per type of procedure, but the large number of examinations performed per one hospitalization period. All these lead to cumulative doses, to which it is likely that several others be added during childhood.

Introduction
Medical diagnosis using ionizing radiations to all groups of children requires a special attention because of the children stand for that category of population with the highest radio – sensitivity and for whom the risk of cancer induction is 2 up to 3 times higher than that for adults. Such a risk is determined by both a longer life expectancy in children, this meaning a higher potential of expression of any possible effects of ionizing radiations, as well as by the anatomic, biochemical and physiological characteristics, different from one age group to another and which are also very distinct from an adult. The big number of exposures, the incorrect use of the physical

parameters of radiological equipments, the poor performances, these may all eventually lead to higher entrance surface doses to patient (Iacob et al. 2007).

Pediatric radiologists should very well know the relation between the benefit of radiological examinations and the risk of cancer induction. The ALARA principle is the best guidebook radiologists can use in order to establish the risk benefit - balance when talking about radiological examinations (Cook et al. 1998).

Knowing the current trends of the doses received by patients during radiological examinations in each and every section, may represent a guidebook when choosing the measures required to be taken for the dose reduction in view of an efficient optimization of the patients' radioprotection and for the purpose of minimizing the risk that such an exposure to ionizing radiations involves (Cook et al. 2001).

Material and methods

The study has been carried out in the anesthesia and intensive care unit (ATI) and in the pediatric department, in the greatest hospital in Dolj County, between 2007 and 2008. The study describes on the one hand the frequency and distribution of the radiological examinations, and on the other hand it estimates the entrance surface doses for the patients during the most significant radiological procedures. Radiological examinations are carried out with two types of installations:

- a mobile installation with X rays - the Polymobil 10 type -, with a total filtration of 3.4 mmAl
- a fix installation of the ELTEX 400 type, with a total filtration of 2.5 mmAl.

The measurement of physical parameters for the two installations and of the entrance surface doses have been carried out with a multi – functional instrument for testing quality of radiological systems of the RMI – 242 type. A statistical processing has been conducted, by comparing the average values, obtained for the entrance surface doses with the reference values by means of the Student test (Guide 2002).

Results

Frequency of radiological examinations within the ATI department:

Table 1. Radiological examinations frequency per years and types of procedures.

Examination type	2007	2008
Pulmonary - abdomen	270	249
Pulmonary	11	12
New born babies	2974	3221

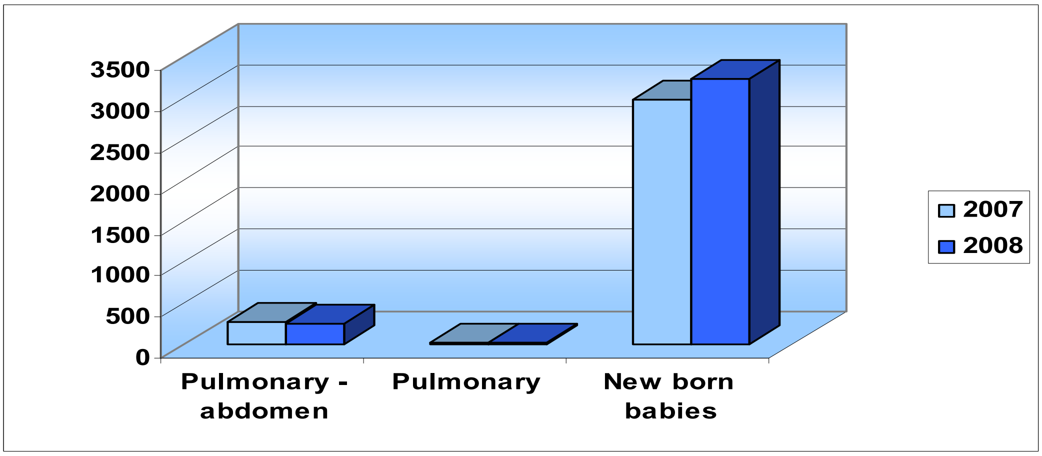

Fig. 1. Radiological examinations frequency per years and types of procedures.

One may find that the most frequently performed radiological procedures have been the pulmonary – abdominal ones, as a consequence of breathing and digestive problems of new born babies and of the premature babies. In 2008 one may find a slight decrease in the number of radiological investigations, although the number of new born babies has increased. Such decrease might be explained by the fact that both the neonatology physician and the radiologist have tried to get, wherever possible a number of radiological information or medical records which are relevant so as to avoid any useless medical irradiations.

The distribution per child of the investigations performed was:

Table 2. The distribution per child of investigations performed.

No. of x – rays	***1***	***2***	***3***	***4***	***5***	***6***	***7***	***8***	***9***
No. of children	132	234	53	27	25	41	15	10	5

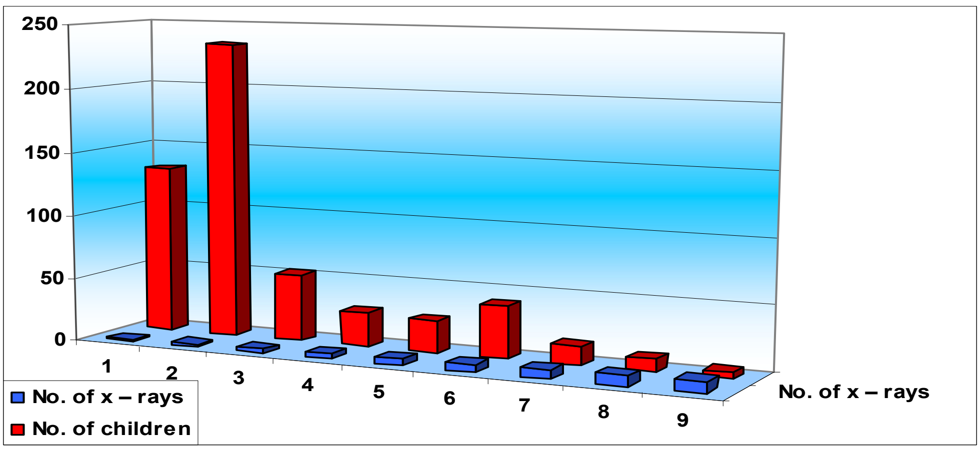

Fig. 2. The distribution per child of investigations performed.

The longest hospitalization periods within the Intensive Care Unit (maximum 70 days), have been for prematurely new born babies, 2 being the high number of radiological examinations conducted per child. The maximum number of x – rays examinations carried out per child is significantly low, namely nine, and they have been performed to premature babies having the smallest weight at birth. (1.5 kg).

Table 3. Frequency of investigations within the pediatric radiology department.

Year	Pulmonary	Skull	Spine	Extremities	Pelvis
2007	2550	1066	424	1331	114
2008	2607	785	478	2805	165
Total	4157	1851	902	4136	279

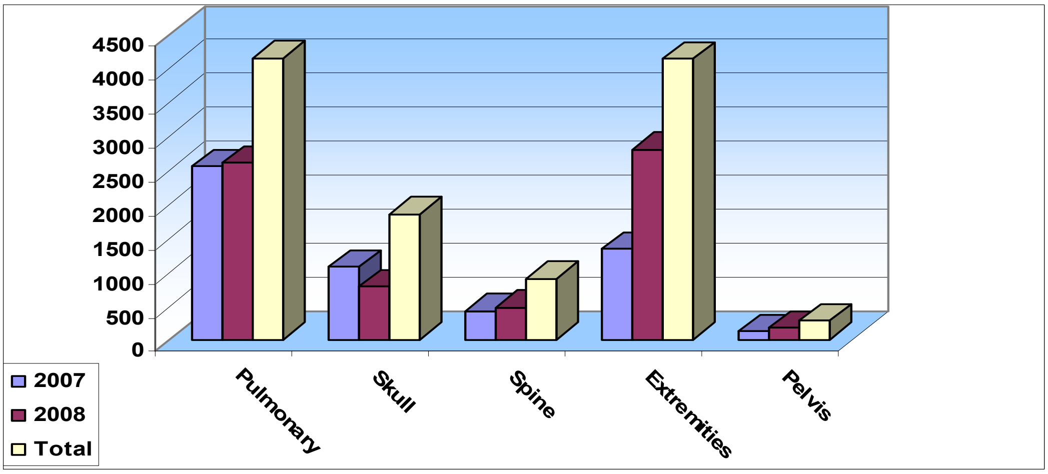

Fig. 3. Frequency of investigations within the pediatric radiology department.

In terms of the distribution of radiological examinations per anatomic areas, one finds that pulmonary and extremities radiological examinations are the most frequent ones, being the most characteristic for this category of population.

The average values for the entrance surface doses per type of examination for the children within the Anesthesia and Intensive Care Unit are:

Table 4. Entrance surface doses.

Examination Type	Entrance surface doses µGy	kV/mAs	Ord. 285* µGy
Pulmonary -abdomen	94	52-58/2.5	-
Pulmonary	90	52-57/2.5	80

* Order no. 285/79/2002 of the Ministry of Health and Family and of the National Commission for Nuclear Activity Control regarding people's exposure to ionizing radiations in case of medical examinations.

The highest value of the entrance surface doses is in the case of the pulmonary – abdominal examinations, the difference from the pulmonary examination being relatively small. Even if the doses for the first type of an investigation are higher, it is preferable that when the physician requires information for the two areas, one shall perform only one single exposure, thus avoiding the superposing. The increased values of the doses might be explained by the fixed value of filtration (3.4 mmAl), without any possibility of an additional filtration (Wraith et al. 1995).

Here are the average values for the entrance surface doses per type of examination and per age groups, for the children within the pediatric department and the comparison with the reference levels are presented in table 5.

Table 5. Average values for the entrance surface doses per type of examination and per age groups in mGy.

Examination Type	0 – 1 years	1 – 3 years	4 – 7 years	5 years	8 – 11 years	12 – 15 years
	Craiova	Craiova	Craiova	Ord. 285	Craiova	Craiova
Pulmonary AP, PA	0.28±0.01	0.36±0.02	0.40±0.02	0.1	2.88±0.10	3.01±0.12
Pulmonary LAT	0.39±0.01	0.40±0.02	0.61±0.04	0.2	3.12±0.14	3.25±0.15
Skull AP	0.88±0.03	1.01±0.07	1.52±0.06	1.5	3.39±0.14	3.45±0.16
Thoracic spine AP	0.83±0.02	1.18±0.09	2.81±0.11	-	3.14±0.12	3.75±0.17
Pelvis AP	0.50±0.01	1.01±0.08	1.89±0.08	0.9	3.32±0.11	3.44±0.12
Extremities	0.60±0.02	1.29±0.09	1.70±0.08	-	2.91±0.09	3.55±0.13

When comparing with the reference dose levels, for one single exposure and for the 5 year old child, one finds that in the case of the lung, the doses that we have measured are 4 and respectively 3 times higher for the two projections and two times higher in case of the pelvis. We have found comparable values with the existing reference levels, in terms of the skull x – ray examination (Sorop et al. 2008).

The values of the Student test show statistically significant differences in terms of the pulmonary x - rays (AP and LAT) and in the case of the pelvis AP ($p<0.001$) as well as a series of statistically insignificant differences in the case of the skull AP ($p>0.05$). For all the other types of procedures there are no reference levels.

Discussion

The pulmonary x – ray examinations and the extremities examinations hold the first position, being given by the age specific pathology.

The radiological equipments used both in the ATI department for babies and in the pediatric departments are not especially designed for pediatric radiology and they are not adequate from the point of view of the requirements of the standards regarding the technical parameters playing a very significant part in terms of the doses received by each and every patient (Lindskoug 1992).

For the purpose of getting accurate diagnosis–related information, a very important part is played by the quality of the radiological image, which is conditioned by the technical parameters (Mooney, Thomas 1998).

The doses received by children (which are three and four times higher than the reference levels) may also be explained by the use of the low kilo - voltage technique (which involves soft X radiations beams, associated with high doses given to the patient).

In order of getting a child's diagnosis using radiations, with a minimum risk, it is important for the medical staff to have a special training, knowing the child's anatomy and physiology, and for the environment where this medical act is carried out, to be warm and friendly.

Every clinician shall have to understand his/her responsibility, as well as the collective responsibility, for providing the quality of the medical act. All these might lead to the decrease of the number of unjustified investigations and also to the decreasing of the doses per patients.

The cooperation deficiencies and any functional particularities (faster heart beats, fast breathing and incapacity of holding breath upon command) are also other reasons for a deterioration of the quality of the image, leading to the repetition of the x – ray examinations.

The development of certain working protocols, at hospital level, would be an opportunity of improving the clinical system and the working procedures, in such a way as to increase the medical care offered to the patient (Bahnarel et al. 2007).

Conclusions

In the case of new born babies, what we should worry about is not the doses resulted per type of procedure but the fact that such examinations also have the tendency of being repeated during the child's hospitalization period, and such repeated procedures lead to cumulative doses, with several others likely to be added during childhood.

Abstract

Introduction: Radiation protection depends on many factors. This study deals with the human factor, the radiology technicians. If all technical malfunctions are excluded they are responsible for the patient dose. Depending on their education and experience technicians perform X ray examinations with various end results: image quality, entrance surface dose, patient interaction etc.

Patients and methods: The study group of 60 children (for each of three technicians 20 children) was chosen that had a clinical indication for a chest X ray examination (standard PA radiogram). The age of the patients varied between 6–12 years, the weight between 20–50 kg and the height 110–150 cm. All parents were informed about the aim and the experimental details of the study. A Shimatzu X ray machine was used in all cases. Radiophotoluminescent (RPL) and thermoluminescent dosimeters (TLD) were applied at the entrance of the beam in center of the X ray field to measure the entrance surface dose (ESD). The three differently experienced technicians were unaware of the point of the study. Parameters that were noted were the kV, mAs and the size of the field. The radiologists interpreting the radiogram, as well as the scientists interpreting the dose were blinded.

Results: The dosimetry results with both dosimetry systems show a good correlation of ESD as a function of mass body index (MBI) between two technicians. Doses were significantly higher for the third one. The ESD values varied between 0.05–0.5 mSv.

Discussion: This work shows the importance of continues education and good teamwork for dose reduction. In a sequel study after additional education interference with the same three technicians we hope to have results that would show a better dose reduction.

Issues and practices concerning pregnancy and ionising radiation

Schreiner-Karoussou, Alexandra
Direction de la Santé, Division de la Radioprotection, Luxembourg

Abstract
A literature review in relation to the irradiation of patients and staff during pregnancy was carried out. A number of publications describing procedures to be followed in the case of a pregnant patient who needs to have a radiological examination and in the case of pregnant staff who work in a department where they could be exposed to radiation were reviewed.

A review of existing practices in 13 European countries was carried out by sending a questionnaire to representatives in each country. The questionnaire addressed the following issues : the application of the 10 day rule, patients who are pregnant and need a radiological examination or a nuclear medicine examination , staff and carers who are or may be pregnant and who are working in a radiology department or in a Nuclear medicine department.

From the review, it was found that the existing practices with respect to irradiation of patients and staff during pregnancy vary enormously from country to country. There is no harmonisation on this issue at the European level. From the literature review and the review of practices, a number of ethical issues were identified and exposed and a number of conclusions were drawn.

Introduction
The Medical Exposure Directive 97/43 (C.E.U. 1997) requires special attention for the protection of the unborn and breast fed child who are exposed to ionising radiation for medical purposes. This is because the unborn child, the breast fed child as well as young children are particularly vulnerable to ionising radiation. Along with other risks, there is the risk of malformation and mental retardation for the unborn child and there is a risk of radiation induced cancer which may be three times as high as for the average population (ICRP 2007) . However for diagnostic exposures the risk of deterministic effects appearing although not impossible is extremely unlikely. The potential benefit of the examination or treatment involving ionising radiation will in most cases be for the mother and only indirectly for the child, whereas it will incur a risk. This is different to the normal situation where one person namely the patient, incurs the risk but also derives the benefit of the examination or treatment (E.C. 100 1998). Pregnancy is also an important issue for staff working with ionising radiation. The moment the pregnancy is declared the employer is obliged to ensure the protection of the fœtus. This means

that the working conditions of the pregnant worker, after the declaration of pregnancy, should be such as to make it unlikely that the additional dose to the conceptus will exceed 1 mSv during the remainder of pregnancy (C.E.U. 1997). A number of ethical issues concerning irradiation of patients and staff during pregnancy were identified and these are presented in this paper. A review of practices concerning pregnancy and ionising radiation in various European countries was also carried out, the results of which are also presented.

Literature review in relation to irradiation of patients and staff during pregnancy

A literature review in relation to irradiation of patients and staff during pregnancy was carried out.

Council Directive 97/43 Euratom of 30 June 1997 on health protection of Individuals against the dangers of ionising radiation in relation to medical exposures. (C.E.U. 1997). The Medical Exposure Directive requires special attention for the protection of offspring of pregnant and breastfeeding patients exposed to ionising radiation for medical purposes. The prescriber of the exposure and the practitioner are obliged to ask the woman of childbearing age if she might be pregnant or missed a period. In the case where pregnancy cannot be excluded the practitioner and the radiographer shall treat the patient as if she were pregnant.

Radiation protection 100. Guidance for protection of unborn children and infants irradiated due to parental medical exposures (E.C. 100 1998). This guidance is addressed to prescribers, practitioners responsible for diagnosis or treatment, to nurses, to medical physicists and other professional staff who are in contact with the patient, e.g. such as midwives and gynaecologists. Furthermore the report is of interest to regulatory authorities.

Advice on Exposure to ionising radiation during pregnancy. Diagnostic Medical Exposures. Joint guidance from National Radiological Protection Board (NRPB), College of Radiographers, Royal College of Radiologists (NRPB 1998). The main objective of the NRPB advice concerning in utero exposures to ionising radiation is "to prevent unnecessary exposure of the foetus when medical diagnostic procedures involving ionising radiation are indicated during pregnancy". This is achieved by the introduction of the 10 day rule.

Medical and Dental Guidance Notes. Institute of Physics and Engineering in Medicine (IPEM 2002). A lot of information in these guidance notes has been published in various other references but it is helpful to have it brought together in one authoritative source covering the healthcare sector. The Guidance Notes is an excellent and thorough publication, which combines useful advice and a comprehensive list of relevant references.

Working safely with ionising radiation: Guidelines for expectant or breastfeeding mothers (HSE 1999). This leaflet provides advice for female employees who may be exposed to ionising radiation during their work. It is specifically aimed at those women who are thinking of having a baby or are already pregnant or breastfeeding.

ICRP publication 84. Pregnancy and medical radiation (ICRP 2000). This publication is concerned with the diagnosis of pregnancy, informed consent, and radiation effects on the embryo/fœtus, and the management of pregnant patients undergoing diagnostic radiology, nuclear medicine or radiotherapy. Occupational exposure of pregnant workers and research involving pregnant females is also covered.

Radiological protection of the unborn child. Recommendations of the commission on radiological protection and scientific grounds (Berichte 2006). This publication concerns the radiological protection of the unborn child in the case of occupationally exposed women who work with radionuclides.

The 10-day rule and the 28-day rule

The National Radiological Protection Board issued ASR8 (Exposure to ionising radiation of pregnant women: advice on the diagnostic exposure of women who are or may be, pregnant) in 1985. This advice suggested that there would be no risks to the conceptus following irradiation during the first 10 days of the menstrual cycle and that subsequent risks in the remainder of the first 4-week period would be likely to be so small that no special limitation on exposure was required – sometimes known as the "28-day rule" (NRPB 1998). Diagnostic exposure of women only during the first ten days after the beginning of the last period is what is called the ten day rule. All requests for radiological examinations of female patients, which place the uterus in or near the primary beam or nuclear medicine examinations which are likely to result in a dose to the unborn child up to 10 mGy, should include the date of the last menstrual period. The prescriber and practitioner or radiographer should ask a patient beyond day 10 of the menstrual cycle whether she might be pregnant. This enquiry and the patients answer should be recorded in writing. If the answer is no, the examination may proceed. If the answer is yes or uncertain, the examination should not proceed. In cases of medical emergency, the practitioner or the prescriber, if necessary following discussion with the practitioner or radiographer and taking justification into account may decide to proceed with the examination (R.S. 2000).

Review of existing practices in various European countries concerning the 10-day rule

Thirteen countries were reviewed by sending them a questionnaire. The U.K., Ireland, Cyprus, Bulgaria and Hungary apply the 10day rule for high dose procedures. In Italy and Austria it is the prescribing physician and the radiologist who ask whether the patient is or might be pregnant. In Greece and in Luxembourg it is the radiographers who ask whether the patient is or might be pregnant and in Spain the 10day rule is not applied. In Poland and Luxembourg a urine pregnancy test is carried out on women of childbearing age for interventional radiology (IR) procedures. In Poland the 10day rule is applied only for (IR) procedures. In Holland and in Luxembourg a sign is usually present in the radiology departments (in the changing cubicles) on the risk of pregnancy and radiation. In Slovenia the 10day rule used to exist in the previous radiation protection legislation but it wasn't applied. In the new legislation there is no such rule.

Review of existing practices in various European countries concerning patients who are pregnant and need a radiological examination

Thirteen countries were reviewed. In all the countries reviewed special attention to justification and optimisation issues is given when a pregnant patient needs a radiological examination. In Bulgaria, Italy, Austria and Poland X-ray examinations on pregnant women are not allowed unless it is an emergency and the life of the patient is in danger. In Hungary it is the prescriber who decides on whether the examination needs to be performed or not. In Italy, Greece and Cyprus a medical physicist is involved in order to calculate the dose to the foetus. Italy seems to be the only country where this matter is regulated by law

Review of existing practices in various European countries concerning staff and carers who are or may be pregnant and who are working in a radiology department

In Bulgaria, Slovenia, Hungary and Italy the worker is obliged to declare her pregnancy. In Luxembourg the worker is automatically placed in another department. In Hungary the worker must announce her pregnancy and after this she isn't allowed to work with ionising radiation anymore. She can continue working in the X-ray department but only to carry out administrative work. In Bulgaria, Slovenia, Italy, Poland, Greece, Spain, Cyprus, Holland and Ireland the worker can continue to work as long as the dose to the child to be born doesn't exceed 1mSv (C.E.U. 1996). In Cyprus, Spain, Italy and Slovenia the worker can choose not to work with radiation. In most countries pregnant carers are not allowed to work in X-ray Dpts.

Review of existing practices in various European countries in nuclear medicine concerning staff, patients and carers who are or may be pregnant

In all countries a nuclear medicine examination is carried out on a pregnant patient only if it is absolutely necessary and then it is optimised to give a dose as low as achievable. Breastfeeding patients are informed of the need to either interrupt or cease breastfeeding depending on the diagnostic or therapeutic procedure involved. In most countries the pregnant staff can continue working as long as there is no risk of contamination. In Luxembourg, Greece, Cyprus and Slovenia the pregnant staff is removed and placed in another department.

Identification of existing issues concerning patients

The International Commission on Radiological Protection in its publication 84 says the following: "Thousands of pregnant patients and radiation workers are exposed to ionising radiation each year. Lack of knowledge is responsible for great anxiety and probably unnecessary termination of many pregnancies. For many patients, the exposure is appropriate, while for others the exposure may be inappropriate, placing the unborn child at an unjustified increased risk." (ICRP 2000). One may well ask why this is the case. From this statement a number of issues arise. Notably the issue of education and information. It is important that the public be informed of the risks of ionising radiation during pregnancy. This can be achieved with simple information leaflets, articles in journals or through television programs. There seems to be a lack in general of information on the risks of pregnancy and ionising radiation for the public as well as the healthcare personnel.

In countries where large foreign communities exist it is important that the risks of pregnancy and ionising radiation be explained in the appropriate language. There is a risk that the female patient may not understand the enquiry on whether she is pregnant, or breastfeeding.

The 10 day rule should be applied if a diagnostic examination or treatment is planned which involves a high dose to the uterus or else a pregnancy test should be performed (E.C. 100 1998).Although the efficacy of a pregnancy test is another issue that needs to be looked at. Most pregnancy tests look for the presence of human chorionic gonadotropin (hCG) in the blood or urine. hCG can be detected in urine or blood after implantation, which occurs six to twelve days after fertilization. This results in false negatives if the test is performed during the very early stages of pregnancy (Wilcox et al. 1999). If a pregnant patient needs a radiological procedure in which the X-ray beam irradiates the foetus directly, and this cannot be delayed until after the pregnancy, it should be adapted so as to give as low a dose as possible to the foetus (ICRP 2000) . The principles of justification and optimisation are in this case of extreme importance. The procedure should be carried out by an experienced radiologist, cardiologist in case of a cardiac interventional procedure, and a medical physicist should be involved.

There is limited information on research and pregnancy in the council directive 97/43 (C.E.U. 1997) however the involvement of pregnant females in research should be discouraged. Pregnant women should not be asked to take part in any research projects involving irradiation to their unborn child, unless the pregnancy itself is essential to the research or therapeutic research which may be life saving for the mother (E.C. 99 1998). Another important ethical issue is that the pregnant patient has the right to know the magnitude and type of potential radiation effects that might result from in-utero exposure (ICRP 2000) .

Identification of existing issues concerning staff

Training of the personnel on the subject of pregnancy and radiation protection is very important. Lack of training leads to the problem of radiophobia. It is important that radiation protection issues be properly explained to pregnant staff so that she can make an informed choice about what she should undertake. Female personnel should have the right to decide if they want to continue to work in a radiology department and not be automatically placed in another department. Another ethical issue that could be looked at is whether it is appropriate to apply the same dose limit to the fœtus as a member of the public, given that the fœtus is generally considered to have a higher radiosensitivity (Faulkner 2005).

Discussion

From the literature it can be seen that most diagnostic procedures which are performed correctly present no measurable increased risk of prenatal or postnatal death, developmental damage including malformation, or impairment of mental development over the backround incidence of these entities. High dose procedures such as abdominal and pelvic computed tomography that deliver doses to the foetus of some tens of mGy may carry significant risks with a doubling of the natural cancer risk in the unborn child. However this is unlikely to be a reason for the termination of the pregnancy. Absorbed doses below 100 mGy should not be considered a reason for terminating a pregnancy. Most nuclear medicine procedures do not result in high doses to the embryo and foetus. However, some radiopharmaceuticals that are used in nuclear medicine can pose significant risks to the embryo and foetus (NRPB 1998, ICRP 2000). In reference to the above mentioned introduction of the ICRP publication 84 it would seem that education, training and information for the healthcare personnel and the public is of great importance and that a number of the above mentioned ethical issues could be solved this way.

From the review of practices it has been seen that there no harmonisation at a European level and this is something that still needs to be looked at.

Conclusions

The 10day rule is not applied in all the countries reviewed. The manner in which this issue is treated differs from country to country. The person who determines whether a woman of childbearing age is or might be pregnant differs from country to country. In only two countries a urine pregnancy test is carried out regularly on women of childbearing age who have to undergo IR procedures.

Special attention is given to optimisation and justification of the examination in all countries. Who decides whether the examination should be done i.e. the radiologist or the prescriber differs from country to country. A medical physicist is involved in this issue in only a small number of countries.

The existing practices in various European countries concerning staff and carers who are or may be pregnant and who are working in a radiology department vary enormously. There is no harmonisation on this issue at a European level

Special attention is given to optimisation and justification of the examination of a pregnant patient in Nuclear Medicine. A medical physicist is involved in this issue in only a small number of countries. The existing practices in various European countries concerning staff who are or may be pregnant and who are working in a Nuclear Medicine department vary enormously. There is no harmonisation on this issue at a European level.

Funding

This work was undertaken with the support of the European Commission (SENTINEL project contract no. 012909) as part of the sixth Framework Programme.

Quality development and dose optimisation in native pediatric radiography in a maternity hospital

Parviainen, Teuvo[1]; Vinnurva-Jussila, Tuula[2]; Niskanen, Kaija[3]; Ojala, Päivi[2]
[1] STUK – Radiation and Nuclear Safety Authority, Radiation Practices Regulation, FINLAND
[2] HUS, Kätilöopisto Maternity Hospital, FINLAND
[3] HUS, Children's Hospital, FINLAND

Abstract

Kätilöopisto is the biggest maternity hospital in Finland. In addition to radiography of newborns and mothers, also the native X-ray examinations of children under 16 years in Helsinki area were earlier centrally taken care by Kätilöopisto hospital. When X-ray imaging was thus increasing, the need for systematic estimating and developing the technology used in the examinations, measuring radiation doses, assessing the clinical image quality and own working methods became current. The hospital started a quality improvement project in 1999 in cooperation with Radiation and Nuclear Safety Authority (STUK). The radiologists and radiographers of the Department of Radiology have participated in the developing work. The aim is to produce an optimal radiodiagnosis with as low X-ray dose as possible following the common good practice.

The methods and results of the development project, changes to radiology practices and factors affecting these changes from the past 10 years are presented. The project has also involved monitoring radiation doses and assessing the clinical image quality in children's X-ray examinations and pelvimetric examinations. Special attention has been paid to radiation doses of newborns and the quality of examinations. Among others, in certain examinations, the radiation dose has been reduced to one third of the earlier dose. The project has proved an excellent starting point for developing good practices. On the basis of the results of the study, objective reference levels of the examinations of the department have been set on picture quality and on radiation dose. The quality development project is still continuing.

Comparison of results of quality control tests of the mammography screening in Mazovia province in 2007 and 2008

Fabiszewska, Ewa; Grabska, Iwona; Jankowska, Katarzyna; Bulski, Wojciech
Maria Sklodowska – Curie Memorial Cancer Centre and Institute of Oncology, Medical Physics Department, POLAND

Abstract

In 2007 and in 2008, quality control tests were performed respectively in 48 and 46 facilities performing mammography screening. For this purpose a comprehensive system and methodology of testing was established.

On the basis of existing legal regulations in Poland, it was decided that as a part of quality control testing the following items should be checked at a facility: equipment, organization of the examinations, correctness of the basic and specialist tests (only in 2007). Additionally a group of tests, so called supervision tests, was listed. One part of the test dealt with physical and technical parameters essential for the quality of mammography images, the other part was used to evaluate the doses absorbed by the examined women. The tests were carried out by the physicists from Mazovia Regional Coordinating Centre. These physicists had to prepare a report according to standard protocol, providing the evaluation of particular tests.

A controlled facility could get maximum score of 84 points in 2007 and 365 points in 2008. An evaluation of the examinations in a facility was rated according to a percentage of scored points: at least 80% – high level, from 79% to 60% – medium acceptable level, below 60% – low non-acceptable level.

In 2007, according to these criteria only 8% of facilities were scored at high level quality of screening examinations, 35% were scored at medium acceptable level, and 56% at non-acceptable level. In 2008, only 7% of facilities were scored at high level quality of screening examinations, 59% were scored at medium acceptable level, and 35% at non-acceptable level.

Obtained results indicate a slight improvement of the quality of mammography screening examinations. However, the quality is still not acceptable and sholud be further improved in order to be able to contribute to the decrease of breast cancer mortality which is the prime aim of the screening.

Evaluation of dose for routine exposure in mammography screening in Mazovia province in 2007 and 2008

Jankowska, Katarzyna; Grabska, Iwona; Fabiszewska, Ewa; Bulski, Wojciech
Maria Sklodowska – Curie Memorial Cancer Centre and Institute of Oncology,
Medical Physics Department, POLAND

Abstract

There is a significant risk of radiation-induced carcinogenesis associated with x-ray mammography. Therefore determinaton of average glandular dose is an important part of quality control of mammographic imaging systems. This study presents estimated doses for routine exposure using 45 mm thick PMMA blocks at mammography facilities in Mazovia Province in 2007 and in 2008.

Material for this study constituted data from most of mammography screening facilities in Mazovia Province in 2007 and 2008. The method consists of two parts, i.e, the determination of tube voltage (kV), focal spot charge (mAs), type of anode and additional filter for routine exposure of standard breast. The second part was measurement of entrance surface air kerma (wihout backscatter) at these parameters. Afterwards, the entrance surface air kerma was calculated at the upper surface of the PMMA. Furthermore the half value layer (HVL) was calculated for tube voltage used during routine examinations. The average glandular dose was calculated according to Dance. Estimated average glandular dose was compared with achievable value for 45 mm thick phantom (i.e 2 mGy) from "European Guidelines for Quality Assurance in Breast Cancer Screening and Diagnosis".

In 2007, established average glandular doses at all mammography facilities ranged from 1,19 mGy to 4,14 mGy. In 2008, established average glandular doses in all mammography facilities ranged from 1,07 mGy to 3,95 mGy. The average glandular dose exceeded limiting value at 52% mammography facilities in 2007 and at 28% mammography facilities in 2008.

Obtained results of average glandular doses for 45 mm thick phantom reached alarming high values and they depended on wrong setting of technical parameters of mammography equipment.

Doses received by women in screening mammography examinations in Poland in 2007

Fabiszewska, Ewa; Jankowska, Katarzyna; Grabska, Iwona; Bulski, Wojciech
Maria Sklodowska – Curie Memorial Cancer Centre and Institute of Oncology,
Medical Physics Department, POLAND

Abstract

Purpose: The aim of this study was the estimation of the radiation risk for women undergoing screening mammography examinations. This is the first study of this kind in Poland concerning radiation protection of patients at the national level.

Methods and material: Materials for this study are the data from 250 screening mammography facilities in Poland. The following parameters were collected: the breast thickness after compression, the high voltage, the mAs values, material of the anode, additional filters used during the exposition. Data from 44992 expositions were collected. For every mammography facility standard average glandular doses for routine exposures were calculated. Furthermore, average glandular doses for individual mammography examinations, according to the methods proposed by Dance, were calculated. Tolerances were taken from the "European guidelines for quality assurance in breast cancer screening and diagnosis".

Results: Established average glandular doses in 250 mammography facilities in Poland in 2007 range from 0.12 mGy to 14.56 mGy with an average of 1.99 mGy. At only 32 mammography facilities all expositions did not exceed acceptable levels of the average glandular dose. At only 18 mammography facilities all expositions did not exceed achievable levels of the average glandular dose.

Conclusions: Average glandular doses obtained for women undergoing mammography screening examinations reach high values and they depend on technical parameters of mammography equipment. In order to reduce the radiation risk for women undergoing screening mammography examinations, the facilities which do not conform to the standards recommended by the European Commission should improve the quality of their examinations or be closed down.

Implementation of quality assurance/quality control programme in mammography practice at the University Hospital of Osijek

Abstract
The radiologist's objective is to obtain accurate diagnostic information from mammography while keeping radiation dose to the breast acceptable. Image quality and patient doses in mammography depend on large number of factors such as film speed and contrast, film processing, tube voltage, breast size and composition, and automatic exposure control. Also, image viewing conditions can considerably influence overall diagnostic accuracy of mammography, especially its sensitivity. Due to number of steps involved in this process, the potential for mistakes increases. Reproducible high-quality images with reasonably low radiation doses are, in general, assured by comprehensive quality assurance / quality control (QA/QC) program and this is demanded by the Croatian radiation protection law.

The national audit of mammography equipment performance, image quality and dose in Croatia was done recently. Results showed large variations in image quality and patient doses and revealed the need to continuously monitor and optimize mammography techniques. Survey pointed out that main problem in the Croatia is the lack of written QA/QC procedures. Consequently, equipment performance, image quality and dose are unstable and activities to improve image quality or to reduce the dose are not evidence based.

At the University hospital of Osijek mammography QA/QC programme, based on EC (European Commission) guidelines, was implemented during the year of 2007. After we did the corrective actions based on measured data and image quality assessment, technical parameters are now within acceptable levels given by EC guidelines. Image quality is improved significantly and rate of rejected images is much less than before implementation of programme.

Introduction

The radiologist's objective is to obtain accurate diagnostic information from mammography while keeping radiation dose to the breast acceptable (1, 2). Reproducible high-quality images with reasonably low radiation doses are, in general, assured by comprehensive quality assurance / quality control (QA/QC) program (2, 3) and this is demanded by the Croatian radiation protection law.

The national audit of mammography equipment performance, image quality and dose in Croatia was done recently (4). Results showed large variations in image quality and patient doses and revealed the need to continuously monitor and optimize mammography techniques.

At the University hospital of Osijek (UHO) mammography QA/QC programme, based on European Commission (EC) guidelines (2), was implemented during the year of 2007. In this work the impact of its implementation will be presented as comparison of the rejection rate and the image quality before and after QC implementation.

Material and methods

As a first step, the film reject rate and the image quality assessment within two weeks were done at 4 mammography facilities (A, B, C and D) in eastern part of Croatia in order to compare the obtained data with the data obtained after implementing QA/QC programme based on EC guidelines (2).

The image quality assessment was done according EC image quality criteria (5). The patients whose images were assessed were randomly picked at facility A, 20 of them before QC and 22 after QC. In facilities B, C and D the number of randomly picked images was 20, 20 and 19 respectively. The quality of images was assessed and scored by on site radiologists. At all facilities same radiologist performed the image quality assessment before and after implementation of QC. Four images (cranio-caudal (CC) right breast, CC left breast, medio-lateral-oblique (MLO) right breast, MLO left breast) were evaluated individually for each patient using the questionnaire according to EC quality criteria (5).

Causes of the film rejections fit into seven different categories: too light, too dark, mechanical problem, artefact, positioning problem, patient motion and administrative mistakes. Afterwards, the plan was to make necessary corrections and repeat the survey.

Only minor corrections were made in three departments and image quality was slightly improved. The most common corrective actions were education of technologists, cleaning screens and developing unit maintenance. More complicated and/or more expensive corrections couldn't be done. The main reasons were the lack of financial resources, inadequate staff training and the lack of willingness to cooperate. For this reason, QA/QC programme based on European guidelines [2] was installed only at the University hospital of Osijek (UHO) where these resources already existed.

Siemens Mammomat 3000 Nova, dedicated developing unit (Curix 60, AGFA) and old non-dedicated image viewing box has been used for mammography in UHO at the time of installation. To measure the performance level of mammography practice in UHO before implementing QA/QC programme, following parameters were tested: X-ray tube voltage accuracy and reproducibility, X-ray output, dose to standard breast, half-value layer (HVL), viewing conditions, dark chamber, automatic exposure control

(AEC) performance and film-processing data. Some parameters are changed to comply with typical values of EC guidelines (2).

Afterwards, QC with frequencies of the tests, typical values and tolerances are implemented according to EC guidelines (2). Constant analyses of processing unit as well as constant checks of optical density at the centre of phantom are done on daily basis and other tests are done weekly or annually. Image quality assessment and rejected image analysis is performed once a year, again within two weeks. The intention of quantitative analysis of film rejection causes is to detect the most common problems. The images rejection rates obtained at the UHO as well as the rate of causes of rejection before and after QC implementation were compared and analysed. The rate of image rejection and image quality assessment for other facilities was analysed and presents the situation encountered before and after corrective actions.

Results

Table 1 shows the characteristic parameters of mammography before and after implementing the QA/ QC programme and comparison with tolerances and typical values (2).

Table 1. Characteristic parameters of mammography before and after implementing the QA/ QC programme and comparison with tolerances and typical values.

	Before QC	After QC	Tolerance	Tipical values
D_{min}	0.22	0.23	0.15 - 0.25	
D_{max}	3.74	3.90	-	~ 4.00
M_{Grad}	3.60	3.40	-	3.0 - 4.0
$Grad_{1,2}$	3.36	4.40	-	3.5 - 5.0
Speed	1.83	1.70	-	-
OD	1.16	1.65	1.5 – 1.9	
AGD (mGy)	0.8	1.1	< 2	
Resolution (lp/mm)	14.5	14.5	>12	
Large detail contrast (%)	2	1	<1.5	

Table 1 show that the ODs of the images were lower than recommended (2). Lighter images were used because of luminance of viewing box was 1200 cd/m^2. Mammography dedicated viewing box was acquired and OD increased.

Image developing parameters before and after implementing QA/QC programme are shown in Figures 1, 2, 3, 4.

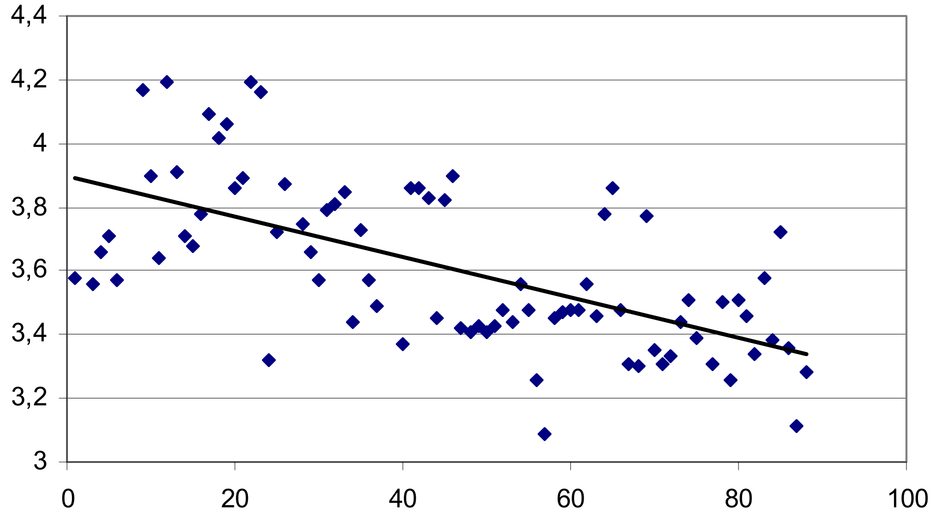

Fig. 1. M_{Grad} values before replacing developing unit. On x axis are days.

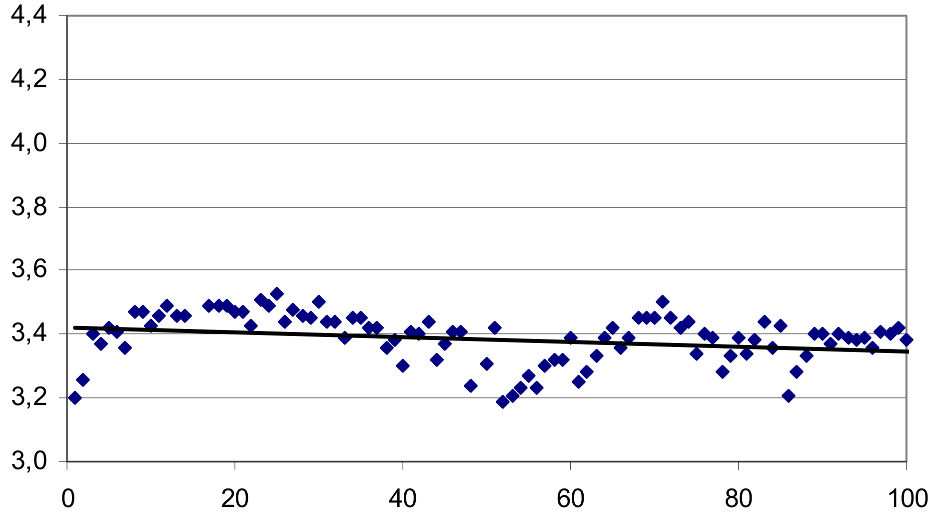

Fig. 2. M_{Grad} values after replacing developing unit. On x axis are days.

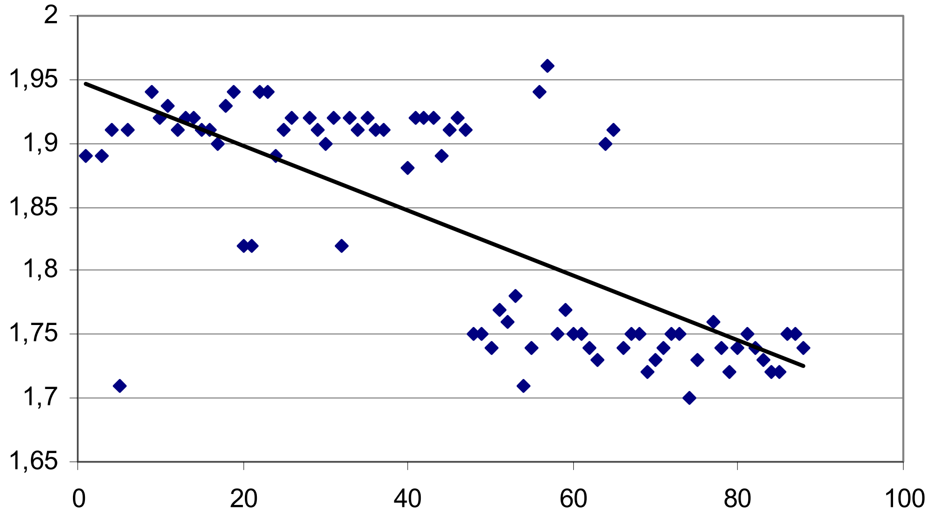

Fig. 3. Speed values before replacing developing unit. On x axis are days. On day 50 the ventilation is installed.

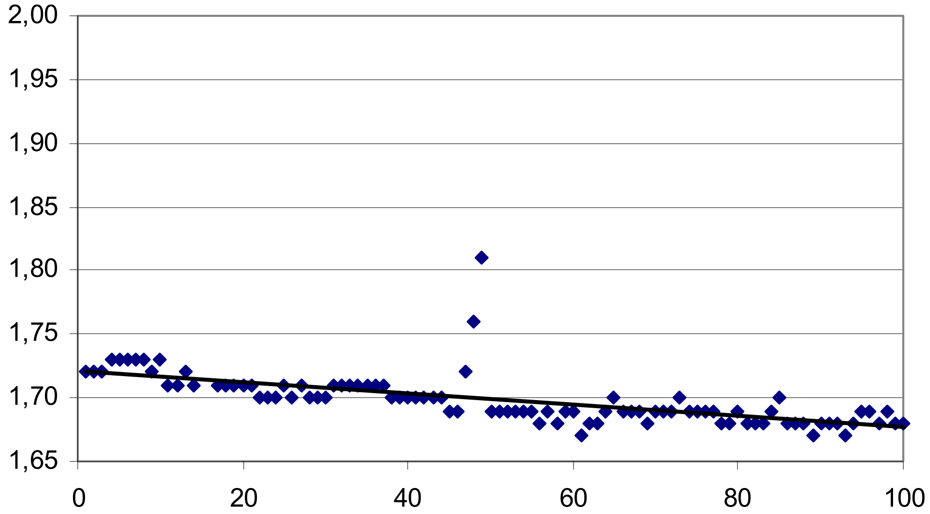

Fig. 4. Speed values after replacing developing unit. On x axis are days.

Image developing parameters at the beginning varied in time because of non-adequate developing unit (the unit is for low-volume processing or backup).

Figure 5 shows image rate rejection before and after corrective actions (in UHO after QA/QC programme implemented) and Figure 6 shows causes of image repeating.

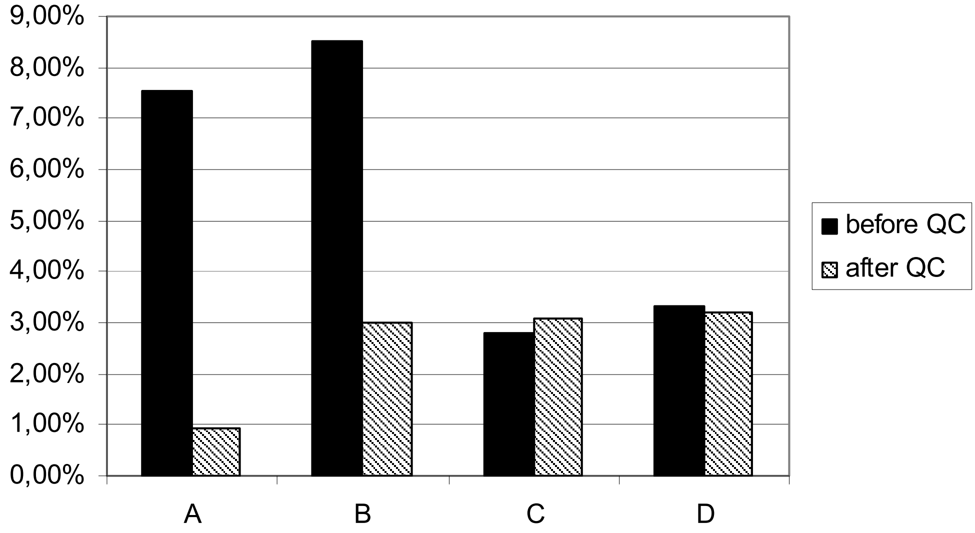

Fig. 5. Image rate rejection before and after corrective actions (in UHO after QA/QC programme implemented).

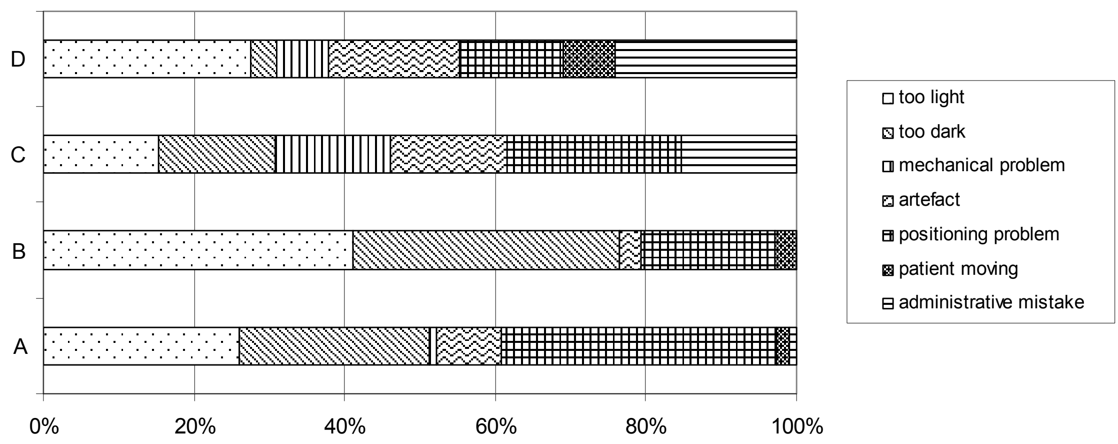

Fig. 6. Causes of image repeating in all four facilities.

The main reason of image repeat at dpt B was too dark or too light image. The reason was non functional AEC. Maintenance was called and AEC enabled.

Figures 7 and 8 show the EC criterion fulfilment, before and after implementation of QA/QC programme or corrective actions, in CC and MLO projections, respectively for all dpts.

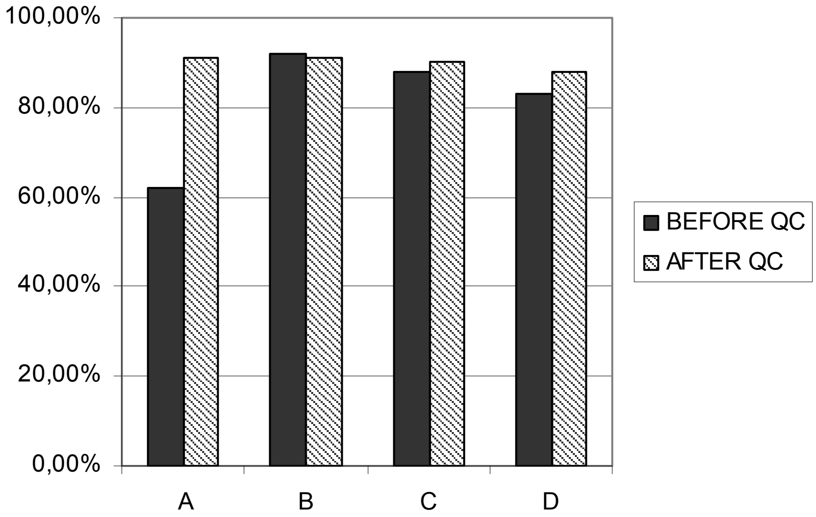

Fig. 7. EC criterion fulfilment, before and after implementation of QA/QC programme or corrective actions, in CC projection for all surveyed facilities.

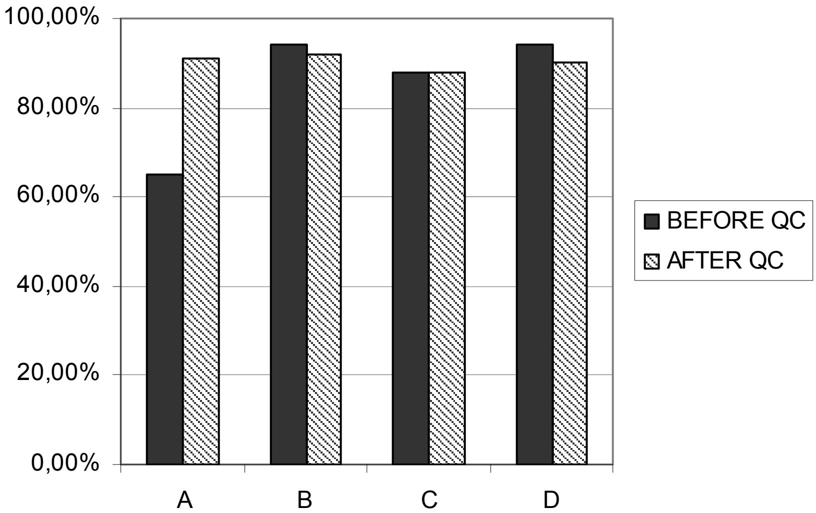

Fig. 8. EC criterion fulfilment, before and after implementation of QA/QC programme or corrective actions, in MLO projection for all surveyed facilities.

Discussion

The mammography is, in a technical sense, one of the most demanding radiographic procedures, image quality and the patient dose critically depend on equipment and its performance, as well as on radiographers' skill. We showed that even simple corrective actions as cleaning of screens, education or somewhat complicated as AEC enabling can considerably improve mammography image quality (Figures 6, 7, 8). It was surprising that rate rejection was low and fulfilment of EC criterions high in C and D dpts. As discussed before (6), the reason can be in high tolerances of radiologists and not high image quality.

In UHO comprehensive QA/QC programme was implemented and the data analyzed. According to these analyses, new equipment has been acquired (processing unit and viewing box) and working modality (higher OD) has changed. Though higher OD means higher patient dose (Table 1) it improves diagnostic information (3, 7).

Conclusions

There are many proofs of improvements in image quality and patient dose reduction in mammography by implementation of simple and low-cost measures (6, 8). IAEA highlighted the need to evaluate the situation in different countries, to identify the points where corrective actions are needed and to document the improvements in order to achieve an effective optimization of mammography practice (8).

In Croatia, QA in diagnostic radiology is a regulatory requirement. Furthermore, national committee for QA in mammography has been established by the National Radiology Association, but there is still no detailed framework for QA implementation, only pilot projects in a few University hospitals where physicists are available.

Abstract

The Nordic countries (Denmark, Finland, Iceland, Norway and Sweden) have many similarities as for the status of using radiation in health care and in the regulatory control of radiation practices. Therefore, the importance of co-operation between the Nordic radiation protection authorities has long been recognized and manifests through Working Groups (WG) established for several fields of interest. The Nordic WG for X-ray diagnostics has been operational for over 30 years. The main tasks are to exchange information on the national activities in the field of X-ray diagnostics, to discuss problems for regulatory issues and to undertake joint efforts of research. The results are published as Nordic reports or scientific papers in international journals. In a recent joint project, patient doses in paediatric CT examinations were studied in order to pay attention to the increased need for careful optimization. Comparison of the characteristics of X-ray diagnostics in the Nordic countries indicate that the level of professional resources is somewhat varying. For example, the number of radiologists per number of X-ray examinations is rather constant (about 0,15 radiologists/1000 examination) but the number of physicists in diagnostic radiology varies from about 0 to 13 physicists/million examinations. The annual joint meetings, joint research and other joint activities have ensured effective exchange of information for developing the national regulatory activities and for promoting consistent methods of quality assurance and dosimetry. This paper compares some characteristic features of the use of radiation for X-ray diagnostics in the Nordic countries and the activities of the radiation protection authorities in this field, in particular for the modern X-ray diagnostic practices (multi-slice CT etc) highlighting the importance and achievements of effective co-operation between the authorities.

Introduction

The Nordic countries (Denmark, Finland, Iceland, Norway and Sweden) have many similarities as for the status of using radiation in health care and in the regulatory control of radiation practices. Therefore, the importance of co-operation between the Nordic radiation protection authorities has long been recognized and very practical co-operation has existed for decades. The practical co-operation manifests through Working Groups (WG) established for several fields of interest. The WGs have sometimes been established for specific tasks, but usually they have mandates for working more permanently on a specific topic area.

One of the permanent Nordic WGs deals with X-ray diagnostics and has been operational for over 30 years. The main tasks are to exchange information on the national activities and achievements in the field of x-ray diagnostics, to discuss problems and development for regulatory issues and to co-ordinate or undertake joint efforts of research. The results of the work are published in the series of the Report on Nordic radiation protection co-operation or as scientific papers in international journals. In a recent joint project [1], patient doses in paediatric CT examinations were studied in order to pay attention to the increased need for careful implementation of the optimization principle.

This paper compares some characteristic features of the use of radiation for X-ray diagnostics in the Nordic countries and the activities of the radiation protection authorities in this field, highlighting the importance and achievements of effective co-operation between the authorities.

Health care structure and characteristics of radiological practices

All Nordic countries have a good public health care system while there are also private hospitals and practitioners. In Sweden and Norway, the health care system is organized by county or Health Trust, which is a legal entity and has the licence for radiological procedures. The radiation protection legislations are rather up-to-date while the need of some improvements has been identified in some cases, e.g. modification in the supervision of screening programs (Finland), non-ionizing radiation (Sweden; covered only partly by the present regulations; Denmark; no legislation exist covering the medical field), Diagnostic Reference Levels not established (Iceland), training and education in radiation protection (Norway; define adequate level of competence and skills), medical physicists in hospitals (Norway; quantification) and changing the legislation to more general terms (Denmark; to better match modern equipment).

Some characteristics of the medical use of radiation in the Nordic countries are compared in Table 1. While there are no significant differences between the countries, the level of professional resources is somewhat varying. The number of radiologists per 1000 examinations is almost the same, 0,13-0,15, while there are higher variation in the number of physicists and radiographers. This may partly be associated with different responsibilities of these professionals, but generally the number of physicists seems very low.

Activities of the authorities

All authorities take care of the licensing procedure for radiological practices and perform regulatory inspections to ensure the compliance of practices with the legal requirements. A challenge within licensing issues is the rapid development in modern X-ray diagnostic practices used outside radiological departments, like 3D mobile C-arms for use in surgery and Cone Beam CT for use in dentistry. Further, the development in MSCT raises the question about justification of screening of asymptomatic patients outside national screening programs. The inspection policy and methods vary somewhat between the Nordic countries and is described in more detail below (see section Inspection Workshop).

Besides the actual regulatory activities, all Nordic authorities undertake training efforts, prepare and issue guidance on radiation protection and radiation measurements, maintain the national measurement standards for radiation metrology and, to varying extent, undertake research on radiation metrology, radiation protection and quality assurance techniques.

Training of the users of radiation has been considered as one of the key activities of radiation protection authorities, in order to promote the safe use of radiation. Therefore, the actions for training seem very intensive as can be seen from the examples in Table 2.

All authorities also undertake research activities, some of them being joint Nordic efforts, resulting in a number of scientific publications annually. Some recent research topics have been devoted to:

- Determination of patient doses in paediatric examinations (Finland)
- Patient doses in diagnostic radiology (Iceland, Sweden)
- Pilot study: Occupational personal doses in interventional radiology (Denmark)
- Testing of the IAEA Code of practice for x-ray diagnostic dosimetry (Finland)
- Dentists and veterinarian surveys (Norway)

All authorities also have relatively extensive participation in national and international cooperation. Most of the authorities participate in working groups or other activities of, e.g., HERCA (Cooperation between European radiation protection authorities), IEC (International Electrotechnical Commission, standardization activities), EMAN (European Medical Alara Network) and EURAMET (European Metrology cooperation).

Table 1. Comparison of some statistical information between the Nordic countries, on the use of radiation in health care.

	Denmark	Finland	Iceland	Norway	Sweden	Average
Number of inhabitants, million	5,52	5,26	0,32	4,81	9,26

Inspection Workshops

A part of the co-operation between the Nordic radiation protection authorities has been a regular "Inspection Workshop", which has now been organized for three times (every second year). The last one was organized in Norway in 2009 with 20 participants. The Workshops has not only dealt with X-ray diagnostics but covered all medical disciplines, i.e. X-ray diagnostics, nuclear medicine and radiotherapy. In the Workshops, the status of inspections in the medical field in the various countries has been reviewed, followed by working group discussions, comparisons and analysis of the inspection methodology and results. Common findings from the inspections have been recorded. Some specific topics have also been addressed, such as implementation of the justification principle or level of skills for radiation protection in cardiology.

The inspection frequency varies between the countries, but the type of inspection and the inspection procedure are fairly similar, although Denmark and Finland seem to have more technical/measurement elements in the inspection. Denmark is currently revising the inspection procedures towards fewer measurement elements. Comparison of the number of inspections is not straightforward because some countries count inspections for each piece of equipment and others for each county or health trust. A typical finding from inspections, common for all countries, is the lack of competence among the radiation users, especially outside Radiological departments.

Summaries of the observations from the latest Inspection Workshop are shown in Tables 3 and 4.

Table 3. Characteristics of regulatory inspections for X-ray diagnostics in the Nordic countries.

Country	Frequency, y	Fee	No of inspectors/ inspection	Inspector training
Finland	3-5, mammo-screening 2	Inspection fee per equipment	1-2	On-job training. Hospital background
Sweden	5-10; in future 5	Annual fee	2	Special course. Hospital background
Norway	5-10	No fee	2	On-job training. Special course. Supervision by seniors
Iceland	2-4	Inspection fee per equipment + lisencing fee	1-2	On-job training. Internal training program with certification
Denmark	5	Fee per equipment		On-job training. Internal courses

Table 4. Organization of regulatory inspections for X-ray diagnostics in the Nordic countries.

Country	Choice of object	Procedure	Focusing	Follow-up
Finland	By risk based pre-defined periodical system	Specialized inspectors in diffrent areas	No. Focused topics in Clinical audits.	Recorded in a register with a deadline.
Sweden	By order and risk analysis	Opening meeting. Inspection. Interviews. Closing meeting	Both general and focused inspections.	Report on corrective actions required. Special re-inspection.
Norway	By knowledge and prioritized areas	Request for documentation. Opening meeting. Inspection. Interviews. Closing meeting.	Competence outside radiology department	Report after inspection with schedule for corrective actions required.
Iceland	By activity and risk analysis, also by findings in provious inspections.	Both technical and QA reviews. Closing meeting.	Patient doses and QA procedures	Report on corrective actions required in 1-6 months, less important on next inspection. Followed up.
Denmark	Reported problems, high doses, new types of equipment No fixed intervals	QA systemm revies for hspitals and larger clinics	QC and shielding	Discussion at the time of inspection; report on corrective actions required

Conclusions

The annual joint meetings, joint research projects and other joint activities of the Nordic WG on X-ray diagnostics have ensured effective exchange of information in the field of diagnostic radiology. This has been of high importance for developing the national regulatory activities and for promoting consistent methods of quality assurance and dosimetry.

Abstract

Diagnostic reference levels (DRLs) are important tools for optimisation in diagnostic radiology. The European directive on medical exposures [1] requires member states to promote the establishment and use of DRLs, and thus Denmark, Finland, Sweden and all of the Baltic countries are required to establish DRLs. Individual patient doses should not be compared with the DRL, but average patient doses for a given examination in a hospital are to be compared with the DRL.

Common Nordic DRLs were recommended in 1996 for 6 conventional examinations [8]. These values are still in use in Iceland, while – based on national surveys etc. – Denmark, Finland and Sweden have set and revised national DRLs, and Norway have just set national DRLs. Additional DRLs have gradually also been set for CT and mammography as well as for cardiologic and paediatric examinations. DRLs were first set in Lithuania 5 years ago, and have been modified once, while DRLs are currently being set in Estonia.

The Nordic Working Group on X-ray diagnostics has in cooperation with representatives from Estonia and Lithuania conducted a study of DRLs. The choice of dose quantities measured as well as current and previous values of DRLs are compared among the Nordic and Baltic countries, and the process of revision in the different countries is described.

The trend for radiographic and fluoroscopic examinations is that the dose levels and thus the DRL values have decreased over the years. For CT, the dose levels are more constant.

Introduction

Diagnostic reference levels (DRLs) are important tools for optimisation in diagnostic radiology. The concept of DRLs was introduced by the 1990 recommendations of ICRP [4]. The European directive on medical exposures [3] requires member states to promote the establishment and use of DRLs, and thus Denmark, Finland, Sweden and all of the Baltic countries are required to establish DRLs. Individual patient doses should not be compared with the DRL, but average patient doses for a given examination in a hospital are to be compared with the DRL.

DRLs were introduced in the Nordic countries through a common set of recommended values for three conventional and three fluoroscopic examinations, published by the Nordic Working Group on X-ray diagnostics (collaboration between the radiation protection authorities in the five Nordic countries) [8].

DRLs are set based on surveys of the patient doses used for a given type of examinations of a group of patients of standard size. For setting of national DRLs, a national survey of patient doses is thus necessary. In most cases, the DRL is set as the third quartile of the patient doses found in the dose survey. DRLs are conventionally set in dose quantities that are relatively readily available to the user of the x-ray equipment. For conventional examinations, the main quantity is the total DAP for the examination while in some cases the entrance surface dose (ESD) for different projections is used. For fluoroscopy, the main quantities are the total DAP for the examination and the fluoroscopy time. For CT, DRLs can be set for the CTDI as well as for the total DLP for the examination.

Material and methods

Based on collaboration between the Nordic Working Group on X-ray diagnostics and representative from the radiation protection authorities in Estonia and Lithuania, previous and current national DRLs from the 7 countries have been collected. The DRLs have been taken from the national guidelines and from results of dose surveys carried out by the authorities. Estonia does not have national DRL values yet, but recommended DRL values have been published [5, 7] based on limited surveys.

DRLs can be set both nationally and locally, in this document only national DRLs will be considered.

Results

The number and type of examinations for which diagnostic reference levels have been set and the values of the DRLs have been compared between the seven countries in the study.

Number of diagnostic reference levels and types of examinations

Table 1 shows the number of currently valid national DRLs in the different countries. The main number shown is the number of different examinations for which DRLs have been set. In some countries, DRLs for several quantities (e.g. total DAP and fluoroscopy time) have been set for the same type of examination, and the number in parentheses is the total number of DRLs set. Estonia has no national DRLs yet, and has not been included in the table.

Table 1. Number of examinations for which DRLs have been set. In cases where DRLs have been set for more than one quantity for each type of examination, the number in parentheses shows the total number of DRLs. The last row shows the average number of examinations of adults for which DRLs have been set and the average number of DRL values.

Country	Adult patients					Paediatric patient
	Conv.	Fluorosc.	Cardiac	CT	Mammogr.	
Denmark (DK)	4	1		9	1	4 (6)
Finland (FI)	5§ (12)	1	2 (4)	4 (9)	1	3 (8)
Iceland (IS)*	4 (8)	2				
Lithuania (LT)	7 (22)	3 (6)		5	1	
Norway (NO)	8	1	1	10 (20)	2	
Sweden (SE)	4	1	1	4 (8)	2 (4)	
Average	14 (22)					

§ Additionally, Finland has DRLs for two types of dental examinations
* Identical to the common Nordic DRLs from 1996

All countries have DRLs for conventional examinations of thorax, pelvis and lumbar spine, while all but Lithuania have DRLs for IV urography. Finland, Lithuania and Norway also have DRLs for various other examinations, e.g. abdomen, skull, thoracic spine and hip joint. Only Finland and Lithuania have DRLs for several quantities for the same examination, in both cases for entrance surface dose (ESD) for different projections as well as for the total DAP for the examination, while the other countries have DRLs only in terms of DAP.

The only fluoroscopic examinations, for which all countries have set DRLs is barium enema. Lithuania in turn has DRLs for chest and for barium swallow and Iceland for barium meal. All countries have DRL values for the total DAP for the examination, while Finland and Lithuania also have values for the fluoroscopy time.

Only Finland, Norway and Sweden have DRLs for cardiac examinations. All three have values for coronary angiography, and Finland has a value for PTCA also. All three countries have DRLs for total DAP, while Finland in addition has DRLs for fluoroscopy time.

All countries except Iceland have DRLs for CT examinations of head, thorax and abdomen and for different parts of the spine. In addition, Lithuania and especially Denmark and Norway have DRLs for a range of specialised CT examinations in the pelvic and abdominal region. Finland, Norway and Sweden have DRLs for the total DLP of the examination as well as for the CTDI value, while Denmark and Lithuania uses only the total DLP.

Denmark, Finland and Lithuania have DRLs for clinical mammography, and Norway and Sweden have DRLs for both clinical and screening mammography. Sweden has DRLs for each exposure as well for the full examination, while the other countries have only one value (either for one exposure or for the full examination).

Most DRLs are set for adult patients of standard size, as is also the case for all of the values mentioned above. Due to the large variations in size, it is more difficult to set DRLs for paediatric patients. Some examinations are carried out primarily on special age groups (or an age group can be selected as reference), and DRLs can be set for these special age groups. Denmark and Finland have set DRLs for a few paediatric examinations of special age groups: abdomen for infants up to 12 month (DK), sinuses for children 7 – 15 years (FI) and Mictiocystography (MCU) for infants up to 12 month and for children 1 – 5 years (DK and FI). For other examinations patients of all ages are included, and one approach here is to set the DRL as a function of the size of the patient. Denmark and Finland have used this approach to set DRLs for thorax examinations (DK and FI) and for pelvis examinations (DK). In Denmark, the equivalent diameter (based on the height and weight of the child) [2] has been used to describe the size of the patient, while in Finland the actual thickness of the patient has been used. For MCU, both countries have set the DRL in terms of DAP. For the remaining examinations, Denmark has used ESD, while Finland has used both ESD and DAP.

In a previous project in the Nordic Working Group on X-ray diagnostics [1], the aim was to set DRLs for paediatric CT examinations also, but it turned out that the number of examinations carried out was too small to give the required statistical basis.

Table 2. Overview of the development of diagnostic reference levels (DRLs) in the Nordic countries, Estonia and Lithuania.

Country	
Denmark (DK)	Nordic recommendations: 1996 National DRLs: May 2001 Revised DRLs: January 2007
Estonia (EE)	Limited dose surveys: 2002-2006 (recommended DRLs published in scientific papers) National DRLs: Currently being set
Finland (FI)	Nordic recommendations: 1996 National DRLs: December 2000 Revised DRLs: January 2006 Revised DRLs: April 2007 Revised DRLs: January 2009
Iceland (IS)	Nordic recommendations: 1996 (still used as national DRLs)
Lithuania (LT)	National DRLs: December 2004 Revised DRLs: January 2009
Norway (NO)	Nordic recommendations: 1996 National DRLs: Values are set, publication planned around May 2010
Sweden (SE)	Nordic recommendations: 1996 National DRLs: October 2002 Dose survey: 2005-2006 Dose survey: 2008

Values of diagnostic reference levels

Table 2 shows an overview of how DRLs have been/are being set and revised. The first values were the common set of recommended DRL values established in 1996 by the Nordic countries. When the EC Medical directive was implemented in the beginning of the 2000s, Denmark, Finland and Sweden set new national DRLs, partly based on the common Nordic values but supplemented by values for CT and mammography, and in Sweden also for cardiac angiography. Estonia and Lithuania joined the EU in 2004, and Lithuania set national DRLs at the end of 2004. In Estonia limited dose surveys were conducted about 5 years ago and recommended DRLs were published in scientific papers [5, 7], but national DRLs are only now under way. Iceland and Norway are not members of the European Union, and are thus not required to set national DRLs. Iceland has continued to use the DRL values from the Nordic recommendation. Norway has recently set new national DRL values, which are included here; publication is planned for May 2010.

Denmark, Finland and Lithuania have revised their national DRLs based on national dose surveys within the last few years. In Denmark, only the values for the conventional examinations were revised, a revision of the remaining values is still pending. In Finland and Lithuania, the values for all types of examinations were revised, and also certain types of examinations were added to or removed from the list of DRLs. In Sweden, the DRLs have not been revised, but nationwide dose surveys have been carried out twice, and the results (third quartile) from these surveys have been included here. These results from the dose surveys will also be referred to as DRLs and be included in the comparison below. Also, even though the values from Estonia are not official national DRLs, they have also been included in the comparison.

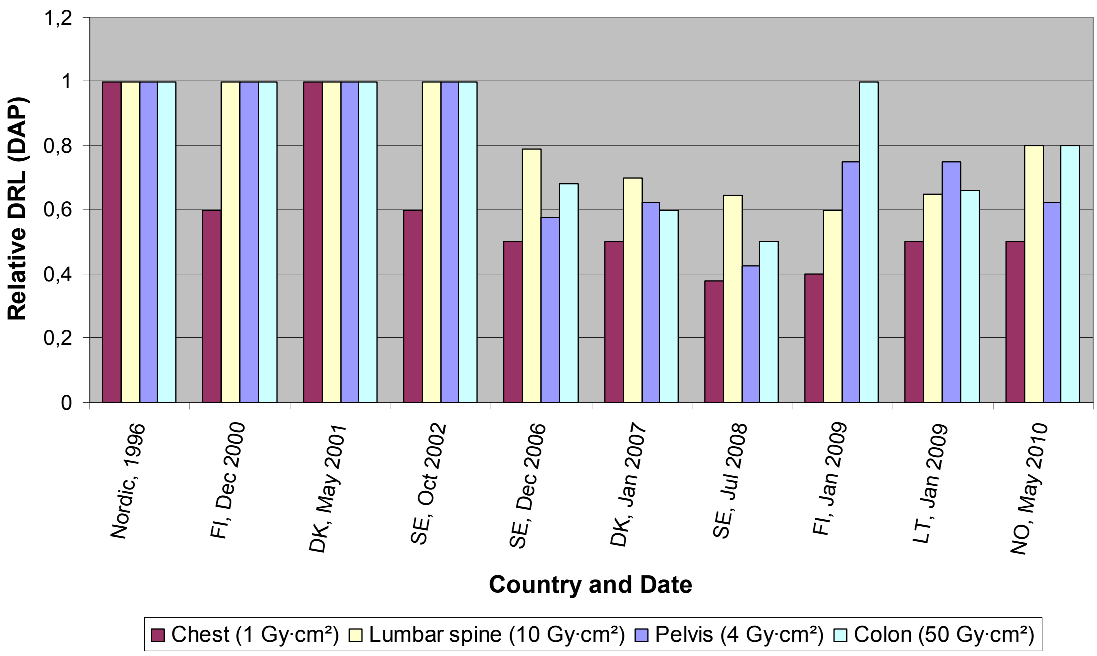

Figure 1. Development of the value of DRL (total DAP for the examination) for three conventional and one fluoroscopic examinations. The value of each DRL is shown relative to the value of the original common Nordic DRL, the value of which is shown in the legend.

Figure 1 shows the development in the DRL values for total DAP for conventional and fluoroscopic examinations, as shown by the ratio of the relevant DRL to the common Nordic DRL from 1996. The examinations, three conventional and one fluoroscopic, for which DRLs have been set by nearly all countries (in Estonia, no value for colon has been proposed), have been included in the figure. Since the first set of DRLs from Lithuania and the recommended values from Estonia were given only in terms of ESD they could not be included in figure 1. Instead, the development in the DRL values for ESD for selected individual projections of the three conventional examinations is shown in figure 2. The figures show that in general, the DRLs have been decreasing over the last decade. Looking at any single country, the DRLs have been constant or decreasing, but there is some variation in the values between the different countries. The DRL values from Lithuania and Estonia for ESD are generally higher than the Nordic values, but the 2009 values from Lithuania are considerably lower than the 2004 values. The 2009 DRL values for DAP from Lithuania are also in the same range as the newer values from Denmark, Finland, Norway and Sweden.

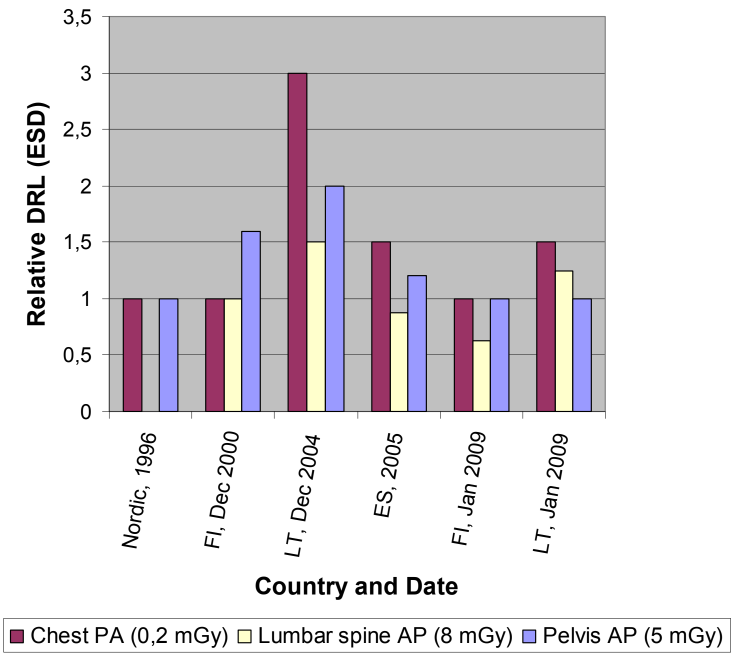

Figure 2. Development of the value of DRL (ESD for one projectin) for three conventional examinations. The value of each DRL is shown relative to the value of the original common Nordic DRL/DRL from Finland 2000, the value of which is shown in the legend.

Figure 3 shows the development in the DRL values for DLP for CT examinations, as shown by the ratio of the relevant DRL to the first DRLs values set, the DRL values of Finland from 2000. Included in the figure are the three CT examinations for which DRLs have been set by the largest number of countries – all except Estonia and Iceland. The first set of DRLs for Lithuania had to be excluded, since the DRLs were not given as DLP values. Overall, figure 3 shows that the DRLs for CT examinations have been relatively constant.

The DRLs for mammography and for cardiac examinations have not been compared between the countries here. For mammography, some countries have DRLs for the entire examination, while others have DRLs for single exposures. This makes a direct comparison very difficult. For cardiac examinations, DRLs have only been set by three countries.

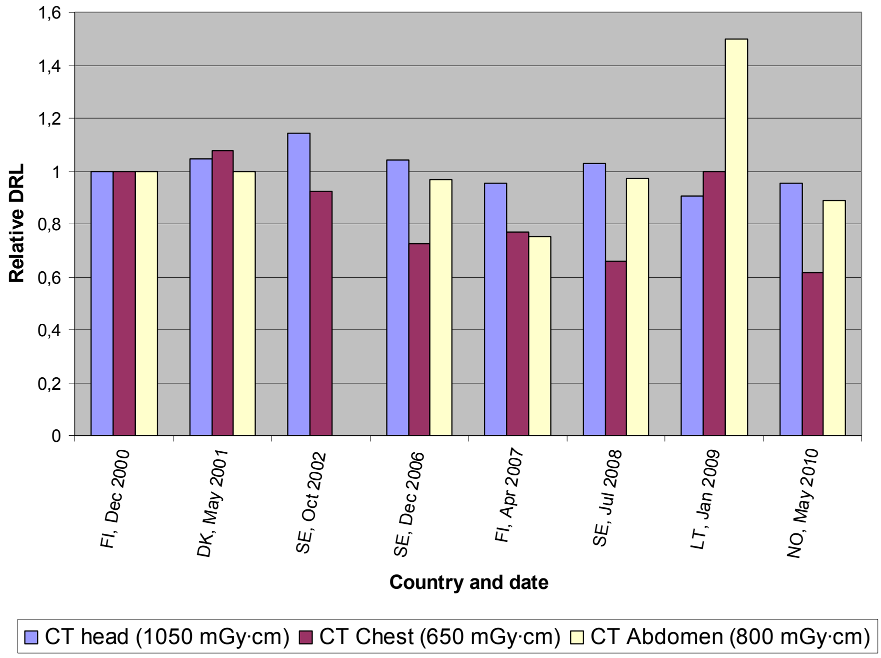

Figure 3. Development of the value of DRL (DLP for the examination) for three CT examinations. The value of each DRL is shown relative to the value of the original common Nordic DRL, the value of which is shown in the legend.

For paediatric examinations, only Denmark and Finland have set DRLs. For MCU, the Danish DRLs were based on the Finnish values, consolidated by results from a Danish survey, so the values are identical. The only other paediatric examination where both countries have DRLs is chest. Figure 4 shows a comparison of the DRL values for ESD as a function of the size of the child. The Danish DRLs are given in terms of the equivalent diameter, but have been converted approximately to actual thickness by using data for growth curves for Danish children [2].

Discussion

As can be seen from Table 1, the number of examinations for which DRLs have been set as well as the total number of DRL values vary considerably between the different countries. The number of DRLs for examinations of adult patients varies between 6 and 22 with an average of 14. The number of examinations for which DRLs have been set is quite similar in Denmark, Finland, Lithuania and Sweden, while Iceland and Norway have set DRLs for considerably fewer and more examinations, respectively.

Finland and Lithuania normally have DRLs for several quantities for the same type of examination, while Denmark and Iceland in general only have one DRL per examination. Norway and Sweden are in between, having set DRLs for several quantities for some examinations and only one DRL for some.

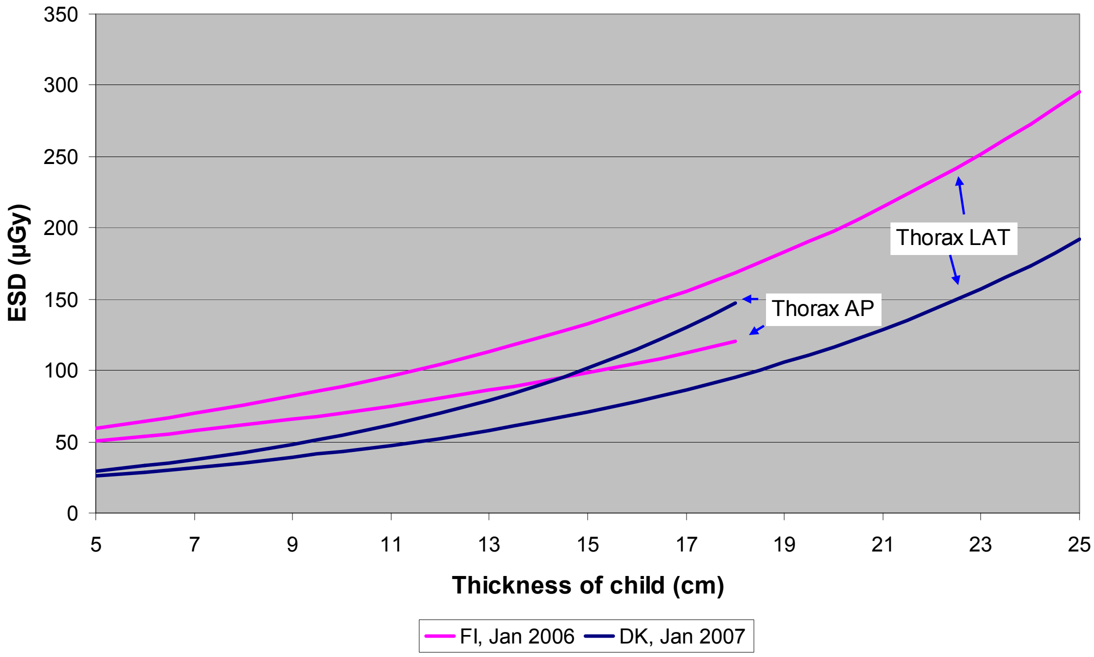

Figure 4. Comparison of the DRLs for paediatric chest examinations.

The development in the DRLs values in the Nordic countries has been quite similar over time, although there are also some differences between the countries. For conventional examinations, the values have decreased between 25 % and 60 %, reflecting the development in equipment and probably also the focus on optimization during this period. For the fluoroscopic examinations, represented by colon (barium enema), the decrease is smaller, and in Finland the value is unchanged. For CT, the DRL values have been quite constant, except for CT chest were the recent values from Sweden and Norway are 40 % lower than earlier values.

The DRL values from the two Baltic countries, Lithuania and Estonia from around 2005 were generally higher than the values from the Nordic countries, especially the Lithuanian DRL for the ESD for Chest PA, which was 200 % higher. However, the recent DRLs from Lithuania are much lower and for conventional and fluoroscopic examinations quite similar to the recently set Norwegian values. For CT, the recent DRLs from Lithuania are still somewhat high, especially the DRL for CT abdomen, which is 50 % higher than the Nordic values.

For the paediatric DRLs for Chest AP and LAT, the dependence on patient size is quite similar for the Danish and Finnish values. The DRL values for Chest AP are quite similar, although the Danish values increase slightly more with increasing patient thickness than the Finnish. Thus, the Danish values are lowest for small patients, but higher for larger patients. The Danish values for Chest LAT are consistently lower than the Finnish values, from 30 % lower for the larger patients and up to nearly 60 % lower for the smaller patients. Comparing the values for the two projections, there is also an interesting difference. The Danish values for LAT are lower than the values for AP, while the Finnish values for LAT are higher.

Conclusions

The DRLs of the Nordic countries and two of the Baltic countries, Estonia and Lithuania, have been compared. For conventional and fluoroscopic examinations, the general trend is that the DRLs have decreased over the last 10 years, indicating that the patient doses for these examinations have decreased. For CT, the DRLs are more constant, reflecting that the patient doses have not decreased.

Modification of nuclear medicine diagnostic reference levels in Austria

Stemberger, Andreas[1]; Hefner, Alfred[2]; Staudenherz, Anton[3]
[1] Rudolfstiftung Hospital, AUSTRIA
[2] Seibersdorf Laboratories, AUSTRIA
[3] Medical University of Vienna, AUSTRIA

Abstract

Aim: Diagnostic reference levels (DRLs) are implemented to optimize diagnostic medical examinations using ionizing radiation. In Austria DRLs were established for the first time 2005 by the Austrian medical radiation protection regulation. In a nation wide survey we asked for daily routine patient details. The aim was to adjust the DRLs in Austria, considering new device developments as well as modified acquisition protocols.

Materials and methods: Using pooled data of 5320 patients from the survey, descriptive statistics was done. Frequency, age distribution and mean applied activities were determined, whereby we estimated also an individual effective dose for particular examinations. An extrapolation concerning the cumulative exposure of the population were also taken into consideration.

Results: In Austria the most frequent examination was thyroid scintigraphy using 99mTc-pertechnetate (23.2%), followed by heart (19.7%), bone (18.7%), renal (8.6%), PET-FDG (7.7%) and lung (7.5%) scintigraphy. About 150000 nuclear medicine procedures in 71 nuclear medicine facilities were performed 2008. An extrapolation revealed 35000 thyroid, 28000 bone, 29500 myocardial 12900 renal, 11500 PET-FDG, 11200 lung and 21900 miscellaneous scintigraphies. Regarding the number of nuclear medicine examinations per 1000 Austrian residents, Austria is located on the fourth place in comparison with 8 other European countries. The average effective dose for a nuclear medicine procedure was 3.9 mSv (range: 0.2–22.2 mSv). A mean effective dose of 0.07 mSv per year and resident was estimated. The additive part of the nuclear examinations compared to the total natural effective dose of 3.8 mSv per year could be stated as marginal.

Conclusion: Due to our survey results we suggested a modification of the DRLs in 73%. These alterations will be presented and implemented in a revised version of the forthcoming amendment of the Austrian medical radiation protection regulation.

Medical exposure to ionizing radiation in Switzerland – implementation of national diagnostic reference levels in radiology and nuclear medicine

Treier, Reto[1]; Trueb, Philipp R.[1]; Roser, Hans W.[2]; Stuessi, Anja[1]; Samara, Eleni[3]; Aroua, Abbas[3]; Verdun, Francis[3]; Zeller, Werner[1]

[1] Federal Office of Public Health, Bern, SWITZERLAND

[2] University Hospital Basel, Basel, SWITZERLAND

[3] University Institute of Applied Radiation Physics, Lausanne, SWITZERLAND

Abstract

The frequency and complexity of medical radiological procedures using ionizing radiation has been increasing continuously over the past years. As a direct consequence also patient doses have been increasing significantly. Since there are no dose limits for patients when applying ionizing radiation in medicine radiation protection is based on two basic principles – justification and optimization.

The concept of diagnostic reference levels (DRLs) first introduced in 1996 by the International Commission on Radiological Protection represents a powerful tool for dose optimization of radiological procedures. In Switzerland, DRLs are implemented in the national legislation. Radiology departments are obliged to compare periodically patient doses to DRLs and to optimize their procedures if necessary.

The Federal Office of Public Health (FOPH) provides national DRLs in the field of nuclear medicine (based on a national survey in 2004), interventional radiology (IR) and cardiology (based on a national survey in 2002) and computed tomography (CT) (partly based on a national survey in 1998 and on literature). However, effective optimization of radiological procedures is only feasible if DRLs are periodically adapted to the local practice and the actual state of technology. Therefore, national surveys have been repeated in IR and cardiology in 2007 and in CT in 2007-09 to collect actual dose data. These data are statistically analyzed and DRLs will be adapted. In a further project, examination parameters in radiography were collected to derive DRLs for the entrance-surface-dose. National DRLs are published in technical bulletins and are available for free on the FOPH webpage.

Periodical audits of the radiology departments and the on-site comparison of local patient doses to national DRLs are most effective for optimizing radiological procedures. To assess the change of patient doses over time for each radiology department the FOPH is establishing a national data base of medical radiological examinations.

Introduction

Over the past years, a continuous increase in the frequency and complexity of radiological procedures applying ionizing radiation has been observed. Today, annually worldwide, more than 3,600 million X-ray examinations are performed in radiography and around 37 million nuclear medicine and 7.5 million radiotherapy procedures are carried out (WHO 2008). As a direct consequence, the contribution of the medical application of ionizing radiation to the collective dose has also been increasing. Although the diagnostic and therapeutic benefits to the patients are enormous the widespread use of radiological procedures becomes a major concern in health care.

Since in medicine there are no dose limits for patients radiation protection is mainly based on two pillars – justification (i.e. provide more good than harm to the patient) and optimization (following the ALARA principle "as low as reasonably achievable") of radiological procedures, as first introduced by the International Commission on Radiological Protection (ICRP 1996). One powerful tool for optimization of radiological procedures represents the concept of diagnostic reference levels (DRLs). In diagnostic radiology, DRLs are derived empirically by determining the 75th percentile of the distribution of a defined dosimetric quantity for routine conditions and for standard patients. In nuclear medicine, DRLs are defined by the median of the applied activities. DRLs are specific to a country or region assessing the local radiological practice and should be periodically updated. The application of the concept of DRLs helps the radiologists, nuclear medicine professionals and radiographers to identify and optimize those radiological procedures which provide unusually high patient doses. In Switzerland, the concept of DRLs has been implemented in the national legislation (Swiss Federal Council 1994). Article 37a of the Radiological Protection Ordinance enables the Federal Office of Public Health (FOPH) to issue recommendations on radiation doses for diagnostic procedures in the form of DRLs taking into account data from national surveys and international recommendations. Furthermore, radiology departments are obliged to compare periodically patient doses to national DRLs and to optimize their procedures if doses exceed systematically corresponding DRLs.

The FOPH provides national DRLs in the field of nuclear medicine (based on a national survey in 2004), interventional radiology (IR) and cardiology (based on a national survey in 2002) and computed tomography (CT) (partly based on a national survey in 1998 and on data from literature). These radiological procedures contribute most to the collective dose of the Swiss population (Aroua et al. 2003) and thus DRLs are considered to be an essential tool for dose optimization in these fields. However, effective optimization is only feasible and reliable if DRLs are periodically adapted to the local practice and the actual state of technology. Therefore, national surveys have been repeated in IR and cardiology and in CT to collect actual dose data. Taking into account that by far most of the examinations are performed in radiography a further project of the FOPH was launched in 2009 to collect examination parameters of common radiographic examinations and to derive DRLs for the entrance-surface-dose. Simultaneously to data collection, a data base has been developed allowing further statistical analysis of dose data and the derivation of actual DRLs.

This paper provides a summary of actual national DRLs in nuclear medicine and diagnostic radiology in Switzerland.

Material and methods

Nuclear medicine

In 2004, a nationwide survey was performed and following data was collected: age and gender of the patients; type of examination; applied radionuclide and pharmaceutical; type of application; and applied activity (Roser 2006). Median values of the distribution of the applied activities were calculated. Based on these median values, practical experiences of nuclear medicine professionals, as well as DRLs of the neighboring countries Germany and Austria national DRLs were defined.

IR and cardiology

The first survey in the field of IR and cardiology in Switzerland was conducted in the university hospitals in 2002 to study the clinical practice of 8 fluoroscopic examinations. From 2006-2007, a second survey was performed including 32 small and medium sized hospitals (Trueb et al. 2009). For each center, dose data of 20 patients for the most frequent examinations were collected. These two surveys provide the basis for the derivation of the DRLs for the dose-area-product (DAP), the fluoroscopic time (T) and the number of images (N).

CT

DRLs in CT were introduced for 21 indication-based CT protocols which based partly on a national survey performed in 2004 (Aroua et al. 2004) and on recommendations of the European Commission (European Commission 1999). In 2007, a new project was launched by the FOPH with the aim to collect dose data (volume computed tomography dose index ($CTDI_{vol}$) and dose-length-product (DLP)) for every Swiss radiological institute operating a CT scanner and to adapt the previously defined DRLs to the actual practice (Treier et al. 2009).

Radiography

38 private radiology institutes and hospital radiology departments operating a digital X-ray system (either computed radiography (CR) or digital radiography (DR)) participated in a survey that was performed last year (Theiler 2009). Each radiology site provided exposition parameters (tube voltage, tube current, and focus-skin-distance) of 20 patients for three common types of radiographs (chest, pelvis, and lumbar spine, all in ap or pa projection). This allowed the entrance-surface-dose (ESD) to be calculated. The resulting DRLs were compared to the DRLs based on the European directive (European Commission 1999).

Data base

A national data base (DAMEX: data base of medical radiological examinations) has been developed based on Microsoft Access 2003 to collect and store patient doses and examination parameters of the national surveys. So far, DAMEX contains dose data of the surveys in CT and radiography as well as data specifying the X-ray units and radiology departments.

Results

National DRLs for nuclear medicine, IR and cardiology, CT, and radiography are published in technical bulletins of the FOPH and are available for free at

http://www.bag.admin.ch/themen/strahlung/00044/00071/index.html?lang=de
for nuclear medicine (L-08.01.pdf) and at

http://www.bag.admin.ch/themen/strahlung/02883/02885/02889/index.html?lang=de
for IR and cardiology (R-06-05.pdf), CT (R-06-06.pdf), radiography (R-06-04.pdf).

In the following paragraphs selected results of these technical bulletins are presented.

Nuclear medicine

The most frequently used radionuclide in nuclear medicine is technetium (Tc-99m) in combination with the pharmaceutical MIBI (cardiolite). In case of positron-emission-tomography (PET) examinations fluorine (F-18) together with the pharmaceutical FDG is most widely applied. In table 1 DRLs for common examinations in nuclear medicine using Tc-99m and F-18 are presented.

Table 1. DRLs (median) for common examinations in nuclear medicine using Tc-99m MIBI (cardiolite) and F-18 FDG.

Examination	Radionuclide	Pharmaceutical	Application	DRL [MBq]
Thyroid	Tc-99m	MIBI (cardiolite)	intravenous	170
Parathyroid	Tc-99m	MIBI (cardiolite)	intravenous	550
Myocardium	Tc-99m	MIBI (cardiolite)	intravenous	300 + 900 * 2 x 600 **
Tumors	Tc-99m	MIBI (cardiolite)	intravenous	740
Tumors (PET)	F-18	FDG	intravenous	350
Neurology (PET)	F-18	FDG	intravenous	200

* one-day protocol: 300 MBq and 900 MBq

** two-days protocol: two times 600 MBq

IR and cardiology

DRLs for five types of interventional examinations (coronary angiography, percutaneous transluminal coronary angiography (PTCA), cerebral angiography, angiography of the lower limbs, and PTA of lower limbs) are shown in table 2. Values for small and medium sized hospitals are compared to those of university hospitals.

Table 2. DRLs (75th percentile) for DAP [Gy·cm²], fluoroscopic time T [min], number of images N.

Examination	Measure	Small and medium sized hospitals	University hospitals	Ratio
Coronary angiography	DAP T N	110 10 1500	80 7 1400	1.38 1.43 1.07
PTCA	DAP T N	150 20 1800	110 20 1500	1.36 1.00 1.20
Cerebral angiography	DAP T N	160 8 240	125 15 480	1.28 0.53 0.50
Angiography of lower limbs	DAP T N	70 8 150	210 8 150	0.33 1.00 1.00
PTA of lower limbs	DAP T N	70 22 180	460 25 200	0.15 0.88 0.90

For coronary angiography, PTCA, and cerebral angiography the DRLs of the DAP in the small and medium sized hospitals are 30-40% higher than the DRLs in the university hospitals. In contrast, DRLs for angiography and PTA of lower limbs are smaller by a factor 3-7.

CT

Standard CT protocols of the skull/brain, thorax, and abdomen/pelvis are most frequently applied in Swiss radiology departments. Results of the surveys in 2004 and 2007-2009 for these 3 examination types are summarized in table 3. Interestingly, changes in DRLs between the two surveys are very small.

Table 3. DRLs (75th percentile) for $CTDI_{vol}$ and DLP of standard examinations of the skull/brain, thorax, and abdomen/pelvis.

Examination	Indication	Survey 2004 $CTDI_{vol}$ [mGy]	Survey 2007 $CTDI_{vol}$ [mGy]	Survey 2004 DLP [mGy·cm]	Survey 2007 DLP [mGy·cm]
Skull/brain	Metastases, abscess	60	65	1000	1000
Thorax	Angiography, pulmonary embolism	15	15	450	450
Abdomen/pelvis	Emergency, abscess	15	15	700	650

Radiography

Results demonstrated that the calculated DRLs based on the survey were significantly lower than the existing DRLs as proposed by the European Commission (table 4). Further analysis has shown slightly lower ESD values for DR-systems compared to CR-systems (data not presented) mainly caused by the improved detector quantum efficiency of solid state detectors compared to phosphorous imaging plates.

Table 4. DRLs for ESD [mGy] of radiographs of the chest, pelvis, and lumbar spine.

Examination	European Commission	Survey 2009	Ratio
Chest ap/pa	0.3	0.16	0.53
Pelvis ap	10	3.19	0.32
Lumbar spine ap/pa	10	6.58	0.66

DAMEX

In total, data of 187 hospitals and private radiology institutes participating in the surveys in CT and radiography were recorded. 214 CT scanners and 43 radiography units provided 1973 and 2320 patient dose data sets, respectively. The structure and complexity of DAMEX is depicted in figure 1.

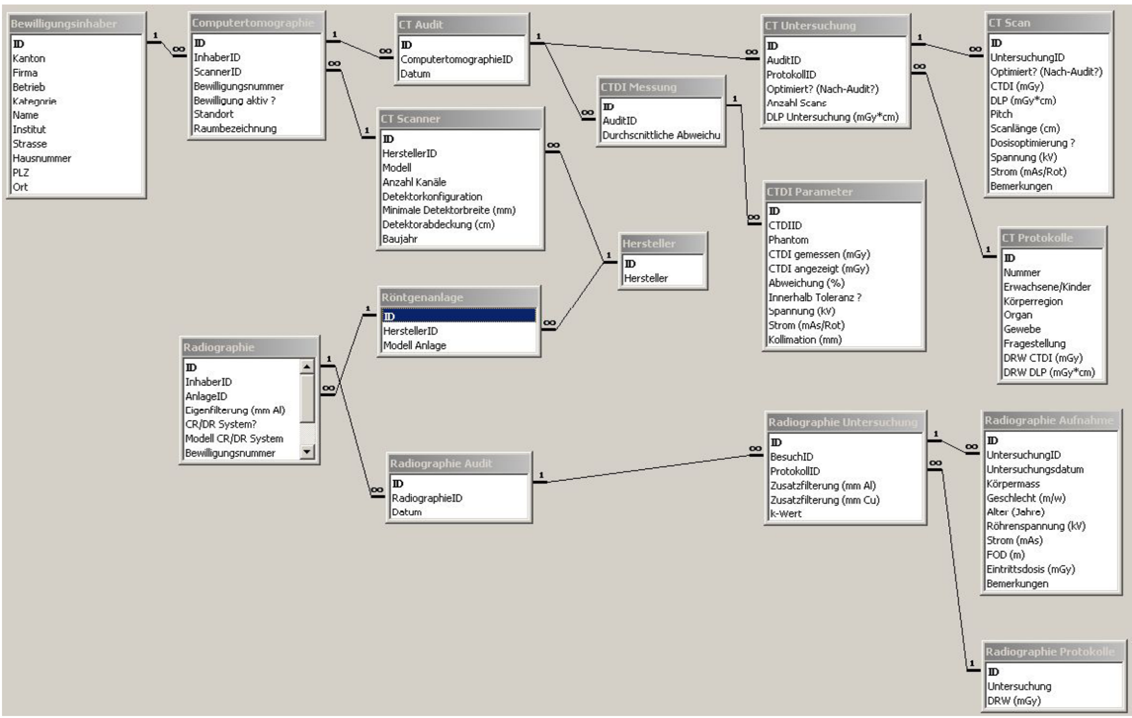

Fig. 1. Screenshot illustrating the tree structure of DAMEX and the relationships between the different tables.

Discussion

DRLs for nuclear medicine, IR and cardiology, CT, and radiography were derived based on nationwide surveys performed in the last few years in Switzerland. In IR and cardiology and CT surveys have been repeated to adapt DRLs to the actual practice. DRLs are published in technical bulletins and uploaded on the FOPH website.

Results for IR and cardiology have shown significant differences in the DRLs between small and medium sized hospitals and university hospitals. The reasons are manifold. University hospitals often treat complex cases where an increased dose is necessary. Also, the experience of the operator plays an important role. Junior doctors more often work in university hospitals and need more time to perform certain examinations. To avoid these problems DRLs could be defined separately depending on the size of the hospital. For CT, the change in DRLs from the first to the second survey was only minor although technical advances of CT scanners have significantly improved the radiation efficiency. This indicates that the concept of DRLs has not yet been correctly applied for CT examinations in clinical routine. In radiography, national DRLs were much lower compared to those defined by the European Commission. One reason for this remarkable result represents the high optimization potential of digital imaging systems (particularly DR-systems) when compared to screen-film combinations.

For data collection and statistical analysis of patient doses a data base using the software package of Microsoft Access has been developed. Data for IR and cardiology and CT have already been entered. An extension of the data base is scheduled since more surveys will follow.

Conclusions

In Switzerland, much effort has been made to optimize radiological procedures aiming at the reduction of patient doses. National DRLs for various fields in radiology have been defined and published in technical bulletins. Periodical audits of the radiology departments are performed and local patient doses are compared on-site to national DRLs. By establishing a national data base and continuously collecting dose data the development of patient doses over time can be assessed. However, the other basic principle in radiation protection, i.e. justification of radiological procedures, has been almost completely neglected so far. Thus, the FOPH is planning to launch a project to introduce clinical audits in Switzerland. Clinical audits are systematic and continuous assessments of all radiological processes performed during the clinical pathway of the patient. The aim is to identify and eliminate those radiological procedures that are not justified and to optimize the justified procedures. For a successful implementation of clinical audits a close collaboration of all the involved stakeholders (nuclear medicine professionals, radio-oncologists, radiologists, radiographers, medical physicist, and authorities) is mandatory.

Abstract

Medical exposure of patients in diagnostic radiology is the highest source of population artificial irradiation. Optimization of radiation protection in diagnostic radiology should be focused on reducing patients doses obtained from most wide-spread medical examinations while keeping high quality of diagnostic information. International Basic Safety Standards (BSS-115) established guidance levels of patient doses for diagnostic radiography. Different countries can use these values until national diagnostic reference levels are defined. Since 2009 the scientific research of patient doses in diagnostic radiology has started in Ukraine. The main purpose of this work is to evaluate the structure and parameters of X-ray diagnostic examinations, the current state of X-Ray diagnostic units, radiation output of X-ray units in different hospitals, and to measure patient doses for 5 main radiography examinations: chest; cervical spine, thoracic spine, lumber spine, pelvis (for main projections). The measurements of radiation parameters were carried out for 35 X-ray diagnostic units from 12 large hospitals of 5 Ukrainian regions. The entrance surface doses were measured for more than 600 patients with TL-detectors LiF type MTS-N (Poland). For different types of X-ray units the values of entrance surface doses differ in 20–40 times. For chest X-Ray the average dose was about 0.83 mGy. The maximum average patient doses were observed for thoracic spine diagnostic examinations – 19.7 mGy (AP), 35 mGy (LAT) and for lumber spine: 18.5 mGy (AP) and 46 mGy (LAT). At present the measurements of patient doses in Ukrainian hospitals are continued. To establish diagnostic reference levels for main radiography examinations the study of patient doses distribution will be done.

Real-time measurement of ovaries dose burden for I-131 treatment patient

Abstract

The ovaries dose burden for post-operation thyroid cancer patient undergoing I-131 treatment is estimated by directly measuring ovaries skin entrance dose. Iodine-131 environmental dose rates are determined in real-time basis at 1 meter distance from the patient body to check for the regulatory compliance.

Dual digital dosimeters are deployed at the patient's ovaries proximity skin location (OS-1 meter) and at 1 meter distance away from the body surface (EV-1 meter). The OS-1 meter is operated in accumulated mode to totalize the overall dose burden during the I-131 treatment and the EV-1 meter is operated in dose-rate mode to monitor instant environment dose rate read-outs, respectively. Both of the measurements are recorded in hourly basis for up to 4 consecutive days. The times and multiple trips to the bathroom during 4-day period are also been tracked by patient herself. The ovaries dose burden determined by the ovaries skin entrance dose is at a 0.075 rad/mCi (mGy/3.7MBq) value for 4 days accumulated data in this study which is about half of the value from the nuclear medicine reference manual. Iodine effective half-life by using the imaging ROI data is at a 15.4 hours in our case of study, but the whole body iodine clearance half-lives can vary between 6 to 16 hours depending on foods and water taken and how often bathroom trips conducted. The correlation ratios between OS-1 and EV-1 meters read-outs can vary between 22 to 38 from time to time due to I-131 bio-distribution differences during our 4 days of observations. The ovaries dose burden can be measured directly by using real-time digital dosimeter. Real-time environmental dose rate verification, below than 50 micro-Sv/h required, can be used to meet the safety compliance when we are allowed to discharge an I-131 patient.

Introduction

When post-operation thyroid cancer patients were treated with large doses of Iodine-131 for targeted therapy, he or she would have significant radiation doses delivered to extrathyroidal tissues that might induce some side effects. Recently, these side effects, including bone marrow insufficiency and late occurrence of extrathyroidal cancer and leukemia, have been published extensively elsewhere. (Sawka 2009; Brown 2008;

Remy 2008) There was also a concern about young females with I-131 ablation treatment after Chernobyl accident. (Travis 2006) With the completion of our new I-131 therapy ward, we have been receiving more thyroid cancer patients who are still in reproductive age. We are more interested in ovaries dose-related infertility among young females who need larger doses of I-131 therapy and would like to monitor environment dose rate for radiation safety compliance for the general public.

In our present of study, the ovaries dose burden for post-operation thyroid cancer patient undergoing I-131 treatment is estimated by directly measuring ovaries skin entrance dose. Iodine-131 environmental dose rates are determined in real-time basis at 1 meter distance from the patient body to check for the regulatory compliance before releasing a patient. Iodine effective half-life is also determined by using time-profile of gamma scintigraphic images at the remnant of thyroid tissues for bio-effective or bio-clearance evaluations.

Material and methods

Real-time, dual digital G-M dosimeters are deployed at the patient's ovaries proximity skin location (OS-1 meter) and at 1 meter distance away from the body surface (EV-1 meter). These miniature dosimeters were selected and evaluated among others earlier for the dose-response accuracy, reproducibility, linearity check that was verified for the suitable use in our dose assessment applications. The OS-1 meter is operated in accumulated mode to totalize the overall dose burden during the I-131 treatment and the EV-1 meter is operated in dose-rate mode to monitor instant environment dose rate read-outs, respectively. Both of the measurements are recorded in real-time basis during awakening hours continuously for up to 4 consecutive days. The frequency of multiple trips to the bathroom during 4-day period is also been tracked and recorded by patient herself.

The effective half-live of iodine uptake by the thyroid remnant is determined by using selected region of interest (ROI) total counts of gamma scintigraphic images at the neck area at 6 hours and 24 hours after I-131 drug being administered. Other whole body I-131 clearance rate was estimated for various time-frames, which was strongly affected by the patient foods consumed and frequency of bath-room trips. The average whole body clearance rates were calculated by the EV-1 meter read-outs located at one meter distance away from the patient.

Results

There are 40 consequent data taken during about 88 hours time span after I-131, with total activity of 75 mCi (2.78 GBq), is orally administered. Some real-time raw data are listed in Table 1 for demonstration purpose, including the initial and final readouts on the EV-1 and OS-1 dosimeters, respectively. Based on the last integral dose reading on the OS-1 meter, the ovaries dose burden determined at the ovaries skin entrance location gives a value of 56.3 mSv (5.63 rad). This is equivalent to a value of about 0.075 rad/mCi (mGy/3.7MBq) that is about half of the value from a nuclear medicine reference manual. (Kuni 1997) Iodine-131 effective residence half-life of the thyroid remnant by using the imaging ROI data is about 15.4 hours in our case of study. The whole body iodine clearance half-lives can vary between 6 to 16 hours depending on foods and water taken and how often bathroom trips conducted. The whole body I-131 clearance half-lives are calculated from Table 1 EV-1 dose rate meter at one meter distance. The correlation ratios between OS-1 and EV-1 meters dose rate read-outs can vary from 22 to 38 at different time based on our 4 days of observations. (Table 2)

Table 1. Data recorded on the dual dosimeters based on 4 days observation.

Approximate Time Elapsed	OS-1 Dose Integral Meter (milli-sievert)	EV-1 Dose Rate Meter (micro-sievert/h)
0 h (started)	0	149
6 h	14.4	77.3
12 h	24.0	58.9
24 h	39.4	39.2
2 d	50.8	7.80
3 d	54.5	6.39
88 h (ending)	56.3	4.16

Table 2. Correlation ratios between OS-1 and EV-1 dose rates at various time frames.

Approx. Time Elapsed	Derived OS-1 Skin Entrance Dose Rate (microsievert/h)	EV-1 Dose Rate (microsievert/h)	Correlation Ratio (OS-1/EV-1)
1 h	3140	82	38.2
2 h	3340	94	35.5
6 h	1910	77.3	24.7
12 h	1510	58.9	25.6
24 h	867	39.2	22.1
48 h	300	7.80	38.5
3 d	144	6.39	22.5

Conclusions

In this case study, we have demonstrated that the ovaries gamma dose burden can be measured directly by using real-time digital dosimeter at ovary skin entrance location.

This dose burden has assumed a minimum beta dose contribution within ovary tissues. Effective residence half life of I-131 at thyroid remnant can be determined by the gamma scintigraphic imaging at the neck location. Real-time environmental dose rate verification can be conducted by the EV-1 meter, that is required to be less than 50 micro-Sv/h, to meet the safety compliance when we are allowed to discharge an I-131 treatment patient.

Abstract

The objective of this work was to perform a dosimetry study of 11 CT scanners located in Brazil and to evaluate the image quality of these equipments. The volume CT air kerma index (C_{VOL}) and the air kerma length product (P_{KL}) were estimated for each procedure on the basis of the normalized weighted air kerma indices in CT standard dosimetry phantoms ($_nC_W$), supplied by the ImPACT group. The scanning parameters for adults were collected for head, chest, high-resolution chest, abdomen and pelvis examinations. For each procedure and each institution 15 examinations, randomly selected, were evaluated and the following parameters were registered: tube voltage and current, gantry rotation time, collimation and slice thickness, pitch or increment, scan length and the scanner dose index indication. The image quality was evaluated using the ACR CT accreditation phantom, manufactured by Gammex. The results indicate that efforts should be concentrated in the maintenance of the equipments and specific training of the technicians. Most of the scanners have showed some non-conformity. For dose evaluation, the results showed a wide variation of air kerma values for the evaluated institutions. The range of C_{VOL} values for head scans varied between 18 and 105 mGy and the P_{KL}, from 256 to 1632 mGy.cm. For chest scans, the C_{VOL} values varied from 8 to 30 mGy, and P_{KL} values from 153 to 1120 mGy.cm For abdominal scans the CVOL values varied from 8 to 19 mGy and PKL values from 240 to 805 mGy.cm. Conclusions: Although the C_{VOL} and PKL values for most procedures performed in the institutions are compatible to the European reference levels, the image quality did not attend all ACR CT accreditation requirements.

Introduction

In Brazil, in the last years, there was an exponential increase in the number of CT scanners installed, especially multi-slice CT scanners (MDCT). This new technology created important advances in imaging modalities. New applications such as CT angiography and virtual endoscopy are a reality in many centers. However, as a result of the rapid development of these technologies, its use has become more widespread and the patient dose should be a health concern. According to UNSCEAR 2000, CT scans represent 34% of the annual collective dose of all X-ray diagnostic procedures. Recent studies indicate that the tendency of the dose is to increase, due to the possibility to carry one procedure in fraction of seconds with high special and temporal resolution. The tendency is also to increase the irradiated volume (thorax-abdomen-pelvis).

However, there is a lack of preparation of the professional involved in this practices. There is no quality assurance programs implemented in the services and the evaluation of patient dose is not a practice in the services. Consequently, the protocols are used without one plan for optimization specially, for paediatric patients.

The amount of radiation dose received from a CT scan depends on two main factors, the design of the scanner and the way it is used. Especially the MDCT can potentially result in higher radiation risk to the patient due to its increased capabilities such as long scan lengths at high tube currents with faster acquisition times and multi-phase contrast studies. The selected scanning parameters, such as kV, mAs, table increment/pitch and scan length, will mainly affect the radiation dose to the patient.

These parameters should be evaluated for dose reduction including those that can be modified based on patient size, study indication such as tube current, gantry rotation time, pitch, tube potential, scan covered, radiographic shields, automatic exposure control techniques, and noise reduction filters (Bongartz, 1999;Tsapaki, 2006).

A national survey never has been done in Brazil so far. However, in 2007, some Brazilian institutions participated in a survey carried out in Latin America under the IAEA Technical Cooperation Regional Project RLA/9/057: Radiological protection of patient and in medical exposure (Dias et al, 2007). The objective of this work was to evaluate the patient dose in different states of the country in order to be able to conduct a national survey in a near future.

Material and methods

In this study, institutions located in Rio de Janeiro, Pernambuco and Paraná have participated. The Table I show the distribution of the equipments in the states, the main characteristics of the equipments.

Methods for Estimate the CT dose indices

Values of Cvol and PKL were calculated for each axial or helical sequence on the basis of the representative n*C*W coefficients published by IMPACT [4] or when available the n*C*W value obtained in the dosimetry. For scanners operated in auto dose reduction mode with automatic tube current modulation, doses were calculated using reported values of (average) tube current or mAs that included the effects of modulation [5].

The volume CT air kerma index (C_{VOL}) and the air kerma length product (P_{KL}) were estimated for each procedure on the basis of the normalized weighted air kerma indices in CT standard dosimetry phantoms ($_nC_W$), supplied by the ImPACT group .The scanning parameters for adults were collected for: head, chest, high-resolution chest, abdomen and pelvis examinations. For each procedure and each institution, in Table 1, 15 examinations, randomly selected, were evaluated and the following parameters were registered: tube voltage and current, gantry rotation time, collimation and slice thickness, pitch or increment, scan length and the scanner dose index indication.

Table 1. Main characteristics of the evaluated CT Scanners.

State	Institution	Manufacturer/ Model	Scanner/Type	Number of Chanels	Year of Installation

Obs: SSCT: Single-Slice CT Scanner; MSCT: Multislice CT Scanner

Methods for Estimate the CT dose indices

Values of Cvol and PKL were calculated for each axial or helical sequence on the basis of the representative n*C*W coefficients published by IMPACT or when available the n*C*W value obtained in the dosimetry. For scanners operated in auto dose reduction mode with automatic tube current modulation, doses were calculated using reported values of (average) tube current or mAs (product current time) that included the effects of modulation (Shrimpton, et al, 2005).

The volume CT air kerma index (C_{VOL}) and the air kerma length product (P_{KL}) were estimated for each procedure on the basis of the normalized weighted air kerma indices in CT standard dosimetry phantoms (${}_{n}C_{W}$), supplied by the ImPACT group The scanning parameters for adults were collected for: head, chest, high-resolution chest, abdomen and pelvis examinations. For each procedure and each institution 15 examinations, randomly selected, were evaluated and the following parameters were registered: tube voltage and current, gantry rotation time, collimation and slice thickness, pitch or increment, scan length and the scanner dose index indication.

Guidelines to optimize the protection during CT procedure include diagnostic reference levels (DRL) (Tsapaki,2006). The dose parameters suggested are the weighted CT kerma index (CW) and the kerma-length product (PKL).

Image Quality Evaluation

In this study, the ACR accreditation phantom, from Gammex, model 464, was used. The phantom allows evaluating the accuracy of positioning and alignment, accuracy of CT number, slice thickness, low and high resolution and uniformity of the CT number.

According with the instructions of the phantom manufacturer, the phantom images were acquired using the facility's typical head, high-resolution chest and abdomen exam protocols depending on the parameter evaluated.

Results

For each state, the number of participating hospitals varied. The scanners mode were approximately 46% multislices and 54% single slices.

Evaluation of Cvol and PKL mean values

The technical factors used by the participating hospitals revealed that in all procedures the tube voltage was 120 kVp but a very large variation of mAs was verified. The maximum values were higher than the values reported in the literature. Consequently, the inadequate choice of the exposure parameters resulted in unnecessary doses.

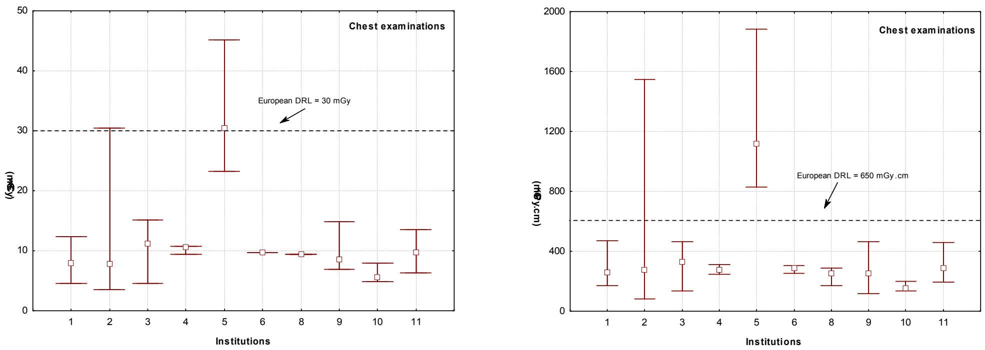

Fig. 1. Variation of the values of Cvol (a) and PKL (b) of the Chest examination in each institution.

The ranges of C_{vol} and P_{KL} are observed in the Figure 1 (a) and (b) respectively. Only the Institution 5 presented values higher than the DRL for chest. In the same institution is observed a large variation in the Cvol and DLP values, especially in the institution 2 and 5. In the sample, the average values were very similar, except in the institution 5.

The results of the values of Cvol and PKl for hi-hesolution can be shown in Figure 2.

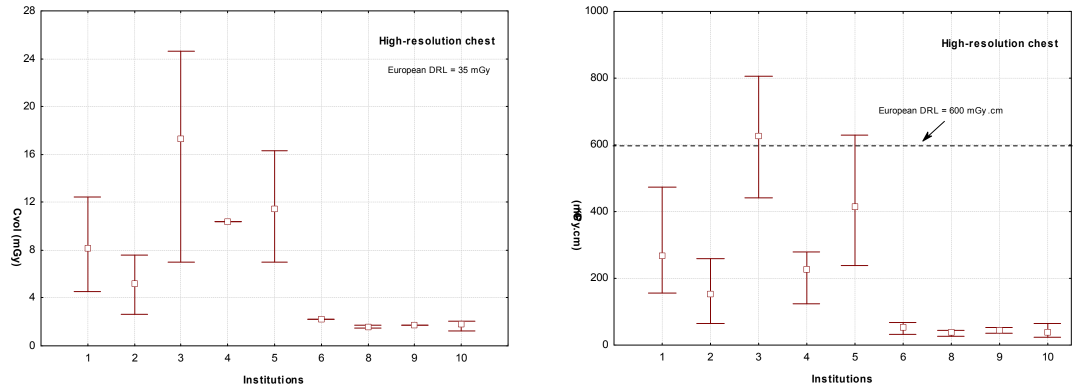

Fig. 2. Variation of the values of Cvol (a) and PKL (b) of the Hi-Resolution chest examination in each institution.

Figure 3 and 4 presents the results for abdomen and pelvis respectively. One institution from Curitiba doesn't carry out the pelvis procedure. All institutions from Recife don’t carry out both exams in their routine .

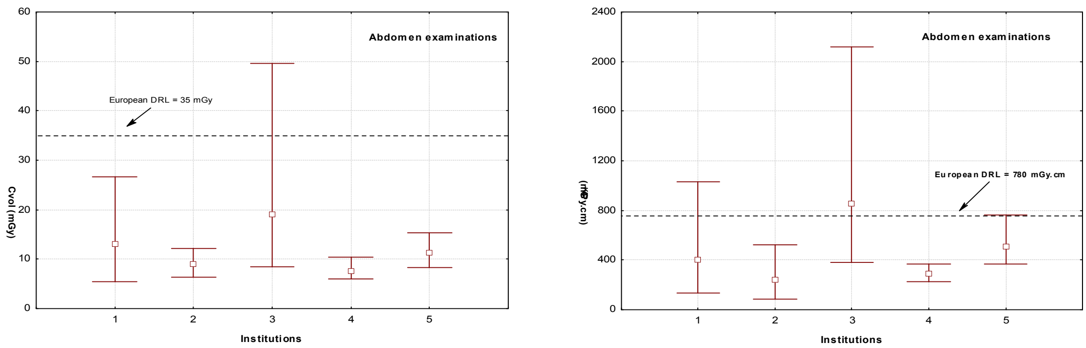

Fig. 3. Variation of the values of Cvol (a) and PKL (b) of the Abdomen examination in each institution.

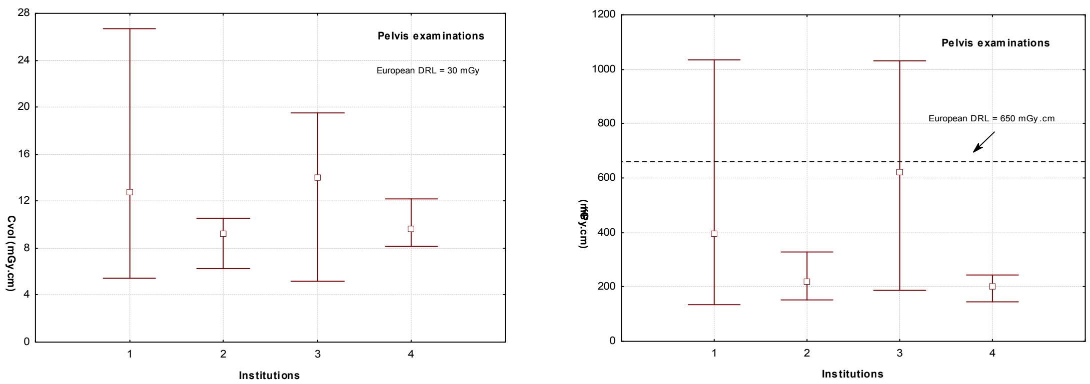

Fig. 4. Variation of the values of Cvol (a) and PKL (b) of the pelvis examination in each institution.

Evaluating the cvol and PKL values in abdomen and pelvis procedures we can observe that the scan lengths between these patients for each procedure presented consistency. The Institution 3 showed the biggest difference range in Cvol and PKL in the abdomen procedure. In the case of pelvis procedure, the biggest difference was in the Institution 1. It was also observed that most of the institutions presented values lower than the DRL for both procedures.

In head procedures (Figure 5), in four institutions the averages Cvol were higher than the DRL. The institution 2 showed a substantially wide range of doses in their centers.

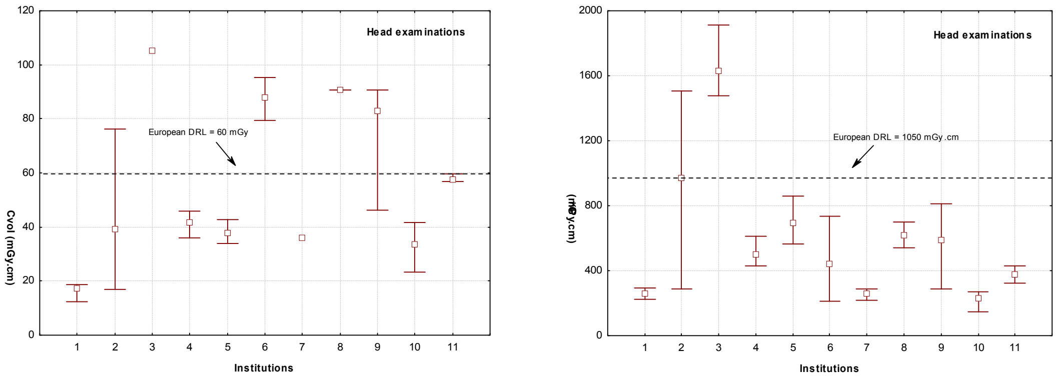

Fig. 5. Variation of the values of Cvol (a) and PKL (b) of head examination in each institution.

In the Figure 6 are presented the comparison of the dose between the different states for the five different procedures.

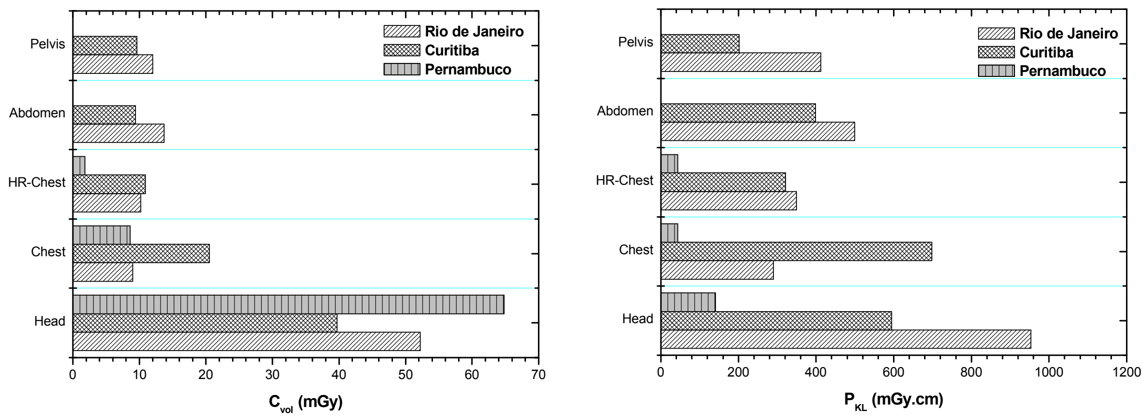

Fig 6. Variation of the values of Cvol (a) and PKL (b) for the five procedures in each state of Brazil.

Evaluation of Image quality

The Figure 7 indicates the percentage of conformity of the parameters with the international requirements. It is possible to observe that only the uniformity and slice tickness was completely adequate in all equipments and only on scanner comply with the requirements of CT number.

All institutions presented at least one no conformity. Many scanners failed in more than 50% of the parameters evaluated and in some cases did not comply up than 80% of the ACR requirements. The conformity of low contrast resolution was observed only in 67% of the institutions.

Only slice thickness accuracy and uniformity was adequate in 100% of the scanners but only one scanner comply with the requirement of accuracy of CT number. Also image noise was verified in 50% of the scanners and all of them were artifact like a ring.

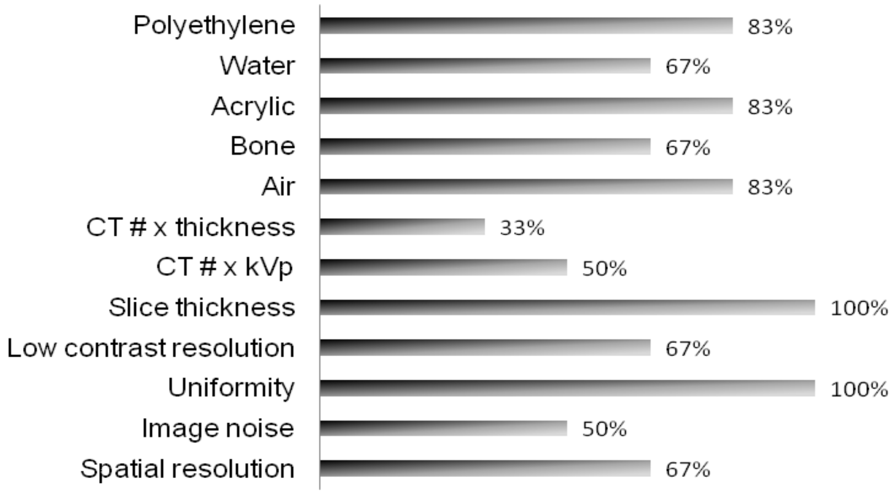

Fig 7. Frequency of acceptability of each criteria of image quality.

Discussion

The first information we have had during this work was the lack of appropriate training and especially of one program of continuum education. The professionals did not know all the equipments resources and the possibility to get better results in the procedures.The recommendation is to carry on the exams according exactly to the protocol, independently of the age, weight and size of the patient.

For the conduction of the tests many times was necessary to chance some parameters. This was a special problem for them because they didn't know how to conduct some procedure that was out of their routine practice.

The results of the Chest for Institution 5 of C_{vol} and PKL values were 1,5% and 72 % respectively higher than the DRL for chest. Considering the maximum C_{vol} and PKL, the values were respectively 45% and 189% higher than the DRL.

The wide range of conformity in low contrast observed in most of 60% of the all CT evaluated increase the risk of poor diagnostic, due the poor resolution doesn't allow visualization an indication of disease.

The spacial resolution test verified the ability of the scanner to detect small lesions that has attenuation values which differs greatly from those of surrounding tissue. The results showed that only 67% of the institutions are within the limits minimum acceptable. The physical size is also thought of in terms of detail to be discerned. It is expecting to resolve at least 5lp/cm for adult abdomen and 6 lp/cm for high-resolution chest.

In addition, the staff should know the equipment and the system with which they work to know how to identify the error messages and possible causes of failures. To ensure the production of images with a diagnostic quality, the equipment must be properly calibrated and subjected to a rigorous routine of quality control, including regular tests and verification of the professionals routine.

The conformity only in 50% of the CT's in noise level implies that the accuracy of detectability of small or low contrast lesions could be seriously affected .

Conclusions

In all Brazilian institutions the C_{vol} and P_{KL} values obtained in this survey was lower that the DRL European guidelines. However in all procedures, large ranges were observed in patient radiation doses in the different centers.

For these routine examinations the European Guidelines (Bongartz, 1999) recommends a pitch equal a 1. However in this study, the pitch ranged from 0,2 to 1,35 in all procedures.

It's necessary to inform Institution 5 about the dose values for chest procedures and maybe orientate for protocols review.

In Brazil, only few institutions carry out image quality evaluation. In general, there isn't a quality assurance implemented. Also, we don't have a CT accreditation program. institutions perform the exams without an adequate control of the performance of the scanners.

Also, we verified the lack of training of the professionals involved in the exam, especially in the centres where the new technologies were implemented.

Ackowledgments

The authors thanks the institutions participating for allow the study and also the CNPq for the financial support.

Abstract

Objective: Radiofrequency ablation (RFA) of tumors has gained significant interest and acceptance in the last decade due to its potential to produce a large volume of cancer cell death in a controlled fashion. It is successfully used under CT guidance to treat certain tumors of lung, liver, kidney, and bone. The objective of the study was to calculate the effective and skin doses in patients that underwent repeated CT guided radiofrequency ablations (RFA).

Materials and methods: The retrospective review included patients having more than 3 RFA ablations during the study period (June 2003-June 2009). The dose length product (DLP), effective dose (E), skin dose profiles, as well as the peak skin dose (PSD) for both the bottom and upper patient skin surface were calculated for each RFA using appropriate methods and software developed during the study. For each patient, the cumulative DLPc and Ec were also calculated from the sum of the respective figures of each individual procedure. To calculate the PSD, the skin dose profiles of each procedure were projected on the same scale using anatomical points for reference and then they were summed up.

Results: Five patients were analyzed. Four of these patients had totally 3 RFA and one had 11 RFA during the study period. DLPc, Ec and PSDc range values were 5569-9642 mGycm, 83-173 mSv and 774-3364 mGy, respectively. Median E and PSD for each RFA were 35 mSv and 400 mGy. For comparison purposes, a routine abdominal CT imparts approximately 8-10 mSv.

Conclusions: DLPc, Ec and PSDc vary greatly even for the same patient. However, the high radiation dose associated with repeated RFA shows the need to monitor in more detail these patients.

Introduction

Computed tomography (CT) is one of the imaging techniques currently used to perform Radiofrequency ablation (RFA). This interventional technique has gained significant interest and acceptance in the last decade due to its potential to produce a large volume of cancer cell death in a controlled fashion. It is successfully used under CT guidance to treat certain tumors of lung, liver, kidney, and bone. The main advantages of CT guided RFA compared to ultrasound or magnetic resonance are that it can be repeated many times if required, with much lower cost compared to MRI and that it provides a more detailed imaging than ultrasound. [Laspas F]. Patients can be treated more than once with CT guided RFA. It should be noted however, that the issue of radiation dose in CT has received a lot of attention during the last years. There is evidence that 1.5-2% of cancers may eventually be caused by the radiation dose used in CT [Brenner DJ]. Furthermore, the media occasionally contains exaggerated articles regarding CT radiation doses. These articles can be very easily misinterpreted by the general population who is not sufficiently knowledgeable to accurately assess such information, thus leading to unnecessary stress to the patients [McCollough CH]. Taking all these factors into consideration, we evaluated patient doses in patients who undergone more than 3 CT guided RFA procedures.

Material and methods

A wide range of CT guided interventions are performed in the CT department of Konstantopoulio general Hospital such as biopsies, RFA's, abscess drainages and nephrostomies. Patients who underwent more than 3 RFA procedures were included in the study. During the study period (June 2003-June 2009), 15 patients underwent more than 3 RFAs. Seven of the patients were treated 7 times, 6 patients were treated 4 times, 1 patient was treated 6 times and finally 1 patient was treated 11 times. The X-ray machine used was a single-slice helical CT scanner without CT fluoroscopy capability (Prospeed SX Power, General Electric Medical Systems, Milwaukee; WI, USA). All procedures were performed by an operator with more than 25 years of experience in various CT guided interventional techniques. To evaluate the lesion's immediate response to ablation and to identify any potential complications, dual-phase dynamic contrast-enhanced CT was performed. Follow-up was performed including dual-phase dynamic contrast-enhanced CT at 1, 3 and 6 months after RFA.

Using the DICOM data, the Dose Length Product (DLP), the effective dose (E), the patient skin dose profiles, as well as the peak skin dose (PSD) for both the bottom and upper patient skin surface were calculated for each RFA using appropriate software developed for this purpose. For each patient, cumulative DLPc, effective dose (Ec) and PSDc were also calculated from the sum of the respective figures of each individual procedure. More specifically, to calculate the cumulative PSDc, the skin dose profiles of each procedure were projected on the same scale using anatomical points for reference and then they were summed up.

Results

Mean age of patient sample was 71 ± 9 years. DLPc, Ec and PSDc range values were 5569-9642 mGycm, 83-173 mSv and 774-3364 mGy, respectively. Median E and PSD for each RFA were 35 mSv and 400 mGy. More analytically, Table 1 shows the radiation doses in terms of E and PSD for 4 patients having 3 RFAs. Table 2 shows the radiation doses in terms of E and PSD for a patient that had 11 RFAs. The age of each patient is also presented. The youngest patient (53 years) underwent the biggest number of RFA techniques (11 in total) having 2 lesions treated. The results varied greatly even for the same patient depending on the treatment site, the number of lesions, or lesion size. Total Ec and PSDc also varied immensely, depending not as much on the number of RFAs performed but mainly on the difficulty of each one. Indeed in our study, the larger dose values were observed for patient 1 who had 3 RFAs and not for the patient 5 who had 11 RFAs. Patient 1 had one anatomical location treated (PSDc reached approximately 3.4 Gy), whereas patient 5 had 2 anatomical locations treated (PSDc reached 0.95 Gy in the one anatomical site treated and 1.6 Gy in the other).

Table 1. Radiation doses in terms of effective dose (E) (in mSv) and Peak Skin Dose (in mGy) are shown for 4 patients having 3 radiofrequency ablations (RFA). The last row presents total E and PSD values.

Discussion

A major drawback of the study at this stage is that the estimation of radiation dose (PSD and E values of each RFA) requires the manual extraction and inputting of all DICOM data in the software developed for this purpose in our department. This results in a very time consuming estimation of PSD and E, making the process extremely difficult to do in routine. Initial results, however, indicate that radiation doses can be rather high. It was not possible to compare with other studies because no similar data existed until the completion of this paper. Despite the high E, it should be noted that these repeated procedures are usually carried out in patients where malignant tumours are already present and their medical condition is life threatening. On the other hand, it is not uncommon to have young patients undergoing multiple RFA procedures and one must take this into account when attempting to treat them. Just for comparison purposes, a routine abdominal CT imparts approximately 8-10 mSv to the patient, which is four times less than a typical CT guided RFA.

Conclusions

Initial results show that high radiation doses are associated with repeated RFA and there is definitely need to monitor in more detail these procedures. It is important to note that the particular techniques could not be prohibited on the grounds of radiation risk. The reasons are both prolongation of life expectancy and improvement of the quality of life. These factors certainly justify small radiation risks. However, the fact that high amount of radiation dose can be accumulated must be taken into account when attempting to treat young patients.

Abstract

The implementation of the European Directives introduced a number of new tasks to the radiology departments. It was stated that the determination of radiation doses are an important issue in the framework of radiation protection of the patient. And special attention is given to high-dose procedures, like interventional cardiology (IC) and radiology (IR).

Radiological departments are legally obliged to register dose-area-product (DAP) values for every patient undergoing IR and IC procedures. A large national multi-centre project on dose evaluations for IC and IR performed a few years ago, showed that centers with similar average DAP-values, could still result in significant different average effective dose values. Simply register DAP-values is therefore not always the only and most adequate tool for optimization at IC and IR. The additional calculation of effective dose could enable medical physicists to determine and evaluate dose values which will more connect to radiation risk evaluation, if necessary.

In the past conversion coefficients (CCs) from DAP to effective dose have been calculated systematically for different anatomical regions and projections for conventional radiological procedures. The use of these published CCs, however are not appropriate for the calculation of effective dose for IC and IR. The irradiated field sizes deviate from those in conventional radiology. Moreover, the requested CCs according to the beam qualities used for these complex procedures are not included in the published conversion tables. In the framework of patient dose optimization, however, there is a need to the availability of systematic tables with CCs who will allow the calculation of the effective dose for the complete offer of IC and IR procedures.

In this paper is described how the CCs are calculated for the most common and used radiation fields in IC and IR. The systematic tables with CCs can be obtained at the Federal Agency of Nuclear Control (www.fanc.fgov.be).

Introduction

The implementation of the European Directives (97/43/Euratom) into the Belgian legislation introduced a number of new tasks to the radiology departments. It was stated that the determination of radiation doses are an important issue in the framework of radiation protection of the patient. And special attention is given to high-dose procedures, like interventional cardiology (IC) and interventional radiology (IR).

The need of dose auditing and patient dosimetry is emphasized in relation to optimization of radiological procedures. Moreover, radiological departments are legally obliged to register dose-area-product (DAP) values for every patient undergoing IR and IC procedures. As these procedures were considered as a priority, the Belgian Federal Agency of Nuclear Control financed a very large national multi-centre project on dose evaluations for IC and IR procedures a few years ago (Bosmans 2006). From this project, however, we learned that only DAP registration for optimization purposes is not always adequate. Measurements in almost 20 hospitals showed that centers with similar average DAP-values, could still result in significant different average effective dose values. This was caused by a different use in copper filtration during the procedures. With complex interventional procedures the risk of deterministic skin damage to the patient exists. To prevent this, the use of additional filtration is recommended. At new modern equipment, the amount of filtration is automatically introduced by the system, depending on the procedure and the patient. More and more also the use of other types of filtration is investigated for these kinds of procedures.

Simply register DAP-values is therefore not always the only and most adequate tool for optimization at interventional procedures. The additional calculation of effective dose could enable medical physicists to determine and evaluate dose values which will more connect to radiation risk evaluation, if necessary.

The effective dose can be calculated by multiplication of the registered DAP-values and appropriate conversion coefficients (CCs). In the past such coefficients have been calculated systematically for different anatomical regions and radiation projections for conventional radiological procedures. The use of these published CCs, however are not appropriate for the calculation of effective dose for IC and IR procedures. The irradiated field sizes and regions deviate from those in conventional radiology. Moreover, the requested CCs according to the beam qualities used for these complex procedures are not included in the published conversion tables. In literature (Kemerinck et al. 1999), (Schultz et al. 2003), (Kemerinck et al. 2003), (Kicken et al. 1999) some CCs can be found for specific interventional procedures, calculated according to the need of the specific study. In the framework of patient dose optimization, however, there is a need to the availability of systematic tables with CCs who will allow the calculation of the effective dose for the complete offer of IC and IR procedures, if needed.

In this paper is described how the CCs are calculated for the most common and used radiation fields in interventional cardiology and interventional radiology. The systematic tables with conversion coefficients can be obtained from the authors or at the Federal Agency of Nuclear Control (www.fanc.fgov.be).

Material and methods

Choice of Monte Carlo code

The Monte Carlo code that is used in this project is *MCNP-X (v 2.5.0)* (Pelowitz et al. 2005). This code has been used frequently in medical physics and allows reliable dose calculations for photon radiation sources. The calculations are performed by 2 institutes: the department of medical Physics of the University of Ghent (UGent) performed the necessary calculations for the IC procedures and the Belgian Nuclear Research Centre (SCK•CEN) performed all calculations for the IR procedures. The same and most recent libraries, containing all cross sections and material data, are used by both institutes.

X-ray source definition

An important input parameter for the Monte-Carlo simulations is the X-ray source design. Different possibilities exist to model an X-ray source in the *MCNP-X* environment. A small intercomparison with a simplified geometry showed that the approach of both institutes resulted in the same values.

With respect to the definition of the X-ray spectrum, the "IPEM-78 – Catalogue of Diagnostic X-ray Spectra" (Cranley 1997) was used. This publication provides a valuable software tool for generating X-ray spectra based on parameters kVp, filtration, anode angle and kV signal ripple. In clinical practice a large variety of X-ray spectra are being used. For the interventional applications in this project, kVp-values typically range from 60 to 130 kVp. Filtrations can be based on a single aluminium filtration (2.5 – 6 mm Al) or on a combination with copper filtration (0.1 – 0.9 mm Cu). As it is practically impossible to simulate all possible kV/filtration combinations for all clinical projections, an alternative approach is used within the project.

We have decided to use X-ray spectra definitions based on half-value layers (HVL). In fact, different kVp/filtration combinations may result in the same HVL-values as illustrated in figure 1.

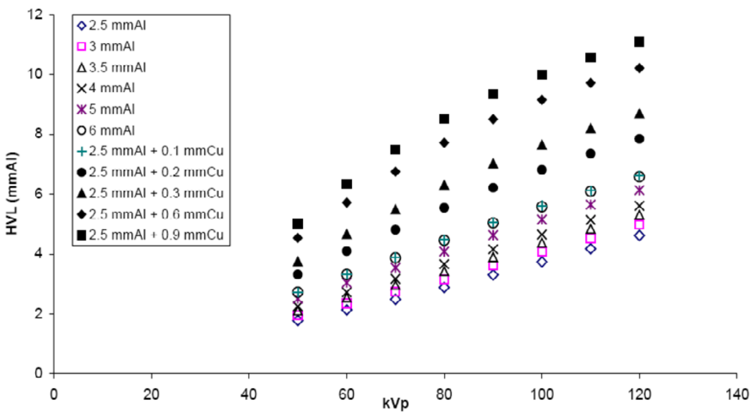

Fig. 1. **Half-value layer values for different kVp and filter combinations.**

Therefore, simulations based on a HVL-range that is clinically relevant would be interesting. In order to test the feasibility of this approach, Monte Carlo calculations were performed on a mathematical anthropomorphic phantom using different kVp/filtration settings – all resulting in the same HVL. The latter simulations showed that DAP-to-effective dose conversion coefficients simulated with the "HVL method" deviated maximum 5% of the values simulated with the exact spectrum.

For interventional radiology procedures, an anode angle of 14° was used, whereas for interventional cardiology procedures the spectra are generated based on an anode angle of 9°.

X-ray fields and projections

The X-ray field sizes and projections are other important factors to be taken into account for the simulations. In table 1 and 2, an overview of typical clinical settings is given for IR and IC, respectively.

Table 1. X-ray fields and projections considered for interventional radiology procedures.

Choice of anthropomorphic phantom

In view of the new recommendations of ICRP (ICRP 2008) and the definition of additional radiation sensitive organs (salivary glands, adipose tissue, connective tissue, extra thoracic airways, heart wall and lymphatic nodes) for the calculations of the effective dose, the choice of an anthropomorphic phantom was not straightforward. Current mathematical phantoms are not appropriate for calculating the revised definition of the effective dose as they do not contain these 'new' organs. The choice of a voxel-phantom, for which a larger amount of organs are segmented, seemed more appropriate. At the start of the project, the standard ICRP voxel phantoms were not available. Other appropriate and available phantoms with standard dimensions are the MAX06 and FAX06 phantoms (Kramer et al 2006). These are very detailed phantoms constructed from voxels of 1.2 x 1.2 x 1.2 mm³. The total MAX06 phantom consists of 474 x 222 x 1359 = 143.004.582 voxel elements. All necessary organs are present and realistically segmented. However, when this phantom is converted into a format suitable for *MCNP-X*, input files are created from 20 to 30 MB. Such large input files require a lot of computer memory and some test calculations demonstrated that this memory capacity is not available in both UGent and SCK•CEN. Hence, the calculations could not be performed with these phantoms.

A large family of voxel phantoms is available at the Helmholtz Zentrum München – German Research Center for Environmental Health and we decided to test the Golem (Zankl, Wittman 2001) and Laura phantoms. These phantoms have body characteristics similar to the reference persons. Golem is constructed from voxels of 2.08 x 2.08 x 8.0 mm³. His height is 176 cm and weight 68.9 kg. Laura is constructed from 1.875 x 1.875 x 5.0 mm³ voxels. Her height is 167 cm and weight 59 kg. A cross section of both phantoms is given in figure 2. Both phantoms have a realistic number of voxels that can be handled by *MCNP-X*. Test runs showed that CPU time of maximum 130 minutes are needed for the transport of 10E06 particles (for F6 and *F8 tallies) on the computer clusters of UGent and SCK•CEN, resulting in relative errors for the organs in the radiation field lower than 1%.

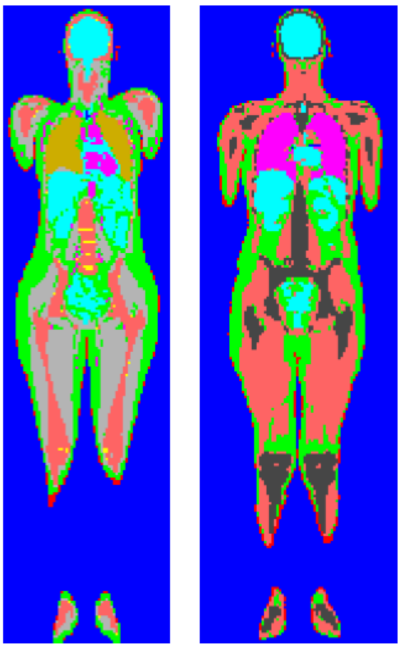

Fig. 2. Cross sections of the LAURA (left) and GOLEM (right) voxel phantoms.

As red bone marrow and bone surface are not segmented within the Golem/Laura phantoms, correction factors to the mean skeleton dose were calculated based on the material composition and density of red bone marrow, yellow bone marrow and cortical bone structures throughout the human body (Zankl et al. 2007). For the gall bladder and small intestine no distinction is made between wall and contents in the Golem phantom. Golem does not have breast (glandular tissue) and salivary glands and both phantoms do not have oral mucosa nor lymphatic nodes. The dose to the oral mucosa was approximated by the dose to the tongue and the dose to the lymphatic nodes was approximated by that to other distributed tissue, like muscle or adipose tissue.

Results

For interventional radiology, the following spectra are considered:

- Head: from 80 to 100 kVp in steps of 10 kVp
  from 3 mm Al to 6 mm Al in steps of 1 mm
  from 0 to 0.3 mm Cu in steps of 0.1 mm

This resulted in a HVL range from 3.5 – 8.5 mm Al

- Neck: from 60 to 100 kVp in steps of 10 kVp
  from 3 mm Al to 6 mm Al in steps of 1 mm
  from 0 to 0.3 mm Cu in steps of 0.1 mm

This resulted in a HVL range from 2.5 – 8.5 mm Al

- Thorax, abdomen and pelvis: Idem as Neck
- Legs: from 60 to 80 kVp in steps of 10 kVp
  from 3 mm Al to 6 mm Al in steps of 1 mm
  from 0 to 0.3 mm Cu in steps of 0.1 mm

This resulted in a HVL range from 2.5 – 6.5 mm Al

Spectra are considered in steps of 1 mm Al HVL for both the Golem and the Laura phantoms and each projection as given in table 1. This resulted in a total number of 262 calculations.

For interventional cardiology, the following spectra are considered:

- Thorax: from 60 to 130 kVp in steps of 10 kVp
  from 0 to 0.9 mm Cu for 2.5 mmAl
  from 0 to 0.3 mm Cu for 3 and 4 mm Al
  in steps of 0.1 mm Cu en 1 mm Al

This resulted in a HVL range from 2.5 to 11.5 mm Al.

For both phantoms and all projections considered in table 2, this resulted in a total number of 240 calculations.

Before the systematical calculation campaign started, a final intercomparison was performed between UGent and SCK•CEN. This should reveal possible differences in processing the voxel-based data. The simulations for this intercomparison was based on the same input file (PA thorax irradiation of the Golem phantom, field size 520 cm^3, 70 kVp, 4 mm Al and 10E06 particles). The results are presented in table 3.

The results show an excellent agreement between the SCK•CEN and UGent simulations with respect to the effective dose/DAP. Individual organ doses show small deviations smaller than 1%. The latter simulation run had a CPU time of 55 min for the SCK•CEN simulations and of 79 min for the UGent simulations.

The results of the systematic calculation campaign are given in organ dose/DAP for both phantoms separately and effective dose/DAP for both phantoms together using the new ICRP103 organ weighting factors. The conversion coefficients between DAP and effective dose are given in table 4a and b for interventional radiology and interventional cardiology, respectively. All tables, including the DAP-organ dose conversion coefficients can be obtained from the authors and from the Federal Agency of Nuclear Control (www.fanc.fgov.be).

Discussion

The ICRP standard voxel phantoms REX and REGINA were not available at the time of the study, so instead the phantoms GOLEM and LAURA are used. The dimensions of these phantoms are really close to the standard phantoms, but still some radiosensitive organs were missing, to be able to calculate effective dose according to the new ICRP103 organ weighting factors. One of the organs missing in the GOLEM phantom is the breast. In this study, the 'average' breast dosis for both phantoms for the effective dose calculation only comes from the breast of LAURA. We could consider a breast dosis of zero for GOLEM to calculate the average breast dose, but the authors believe that a larger error is made compared to only consider the breast dose from LAURA.

In general, we do not expect drastic changes for the conversion coefficients when these calculations would be repeated with the standard REX and REGINA phantoms.

Conclusions

The possibility to calculate organ doses and effective dose from online DAP measurements for interventional radiology and cardiology procedures can be a useful tool and completion for dose optimization purposes. In this project complete and systematic tables with organ dose and effective dose conversion coefficients are calculated from DAP values for these kinds of procedures.

Artifacts found in computed radiographic system

Jakubiak, Rosangela Requi; Krzyuy, Ariadne Maria; Gamba, Humberto Remigio
Federal University of Technology – Paraná, UTFPR, Curitiba, BRAZIL

Abstract

Computed Radiography Systems (CR) are replacing the standard analog systems. In CR, However, as in other diagnostic imaging, artifacts can lower the image quality, simulate pathological lesions and mask the correct diagnosis. Artifacts similar to those found in analog systems, such as artifacts generated by the patient or operator´s mistakes, are very common. Further, there are artifacts related with the system itself: Image Plate (IP), the reader, to soft copy display or the printers. Some CR artifacts have still unknown reasons. *I*n this paper we present some artifacts found in CR systems and solutions to remove them are proposed.

Introduction

Quality Control Programs (QCP) are required for Computed Radiography systems (CR), which are replacing the conventional analog systems. CR systems are based on a new technology for storing the image in phosphorus photostimulable (Solomon et al 1991).The QCP has to evaluate the consistency of the equipment, and ensure the production of diagnostic images with excellent quality.

In this sense, the elimination of possible artifacts in the image is a task that requires the identification of all processes involved in producing the image, since the acquisition until the displaying on a monitor or on a medical radiographic film (Cesar, 2001, Willis et al 2004). The artifacts in the CR images can have their sources in the machine hardware (e.g., the X-ray equipment, grid, image plate, reader, detector), in the software (e.g., algorithms), or even coming from the patient (e.g., positioning, motion) (Seibert et al 2006). If there is a failure at any step of the image production, the final image will be compromised, requiring exam repetition, increasing the radiation dose in the patient (Lth, 2000). Hence, it is necessary to minimize the artifacts.

The main objective of this study is to assess the possible causes of some artifacts, and, when it is possible, propose solutions to remove them. It is important to mention that not all artifacts detected in the CR system have any known cause

Material and methods

Weekly the cassettes integrity are checked and their surface are cleaned with clorhexidine 0.2%. Monthly external cleaning is carried out using ethyl alcohol 99%.

The internal cleaning is only performed when the image plate (IP) is dirt, and this cleaning is done carefully according to manufacturer recommendation. The artifacts caused by dirty points in the IP are similar to those found in analog systems. The cassette identification number in the hard-copy makes the IP localization easier, and thus the cleaning task is quickly performed.

Artifacts related to X-ray examination start to appear soon after the new CR system started to be used. Thus, the physicians were instructed to save the images for future evaluation by the quality control team. Weekly, the physicians report the situation in which the artifacts appeared (patient standard, cassette used, the error message of equipment, etc.) and identify the possible causes of them, seeking for a solution

Results

Since the installation of the computed radiography system in our institution, September of 2006 medical images artifacts were found. The artifacts sources are extensive and may be related to the image plate, the reader, the display, the printer or the operator of the system (Willis et al 2004)..

Figure 1 is an example of a ghost image. Ghost images are the registered image that remains in the IP, even after the image is read and the IP is erased by the reader system. It is related to the erasure cycle efficiency of the reader (Seibert et al 2006). This type of artifact can occur when an improper processing menu is selected, resulting in incorrect histogram normalization and dynamic range scaling. Other causes of ghost images are miss-positioning the object, collimation errors that can occur in high scatter situations, and unusual anatomic variations that confuses the algorithms that identify the useful image information on the detector (Cesar, 2001). The solution could be the use of a smaller IP and to collimate the beam to the specific region of interest of the body.

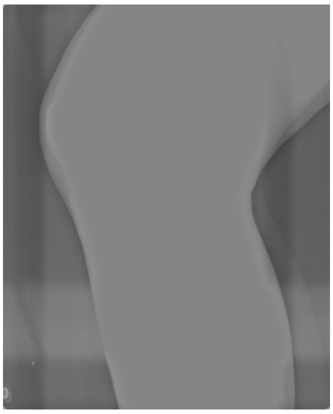

Fig. 1. Ghost image.

However, after working about 4 years with CR systems from the same manufacturer, in two different institutions, we have seen that there is more to learn about this problem. For example, in institution A we detected problems with a worker that did not correctly collimated the beam, and we have never had this kind of artifact.

Nevertheless, in institution B, we had this artifact everyday, with a worker that used the smallest IP practicable and collimates the beam, with adequate dynamic scale (without overexposure).

It is important to mention to the manufacturer that they need to analyze their equipment, not only trying to prove that the failure is in the workers that make the examinations. Of course, the employees should always be directed to comply with all requirements, minimizing the chances of artifacts.

In Figures 2 and 3 shown the appearance of two overlapping exams. This can occur if the latent image on the IP was not complete erased, either by a failure of the reader, or by the incorrect selection of the erasure mode by the technologist. This situation is also called double exposure, when two exposures occur without reading and erasing the first one (Willis et al). Other cause for this artifact is the selection of the incorrect algorithm to read the IP.

Fig. 2. Overlapping examination of foot and shoulder.

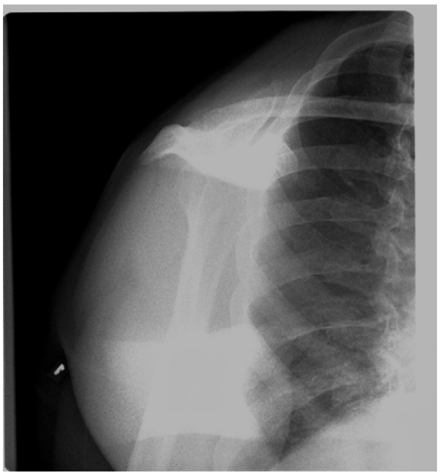

Fig. 3. Overlapping examination.

The system has the algorithms pre-determinate to read the IP, which means that the digital image for CR system is pre-processed. For each anatomical examination there is a specific algorithm which is prepared to read the signal from that anatomical region. If the physician that made a chest exam, but selected the algorithm for pelvis, for example, the images could be like those in figures 2 and 3. Sometimes this kind of problems is correlated with Figure 1.

Other artifact are small black dots, Figure 4. Image points are formed in IP, which causes dark spots on the image acquired later. Images were sent to the system's manufacturer and they informed that these artifacts occurs in tropical countries, where the air has a much higher relative humidity.

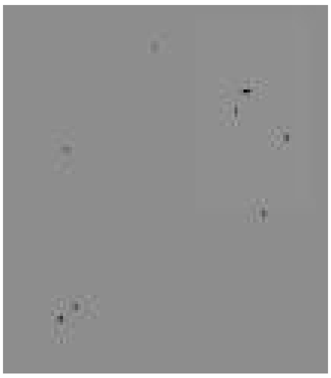

Fig. 4. Artifact due to high air humidity.

It also occured the appearance of objects from previous examination, as in Figures 5 and 6. In Figure 5, can be seen the lead marker (red arrow) used to identify the right side of the patient on an exam of the knee. On an exam of the chest, performed after the examination of the knee, the marker appears on the portion of trachea, and it's also possible to observe subtly the anatomical borders of the first examination (blue arrow). Figure 6 shows a lateral chest examination, where can be visualized the needle used in the urography examination done before.

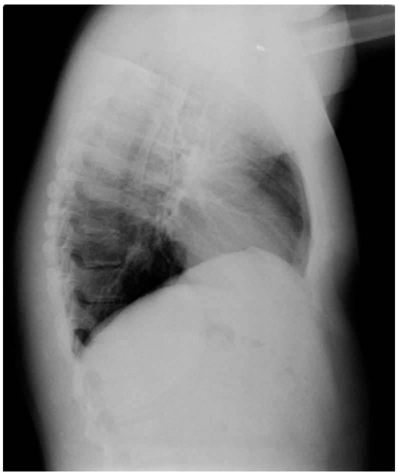

Fig. 5. Residual signal on the image from the lead marker.

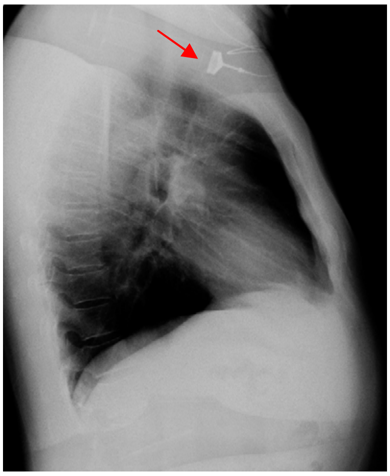

Fig. 6. Residual signal on the image from the urography examination.

It was also detected the presence of white lines in some images of X-ray examinations in both the horizontal direction, as shown by the red arrow in Figure 7, as in the vertical direction, evidenced by the red arrow in Figure 8. Artifacts in this pattern may be caused by dirt on the deflectors mirrors of the reader and should therefore be required the cleaning of the reader.

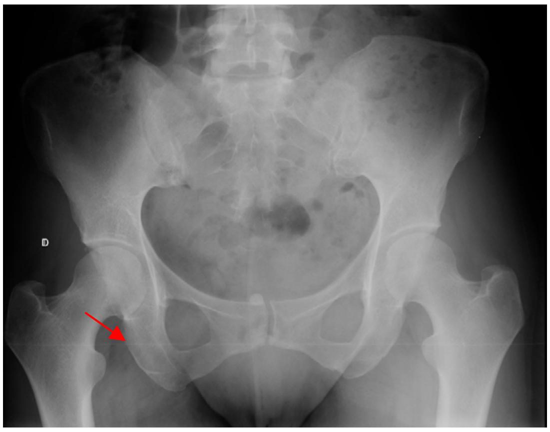

Fig. 7. Image with horizontal pattern of line.

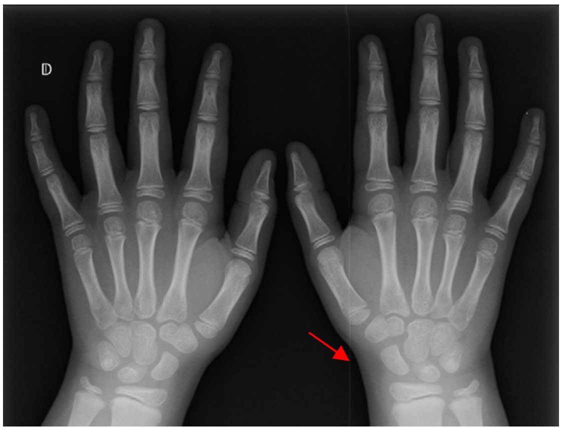

Fig. 8. Image with vertical pattern of line.

Another situation observed during the clinical routine was the appearance of artifacts due to the presence of backscatter radiation. The non-exposed cassette was stored in one side of the cabinet which is located next to the bucky of the X-ray equipment. We verified that when examinations were performed in the bucky and when the stored cassettes in the cabinet are exposed, the examination appear with artifacts, as shown in Figures 9 and 10. The corrective measures in this case was the exchange of the local storage of cassettes and perform the test of influence of other sources of radiation, noting that the local was suitable for the storage, not having been occur this artifact later.

Fig. 9. Image with artifact due the backscatter radiation.

Fig. 10. Image with artifact due the backscatter radiation.

Discussion

Images with artifacts that occur due to operators errors of the CR system, such as inadequate positioning, improper collimation, under or overexposure were shown. To avoid these artifacts an appropriate training period to the worker helps to avoid faults that are not committed during the examinations.

In addition, the staff should know the equipment and the system with which they work to know how to identify the error messages and possible causes of failures. To ensure the production of images with a diagnostic quality, the equipment must be properly calibrated and subjected to a rigorous routine of quality control, including regular tests and verification of the professionals routine.

Conclusions

As the production process of the image in computed radiography system differs from the analog system, this new technology also creates the appearance of new artifacts, without eliminating, however, the appearance of artifacts already known.

In addition, a number of factors affect the image quality in computed radiography, because this modality has distinct processes for the production of the image: data acquisition, processing, IP erasing, viewing and printing and/or storage the image. No device or professional is immune to produce unacceptable images. Therefore, the technologists need appropriate training to use effectively the new technologies and produce images with diagnostic quality. It's the responsibility of the quality control team reporting and taking the corrective measure when artifacts appeared in medical images in order to try minimizing or eliminating the causes of them.

And the manufacturer needs to analyse their equipments failures more seriously, not only trying to prove that the failure is the professional who makes the examinations. To realize the routine test of reports is very important, meanwhile, a bad operation of the reader may interfere in the total process.

Abstract

Patient dosimetry measurement methods were investigated in dental radiology comparing irradiations in a panoramic x-ray unit and a new digital volume tomograph DVT. Results of thermoluminescence dosimetry methods were validated by ionisation chamber dosimetry. Free-air and various in-phantom measurements were carried out in the rotating x-ray fields using maximum adult patient examination settings. Determination of absorbed dose was made in a cylindrical PMMA phantom and in an anthropomorphic Alderson-Rando head phantom. Reference radiation fields at the Dosimetry Laboratory Seibersdorf were used for calibration and determination of x-ray energy correction factors for both detector types. Resulting free-air and in-phantom dose values were up to several mGy whereas effective dose estimates were about 8 µSv and 81 µSv for panoramic radiography and DVT imaging, respectively.

Introduction

Radiation protection of patients during medical exposure is regulated throughout Europe (Council Directive 97/43/Euratom, 1997). The corresponding Austrian regulation necessitates the determination of individual patient dose values or of relevant parameter settings by the holder of authorisation. National diagnostic reference levels were established for a number of clinical x-ray imaging techniques except for dental radiographic applications. Panoramic machines are routinely used in dental radiology applications using a thin vertical beam and synchronously rotating radiographic source and film cassette. New DVT (digital volume tomography) scanners are based on CBCT (cone beam computed tomography) technology for 3D x-ray imaging. The number of DVT systems dedicated to maxillofacial imaging has increased for several years providing different source and detection technologies (Ludlow, 2008). Conventional CT (computed tomography) imaging is also used for various examination modalities in dental practice but was not considered in the current patient dosimetry investigations.

In this study free in air and various in-phantom dose comparisons were carried out in the rotating x-ray fields of a panoramic unit and a DVT using adult patient examination settings, see Figures 1 to 3. Thermoluminescence detectors (TLDs) distributed inside an anthropomorphic phantom was used for determining equivalent dose to organs and effective dose. The best way of calibrating TLDs is within the x-ray radiation field which is to be investigated using a reference detector such as an ionisation chamber. The drawback of this method is the time and effort and the problem of inhomogeneous spatial field distributions as would be expected for rotating x-ray scanners. One of the goals of this study was the introduction of appropriate energy correction factors for calibrating TLDs in reference ^{137}Cs gamma radiation fields.

Fig. 1. Alderson-Rando phantom positioned inside the panoramic unit (left) and slice 7 with four TLD positions 29 to 32 (right).

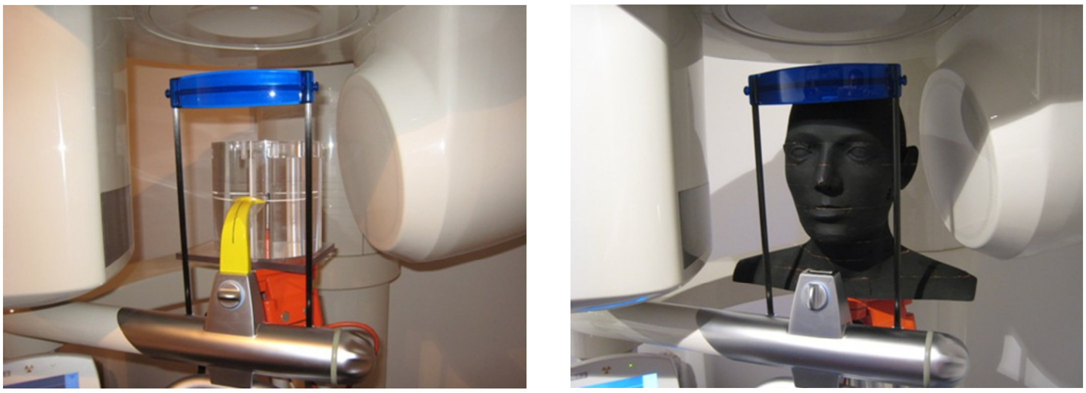

Fig. 2. Phantoms positioned inside the DVT, cylindrical PMMA phantom (left) and Alderson-Rando head phantom (right).

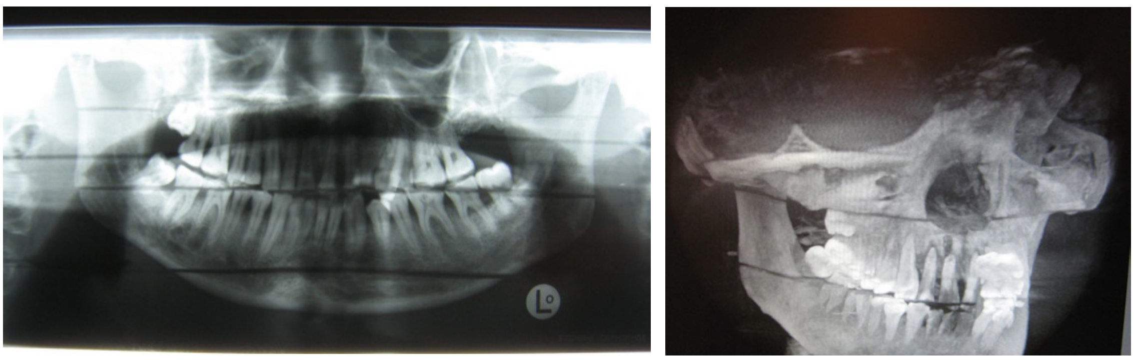

Fig. 3. X-ray images of the Alderson-Rando phantom by the panoramic (left) and DVT unit (right). The air gap between the slices of the phantom can be clearly seen in both images.

Materials and methods

Two x-ray facilities with rotating tube and detector geometries were investigated: a conventional panoramic x-ray unit (Sirona ORTHOPHOS Plus DS) and a new digital volume tomograph (Sirona GALILEOS). The DVT provides a 204° rotating pulsed beam with 200 x-ray images detected by an image intensifier of 21.5 cm diameter within about 14 seconds. A tungsten anode and a total equivalent filtration of at least 2.5 mm Al equivalent were stated by the manufacturer for both units. The "maximum adult" patient settings were used at the DVT, i.e. a tube voltage of 85 kV and a current-time product of 35 mAs. For panoramic radiographs also known as orthopantomograms the maximum tube voltage of 90 kV was chosen with a resulting 130 mAs current-time product.

Two different phantoms were used: a cylindrical PMMA phantom and an anthropomorphic tissue-equivalent Alderson-Rando phantom. The PMMA phantom is a standard CTDI head phantom with a diameter of 16 cm, with a central hole and with four periphery holes 1 cm below the surface. The Alderson-Rando phantom consists of 2.5 cm thick slices but only the first eleven slices of the head and neck region were used. A total of 55 selected locations for TLDs were available at slice 2 to 11. The phantoms were mounted on a stand inside the scanners using bite blocks to achieve preferably reproducible positioning similar to a real patient, see Figures 1 and 2.

Two different detector types were used: a 0.125 cm^3 thimble ionisation chamber (PTW 31010 with UNIDOS electrometer) and passive 3.2 x 3.2 x 0.89 mm LiF:Mg,Cu,P (Thermo Fisher Scientific TLD-700H) thermoluminescence detector chips. Dose results are based on calibration factors and correction factors determined at the Dosimetry Laboratory Seibersdorf traceable to the national standards of the BEV (Austrian Federal Office of Metrology and Surveying). Ionisation chamber readings were corrected for influences of the air density using a mobile temperature and pressure detection device (Thommen HM-30). TLD glow-curves were read out on a 3500 Harshaw manual reader with planchet heating system and WinREMS readout software using an optimized time-temperature-profile (Hranitzky et al. 2008), see Figure 4.

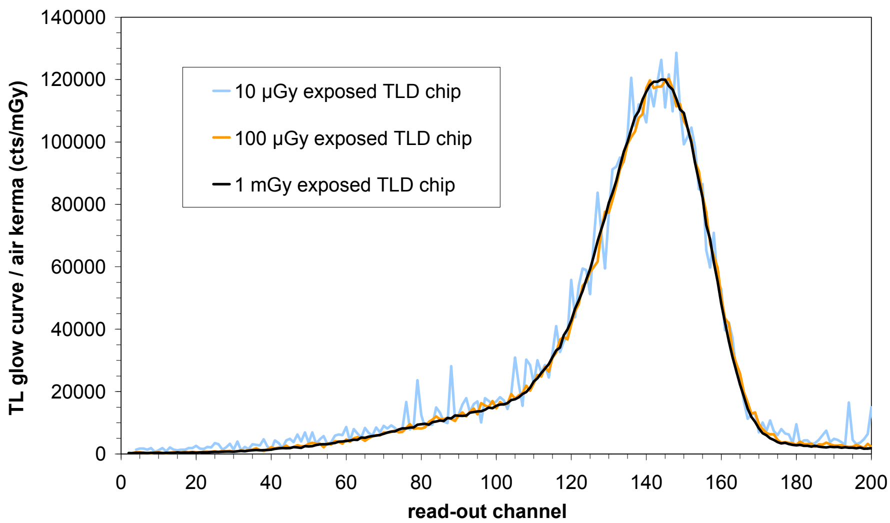

Fig. 4. Examples of TL glow curves at air kerma levels between 10 µGy and 1 mGy normalized to the corresponding air kerma. Read-out channels are distributed within a read-out time of 26.7 s.

TLD dose calculation, air kerma free in air and absorbed dose to water, is based on summing up the whole glow curve signal resulting in a single *TL* value. The dosimetry model for determining dose D_i of a single chip number "i" is based on a simple linear equation:

$$D_i = N \cdot k_Q \cdot (k_i \cdot TL_i - TL_{bg}) \qquad (1)$$

Individual sensitivity correction factors k_i and an average background signal TL_{bg} were considered. The group of calibration TLDs were irradiated at reference conditions in a ^{137}Cs calibration facility at 1 mGy air kerma free in air. X-ray energy correction factors also called radiation quality correction factors k_Q were determined by a diagnostic reference x-ray radiation quality RQR-7 (IEC 61267 Ed2, 2005) with a tube voltage of 90 kV and a first half-value layer of 3.25 mm Al.

Results

TL dosimetry

The relative standard deviation of the mean of TLD dose values were between 1% and 2% using at least 5 TLD chips closely put together in the free-air holder or in the PMMA phantom. TLD calibration was carried out for each measurement using a group of about 10 TLD chips resulting in calibration factors *N* of about 2.1 x 10^{-7} mGy/cts (±3%). The uncertainty estimate is dominated by the influence of the reader stability over several hours of readout time. The radiation quality correction factors k_Q were determined by the response values at 90 kV reference x-ray radiation. Resulting TLD correction factors averaged over five measurements are 1.11 ± 3% and 1.22 ± 3% for air kerma and absorbed dose determination, respectively. The "high" values of the correction factors are due to the energy dependence of the TLDs using a calibration at ^{137}Cs photon energy of about 662 keV. Details on k_Q determination can be found elsewhere (Halda, 2008). For each measurement a group of at least 10 unirradiated TLDs was read-out resulting in an average background TL signal TL_{bg} of about 2 µGy. All measurements starting from TLD annealing to TLD read-out were carried out within a single day. Generally the influence of background subtraction on calculated dose values was negligible. An uncertainty contribution due to linearity and coefficient of variation for low dose values could be neglected in this study.

Ionisation chamber dosimetry

The ionisation chamber calibration was performed in a certified ^{60}Co gamma radiation beam of therapeutic dose rate level at 5 cm depth within a water phantom. Therefore the indication of ionisation chamber is in terms of absorbed dose to water taking into account an air density correction with respect to reference conditions. For measurements free in air a conversion coefficient of 0.92 ± 1% form absorbed dose to air kerma was determined for the ionisation chamber in the ^{60}Co calibration field. A radiation quality correction factor of 0.96 ± 1.5% was determined for 90 kV reference x-ray radiation free in air averaged over seven measurements. The value is consistent with the energy dependence of the ionisation chamber published by the manufacturer for both quantities, air kerma and absorbed dose. Therefore the value of 0.96 was used as radiation quality correction factor for all measurements of the panoramic unit and the DVT. For absorbed dose measurements in the PMMA phantom an additional correction factor for the displacement of the effective point of measurement of the air filled ionisation chamber was taken into account. Based on the dose gradient of the 90 kV x-ray radiation field at the measurement position inside the phantom an effective point of measurement correction factor of 0,98 ± 2% was estimated. The maximum value of the air density correction factor for environmental influences during ionisation chamber measurements was 1,06 ± 0.5% due to a temperature of 24°C and an air pressure of 968 hPa. The uncertainty estimate was based on repeated comparisons of the indicated temperature and pressure to the stationary calibrated reference instruments of the laboratory over a period of one month.

Dosimetry results free in air and in PMMA phantom

The total measurement uncertainty was about 3% and 4% for ionisation chamber and TLD dose results, respectively. 5 detectors chips were closely put together at the same measurement position. All measurements were performed twice within two months for both radiographic units, see table 1. Only one air kerma free in air value is given for the panoramic unit because the first of two measurements was carried out for testing purposes.

Table 1. Comparison of air kerma free in air and absorbed dose in the centre of the cylindrical PMMA phantom, for the panoramic unit (left) and the DVT (right).

PANORAMIC	TLD	ionisation chamber	(TLD-IC)/IC
K_a (mGy) free in air	3.94 (±4%)	3.21 (±3%)	23%
D_w (mGy) in PMMA phantom centre position	1.06 (±4%)	0.98 (±3%)	9%
	0.92 (±4%)	0.94 (±3%)	-2%

DVT	TLD	ionisation chamber	(TLD-IC)/IC
K_a (mGy) free in air	3.73 (±4%)	4.01 (±3%)	-7%
	3.68 (±4%)	3.97 (±3%)	-7%
D_w (mGy) in PMMA phantom centre position	3.18 (±4%)	3.02 (±3%)	6%
	3.12 (±4%)	3.09 (±3%)	1%

Differences between the TLD results and the ionisation chamber results are within several percent. Especially for the air kerma results in the panoramic unit bigger deviations can be seen mainly due to the difficulties in positioning detectors consecutively at the same measurement point. Due to the broad beam geometry in DVT resulting differences were smaller as compared to the thin beam x-ray field of the panoramic unit. As can be seen, air kerma values were quite similar in both radiographic units. For the panoramic unit, the air kerma value depends strongly on the actual measurement position. There is no static rotation axis of the panoramic x-ray unit but its path is curved to follow the shape of the jaw. The central area is exposed up to three times by the fan-shaped radiation beam (Kaeppler, 2007). Using a stack of TLDs a full width at half maximum FWHM of 3.5 mm of the panoramic x-ray beam was determined free in air, which is smaller than the diameter of the ionisation chamber detection volume. Within the phantom a broader beam can be expected due to scattering effects.

Table 2. Comparison of the absorbed dose in the cylindrical PMMA phantom at three different positions: at the centre, at the rear (neck), and at a side position.

DVT	TLD	ionisation chamber	(TLD-IC)/IC
***D* w (mGy)** in PMMA phantom centre position	3.18 (±4%)	3.02 (±3%)	6%
***D* w (mGy)** in PMMA phantom rear position	5.49 (±4%)	5.58 (±3%)	-2%
***D* w (mGy)** in PMMA phantom side position	3.63 (±4%)	3.84 (±3%)	-5%

Only for the DVT x-ray radiation field, measurements at the different positions within the cylindrical PMMA phantoms were carried out. The maximum dose of about 5.5 mGy was found at the neck position. Differences between the available positions can be explained by the path of the x-ray tube which rotates about from one side to the other at the rear of the head with the detector at the opposite side close to the teeth and jaws of the patient. Differences between TLD and ionisation chamber results are again within several percent and therefore consistent within measurement uncertainties.

Two TLDs were positioned inside a hole at selected sites inside the Alderson-Rando head phantom but not all of the 55 positions were loaded with TLDs. In table 3, average absorbed dose values of two TLDs are presented. For both x-ray fields, panoramic and DVT, the maximum dose is located within slice 7, which includes the teeth (see Figure 1). The maximum absorbed dose values are 0.73 mGy and 5.2 mGy for the panoramic and the DVT x-ray field, respectively. It has to be noted that a conversion from absorbed dose to water to absorbed dose to tissue was omitted in this study. Values in brackets of table 3 are relative standard deviations of the two TLD dose values representing a measure of repeatability. The average relative standard deviation of two TLDs is about 3.5% for both units and for all dose levels. Generally absorbed dose values of the DVT irradiation is a factor of about 10 higher compared to the panoramic irradiation at corresponding locations within the Alderson-Rando head phantom.

Equivalent dose to organs and effective dose

The quantity effective dose can be used for estimating nominal risk of stochastic effects associated with radiological procedures. Effective dose is reported to be of value for comparing doses from different diagnostic procedures and for comparing the use of similar technologies (ICRP, 2007). Effective dose E can not be measured directly but is calculated as the sum of equivalent dose values of a number of organs and tissues H_T multiplied by the corresponding tissue weighting factors w_T (ICRP, 2007). Due to a radiation weighting factor of 1 for photon radiation fields, values of equivalent dose in tissue are equal to the average absorbed dose to tissue values. Absorbed dose to tissue D_T was calculated by the mean value of TLD measured absorbed dose D and weighted according to the ratio of the organ mass in the head to the total organ mass in the body, see table 4. A discussion of the mass weighting factors for large organs, especially skin, muscle, and red bone marrow, can be found elsewhere (Looe et al., 2008). Average absorbed dose values were calculated for four radio-sensitive organs, i.e. brain, salivary glands, red bone marrow, and thyroid. Other radio-sensitive organs and tissues in the head and neck region according to (ICRP, 2007) were neglected because of missing TLD positions.

Table 4. Comparison of measured average absorbed dose values D, organ and tissue dose weighted by the organ mass ratio H_T, and effective dose results $E = \Sigma H_T w_T$ for the panoramic (left) and DVT (right) exposure.

PANORAMIC	D (mSv)	H_T (mSv)	$H_T w_T$ (µSv)
brain	0.07	0.07	0.7
salivary glands	0.39	0.39	3.9
red bone marrow	0.08	0.01	1.7
tyhroid	0.03	0.03	1.4
		effective dose (µSv)	**8**

DVT	D (mSv)	H_T (mSv)	$H_T w_T$ (µSv)
brain	0.79	0.79	8
salivary glands	4.03	4.03	40
red bone marrow	0.90	0.15	18
tyhroid	0.37	0.37	15
		effective dose (µSv)	**81**

Conclusions

Resulting free in air and in-phantom dose values were up to several mGy whereas effective dose estimates were about 8 µSv and 81 µSv for panoramic and DVT imaging, respectively. Although dose values of both x-ray units were directly faced in this study it has to be stressed that the results of the two units and parameter settings are not comparable. Maximum adjustable x-ray tube voltage and tube current-exposure time product values were chosen for both units. The higher absorbed dose and effective dose values, in average about a factor of 10, of DVT irradiations as compared to panoramic x-ray irradiations can not be generally applied to other units or parameter settings. Especially image quality and clinical indications were not considered in this study.

A maximum dose value of 0.65 mGy inside an Alderson-Rando phantom was published for panoramic radiography (Cohan, 2002) for an Orthophos C scanner model. This value is close to the measured value of 0.73 mGy in this study. An average effective dose of 10 µSv for panoramic radiography in the UK was reported by the Health Protection Agency (NRPB, 2002). (Looe et al., 2008) reported effective dose values based on (ICRP, 2007) tissue weighting factors of 6 and 16 µSv at about 80 kV for a Philips and a Gendex panoramic unit, respectively. The effective dose value of 8 µSv in this study is in agreement to the published literature.

A maximum dose value of 4.1 mGy inside an Alderson-Rando phantom was published for a DVT 9000 scanner (Cohan, 2002). The maximum absorbed dose to water value of 5.2 mGy in this study is comparable to the reported dose value. The manufacturer of the GALILEOS DVT system stated an effective dose of 90 µSv in the manual based on published data (Ludlow, 2008). The calculated effective dose of 81 µSv agrees with the published results. It has to be noted that the locations of the TLD sites within the available phantom were not perfectly distributed according to the radio-sensitive organs of (ICRP-103, 2007). Additionally, skin, bone surface, oesophagus and remainder tissues and organs in the head and neck region, i.e. muscle, oral mucosa, and lymphatic nodes were not included in the current evaluations for effective dose. Nevertheless their contributions are expected to be rather low to the effective dose results. MCNP Monte Carlo simulations were carried out to validate the measured dose distributions and resulting effective dose values. Currently, simplified simulation models were investigated only for planar x-ray exposure (Halda, 2008). Future investigations are concentrated on simulations of ICRP reference computational voxel phantoms for radiation protection applications.

Acknowledgements

The authors would like to thank Martin Halda for the collaboration during his diploma thesis at the Dosimetry Laboratory Seibersdorf, Dr. Käsmayer dentist in Baden for providing measurement time at the DVT facility, and Dr. Izewska from the IAEA for providing the Alderson-Rando Phantom.

Radiation dose in selective nerve root blocks

Tsapaki, V.; Maniatis, P.; Chinofoti, I.; Papadopoulos, I.; Triantopoulou, Ch.
Konstantopoulio Hospital, Athens, GREECE

Abstract

Objective: Selective nerve root blocks (SNRB) are useful in the treatment of radicular symptoms, due to the infiltration of large amounts of steroids around a particular nerve root resulting in reduction of pain. Fluoroscopic guidance is usually used to perform these procedures. The objective of this study was to measure the radiation dose received by these patients.

Materials and methods: The study included 24 patients undergoing SNRB using a fully digital fluoroscopy X-ray machine Philips Allura FD 20 installed in 2008 in Konstantopoulio Hospital. The following technical parameters were recorded: Kerma Area Product (KAP), cumulative dose (CD), fluoroscopy time (T) and total number of images (F). Patient data recorded were: Age (A), Weight (W) and Height (H).

Results: Median values of KAP, CD, T and F were 26.7 $Gycm^2$, 360 mGy, 3.4 min and 123 images, respectively. Ranges of KAP and CD were 1.8-218.4 $Gycm^2$ and 24-856 mGy, respectively. No correlation was found between KAP and F (0.12), as well as KAP and T (0.04). Furthermore, no correlation was found between CD and F (0.09) and moderate correlation between CD and T (0.56).

Conclusions: Radiation doses vary substantially in SNRB procedures. The fact that they can be repeated to the same patient in certain time intervals calls for more detailed investigation and close monitoring of patients.

Introduction

Selective nerve root blocks (SNRB) are useful in the treatment of radicular symptoms, due to the infiltration of large amounts of steroids and anesthetic drugs around a particular nerve root resulting in reduction of pain [Wagner, 2005]. They have long been a staple of anesthesiologists and orthopedic surgeons, but have been increasingly performed by interventional radiologists [Wagner, 2004]. It is a minimally invasive outpatient technique that can be performed with minimal sedation.

Fluoroscopic guidance facilitates greatly in the accuracy of needle placement, and thus the specificity of the examination. With injection of contrast media, the correct position of the needle in the nerve root sleeve and not in the nerve root itself is confirmed. Furthermore, it helps to confirm that the needle is not positioned in a vascular structure, a situation that could remove the injectate from the injection site and cancel any success of the SNRB [Fenton 2003]. The use of fluoroscopy, however, imparts a certain radiological burden to the patient. It should be noted that there are no data in the recent literature on the level of radiation dose received by the patient during SNRB using fluoroscopic guidance. Taking all these into account, the objective of this study was to measure and evaluate the radiation dose received by patients undergoing SNRB procedures.

Material and methods

SNRBs were performed by a single operator on a Philips Allura FD 20 large area flat panel angiography system installed in 2008 in Konstantopoulio Hospital. All procedures were executed by a single operator with more than 15 years in interventional techniques. SNRBs were performed with the patients in the prone position on the fluoroscopy table. The interventional radiologist is standing next to the patient so as to position the needle and the technologist is seated next to the radiologist so as to move the C-arm in the appropriate position and to facilitate the radiologist during the SNRB. The difference between this technique and other interventional techniques is that the radiologist must stand close to the back of the patient and therefore be very close to the X-ray machine and the scattering medium (patient body). More importantly, the hand of the radiologist is seen in the X-ray image during his attempt to accurately position the needle using the “barrel view” technique.

The following technical parameters were recorded: Kerma Area Product (KAP) and cumulative dose (CD) both of which are provided by the X-ray system, fluoroscopy time (T) and total number of images (F). As patient data are concerned, the following parameters were also recorded: Age (A), Weight (W) and Height (H) of the patient.

Results

The study included 24 patients undergoing SNRB of the lumbosacral anatomical region. The distribution of KAP and CD did not exhibit a normal distribution so the median, minimum and maximum values are estimated. These values are shown in Table 1 together with corresponding values of T, F, A, W and H. Large variation in results was found especially in KAP with max/min ratio of 121, whereas corresponding value for CD was 36. The correlation of KAP and CD was investigated with technical parameters (T, F) and patient data (W, A). The only correlation found (moderate) was between KAP and W (0.4). Furthermore, the only correlations of CD with collected data were for T (0.6) and W (0.4).

Table 1. The Selective Nerve Root Block (SNRB) technical and patient data are presented.

	W (kgr)	H (cm)	A (years)	F	T (min)	DAP (Gycm²)	CD (mGy)
median	78	168	72	124	3.4	26.7	360
min	55	155	30	6	1.0	1.8	24
max	117	195	88	254	10.3	218.4	856

It was not possible to compare with the literature since so similar study existed. There are a number of studies presenting data on SNRB and CT or CT fluoroscopy (Wagner 2004, Carlson et al 2001, Nawfel et al 2000)

Nawfel et al estimated a patient skin dose of 830 mGy when applying 80 seconds of CT fluoroscopy, by using a 90-mA and 120-kVp exposure. This value, however, so a theoretical calculation using the technical parameters, therefore being not specific for the SNRB. It must also be noted that the SNRB can be repeated to the same patient in certain time intervals.

Conclusions

The literature has practically no information on radiation dose levels regarding SNRB. Our study showed that radiation doses can vary substantially. Taking into consideration that: 1) they can be repeated to the same patient in certain time intervals and 2) the limitation of information on radiation dose, shows that more detailed investigation and close monitoring of patients should be done.

Abstract
The number of interventional radiology procedures has been shown to increase over time due to their clinical safety and efficacy. Nevertheless, these procedures may be related to elevated patient radiation dose. Stochastic risk management can be improved by monitoring the dose-area product and comparing it to available dose reference levels (DRL). On the other hand, deterministic effects can be managed by monitoring cumulative dose at the intervention reference point (D_{IRP}). The objective of this study was to provide interventionists a simple and reliable method to control risks associated with the use of ionizing radiation. Patient data for a seven-month period were collected and analyzed for hepatic embolization and cerebral angiography. Data included dose-area product values, fluoroscopy time, number of images obtained during the procedure and D_{IPR}. Patient dosimetry was performed by using high-sensitivity MOSFET dosimeters. The SPSS statistical program was employed for data analysis. Maximum skin dose reached 8.9 and 5.5 Gy during hepatic embolization and cerebral angiography, respectively. Good correlation was found between the MOSFET dosimeters and D_{IRP} during patient study. The 75% percentile of patient dose was calculated and compared with the national DRLs. D_{IRP} should be recorded during the procedure and included in patient's report file for post-procedure reference. Actions have to be taken towards dose optimization. Patient follow-up has to include check for recognized or suspected radiation injury.

Patient dosimetry during biventricular I.C.D. insertion

Abstract

Recent years have seen a great increase in electrophysiological cardiac procedures number and radiological systems are constantly improved to obtain good image quality by upgrading technological performance. Even if patient benefits are clear, these procedures expose patients to X-rays for a long fluoroscopic time; the result is progressively higher patient radiation exposure, both in local skin areas (for example, the skin of the back) and in terms of effective dose and related risks.

In order to evaluate the mean patient dosimetric parameters, we have analyzed 30 biventricular implantable cardioverter defibrillators (ICD) procedures, measuring DAP (dose area product) during the entire procedure and registering all geometrical and physical data that are necessary to reconstruct, via a Monte Carlo simulation, the dosimetric quantities for ICD therapy.

For this reason, for each patient we have collected all X-ray spectrum data (such as kV, mA and time during fluoroscopy and fluorography) related to irradiation geometry (such as focus-to-patient distance, X-ray tube angulations, dimension of X-ray field of view) to obtain a "cumulative dataset" that permit to simulate the intervention.

Using a Monte Carlo code, we have evaluated the dose for each patient (both organ dose as effective dose, to obtain "dosimetrical indexes" for the procedure) to produce a statistical analysis that can be compared with other interventional therapies (for examples, hemodynamic procedures as stent implantation, angiography, percutaneous transluminal coronary angioplasty, etc.).

Even if the dose variability between patient data is great, primary due to the complexity of the ICD insertion, our results demonstrate that patient dose indexes for this particular electrophysiology procedures are not significantly different from the X-ray guided hemodynamic therapies.

Introduction

While several research studies focus on the analysis of the patient dose under hemodynamics procedures, fewer deal with electrophysiology RX guided procedures *[Cusma et al. 1999, Huyskens et al. 1995, Likckfett et al. 2004].*

For this reason, we have decided to investigate this issue and to proceed with the analysis of real patient cases at the Cardiovascolary Department of the University of Bologna.

Since electrophysiology procedures are very diversified and numerous, we chose the procedure that probably involves the highest patient dose values: the biventricular ICD (implantable cardiostimulator defibrillator) insertion for the therapy of heart failure.

In fact, this intervention needs longer fluoroscopy time than the implantation of a single chamber pacemaker for the insertion of multiple guides and three electrodes (the first one in the right atrium, the second one in the right ventriculum and the third in coronary sinus) to resinchronize the cardiac heartbeat.

As one of the scopes of our work is to present a dataset of EPs dose values directly comparable with other interventional procedures, the choice of dose indexes becomes fundamental.

Many authors have decided to focus their works on possible risks for specific areas of the patient body (for example, the skin), analyzing the so-called Maximum Skin Dose (MSD) as dose index for hemodynamic procedures *[Balter 2006, Van de Putte et al. 2000, Wittkampf et al. 2000].* This choice, related with the usage of detectors located on defined positions of the patient skin (such as thermoluminescent detectors or gafchromic films [*Chu et al. 2006*]), permits to estimate the X-ray energy on patient with good precision, but has a spatial limitation due to the detector dimensions (a possible solution is the use of large films located on the operating table, with an underestimation of dose in lateral projections).

In order to obtain not only a single organ data, we have decided to collect the DAP (Dose Area Product) values for every shot (i.e., projection) and reconstruct the irradiation geometry and patient anatomy via Monte Carlo simulation.

Material and methods

The X-ray system

The X-ray machine used in the operative room dedicated to EP procedures at Cardiovascular Department of the University of Bologna is a Sias Synthesis (*www.sias-spa.com/synthesis.htm*; nominal high voltage of 120 kV; half value layer of 3.8 ± 0.1 mmAl equivalent at 100 kV; image intensifier of 9 inches input, with different electronic zoom usable by cardiologists).

In this system, the X-ray tube and the image intensifier (I.I.) are mounted on a U-shaped arch that can rotate around the longitudinal and transverse axis of the patient.

Patient investigations are principally characterized by fluoroscopy, in order to define the guidance of catheters and their localization inside patient thorax, and sometimes by venography for the analysis of positions with high resolution and/or contrast media. During fluoroscopy, the X-ray tube works in continuous mode and uses the automatic exposure control (AEC) to set high voltage (i.e. kV_p) and current (i.e., mA).

The venography instead works in pulsed mode with current fixed at 120 mA and regulates with the AEC only the voltage in order to obtain a defined signal level on the image intensifier.

No changes are introduced during this study, but all the radiological parameters and procedures are executed by cardiologists as usal, in order to obtain significant and realistic data.

Patient group

The choice of patients suitable to represent the procedure had required the selection of candidates who had anatomical and pathological features comparable. In practice, starting from the list of all patients, our cardiologists selected a group of patients to obtain a sufficiently uniform distribution of physical parameters around values described by the so-called ”standard man” *[ICRP 103, 2007]*. This process led us to obtain a group of 30 patients whose characteristics are summarized in Table 1.

Table 1. Population overview.

	Mean	SD
Age (years)	61	12
Height (m)	1,75	0,09
Weight (Kg)	77	15
Avarage BMI (kg/m²):	26,4	-
Number of males	23	-
Number of females	7	-

Procedures

The biventricular implantation (BIV) procedure involves the insertion of catheters guided by fluoroscopy - normally using the so-called brachial access - and positioned by means of venography.

Due to the variability associated with the patient specificity, each operation was divided into radiological projections that compose it. A physicist has followed every procedure in the operating room recording all the information required for dosimetric evaluation of the patient. This allows to know the contributions of each shot to the total dose, and to compare the procedures between them. Data collected for each projection are divided into: X-ray tube parameters and geometric parameters.

X-Ray Parameters

The values of high voltage, current, time, frame numbers and collimation are collected from the console of the system. Since the AEC changes the parameters during the same projection depending on the workload, the values we save for each projection are the mean value of the data parameter presented in the console.

Geometric parameters

In order to know the radiation field investing the patient not only in terms of hardness (i.e., the capability to penetrate inside the body, described by X-ray spectrum) but also in terms of geometrical distribution on the patient body, the relative positions between the X-Ray tube and patient have been studied.

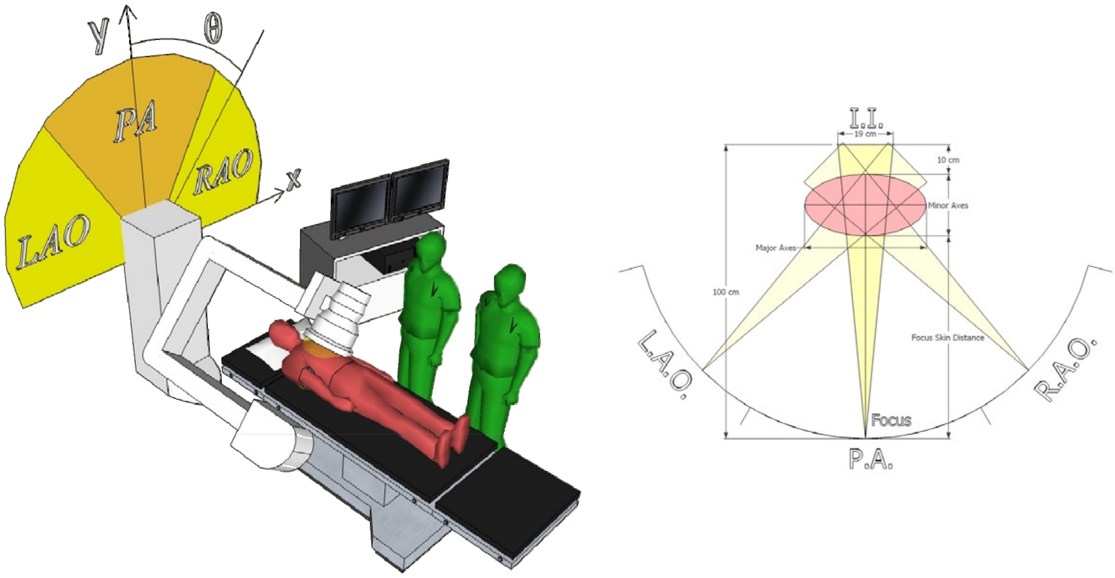

Fig.1-left: Schematic representation of the relative position of the subjects involved during the procedure.Fig 1-right: Representation of irradiation geometry and ICRU model for torax dimension.

The primary beam (which can be considered conical with the vertex on the X-ray focus) rotates around the patient's heart in the XY plane perpendicular to the axis of the patient Z. In angular coordinates, the focus position can be described by θ (theta angle, see Fig. 1), that is the rotation angle respect to the Y axis, and with the distance r. We decided to group the rotation angles based on the position of the tube with respect to the axis Y as in figure 1($\theta = 0 \pm 30°$ is collected as Postero - Anterior (PA) projections, while $-90° < \theta < -30°$ there are Right Anterior Oblique (RAO) projections and $30° < \theta < 90°$ are Left Anterior Oblique (LAO) projections).

Obviously, during the Monte Carlo simulations, this choice introduces an error in the determination of the organ volumes invested by primary X-ray beam as in the evaluation of the relative doses: we have estimated this error and decided to group the angles in order to not excede an uncertainty of 10%, with a computing time reduction of about 30%.

To evaluate the distance between the patient and the X-ray tube we used the model of the elliptical cross section described in ICRU 2005 (Fig.1 right). In that model the average value for our set of patients are min axis 21cm and max axis 42 cm. Each simulation was done with the patient's own geometrical parameters. An evaluation of the relative positions between patient and I.I., as between X-ray tube and I.I., permits to estimate for our sample of patients the FSD (focus skin distance) for every projection. On average, in our sample of patients, we estimate for the PA projection a FSD of 69,1 cm (SD=1,8 cm) while in RAO is 59.6 cm (SD=2.6 cm) and LAO is 67.1 cm (SD=2.8 cm)

Evaluation of dose indexes: organ and effective dose calculations

Starting from the geometrical and the radiological data collected, a commercial Monte Carlo software (PCXMC) was used: the simulation for every patient was divided in all the projection angles described (LAO, RAO, PA), using the tools that allow not only the definition of the X-ray beam shape (i.e., the radiological parameters as kV, mA, etc.) for every shot, but also a free adjustment of the X-ray beam dimension on phantom body.

Obviously, the Cristy and Eckerman phantom implemented in PCXMC was adjusted in height and weight in order to simulate the anatomy of every patients. For everyone, the dose contributions are being estimated both in terms of organ dose (as described by ICRP 103), both in terms of effective dose in order to compare these procedures with other interventional ones.

The Monte Carlo code simulate a number of stories of photons chosen to have a good ratio between statistics and calculation time: our goal is to have a simulation error for the primary organs around 0.2 %. This allow us to choose a number of stories equal to $N_s = 5 \cdot 10^5$ for each projection.

Results

Results can be divided in two parts: the first part concerns the procedure itself with the data collected in the operating room and the second part concerns the organs and the effective dose evaluated by Monte Carlo simulations.

Radiological data

The radiological data are summerized in Table 2. The work parameters of the two diagnostic phases (fluoroscopy and fluorography) are divided in geometric components as described above (RAO, LAO, PA).

Table 2. Median system setup parameters for each projection and measured DAP values.

		PA			RAO			LAO		
		Median	Min	Max	Median	Min	Max	Median	Min	Max

Organ and effective dose calculation

In this study we have focused our attention on the value of organ dose rather than the value of effective dose because our goal is not only to compare ICD implantation with other cardiac procedures, but to have dose indexes directly related to the energy absorption inside patient.

The simulation of each projection gives us the absorbed dose for each organ: the total organ dose is the sum for each patient of the dose absorbed in a specific organ. The distribution of dose values in our population does not follow a gaussian distribution (for example, see Fig. 2 that plots the lung dose of the population). This concerns that the statistical variation of the values are not centred on an expected value and so we treat the representative parameters under the term of median (and range) and not under term of average (and standard deviation).

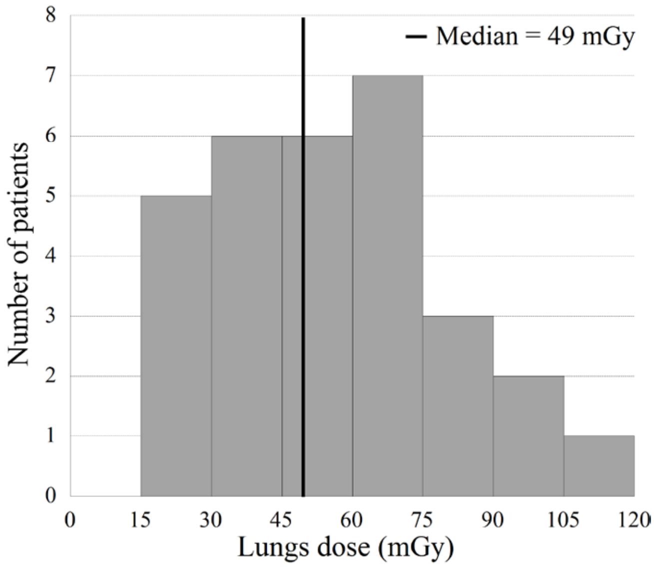

Fig 2. Histogram of the lung dose for our population.

We decided to divide the study of the organ dose in two parts: the skin dose and the internal organs dose. This choice is due to the observation that the region of the skin invested by the X-ray beam certainly receives the greater part of the energy, if compared with all the other organs.

Skin Dose

We associate all the skin doses calculated by PCXMC to the skin mass irradiated by primary X-ray beam. With this operation, we consider as skin organ not all the skin of the body but only the two regions (rear and front) irradiated by the primary beam. The proportion between the total skin area and the irradiated skin area gives us the dose absorbed by the skin. The total skin area is given by ICRP 89:

$$Area_{Skin}(m^2) = 0.0235 \cdot \left(Height(cm)^{0.42246}\right) \cdot Mass(kg)^{0.51456}$$

In this way we can evaluate the skin dose as it is summarized in table 3.

Table 3. Skin dose values evaluated for the different projections.

	Median (mGy)	Min (mGy)	Max (mGy)
PA	115,4	12,7	587,0
RAO	13,4	5,4	260,1
LAO	62,9	3,0	367,4
TOTAL	276,1	98,0	658,5

The skin dose values estimated by this method are comparable with other studies related to cardiac procedures *[Geise et al. 1999, Bor et al. 2009]*.

Dose for internal organ

The Monte Carlo software gives us the dose for each organ defined in ICRP 103. Because of the little region irradiated, there are only some organs in the primary beam or with a dose value reasonably different from zero. In table 4 we present the median values of the internal organ dose for our population while in table 5 we present the organ dose percentages divided in the two diagnostic phases (fluoroscopy and fluorography) and in the three geometrical projections (PA, LAO, RAO).

Table 4. Median organ dose for the BIV insertion procedure.

Organ dose (mGy)				
Organ	**Median**		**Min**	**Max**
Active bone marrow	16,7	(6%)	6,3	43,4
Adrenals	22,7	(8%)	9,3	78,2
Breasts	6,9	(2%)	1,8	14,9
Heart	46,2	(17%)	16,6	95,8

Total	100%	(48%)	100%	(7%)	100%	(45%)	100%	(80%)	100%	(20%)

Effective dose

The estimation of the effective dose (as defined in ICRP 103) may be useful not only for estimating absolute risk associated with BIV implantation but rather permit a direct comparison with other cardiac interventions *[Wielandts et al. 2010, Martin 2007, Drexler et al. 1993]*.

The median value of calculated effective dose is 13.6 mSv in a range of (4.9÷35.1) mSv.

Figure 4 presents a comparison between the effective dose estimated in this study and E values for other common cardiac interventions executed inside Sant'Orsola University Hospital of Bologna *[Compagnone et al. 2005]*.

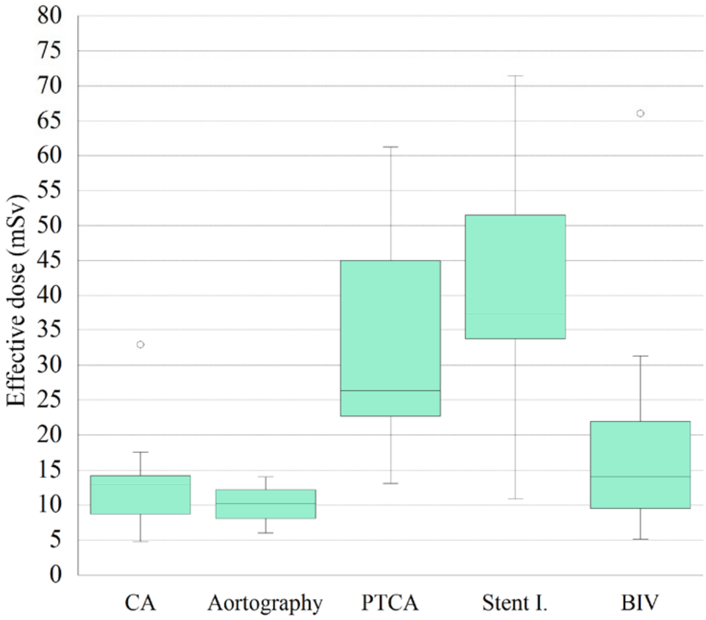

Fig 3. Comparison between effective doses evaluated for different cardiac RX-guided procedures: CA (coronarography); PTCA (Percutaneous Transluminal Coronary Angioplasty); STENT insertion and BIV

Conclusions

This paper has attempted to provide an indication of the patient dose levels associated to a specific electrophysiology procedure (biventricular ICD insertion) in order to have data that can aswer at the patient dose questions presented by many cardiologists *[Smith et al. 2008]*.

In fact, even if the EP procedures are not clearly defined as high dose procedures, organ doses and effective dose values seems to be comparable with – for example - angiographic ones.

Cancer risk from medical radiation exposure: a *pro*gnosis-based *l*ifetime *a*ttributable *r*isk *a*pproximation (*PROLARA*)

Eschner, Wolfgang; Schmidt, Matthias; Dietlein, Markus; Schicha, Harald
Department of Nuclear Medicine, University Hospital of Cologne, D-50924 Köln, GERMANY

Abstract

Purpose: To evaluate the impact of the reduced life expectancy of patients (compared to a non-patient group with same age distribution) on their nominal risk of developing solid cancer from the diagnostic use of radiation.

Method: We define a "*pro*gnosis-based *l*ifetime *a*ttributable *r*isk *m*odifier" (*PROLARM*) as the ratio of risks for non-patient and patient, a dimensionless quantity which indicates how strongly the lifetime attributable risk (*LAR*) is reduced due to the patient's prognosis. We show that an approximation to this ratio can be calculated (named *PROLARA*) which depends only on patient's age at exposure and his/her life expectancy, but is independent of the exact choice of values for the baseline risk of cancer incidence (which varies across populations) and the excess relative risk (*ERR*) from radiation exposure (which remains controversial in the scientific community). *PROLARM* and *PROLARA* were computed for a cohort of n=4285 female patients with metastatic breast cancer, for which all necessary input data where available.

Results: *LAR* of solid cancer is significantly decreased for these patients: *PROLARM* > 20 for all ages at exposure ≤ 65 years. For any reasonable choice of function for *ERR*, the approximation *PROLARA* gives a lower estimate of the reduction in risk. The risk for a patient from the above cohort, exposed at age 50, is decreased by a factor of 29 (*PROLARM*) rsp. 27 (*PROLARA*). In other words, 20 mSv for a patient with metastatic breast cancer correspond risk-wise to less than 1 mSv for a healthy person of the same age.

Conclusion: A major portion of the total dose from diagnostic medical exposures does not constitute an additional cancer risk due to the poorer prognosis of patients compared to non-patients of same gender and age. Our new *PROLARA* concept allows an estimation of the reduction in risk for any pathology when the associated survival is known.

Introduction

Calculations of cancer risk from diagnostic medical use of ionizing radiation have resulted in predicted numbers of cancer cases ranging into the thousands for the most developed countries (Berrington de Gonzalez and Darby 2004, Brenner and Hall 2007).

Those predictions are based on applying the Linear-No-Threshold (LNT) model which may not hold against new radiation biological data, but nevertheless remains the foundation of current practice in radiation protection.

Even with the LNT model, however, the risk from diagnostic radiation exposure is significantly smaller than conventionally projected because those calculations generally neglect the fact that the exposure is not evenly spread among the population, not even among subgroups of a certain age range. Rather, the healthy part of the population will hardly be exposed at all, while most of the procedures, especially the ones with high effective doses, will be applied to patients who are seriously ill.

We have therefore investigated quantitatively the influence of the illness of one particular patient cohort, i.e. their prognosis or life-expectancy, on their nominal risk of developing solid cancer from any diagnostic radiation exposure, compared to the risk for healthy persons of the same age. The method is transferable to any other patient group.

Such calculations involve using values for the excess relative risk (*ERR*) of cancer incidence per unit dose for the exposed population and transporting them into lifetime attributable risk (*LAR*). As there is no generally accepted "best set" of such *ERR* values, we present a novel approach that avoids having to choose a particular *ERR* function.

Material and methods

Using the nomenclature of (Vaeth and Pierce 1990) and (Kellerer et al. 2001), the lifetime attributable risk *LAR* (of a radiation-induced malignancy to become clinically manifest) is a function of age at exposure, *e*, and given by

$$LAR^i(e) = \int_{e+L}^{a_{\max}} ERR^i(a)m(a)S(a)/S(e)\,\mathrm{d}a = \int_{e+L}^{a_{\max}} ERR^i(a)m(a)S'(a,e)\,\mathrm{d}a \qquad (1)$$

where *e* and *a* are age at exposure and attained age, respectively, *m*(*a*) is the baseline cancer incidence rate and *L* is the latent period. The *survival function*, i.e. the probability at birth to reach at least age *a*, is denoted by *S*(*a*). The ratio *S*(*a*)/*S*(*e*) is the conditional probability of a person alive at age *e* to reach at least age *a*. The superscript ^{i} denotes incidence (which is the quantity we are interested in, rather than mortality).
For patients (subscript $_P$), we have

$$LAR_P^i(e) = \int_{e+L}^{a_{\max}} ERR^i(a)m(a)S'_P(a,e)\,\mathrm{d}a = \int_{e+L}^{a_{\max}} ERR^i(a)m(a)P(a,e)S'(a,e)\,\mathrm{d}a \qquad (2)$$

with $P(a,e)$ relative survival of the patient population compared to a standard population of same gender and age.

We define the "prognosis-based lifetime attributable risk modifier" (*PROLARM*) as the ratio of risks for non-patient and patient, a dimensionless quantity which indicates how strongly the *LAR* is reduced due to the patient's lower life expectancy:

$$PROLARM(e) = LAR^i(e)\big/LAR_P^i(e) \qquad (3)$$

It would be desirable to have a quantity which is independent of the exact values of *ERR(a)*, because these remain controversial in the scientific community, and also independent of the baseline risk of cancer incidence, *m(a)*, which varies across populations. This can be achieved by defining the "prognosis-based lifetime attributable risk approximation" (*PROLARA*) which depends only on patient's age at exposure and his conditional life expectancy. With any of the generally accepted choices for *ERR(a)* such as the preferred functions from (NRC 2006) or (ICRP 2007), the following relation holds:

$$PROLARA(e) = \int_{e+L}^{a_{\max}} S'(a,e)\,\mathrm{d}a \Bigg/ \int_{e+L}^{a_{\max}} S'_P(a,e)\,\mathrm{d}a \le PROLARM(e) \qquad (4)$$

In words: the ratio of the integrals over conditional survival for normal and patient is always (slightly) lower than the ratio of the *LAR* integrals in eqn. (3), i.e. *PROLARA* as the ratio of the survival integrals gives a lower limit to the *PROLARM*.

Application to patient cohort

We computed *PROLARM* and *PROLARA* according to eqns. (3) and (4) for a patient cohort where all necessary input data where available. The group consists of n=4285 female patients with metastatic breast cancer. The following input data were used:

Baseline survival (life expectancy): The sex-specific survival function was taken from the latest available statistical data for Germany (www.destatis.de 2009). The data can be modeled by a Gompertz expression of type $S(a) = \exp(-c_1 \cdot \exp(c_2 \cdot a))$ with fitted parameters c_1=5.5E-05, c_2=1.13E-01. (Fig. 1; values differ from those in (ICRP 1991) due to today's longer life expectancy).

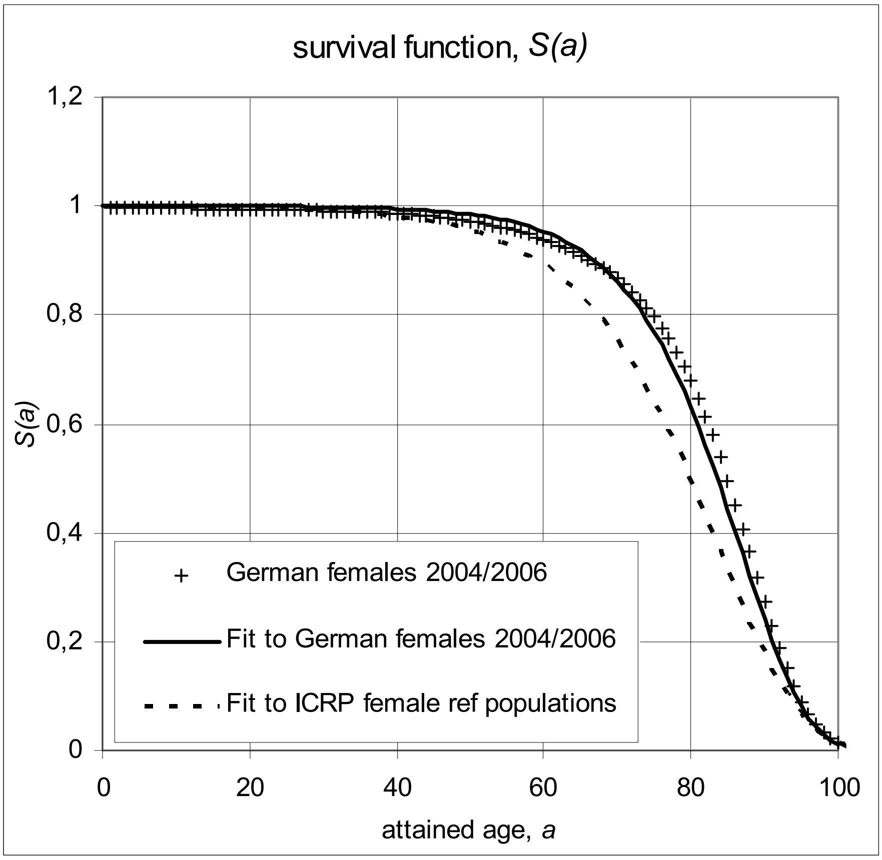

Fig. 1. Baseline survival function for women in Germany and fit to these data as well as fit to the 5 reference populations used in ICRP 60.

Baseline cancer incidence: Although there is no nationwide cancer registry in Germany, extrapolations of the available incidence data to the whole German population have been published (RKI 2008). They are listed for most of the ICD-10 cancer types and various age intervals. We used the data for all solid cancers except non-melanoma skin neoplasms (ICD-10 C00-97 except C44). Fitting a power function $m(a) = k \cdot (\, a / 60\,)^r \cdot \exp(\, -c \cdot (\, a / 60\,)^r\,) + b$ to those data yields parameters k=0.008, r=4, c=0.14 for females, while b, which corresponds to the rate at very young ages, was conservatively set fixed to b=0.0002. Fig. 2 shows the published data and the corresponding fit.

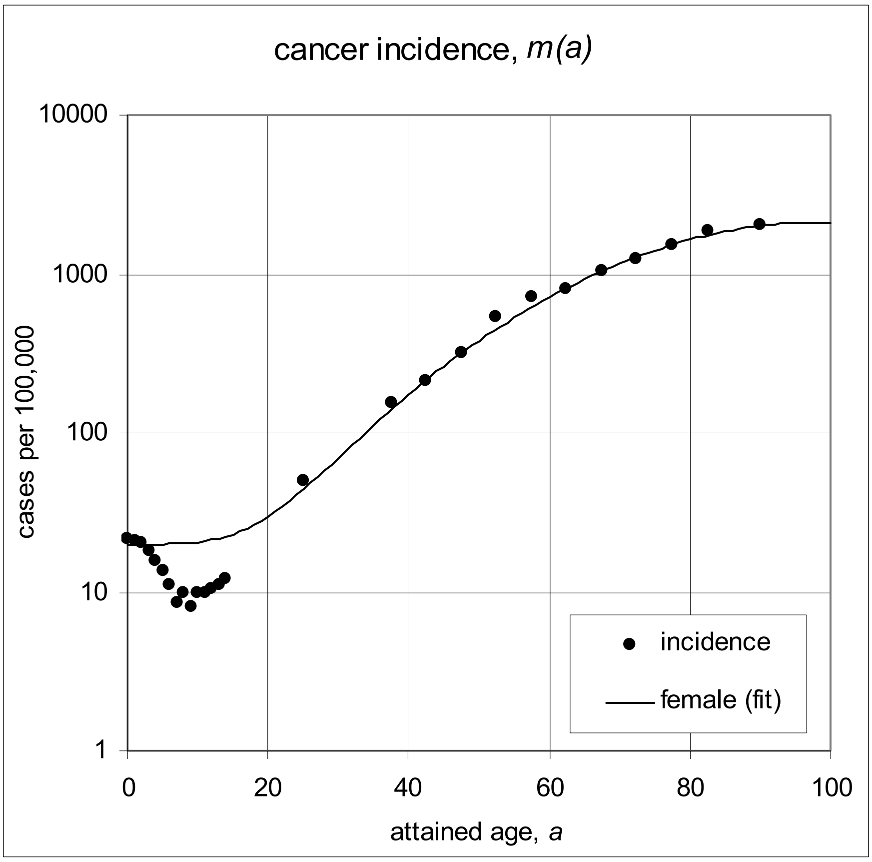

Fig. 2. Age specific cancer incidence for all solid malignancies except non-melanoma skin cancer in women in Germany, 2003. Cases per 100,000 in each age group.

Excess relative risk, ERR: We use the values published in BEIR VII Phase 2 report. The preferred function there for ages at exposure, e, greater than 30 years is of type $ERR(D,S,a) = \beta_S \cdot D \cdot (\eta \log(a / 60))$ where D is dose (Sv), β_M and β_F are the ERR/D for males and females exposed at age 30 at attained age 60, and η is the exponent of attained age. Subscript $_S$ denotes sex. For all solid cancer incidence (again excluding non-melanoma skin cancers), the fitted parameters are β_M=0.33, β_F=0.57, and η=-1.4. The result is displayed in Fig. 3.

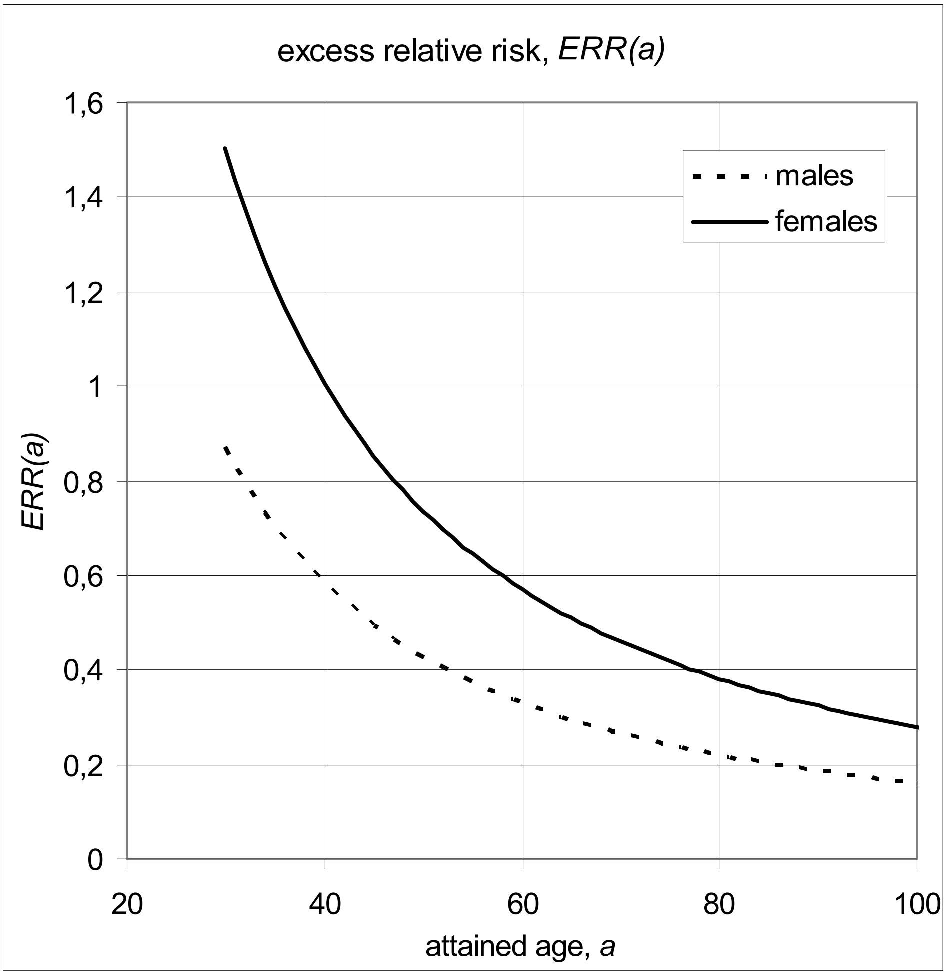

Fig. 3. ***ERR*** **per unit dose for incidence of all solid cancers as function of attained age** ***a*****, for age at exposure e ≥ 30.**

Survival / life expectancy of patients: Survival data (Kaplan-Meier curves) for this particular patient cohort were supplied by the Munich Cancer Registry. Overall survival is available for up to 20 years after diagnosis of metastasis, and survival for sub-cohorts by age group for between 3 and 15 years (Fig. 4). To perform the integration according to eqns. (2) to (4), a fit to these data is needed. In order not to underestimate survival in later years, a logistic function of type $S(a-e)=\left(1+\left(\frac{a-e}{c_1}\right)^{c_2}\right)^{-1}$ is used, with c_1=2.246, c_2=1.27 for the full patient cohort. It is assumed that the radiation exposure under investigation occurs when metastasis is detected, such that Fig. 4 depicts survival after exposure, i.e. the abscissa (years after metastasis) equals attained age minus age at exposure, $a-e$.

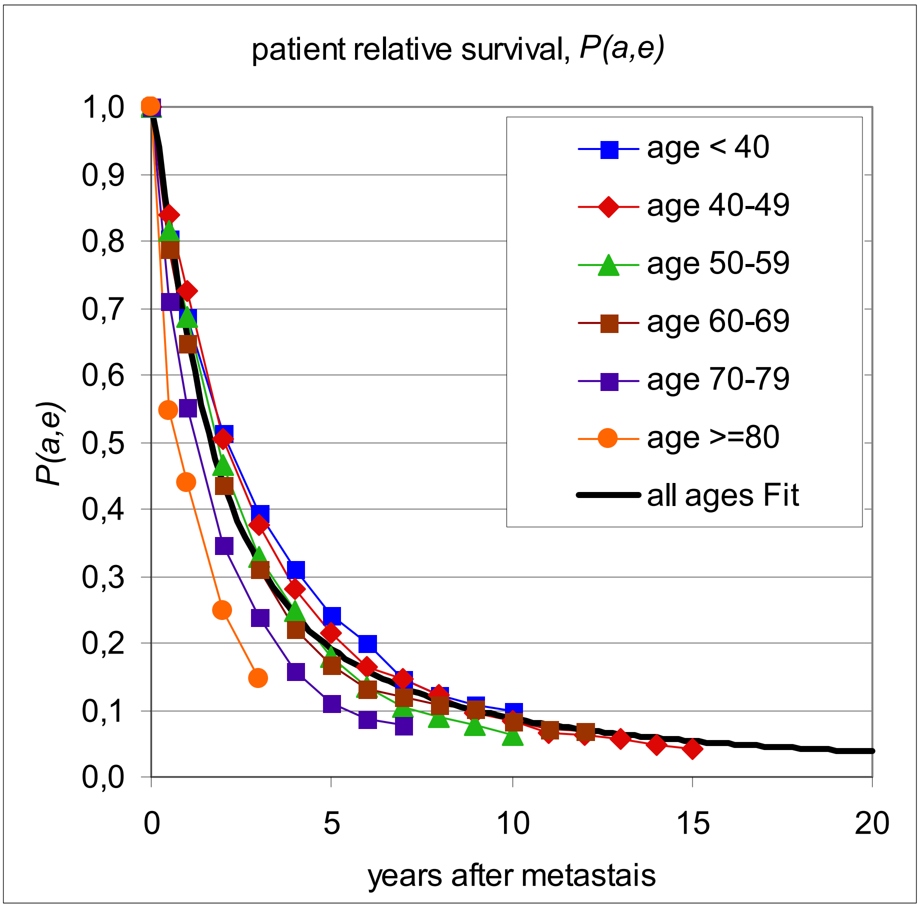

Fig. 4. Relative survival for patients from sub-cohorts by age (data from Munich Cancer Registry).

Results

The above input data were used to calculate *PROLARM* and *PROLARA* for this patient cohort. The effect of patient survival (prognosis) on *LAR* is depicted in Fig. 5a, which plots the *differential LAR* (*dLAR*), i.e. the integrand in eqns. (1), (2), vs. attained age, *a*, in this example for age at exposure *e* = 50 years. *PROLARM* is simply the ratio of the areas under the respective curves.

A very similar diagram can be generated by plotting the conditional survival *S'(a,e)* for patient and non-patient (Fig. 5b). The ratio of the areas under the curves from Fig. 5b yields the *PROLARA* for the given age at exposure, according to eqn. (4).

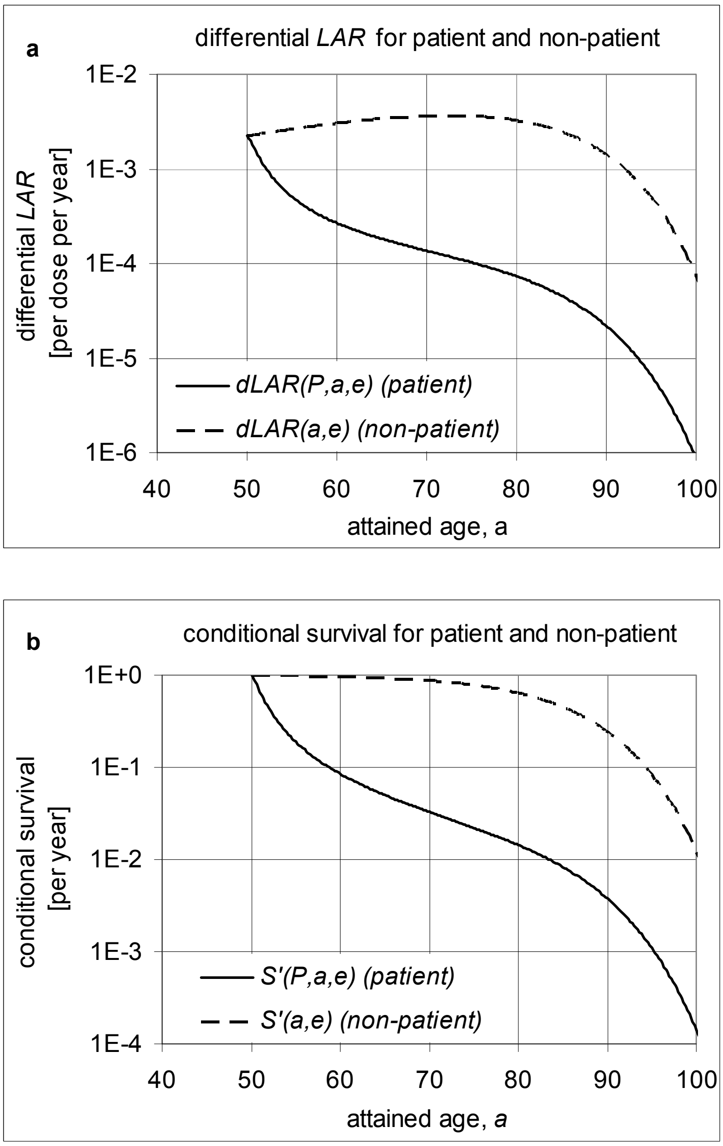

Fig. 5. Comparison of risk (a) and survival (b) for patient and non-patient
a Differential *LAR* (*dLAR*) for patient, *dLAR(P,a,e)*, and non-patient, *dLAR(a,e)*, for *e* = 50 a.
b Conditional survival for patient, *S'(P,a,e)*, and non-patient, *S'(a,e)*, for *e* = 50 a.

Performing the integration for all ages at exposure, *e*, and plotting the quotients of the integrals for non-patient and patient yields the desired diagram of *PROLARM* and *PROLARA* values (Fig. 6; parameters used in integration: latency L=10 years, maximum age a_{max}=100 years.)

From Fig. 6, the following can be seen:

- *LAR* of solid cancer is significantly decreased for patients of any age at exposure compared to non-patients. At younger ages, this decrease is more pronounced (*PROLARM* as well as *PROLARA* > 20 for $e \leq 65$). Using fitted functions for *ERR* as proposed in BEIR VII Phase 2 report, *PROLARM* is always greater than the ratio of the survival integrals. The approximation thus gives a lower estimate of the reduction in risk.
- Integrating over the curves in Fig. 5a for an effective dose of 10 mSv at age $e = 50$ yields *LAR* values of 1.2E-3 for non-patient and 4.3E-5 for a patient from the above cohort, respectively. That is a reduction in risk by a factor (*PROLARM*) of 29. From the approximation using only survival data, i.e. integrating over the curves in Fig. 5b, that ratio (*PROLARA*) is 27.

Thus, a diagnostic procedure with an effective dose of 50 mSv for a patient with metastatic breast cancer corresponds risk-wise to ca. 2 mSv for a healthy person of the same age.

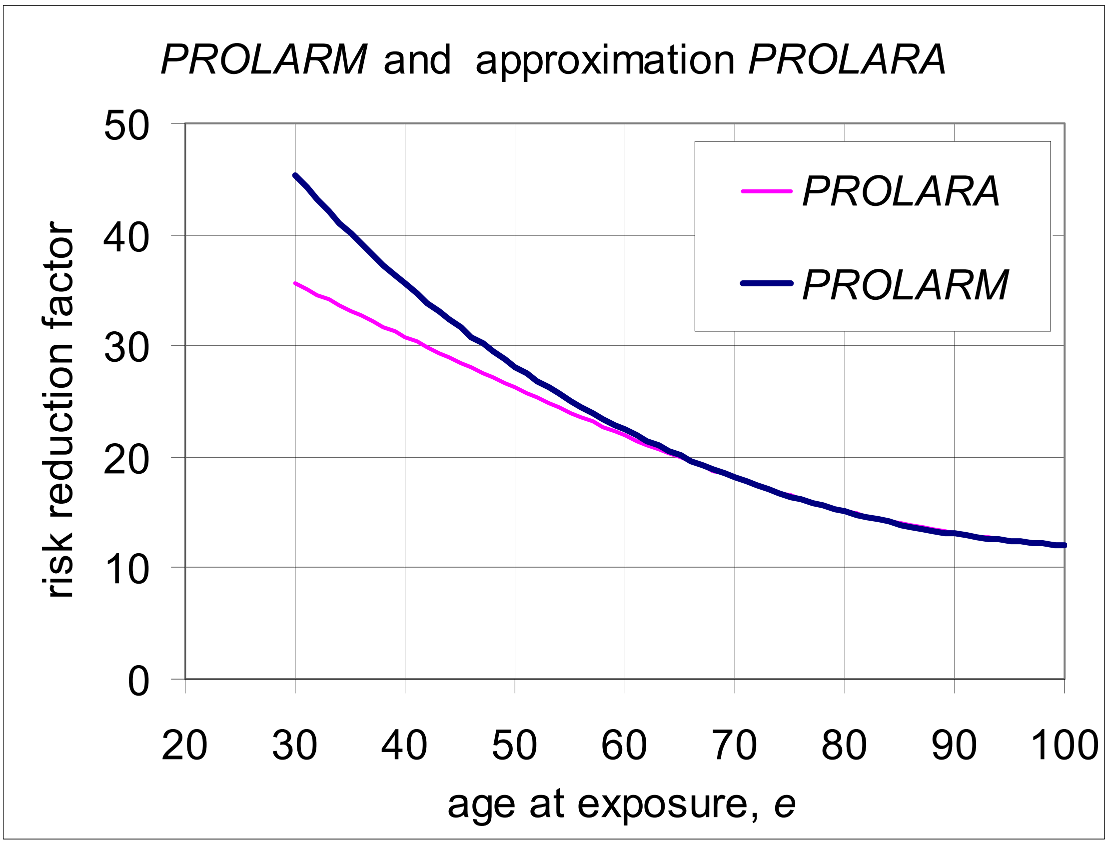

Fig. 6. *PROLARM* and *PROLARA* for the patient cohort under investigation as function of age at exposure, *e*.

Discussion

We introduce a novel method to approximate the reduction in cancer risk from diagnostic radiation exposure for patients based on their difference in life expectancy as compared to non-patients. We had investigated the topic before on an ad hoc basis (Smolarz et al. 1998), but this formal approach allows a general treatment of the topic. Performing the exact computation to yield the *PROLARM* value requires knowledge of the baseline cancer risk for the population under investigation as well as a choice for the excess relative risk (*ERR*). Calculation of the approximation *PROLARA* does not need those but only requires knowledge of the baseline and patient survival curves. Although the *PROLARA* concept was introduced here for only one particular patient cohort, it is transferable to any other.

In order not to rely solely on data from BEIR VII report, we tested *ERR* values from other sources like the (ICRP 2007) recommendations and could verify that the choice of values has only a minor influence on the quantitative results.

In terms of the number of radiation-induced cancers, our results indicate that even within a large cohort of patients exposed to any diagnostic procedure, cancer induction will be undetectable. A major portion of the total dose from diagnostic radiation exposures does not result in any increase in cancer risk at all. To quantitate that amount for other patient groups and diseases shall be the topic of future investigations.

Conclusions

Calculations of cancer risk from diagnostic radiation exposure must take into account the patient's prognosis, i.e. his or her reduced life expectancy compared to an otherwise comparable healthy individual. Our *PROLARA* concept allows for an approximation of the reduction in such risk resulting from any pathology. The approach is both practical and solid in that it only needs data on the patients' survival but is independent of values for the excess relative risk.

Abstract

It has been long known that patients treated with ionizing radiation carry a risk of developing radiation induced cancer in their lifetimes. Factors contributing to the recently renewed concern about the radiation induced secondary cancer include improved cancer survival rate, younger patients population as well as emerging treatment modalities that can potentially elevate secondary exposures to healthy tissues distant from the target volume. Gamma Knife radiosurgery stereotactically delivers a high single dose of external radiation to a small well-defined intracranial lesions. Due to a large amount of dose delivered in a single fraction (10–30 Gy) in stereotactic radiosurgery, dose outside the treatment volume is an important issue. The aim of study was to measure the out-of-field doses during the Leksell Gamma Knife Model C radiosurgery for children. The children population was chosen due to their higher susceptibility to radiation. Also, due to smaller size of their bodies, the larger doses are expected to all out-of-field tissues and organs than for adults for the same irradiation conditions. The purpose was to identify doses delivered to the eye lens, thyroid glands, breasts, sternum, upper abdomen, gonads and knees. According to the phantom measurements of Hasanzadeh et al., Phys. Med, Biol. 51, 4375–4383 (2006), the surface dose is comparable to depth dose and we placed dosimeters at the surface of the skin to measure depth (organ) dose. At the every point of the measurement two types of thermoluminescent dosimeters were placed, LiF:Mg,Ti and LiF:Mg,Cu,P and two radiophotoluminescent glass dosimeters (GD-352M). Preliminary results obtained for two children show very good agreement between different dosimetry methods but very different doses at the sites of the particularly organs, for instance for eyes 1.74% (patient A) and 2.02% (patient B) and for thyroid 0.53% (patient B) and 1.2% (patient A). Doses were expressed as percentage of the mean target dose.

A cohort study of childhood cancer following diagnostic X-rays

Abstract

Introduction: Ionising radiation is an established cause of cancer, yet little is known about the health effects of doses from diagnostic examinations in children. The risk of childhood cancer was studied in a cohort of 92.957 children who had been examined using diagnostic X-rays in a large German hospital during 1976–2003.

Material and methods: Radiation doses were reconstructed using the individual dose area product and other exposure parameters, together with conversion coefficients developed specifically for the medical devices and standards used in the radiology department. Newly diagnosed cancers occurring between 1980 and 2006 were determined through record-linkage to the German Childhood Cancer Registry.

Results: The median cumulative effective radiation dose was 7 μSv. 87 incident cases were found in the cohort: 33 leukaemias, 13 lymphoma, 10 central nervous system tumours and 31 other tumours. The standardized incidence ratio (SIR) for all cancers was 0.99 (95% CI: 0.79 1.22). No trend in the incidence of total cancer, leukaemia or solid tumours with increasing radiation dose was observed in the SIR analysis or in the multivariate Poisson regression. Risk did not significantly differ in girls and boys.

Discussion: Overall, while no increase in cancer risk with diagnostic radiation was observed, the results are compatible with a broad range of risk estimates.

Modelling electron and photon interactions for applications in brachytherapy

[4] Hospital Universitario La Paz, Paseo de la Castellana 261, 28046 Madrid, SPAIN

Abstract
One of the main purposes of specific brachytherapy techniques is positioning radiation sources inside or next to the tumour in order to minimize irradiation of surrounding healthy tissues while assuring delivery of high dose levels to the target volume. For example, Ru-106 plaques (Georgopoulos et al. 2003) and I-125 seeds (Thomas et al. 2008, Fuller et al. 2004) are commonly used for eye melanoma and prostate cancer treatments, respectively. Both applications require a precise dose distribution map defining the appropriate radioactive source implantation by minimizing damage to sensitive areas and concentrating dose inside the tumour volume. Following the method we recently published (Muñoz et al. 2008), here we apply energy deposition models at the molecular level for high energy electrons (0-3.5 MeV) and photons (50-100 keV) as a complementary tool for clinical treatment planifications. Briefly, this model consists of a new Monte Carlo simulation programme which as its input parameters uses the interaction probabilities (cross section) and energy loss distribution function we have previously measured or calculated. Special attention is paid to the effect of low energy secondary electrons which are the main responsible for induced damage via molecular dissociations. Detailed energy deposition images and radiation damage evaluation can be derived from the single particle track structures (photon and electrons) predicted by the present model.

Introduction
It is well known that during the irradiation of biological tissues by different kinds of incident radiation, a large portion of energy dose is eventually deposited in the target material by secondary electrons through multiple collisions. However, only recent discoveries have shown that molecular damage (e.g., molecular dissociations or strand breaks in DNA) can be induced very efficiently even by sub-ionising electrons through

molecular resonances (Boudaïffa et al. 2000, Huels et al. 2003) and dissociative electron attachment (Hanel et al. 2003, Abdoul-Carime et al. 2004). This new understanding of the importance of slow electrons for radiation interactions in biomaterials has still not found its way into diagnostic or therapeutic medical practice, where Monte Carlo calculations become faster by using sophisticated condensed-history algorithms while employing rather simple physical models. For example, most relevant interaction models disregard low-energy electrons by forcing them to instantly deposit all of their remaining energy below a certain cut-off value. This neglects the fact that collectively, low-energy secondary electrons can carry away a considerable amount of energy from the primary particle's path and produce molecular damages there.

The full Monte Carlo code Low-Energy Particle Track Simulation (LEPTS) has been specifically designed by us with the intention to translate the information available through recent investigations into the simulation approach. This is achieved by introducing substantially more details in the electron interaction model and giving a molecular-level description of the processes involved in energy degradation (ionization, neutral dissociation, electronic, vibrational and rotational excitation, and dissociative electron attachment). After having gathered the necessary input data for applications in a water environment (Muñoz et al. 2007b, 2008a), we here show two applications to brachytherapy treatments of our electron transport simulation.

First, LEPTS is used to simulate brachytherapy of the eye with the beta-emitter ^{106}Ru. Uveal melanoma and other malignancies of the eye can be effectively treated by surgically implanting a concave ruthenium applicator tightly around the eyeball (see fig. 1). Second, LEPTS is combined with PENELOPE (Baró et al. 1995) in order to simulate the interaction of photon radiation with water. In particular, we investigate photon radiation with an initial energy distribution as measured for ^{125}I seeds that are used for radiotherapy of prostate cancers but can also be employed for treating lesions affecting the eye. In both cases, the localized dose deposition by the radionuclide benefits treatment outcome by sparing healthy patient tissues while delivering high doses to the clinical target volume. At the same time, these isotopes are suitable for longer-term or permanent implants, assuring the radioprotection of medical staff and third persons in close contact with patients.

Computational methods

Monte Carlo code

Our simulation model LEPTS is implemented in a C++ programme and has been described in detail elsewhere (Muñoz et al. 2005, 2007a). Comparing to other existing Monte Carlo codes like EGSnrc (Kawrakow 2000), Geant-4 (Agostinelli et al. 2003), MCNPX (Hendrick et al. 2007), PARTRAC (Friedland et al. 1998, 2003) or PENELOPE (Baró et al. 1995), the main differences achieved with LEPTS in electron tracking are summarized as follows. First, the present code distinguishes different types of inelastic interactions (ionization, neutral dissociation, electronic, vibrational and rotational excitations where applicable) and treats them with specific routines, thereby permitting that absorbed energy dose be not strictly proportional to the total number of charge pairs generated. Secondly, input parameters (integral and angular-differential interaction cross sections and electron energy loss distributions) are based on experimental data whenever available, which are deemed to generally match the simulated conditions more closely than theoretical predictions and which do not depend on the approximations or simplifications needed for calculating data. Thirdly, all electrons are followed until their complete thermalization (meV range) in the irradiated material without any cut-off limits and without applying any range or energy limits for secondary electron generation. Additionally, all electron tracks are fully simulated and no kind of condensed-history algorithm is applied, implying that the exact locations of all energy losses (and their magnitude) or elastic collision events are revealed through the simulation. The present interaction model thus offers a description of radiation-matter interaction at the molecular level, providing details about interaction types and locations that can be used to identify the spatial distributions of certain events of interest, e.g. molecular dissociations or large-angle scattering events.

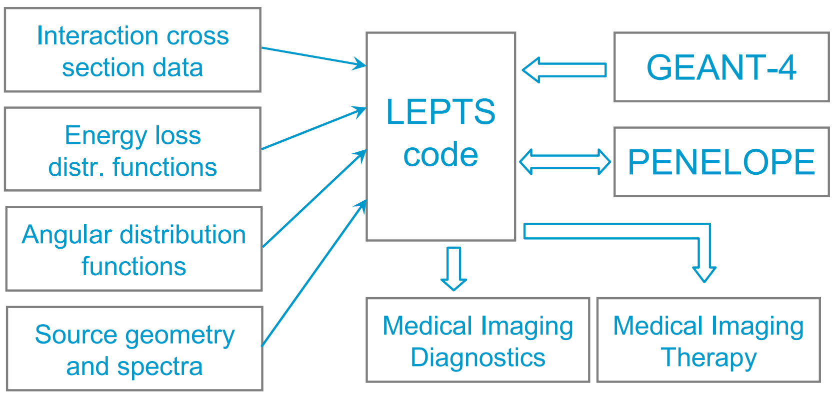

Fig. 1. Scheme of the Monte Carlo code LEPTS. The programme uses geometrical/material definition facilities, sampling mechanisms and graphical output generation from the GEANT4 toolkit but substitutes the electron interactions classes used there by two new routines corresponding to elastic and different kinds of inelastic scattering. Photon physics from either GEANT4 or PENELOPE can be used if necessary.

Incident radiation spectra

106Ru is a β emitter (endpoint energy 39.4 keV) that slowly (T1/2 = 373.59 d) decays to 106Rh. This has a half-life period of 29.8 s before decaying to 106Pd (stable) by different beta decays with a maximum energy of 3.541 MeV. Subsequent γ emissions from palladium have a maximum energy of 1.5623 MeV. The effective electron emission spectrum of the applicator for use in the simulation was determined experimentally by means of three silicon (SiPAD) detectors measuring in coincidence (Muñoz et al. 2008b). The lowest-energy electrons emitted directly from ruthenium are absorbed within the applicator material (see fig. 2b), reducing the applicator's emission to the keV-MeV spectrum of its daughter nucleus rhodium.

Photon emission spectra that were measured with standard solid state spectrometers (Muñoz et al. 2008b) in order to check for possible contamination of the source revealed gamma energies in excellent agreement with the disintegration scheme. However, in order to quantitatively relate electron and photon radiation, relative intensities of the gamma emissions were taken from the Lund Nuclear Data Service (Chu et al. 1999).

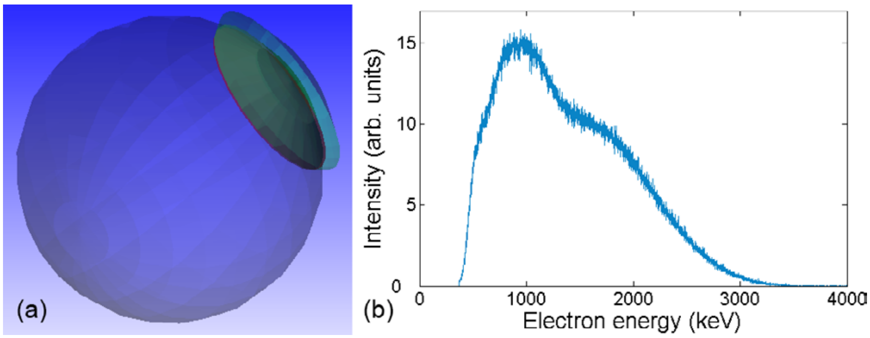

Fig. 2. Ru/Rh applicator used in the simulations: (a) Geometric scheme of the eyeball with the applicator (diameter: 12mm). (b) Experimental β emission spectrum of the applicator.

^{125}I decays with 100% probability to the 35.49 keV state of ^{125}Te by electron capture with a 59.408 day half-life period. There are no transitions to the fundamental level of Te-125. Due to the subsequent relaxation of nucleus and shell, a gamma and X-ray photon emission takes place which is considered as the primary radiation in this model. A standard calibrated solid state Si(Li) spectrometer has been used to determine the energy and intensity of the photons emitted by a ^{125}I brachytherapy seed (see Fig. 3). A representative spectrum shows the γ peak and various X-ray lines in the range 27-32 keV of tellurium. Additionally, we observed X-ray lines between 22-26 keV with an intensity comparable to some of the photons emitted by Te which are attributed to silver (present as the core of the seed onto which the radioactive iodine is adsorbed). These "contaminations" of the spectrum need to be taken into account for realistically modelling applications in brachytherapy (Rivard et al. 2004), and are thus included.

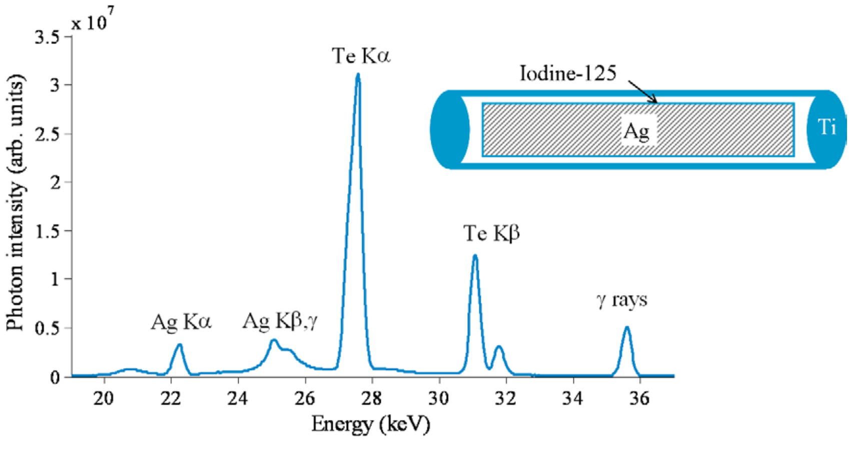

Fig. 3. Photon emission spectrum of an I-125 seed (Amersham Health model 6711, see scheme) measured in perpendicular geometry. Gamma photons (35.49 keV) produced during ^{125}I/^{125}Te-decay as well as the most intense Kα and Kβ X-rays of Te are observed. Additional X-rays at about 22keV and around 25-25.5 keV can be attributed to silver.

Interaction data for electrons in water

The total and partial cross sections needed in order to follow different electron scattering processes in water were obtained from experimental results whenever possible.

Total electron scattering and integral ionization cross sections in water vapour were previously measured between 50 eV and 5 keV (Muñoz et al. 2007b) with a transmission beam technique and using synchronized electron and ion extraction pulses, respectively. Below 50 eV, data from Čurík et al. (2006) and Szmytkowski (1987) (total CS) and Straub et al. (1996, ionization) were used. For elastic collisions and the remaining inelastic channels (rotational excitation for applications in the gas phase, vibrational excitation, electronic excitation, dissociative electron attachment, neutral dissociation), integral CS were derived by combining experimental data (Brunger et al. 2008, Thorn et al. 2007a,b, Itikawa and Mason 2005, Kedzierski et al. 1998, Harb et al. 2001, Cho et al. 2004) with theoretical calculations that were carried out with an optical potential method based on an independent atom approximation including screening corrections (details are described in Blanco and García 2003a,b and 2007). The theoretical total cross sections show very good agreement with experimental ones in the overlapping energy range > 10 eV, hence confirming the validity of the approach and indicating calculated elastic and inelastic CS to be trustworthy as well. For high energies, the electron-molecule collision can be treated as a plane wave interaction with a sum of atoms in the framework of the first Born approximation. Integral elastic and inelastic interaction CS can then be represented by simple energy-dependent formulae (Inokuti 1971, García and Blanco 2000). For want of other data, this method was used at energies greater than 10 keV. Angular distribution functions for scattered electrons were taken from our calculations.

Results and Discussion

Ru-106 plaque therapy

Using a generic setup frequently found in brachytherapy of the eye with concave Ru/Rh plaques (sketched in fig. 2), radiation-induced processes in the volume of interest – the eyeball approximated by liquid water – have been simulated. In this case, the incident photons where simulated using the photon interaction processes integrated in GEANT4. Once a secondary electron is generated, it is further tracked using LEPTS, identically to primary electrons. This permits obtaining the exact location of each interaction event as well as the type of collision produced, the energy deposited, the change of momentum suffered by the photon or electron, and the energy and direction of the secondary electron produced in case of ionizations as the programme output. Figure 4 shows a 2D projection of a small example data set obtained. Each coloured point indicates an inelastic interaction event. Figure 5 shows lateral and transversal sections through the energy deposition map corresponding to the same situation, calculated after simulating approximately 2×106 primary particle histories. The relative depth dose curve along the central axis obtained after normalization (100% at 2 mm depth) is shown in fig. 6. It can be seen that even though the dose gradient is very steep within the first few mm inside the eye, there is still an appreciable amount of energy deposited in greater depths (e.g., ~ 16% in 1 cm depth and ~ 4% in 2 cm depth) due to the applicator geometry (curved surface), the greater penetration of incident photons (compared to electrons which account for the main dose in the entrance region), and secondary electrons depositing small amounts of energy in multiple collisions while slowing down continuously.

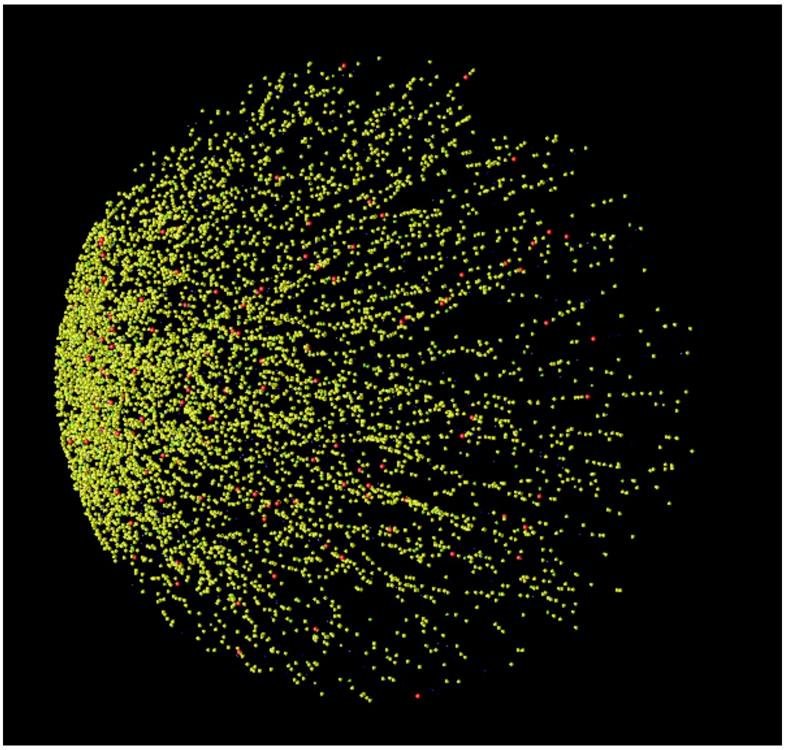

Fig. 4. Map of interactions produced inside the eyeball when irradiated with a Ru/Rh plaque from the left. Inelastic scattering events are colour-coded as follows: yellow, ionization; chartreuse, neutral dissociation; green, dissociative electron attachment; blue-green, electronic excitation; light blue, vibrational excitation; red, Auger electron emission. Photon-induced events are not explicitly shown but their main effect is to generate high-energy secondary electrons which are then followed identically to primary electrons.

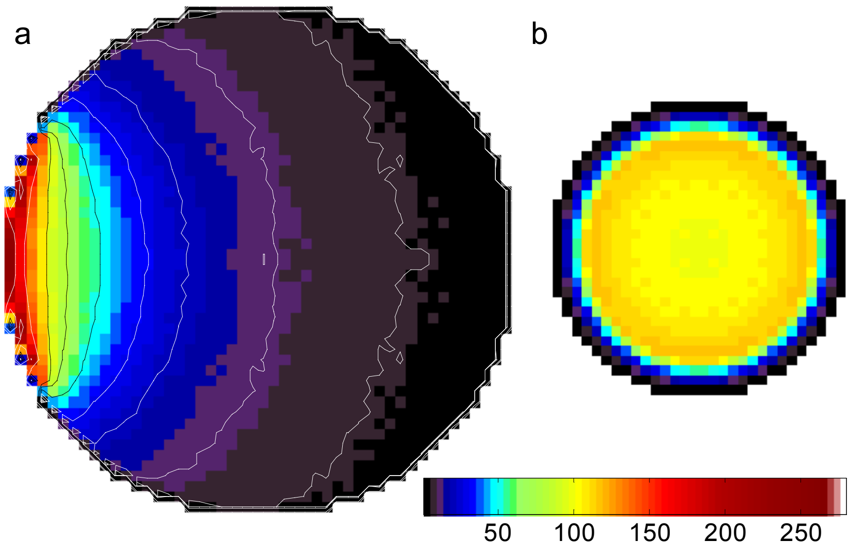

Fig. 5. Relative dose distributions (normalized to 100% in 2mm depth at the central axis) produced by the ^{106}Ru plaque in the eyeball (voxel size: 0.5 mm). (a) Lateral section through the central axis with 200%, 150%, 100%, 75%, 50%, 30%, 20%, 10% and 5% isodose lines shown (left to right). (b) Transversal section in 2mm depth. Both distributions use the same colourmap.

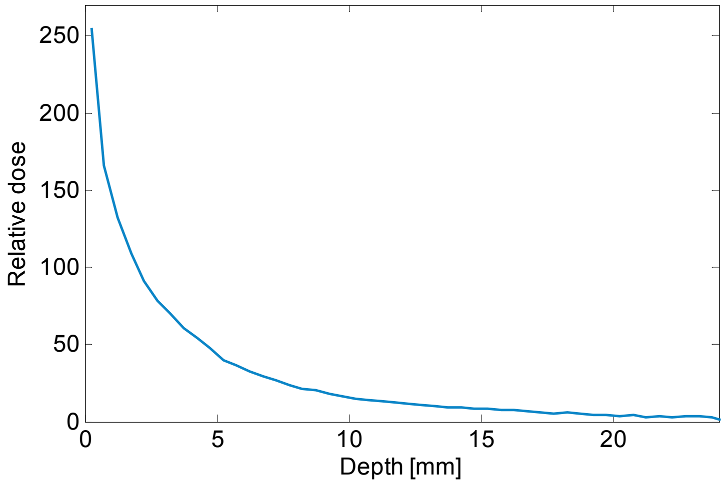

Fig. 6. Relative depth dose curve obtained in the water sphere along the central axis of the applicator. Normalization as in fig. 5.

I-125 seeds

Fig. 7. Simulation of 100 000 photons emitted from a 4 mm (diameter) disk according to the energy distribution measured for I-125 brachytherapy seeds. The simulated volume consists of 10x10x10cm^3 of water vapour at a density of 0.7320 g/cm^3. Different types of interactions are colour-coded as follows: red, photoelectric effect; green, Compton scattering; blue, Rayleigh scattering.

Using LEPTS in combination with PENELOPE (for handling all photon interactions), we simulate the interaction processes induced in water vapour when exposed to photon radiation according to the emission spectrum measured for 125I seeds. The resulting interaction map with H2O molecules, at a density similar to that of liquid water, is shown in Fig. 7. It can be observed that in the geometry used, the photon beam remains laterally well defined, however small contributions to energy deposition can still be found near the boundary of the simulated volume. Photon interactions are coloured according to the type of event produced. It can be observed that photoeffect (red dots) prevails for 125I in water (which, for many purposes, is an acceptable approximation for human tissue), indicating that the main effect of the incident photons is to generate high-energy secondary electrons. This highlights the necessity to include accurate electron interaction data and models into simulation approaches for medical applications, even if the primary radiation consists of photons as with I-125.

In figure 8, one photoelectron track, shown from its generation until complete thermalization, illustrates details of the energy degradation mechanisms. As can be seen, the secondary particle undergoes successive different inelastic interactions with target molecules and thus deposits energy at many points along its track. Furthermore, still more electrons are generated by ionization events.

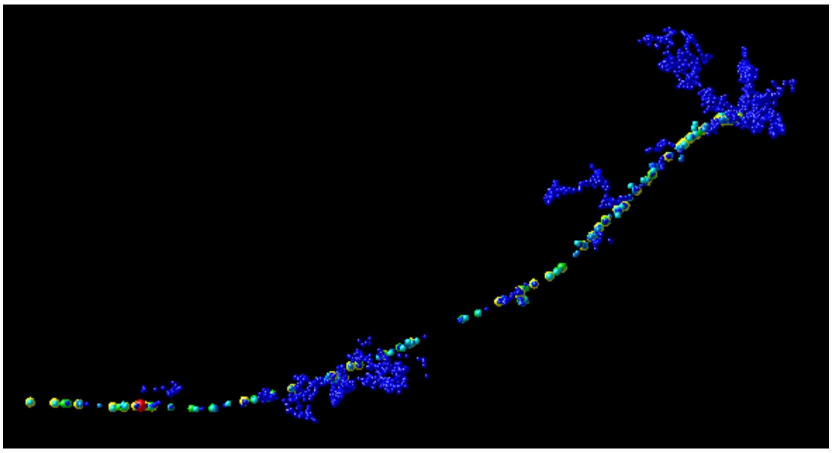

Fig. 8. Example of a photoelectron trajectory (from left to right) showing details about the electron-molecule interactions produced. Collisions are depicted using orange (ionization), yellow (neutral dissociation), green (electronic excitation), cyan (vibrational excitation), light blue (rotational excitation), and dark blue (elastic collision). For clarity, only some of the numerous elastic collisions are shown.

Fig. 9 depicts the energy deposition corresponding to a parallel photon beam of 4 mm diameter penetrating water at a density of 0.7320 g/cm^3. Most of the incident energy is lost immediately after entrance into the medium. 58.4% of the total energy is deposited within the first 2 cm, and 90% of the energy is deposited within 5.1 cm.

Conclusions

Brachytherapy of many tumours requires increased spatial precision due to the sometimes small dimensions of the treatment volume and the close proximity of organs at risk. A high accuracy energy deposition model may thus improve dose calculations and, consequently, treatment outcome. Motivated by this, the recently developed model LEPTS, based on Monte Carlo simulation using critically selected input data, has been applied to determine the energy deposition in water of Ru-106 and I-125, two radionuclides commonly used in brachytherapy. The electron transport model provides detailed information about secondary electron tracks, energy deposition and interaction processes at the molecular level and may thus yield an improved picture of radiation damage in a biomedical context. In order to validate the present Monte Carlo approach, further studies will be aimed at a more realistic simulation of clinical treatments (prostate / eye cancers), including exact geometries of the relevant patient tissues.

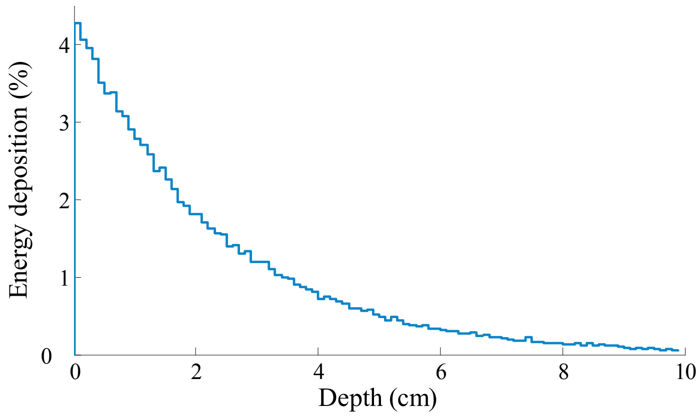

Fig. 9. Histogram depicting the energy deposition by an I-125 source in water vapour supposing parallel photon emission. All contributions for a given depth are summed. The total energy deposited in the simulated volume (same as fig. 7) is normalized to 100%.

Usefulness of specific sensitivity factors of radionuclide calibrators used in nuclear medicine

Bochud, François; Laedermann, Jean-Pascal; Baechler, Sébastien;
Kosinski, Marek; Wastiel, Claude; Bailat, Claude
Insitute of Radiation Physics, UNIL / CHUV, SWITZERLAND

Abstract

In nuclear medicine, the activity of a radionuclide is measured with a radionuclide calibrator that has often an efficiency factor independent of the container type and filling.

To determine the effect of the container on the accuracy of the activity injected to the patient, we simulated a commercial radionuclide calibrator and 18 container types representative of the clinical practice. The instrument sensitivity was computed for various container thicknesses and filling levels. Mono-energetic photons and electrons as well as five common radionuclides were considered. The quality of the simulation with gamma-emitting sources was validated by an agreement with measurements better than 4% in four critical situations.

Our results show that the measured activity can vary up to a factor 2 depending on the type of container. The filling and wall thicknesses only have a marginal effect for radionuclides of high energy but could induce differences up to 5%.

We conclude that dose calibrators used for clinical applications should have efficiency factors specific to a given container type.

Introduction

The dose received by the patient in nuclear medicine depends on the administrated activity. The optimization principle of radiation protection states that this dose should be kept as low as reasonably achievable . For diagnostic exams, "reasonably" means that the dose should not be so low as to prevent the searched pathology to be detected. In radiation therapy, this implies that the dose should be high enough to cure the disease but as low as possible for the healthy tissue. Whatever the context, the first step is to measure the activity with a sufficiently low uncertainty.

What is commonly understood by "sufficiently low uncertainty" depends on the context. Measurement uncertainty (defined here and in the rest of the text as one standard deviation or k=1 [1]) is typically below 1% for primary laboratories operating with liquid sources of well-defined geometries. At the clinical level, activities used for diagnostic examinations are generally administrated with uncertainties smaller than

10%. For radiotherapy treatments, many would like to reach values similar to the common practice of external radiotherapy, around 3% [2].

Prior to injecting patient the activity of radiopharmaceuticals is verified most of the time by re-entrant ionization chambers called radionuclide calibrators or activimeters [3]. It is not clear if activity measurements performed in nuclear medicine departments should take specific account of sensitivity factors specific to the radionuclide, container type (syringe or vial) and measurement geometry. Several radionuclide calibrators found on the market are used with sensitivity factors only dependent on the radionuclide whatever the container type or filling level. Knowing that some manufacturers do provide their instruments with more specific geometric factors, it is of interest to estimate the relevance of this approach for a wide range of conditions encountered in practice.

The goal of this study was to estimate the effect of specific sensitivity factors on the measurement uncertainty for a variety of measurement geometries. We used a Monte Carlo (MC) simulation method that was first validated by comparison with a series of measurements. MC simulations were then performed for different specific radionuclides used in clinic in order to estimate the variation of the sensitivity factor (1) for a large range of container types, (2) for different filling levels and (3) for different container thicknesses. Finally, we performed the same MC simulations for pure photon- and electron-emitters at fixed energies in order to explain the observed results with the specific radionuclides.

Material & method

Dose calibrator

We considered the dose calibrator Veenstra model VDC-405 [5]. The sensitive volume is filled with gaseous argon at a pressure of 12 bars. The chamber walls are 2.5 mm aluminum. The chamber is protected against contamination by a 3.3 mm Plexiglas sleeve, and from external radiation by 3.0 mm of lead.

The details of the measurements of Y-90, Sr/Y-90 and F-18 can be found in [6]. The measurements of Co-57 and Co-60 were performed in the frame of verification procedures at the Lausanne University Hospital. The measurements of I-131 and Tc-99m were collected from various follow up measurements of the dose calibrators at the Lausanne University Hospital.

Monte Carlo code

In this work, we used the version 4.8 of the Monte Carlo code Geant. In our previous publication, we used the version 3 [4]. The main improvements of the present version are the lowering of the cut thresholds, which affects particularly the low density materials such the interior of the chamber, and a better treatment of the ionization process, with the LowEm package. The new version is written in C++, and allows an easier implementation of the geometry. The version 4 gives actually a relative discrepancy between simulation and measurement about two times lower than the version 3 for gamma emitters.

Simulated sources

We simulated mono-energetic sources of pure photon emitters from 20 keV to 4 MeV and of pure electron emitters from 50 keV to 4 MeV. We also simulated five gamma-emitting radionuclides (Tc-99m, In-111, I-123, I-131, Cs-137), one beta plus emitter (F-18) and one pure beta minus emitters (Y-90).

Containers geometry

A representative sample of each container was physically measured in order to estimate the variations of the geometries. The containers were first cut open to allow the measurements of inner diameters and thicknesses. Syringes are manufactured by plastic injection and do not suffer from large geometry variations. The glass vials on the other hand are more prone to variations. However, the measurement in the dose calibrator has a cylindrical symmetry. The variation of the thickness of a vial along its circumference is typically ±0.2 mm. The main geometrical characteristics of the containers used in this study are presented in Table 1.

Table 1: Characteristics of the containers investigated in this study. ID letter "V" is for vial and letter "S" is for syringe.

ID	Long name	Material	Internal diameter [mm]	Height [mm]	Volume [ml]	Standard filling [ml]
V01	Penicillin vial	glass	25.3	53.2	10.0	5.0

S09	Terumo 10ml	plastic	17.4	91.0	10.0	10.0

Parameters tested

For each container, we started by simulating the standard filling condition used in clinic. We then simulated the situation corresponding to the full filling condition and the half-standard condition. Finally, in order to estimate the response of the instrument after injection to the patient, we simulated the situation in which the container only contains a small fraction of the source at its bottom.

Because our physical measurements of the containers showed that a variation of the wall thickness of typically 0.1 mm was encountered in the practice, we also simulated the dose calibrator response to a variation of this amplitude.

Validation of the simulations

Only considering the results of Monte Carlo simulations without comparison with actual measurements is meaningless. We therefore compared our simulations with real measurement in the standard filling conditions. We used container V05 for the Sr-90/Y-90 and the Y-90 sources and container V01 for the other nuclides (Tc-99m, In-111, I-123, I-131, Cs-137, F-18).

Before doing this, we have to notice that a radioactive source induces a current in the ionization chamber that is proportional to the amount of energy deposited in the sensitive volume. During a measurement, the actual current is usually not directly available: The dose calibrator transforms the current by applying a specific calibration factor implemented by the manufacturer in order to display the estimated activity. For the Monte Carlo simulation we have directly access to the energy deposited in the sensitive volume per unit of activity in the source.

The comparison between experimental and simulated results was based on responses normalized to a reference Cs-137 solution in the V01 geometry. All experimental measurements were performed by forcing the dose calibrator calibration factor on the "Cs-137 position".

The metrological traceability of the measured source was guaranteed by a measurement of each source by a secondary standard instrument of our laboratory directly linked to the international reference system (SIR) of the Bureau International des Poids et Mesures (BIPM).

Results & discussion

Validation of the simulations

Experimental and simulated responses normalized to Cs-137 are presented in Table 2. It can be seen that the agreement is better than 4% for the investigated gamma emitters and virtually the same for the beta plus emitter (F-18). The result is however not as good for the two beta minus sources (Y-90 and Sr-90/Y-90) with a statistical difference of 18%.

We can therefore conclude that our simulation model is adequate for gamma-emitting sources while probably in need of improvement for the beta plus emitters.

Table 2: Comparison between measurements and simulations normalized to the Cs-137 condition. An absolute value of z-score below 1.96 indicates no statistical difference at the 95% confidence level.

Condition	Cs-137	Co-57	Co-60	Tc-99m	I-131	F-18	Y-90	Sr-90/Y-90

Sensitivity factors in standard conditions

As an example, Figure 1 presents the dose calibrator sensitivity for monoenergetic photons and electrons. The sensitivity is defined as the energy deposited in the sensitive volume divided by the kinetic energy of the emitted radiation. For photons, it can be seen that the sensitivity peaks above 1% at about 40 keV and plateaus at around 0.1% for higher energies. The sensitivity for electrons is 2 to 3 orders of magnitude below the photons and monotonically increases with the energy. Below around 3 MeV, the electrons only deposit their energy through the bremsstrahlung produced in the source or the instrument surrounding. At 4 MeV, the sensitivity suddenly increases because the electrons start to have energies sufficiently high to directly interact with the sensitive volume.

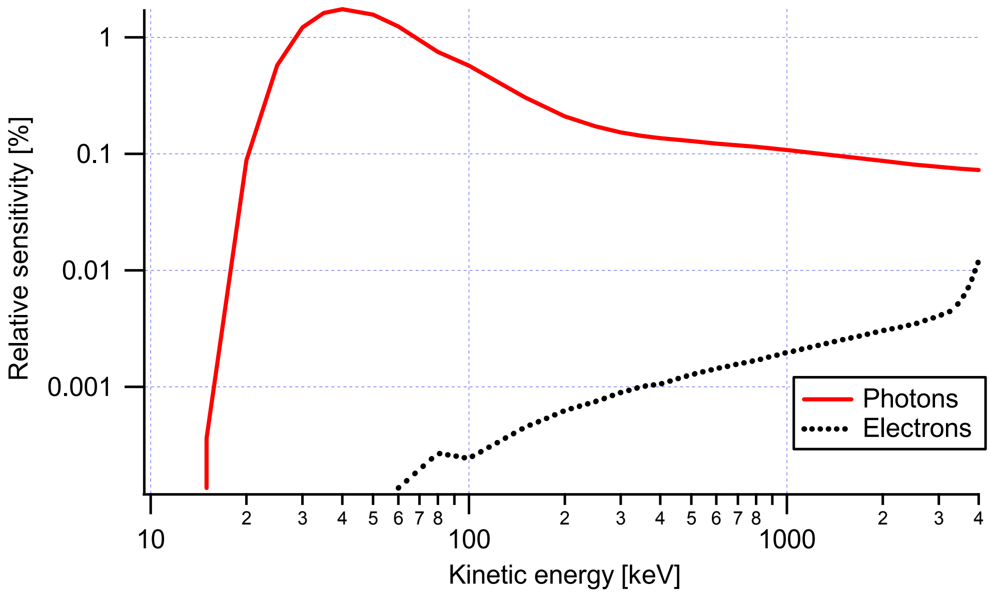

Figure 1. Example of the dose calibrator sensitivity for monoenergetic radiations (container V01 in standard filling conditions; glass density 2.33 g/cm^3).

Figure 2 and Figure 3 show the sensitivity factors of the instrument for each container of interest in standard filling conditions. The values have been normalized to the one of vial V01 with standard filling.

One can see that the sensitivity for photon radiation is smaller than 1% for glass containers. For plastic syringes it is slightly higher with values between -3% to +4%. For electrons, the change of container is relatively modest for the glass vials (V01 to V06) with a variation that can rise up to 16%. For plastic syringes, a change of container for energies smaller than 1 MeV could induce a variation of sensitivity up to 50%. The most dramatic effect arises for plastic syringes containing high-energy electrons for which the sensitivity can increase up to a factor 12.

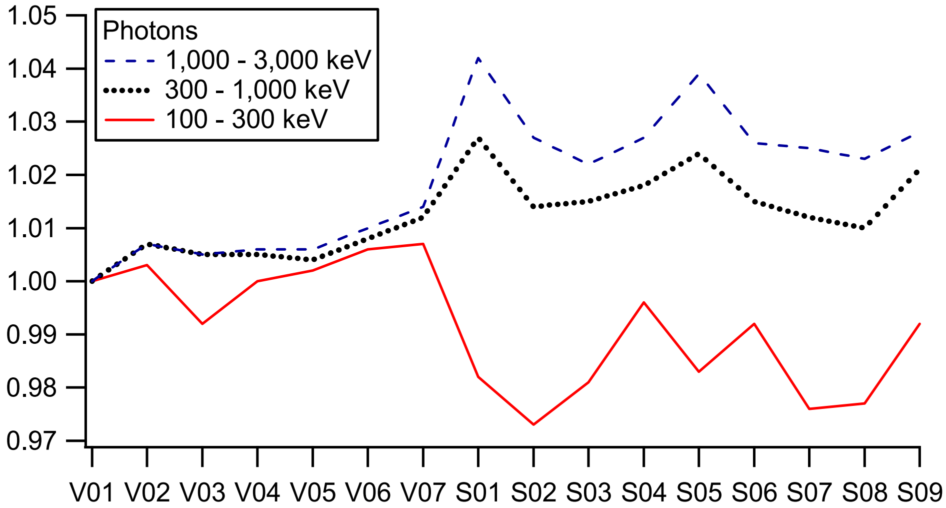

Figure 2. Relative sensitivity factors to photons normalized to container V01 averaged over three ranges of photon energies. Standard filling conditions.

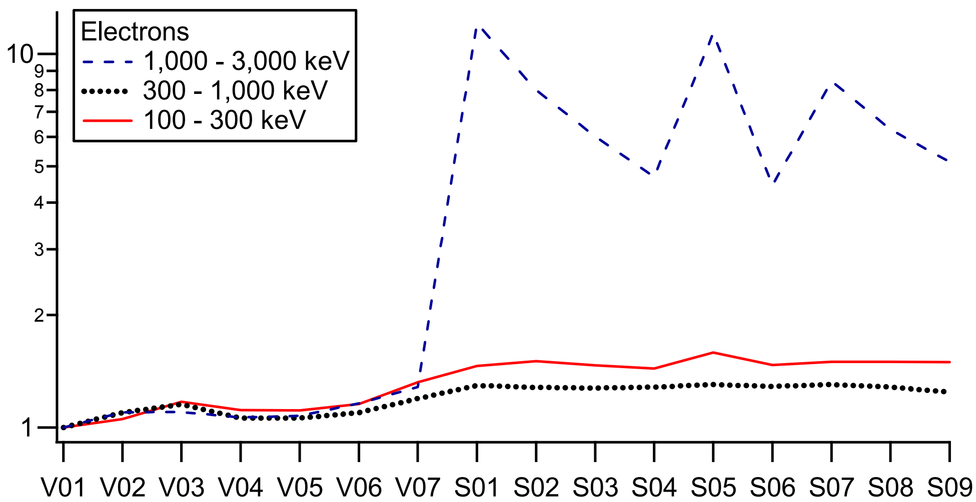

Figure 3. Relative sensitivity factors to electrons normalized to container V01 averaged over three ranges of photon energies. Standard filling conditions.

Figure 4 shows the relative sensitivity factors for a selection of radionuclides at standard filling level. It can be seen that the type of container has the least effect for Tc-99m, F-18 and Cs-137 with variations lower than 4% for glass vials and up to 8% for plastic syringes. For the other nuclides, the variations are also smaller for glass vials than for plastic syringes. However they can go up to a factor of 2.4 for I-125.

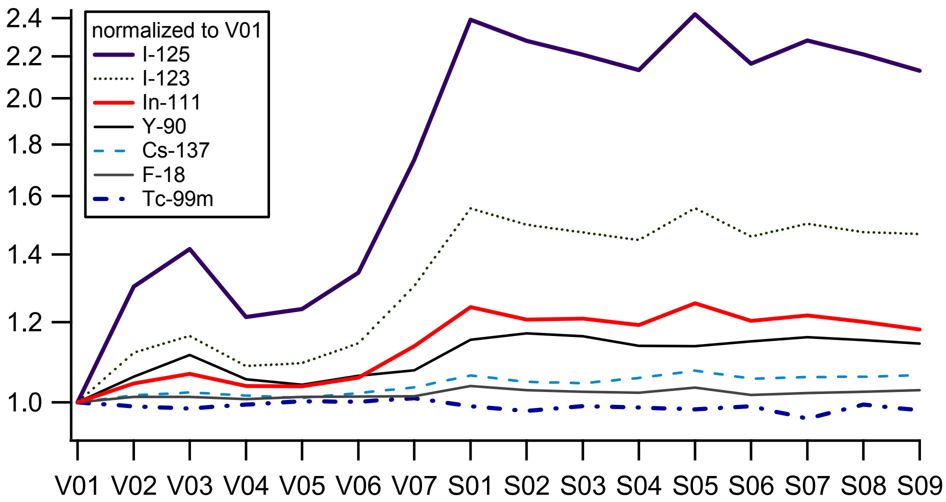

Figure 4. Relative sensitivity factors to different nuclides normalized to container V01. Standard filling conditions

Effect of filling level

The sensitivity factors were computed for different filling conditions as an average of the corresponding energy range for the mono-energetic photons and electrons sources and for the individual nuclides. Each sensitivity factor was normalized to the sensitivity factor in standard filling-condition with the same container (obtained in the previous section) in order to only show the effect of the filling level.

Many containers have standard-filling conditions that are close to their full capacity. This is especially the case for syringes for which a full filling can only be up to 50% above the standard level. In this case, totally filling the container changes the sensitivity factor less than 1% for monoenergetic photons and less than 5% for monoenergetic electrons. The glass vials are usually not filled at their maximum capacity and some of them have a maximum level that can be up to 5 times the standard level. However, the effect on the sensitivity is well below 1% for photons and below 7% for electrons.

The same simulations computed for our set of nuclides show that a full filling of the containers induces a variation on the sensitivity factor less than 3% in most cases. The only exception is for the glass vial V01 totally filled with F-18 (decrease of the sensitivity factor by 9%) and glass vial V04 filled with In-111 (increase of the sensitivity factor by 19%).

Filling only half the containers has a negligible effect on the sensitivity factor for monoenergetic photons: the variation is within Monte Carlo uncertainties (below 1%). For monoenergetic electrons, the effect is significantly higher with a variation up to 10%.

For our selection of nuclides, filling half the containers typically changes the sensitivity factor by less than 4%. The only exception is for glass vial V05 containing Y-90. In this case, the sensitivity decreases by 12%.

We finally computed the sensitivity factors for the container containing only a small volume of radioactive liquid. The effect is small for monoenergetic photons (smaller than 3%). However, for monoenergetic electrons, it can be up to 40%. For our set of nuclides, the effect really depends on the container and the nuclide. The effect is less than 5% for all nuclides except for Y-90 in all glass vials where the effect typically 25%.

Effect of wall thickness

The sensitivity factors were calculated for a variation of wall thicknesses of 0.1 mm. The effect on the sensitivity factor is negligible for all monoenergetic photons and low-energy monoenergetic electrons (below 1 MeV). For electrons in the 1 MeV-3 MeV energy range, the induced effect on the sensitivity factor can go up to 4%.

A change of 0.1 mm of the container wall thickness has a negligible effect for each nuclide of our list. The only exception is I-125 in glass vials for which a difference up to 4% is observed.

Conclusion

Our Monte Carlo model has been validated by measurements for gamma-emitting sources: the observed difference is below 4%. For pure beta emitters, the simulation is not as good and the observed difference is almost 20% for Y-90.

For pure gamma-emitting sources of energies higher than 100 keV, using the calibration factor of one container and measuring with another has a negligible effect with glass vials and an effect up to 4% with plastic syringes. Doing the same with pure beta emitters has a much stringent effect: for glass vials this can induce an error of about 15%, whereas for plastic syringes, the error can be up to 50%. Simulating the same operation for actual sources can produce very small effects for relatively high-energy gamma emitters whereas the error can become higher than a factor 2 for a nuclide such as I-125.

The amount of radioactive liquid actually contained in the container has typically an effect of about 5% for gamma-emitting sources. For electron emitters, the effect is typically twice higher.

Using the dose calibrator for measuring the fraction remaining in a container after injection is not disastrous for gamma emitters: the error is typically within 5%. However, the effect can be much higher for pure beta emitter, with value going up to 25%.

The imperfections of the container wall thicknesses only have negligible effect on gamma emitters of energies above 100 keV. A variation of 0.1 mm in the wall thickness can however induce an error of the order of 5% for high-energy beta emitters or for low-energy gamma emitters such as I-125.

These results therefore suggest using a specific calibration factor for each container and filling level. This is especially the case beta-emitting sources and plastic containers.

Abstract

Y90-microsphere selectively intravascular radiation therapy (SIRT), which is radiation embolism, becomes an alternative method for advanced hepatic malignant control in hepatic metastasis and primary hepatoma. Y90 with pure beta ionizing radiation is an available therapy radionuclide in clinic. In southern Taiwan, Y90-microspheres SIRT in hepatic malignant control is a beginning technique. During past year, we have total six-case procedures. Among them, a uremia patient has colon cancer and massive hepatic metastasis. Due to failure of treatment response to conventional chemotherapy and target therapy, she is advised to receive Y90 microspheres SIRT. Under inform consensus and document approval, the survey procedures including hepatic angiography, abdominal CT and Tc99m MAA shunt study are performed before treatment. Base on metastatic tumor burden and calculated dosimetry, 2.5 GBq of Y90 microspheres is arranged to deliver to hepatic lobe. After successful technique performance, the patient received regular dialysis for medical care in the next two day after radiation embolism treatment. First, we arrange independent dialysis space for this special medical condition in our hospital. For environmental exposure dose evaluation, we directly measure X ray from patient by GM counter. There is inhomogeneous radioactivity distribution in patient's body for example: higher in liver, heart and brain. The exposure dose does not exceed 0.15 mR/ h in one meter distance from body surface. Initially, contamination of radionuclide Y90 in dialysis equipments is a potential issue. However, there is no significant radioactive residual in dialysis tube as waste storage in nuclear medicine department. In conclusion, dialysis is not a contraindication post Y90 microspheres radiation embolism treatment. In this special medical condition, we suggest arrangement of relatively independent dialysis space and awareness of nursing care as patient with conventional nuclear medicine procedure.

Introduction

New radionuclide treatment becomes growing in recent year, while radioiodine has been familiar with ablation and treatment in differentiated thyroid cancer over fifty years. Yttrium90 (Y90) is a pure β-emitter with a physical half-life of 64 h and decays to stable zirconium-90 (Zr90). The average energy of the β particles emitted from 90Y transformation is 0.94 MeV with a mean tissue penetration of 2.5 mm. Y90 microspheres selective internal radiation therapy (SIRT) is a novel approach approved in 2002 by the U.S. FDA for the regional treatment of colonic hepatic metastasis [1, 2]. Recently, unresectable hepatocellular carcinoma is also one of indications [3-5].

As we know, elimination of radionuclide from body is dependent on function of kidney and liver. Therefore, patients with end stage renal disease, uremia become special issue of radiation protection in clinic. Almost non- occupation dose related medical staff concerns radiation exposure or contamination when they care patients with radionuclide treatment. Browsing previous literatures in radioiodine treatment patients with dialysis, there are not few of publications [6-12]. However, it seems few of documents to consider the issue of radiation protection associated with Y90 microspheres SIRT and dialysis. In southern Taiwan, Y90-microsphere SIRT in hepatic malignant control is a new development technique. During past year, we have total six-case procedures. Among them, a uremia patient has colonic massive hepatic metastasis. Herein, we share our primitive experience of clinic hemodialysis scheduling and radiation protection for non-occupation dose related medical staff during hemodialysis after Y90-microsphere SIRT.

Material and methods

This is a 68-year-old female patient with history of uremia under regular hemodialysis and diagnosis as advanced descending colonic cancer recent year. Initially, she received standard surgery and chemotherapy treatments. Unfortunately, progressive hepatic metastasis and minimal ascites were diagnosed by CT imaging. Due to unresectable metastatic massive mass and failure respond to chemotherapy, Y90-microsphere hepatic radioembolization treatment was suggested. Under inform consensus and official approval of DOH in Taiwan, therapeutic procedure of Y90-microsphere SIRT was allowed to execute.

Before treatment, several evaluations as cancer condition by ECOG, the hepatic function and hepatic vascular anatomic survey by angiography were performed to exclude improper patient. During first time angiography, prevent coil was set in pancreatico-duodenal arteries to avoid reflux. In the meanwhile, 99mTc-MAA was injected into hepatic vessels to simulate distribution of microspheres to evaluate exact tumor burden and detect hidden vascular shunt to avoid radiation complication. In our case, 99mTc-MAA scintigraphy showed an acceptable lung/liver shunt fraction (8%), less probability of radiation pneumonitis. For evaluation of treatment response, modern FDG PET/CT scan was arranged before 90Y-microsphere treatment.

Considering issues of efficacy and radiation protection, duration between secondary angiographic Y90-microsphere radioembolization and schedule of regular hemodialysis should be arranged carefully. After consultation with an Australian specialist, hemodialysis was performed before radioembolization procedure. And then the next following hemodialysis was arranged after 72 h later. Based on tumor burden and vascular shunting, therapeutic hepatic dose was delivery into left hepatic lobe with 2.5 GBq of Y90-microspheres.

The radio-pharmaceutics of Y90-microspheres was prepared in department of nuclear medicine, first. Plastic bottle of sterilized Y90-microspheres was transported to angiographic room carefully. In secondary therapeutic angiographic procedure, all of equipment, floor and bed should be covered by water-proof paper to avoid contamination of Y90 with β particle emitter. All of operative staff should wears prevent clothes, either. Radiation safety officers in hospital will check contamination during procedure. After procedure, patient was acquired bremsstrahlung imaging to identify location of Y90-microspheres in nuclear medicine.

After successful technique, the patient received regular hemodialysis in the next two days. Because of primitive experience, independent dialysis space was arranged carefully. Let other patients and nursing staff as far away as possible. Radiation safety officers provide environmental exposure dose evaluation. We measure one-meter distance exposure dose (X ray) and contact skin surface dose of patient by counter. Potential contamination in dialysis machine was survey as detail as possible.

About 4 weeks after treatment, follow-up FDG PET/CT scan demonstrated a dominant reduction of FDG avid metastatic mass in the left hepatic lobe. Unfortunately, the patient was expired due to infection at the 6th week after treatment.

Results

Treatment Response on FDG PET/CT

In figure 1, there is significant reduced FDG avidity in left hepatic lobe with previous Y90-microspheres delivery. Treatment response is demonstrated between pre and post treatment imaging of FDG PET/ CT.

In Angiographic Room

Base on exact preparation of radiation protection as standard protocol and careful catheter procedure by experienced radiologist, there is background environmental activity during counter measurement. In figure 2, angiographic therapeutic procedure and radiation protection equipments were shown.

Bremsstrahlung Imaging

In figure 3, Bremsstrahlung imaging (energy setting around 100 kev and acquisition by Angle gamma camera) demonstrated braking radiation of spectrum X ray from β particle emitter of Y90 via human body (water). Successful localization of microspheres in liver was identified on imaging.

In Hemodialysis Room

Space

The patient was arranged to stay in a corner of dialysis room and away from other patients and nursing staff as possible in our primitive experience. Figure 4 shows the environmental radiation detection.

Measurement

Dose distribution of one-meter distance exposure and skin surface was shown as figure. The maximum dose rate was found to be 0.15 mR/h at one meter distance from body surface and 5 mR/h at patient's chest surface respectively.

Base on bremsstrahlung imaging and direct counter measurement during hemodialysis, low energy X ray is still a source of external exposure for non-occupation dose related medical staff. Therefore, they should be aware of principle of radiation protection when they care patient closely. We consider lead-cloth wearing is not necessary.

Base on sterilization, hemodialysis equipment is closed system. Therefore, partial Y-90 microspheres via blood stay in exchanged tube and can't permeate through membrane. There is no issue of Y90-microsphere contamination in massive diluted dialysis solution. In fact, very low activity is measured in exchanged tube after dialysis.

However, any contamination of body fluid, as blood or urine from patient with Y90- microspheres treatment should be aware of prevention.

Storage of Y90 waste in nuclear medicine

All of residual waste were double packing with plastic bags and put into cages for a period of time for decay, then discharged as Taiwan's regulation.

Discussion

Y90-microsphere radioembolization treatment becomes a choice for hepatic metastasis or primary hepatocellular carcinoma in unresectable condition. More and more clinic application will happen in future day. Consideration of dose exposure of non-occupation dose related medical staff should be aware in the meanwhile. Exact radiation education and assessment of good-practice guidance of radiation protection will be helpful for new medical radionuclide treatment technologic development in clinic.

Although Y90 is a pure β emitter, low energy of X ray is still detectable in distance. There is a physic phenomenon, called "bremsstrahlung". Bremsstrahlung is also called as "braking radiation" or "deceleration radiation". It is electromagnetic radiation produced by the acceleration of a charged particle (β particle) when deflected by another charged particle, such as an atomic nucleus. Bremsstrahlung is a type of "secondary radiation" and has a continuous spectrum. The phenomenon was discovered by_Nikola Tesla during high frequency research he conducted between 1888 and 1897. In our cases, the β particles of Y90 through water of human's body will produce a spectrum of X ray. This phenomenon is demonstrated by gamma camera imaging. No matter why, there is still dose exposure measurement in body surface and one-meter distance away from surface. In comparison with radioiodine treatment, the issue of environmental dose exposure is less considerable. There is no suggestion of lead protection. In general, patient with Y90-microspheres radioembolization allow to stay a single-room ward, not radiation isolated ward. However, non-occupation dose related medical staff should be aware of radiation protection during close care of patient. There is similar protection principle when uremia patient with hemodialysis, as distance, time and shielding.

Contamination of body fluid from patient with radionuclide treatment will become an important issue in clinic care. However, we don't find significant contamination in hemodialysis device due to close system design. But there is still dose exposure in exchanged tube transiently. As our primitive experience, we suggest it seems not necessary changing dialysis schedule base on radiation protection.

Allowable doses to members of public are generally established at 2 mSv per year. Procedure of Y90-microspheres radioembolization potentially provides radiation exposure in non-occupation dose related medical staff. Education program of radiation protection is necessary for modern hospital workers to elucidate the spirit of ALARA.

Conclusions

hemodialysis is not a contraindication post Y90 microspheres radioembolization treatment. In this special medical condition, we suggest arrangement of relatively independent dialysis space and awareness of nursing care as patient with conventional nuclear medicine procedure.

Radiographer students learning dose management of the patients

Henner, Anja
Oulu University of Applied Sciences, FINLAND

Abstract
Radiographers have their Bachelor degree in Universities of Applied Sciences in Finland. It takes 3,5 years and is 210 ECTS. The students have 75 ECTS (2000 hours) in clinical practice in radiological departments. The students (N=21) collected patient data during the clinical practice (16 chest, 1 sinus and 4 lumber spine). The students collected data of ten patients: height, weight, sex, kV, mAs, focus to skin distance, added filtration and equipment. Each student counted for the patients ESD (Entrance surface dose) and compared them to the reference levels given by Radiation and Nuclear Safety Authority in Finland (STUK). Students managed the ESD dose calculation from air kerma (Kinetic Energy Released in Matter) very well. All have sent their signature reports with results and remarks to the department where the data was collected. Radiographers in clinical practice use these reports as a part of QA-system and clinical audit's self-assessment material.

Introduction
In Finland the Radiographers have their Bachelor degree in Universities of Applied Sciences. The Finnish credit system has been updated to comply with the European Credit Transfer and Accumulation System (ECTS) so that the Finnish credits are equivalent to the ECTS credits. The reform came into force on the 1st of January, 2005. Higher education studies are measured in credits (cr). Courses and study modules are credited according to the amount of work they require to attain the required objectives. A student's average study effort of 1,600 hours required for the completion of studies during one academic year corresponds to 60 credits.

It takes 3,5 years (210 ECTS) to get the Bachelor in degree programme of Radiography and Radiation Therapy. The students have 75 ECTS (2000 hours) in clinical practice in radiological departments having all modalities which are used in radiology including also nuclear medicine and radiotherapy. The students start their clinical practice in the end of first year in Health Centres where often only one or two radiographers are working. This offers very individual guidance to the student and possibility to plan the clinical practice together with the staff, teacher and student. The students write a reflective diary in every clinical practice period. They have also different tasks in order to deepen their skills and theoretical knowledge in some area during the practice. The tasks are more meaningful to the student if the results of it can be used in order to develop the practise, not only to make the tasks because they have to be done because of the demands of the curricula.

The principles of justification, optimisation and dose limits for the staff and general public, and the establishment and use of diagnostic reference levels (DRL) are important part of the European Medical Exposure Directive Council Directive 97/43. It has been implemented to Finnish legislation by the statement of the Ministry of Social and Health 423/2000. Dose limits do not apply to patients undergoing medical exposure but the exposures must be justified by a net benefit to the patient before making the decision about exposure. When performing x-ray examinations the exposures must be optimised by maximising radiation protection. The balance between dose and image quality taking in to account the indication for the examination must be found with every patient and every time when having an exposure to a patient. The image quality needed may be high, medium or low. (Bush 2004, International Commission on Radiological Protection 93 2004.)

It is considered that patient protection can be improved by continuously comparing local practice with the dose reference levels of doses to patients (International Commission on Radiological Protection 73 1996). Leitz (2003) believes in a five percent dose reduction, which means 800 manSv/year in Scandinavia. All measured doses should be saved together with the individual exposure data (kV, mAs, grid use, image receptor system and the generator). This is important because the dose received by a patient should be estimated afterwards (Sosiaali- ja terveysministeriö 2000) and according to many studies, the effective dose as well as ESD varies widely - even in the same examination and with similar imaging receptors (e.g. Egbe et al 2009, Willis 2009, Shaefer-Prokov et al 2008).

According to Finnish Radiation and Nuclear safety Authority in Finland (STUK) the doses of the patients must be monitored either as ESD (Entrance Surface Dose) or by DAP (Dose Area Product). The Entrance Surface Dose (ESD) can be defined as the absorbed dose to air at the point where the x-ray beam enters the surface of the patient stressed by the backscatter factor (from 1.29 to 1.46). The backscatter factor depends on the quality of the radiation beam (energy filtration of the x-ray beam and field size) (Harrison 1983, Tapiovaara 1985, Grosswendt 1990, Cranley et al. 1991, European Commission 1996, Harju et al. 2003). The unit for Entrance Surface Dose is mGy. The Dose-Area Product (DAP) is the absorbed dose in the air averaged over the area of the radiation beam multiplied by the area of the beam in the plane where dose is measured. It is normally given in $Gycm^2$ or $mGycm^2$. The dose-area is the same wherever in the beam it is measured as long as the chamber receives no scatter from the patient. Before use, the DAP meter must be calibrated. (Le Heron 1992, Toivonen et al. 2001)

The doses are monitored as an average of ten standard size patients at least every third year for typical examinations. Every year must be done some estimation. The normal size of adult patient is said to be 70 kg +/-15 kg. (STUK 2004.) These levels dose reference levels are not expected to be exceeded for standard procedures when good and normal practice is applied (Council Directive 97/43 Euratom). The dose reference level corresponds to the 3^{rd} quartile, 75% of individuals received a dose less than this value, i.e. these levels are expected not to be exceeded for standard procedures when good and normal practice regarding diagnostic and technical performance is applied (Office for Official Publications of the European Communities 1996, Council of the European Commission 1997). If the doses are too high, in the upper part of dose range, patients may get unnecessarily high doses and if doses are in the lower part, the image quality may be poor (Papadimitriou et al. 2001). It is therefore important to assess image quality in relation to patient dose and be able to get a striking and significant dose reduction.

Flat panel detectors (FPD, direct radiography, DR) offer possibilities for dose reduction but still having at least as good image quality as with computed radiography CR (e.g. Willis, Slovis 2004; McEntee et al 2006; ICRP 93 2004, Bush 2004). According to studies (e.g. Al Khalifah, Brindhaban 2004, Lanca, Silva 2008), lower levels of radiation dose settings can be established also for CR systems than the standard values used for film/screen systems to produce diagnostic images of equal quality.

By monitoring the doses regularly, the creping of doses higher (to reach the better image quality) can be found. The dose reference levels can also be reset on a lower level when having new, more effective detectors (Uffman et al 2008). This means higher DQE (Detective Quantum Efficiency) with better MTF (Modulation Transfer Function).

Material and methods

The first year radiographer students (N=21) collected patient data during the first six weeks or during second three weeks clinical practice in 21 health centres' radiological departments. The focus in these clinical practice periods are on skeleton and chest project (plain) examinations. Mostly the departments used were small, only one or two radiographers on each. In these departments the radiologist visited once a week or rarely. The teleradiology connections were available in all places in order to get consultation when needed. In two departments were ten radiographers and one or two radiologist working all the time. In these places also ultrasound examinations and mammography examinations were made. A physicist was only consulted when needed, usually once a year or less.

The dose monitoring as been regularly done in these departments at least for ten years and the clinical audit has been done once or twice in each place. Each student planned together with the tutoring radiographer and the mentoring teacher, about which plain (projection) examination the material would be most useful to collect. First, because the student needs at least ten patients coming to certain examination, and secondly because the goal is that staff can use the material as an official part of self-assessment for clinical audits. It is useful to have dose monitoring from quite common examination and not from same one every year. The dose reference levels are set to the most common examination for adults (Table 1) and some for children and also for computed tomography (CT) and cardiac interventions (Säteilyturvakeskus 2008).

The students collected data of ten patients with a data collection sheet. The information about patient’s height, weight and sex was recorded for later use in calculation of effective dose to the same patients. Imaging technique including tube voltage (kV), tube current (mAs), size of exposure area, focus to skin distance, amount and material of inherent and added filtration and was recorded. The air kerma with different kVs were found from the measurements made yearly by the technical staff. Also the use of added filtration was taken account in these measurements (Figure 1).

Backscatter factors used in calculations were found from STUK’s publication säteilyaltistuksen määrittäminen stuk tiedottaa. If DAP meter was in use, they recorded also the dose given by DAP. The exposure indexes were recorded in order to analyse later the connection between exposure index and patient dose.

Each student calculated ESD for ten patients on the bases of collected information of the patient and technical values. The doses were compared to the dose reference levels given by STUK. The whole data consist of 16 chest, one sinus and four lumbar spine examinations produced to adult patients in 21 health centres.

Results

On the point of view of the calculated doses all patients were not 55-85 kg in weight, as recommended. Still the average weight was in the recommend range. The chest x-rays were taken with high voltage technique 125-133 kV. Inherent filtration of the x-ray tubes varied from 2,8 mmAl to 3,2 mmAl. Added filtration between 0.1 -0.3 mmCu+1 mmAl was used in eleven (11) places. In five (5) wall stand equipment the added filtration was not available. The doses varied in chest pa (posterior-anterior) from 0,06 mGy to 0,23 mGy and in lateral view 0,08 mGy to 1,3 mGy. The dose reference levels are 0,2 mGy to chest pa and 0,8 mGy to chest lateral view. LÄHDE

In sinuses the lowest dose was 2,28 mGy and highest 2,69 mGy. There was no possibility to use added filtration (inherent filtration was 3 mmAl) and 85 kV was used to all patients. The dose reference level to sinus pa is 5 mGy for adult patient.LÄHDE

In lumbar spine ap doses varied from 1,1 mGy to 6,5 mGy and in lateral from 2,0 to 8,6 mGy, which are under the dose reference levels 6 mGy and 15 mGy. In lumbar spine ap the kV varied between 75 to 83 kV, and 2 mmAl added filtration was used. In lumbar spine lateral kV varied from 85 kV to 98 kV. In one place they used 0,1mmCu+1mmAl as added filtration, in other places only 2 mmAl.

On the point of view of learning dose calculation, all students were able to calculate doses. The formula which was used is

$$ESD = BSF*(h_c/h_p)^2*Q*Y$$

where Q is the output of x-ray beam at distance h_c, BSF is backscatter factor, h_p is the distance from the focus to patient skin and the Y is the mAs used in examination (Parry et al. 1999, Toivonen et al. 2001). The formula gives a reliable result if data collection is made carefully (Toivonen et al. 2001, Kepler et al. 2003).

The most asked questions concerned about the technical measurement sheet (figure 2 and Backscatter factors.

If the air kerma was not measured exactly for the used kV, the student had to draw a graph and take the air kerma /mAs from that. The most difficult information to find out from the technical measurement sheet was the distance used in measurements and what mAs was used in measurements.

The tables with the information of patients and doses were mostly done correctly. Doses were also compared to dose reference levels given by STUK 2009. If the patients were out of range of 55kg - 85 kg the student made a comment of that and discussed the effect to doses based on a larger patient group

Each report had the information of the X-ray department, equipment used with technical information and time schedule of data collection and student's own personal information. Before this official paper was sent back, teacher checked the calculations. Also the technical measurement data sheet was attached for the teacher who checked the calculations, in order to notice that the students had found all information for the calculations correctly. The reports were returned after the period of clinical practice.

Discussion

The education of radiographers is in universities of applied sciences in Finland. The Bachelor degree of radiography and radiation therapy takes 210 ECTS, 3,5 years. The studies include both theoretical studies and clinical practice, which actualises in x-ray departments all over Finland in health centres and hospitals.

According to constructive learning it is more meaningful if the learning tasks are based on real need. The students have from the first clinical practice tasks aimed to deepen some areas in the clinical practice.

Patient's dose follow up is very important part of radiographer's work and offers possibility to deepen and expand the daily work. For this task the students collect data and calculate doses for ten patients. The results are also used in the x-ray department for yearly dose follow up and as a tool of self assessment. The student has to be aware of factors affecting to ESD when collecting the data. Also the technical part, such as air kerma measurements, become familiar. he technical measurement sheet has many parameters and is not so simple to understand. The students have to understand the meaning and effects of added filtration.

The students learned very well the dose calculation and found also the reference levels and there meaning. Also the dependency between patient's size and amount of radiation is easy to point out. To find out the reasons why the doses varies in different places, the students have a discussion in small groups later. Reasons which they have found are e.g. level of used kV, speed class of the detector, use of grid, total filtration, SID (source to image distance), patient's size and size of exposure field.

The students can also compare the Finnish dose levels and technique to those in other countries. It is interesting to find differences for instance in the kV used. In some countries in chest x-rays it is high, 125-135 kV and in some others lower. ESD is reliable, easy and inexpensive way for dose follow-up (Edge 2009, Matthwes, Brennan 2009).

The latest results of research in radiography have shown that there are differences in the focus of education; some programs are more technical oriented, some more caring oriented (Akimoto et al 2009) but in any case more research and discussion of the results is needed (Malamanetiou 2009).

Conclusions

Students managed the ESD dose calculation from air kerma very well. Each student made a table including the information of the department, date of data collection, equipment used in plain examination and minimum, maximum and average doses. The doses were compared to reference levels. After teacher's comments, everyone has sent the signature report with results and remarks to the department where the data was collected. Radiographers in clinical practice use these reports as a part of QA-system and clinical audit's self-assessment material. Also the authority and clinical auditors have noticed the reports and recommend this way of learning and developing the good practices together in co-operation with the clinical staff, radiographer students and universities of applied sciences.

Abstract
A proton therapy centre is planned to be sited in Rome, Italy. It will be based on a medium energy proton accelerator and should be associated to a National Health Institute. At least two treatment station should be realized: a 140 MeV area for shallow tumors therapy and the 200-250 MeV full energy station for deep tumors treatment.

Additional experimental areas are foresee for studying the interactions of low energy, high LET, protons with tissues and the effectiveness of proton therapy on specific pathologies. The project is now in a preliminary design phase. The accelerator is under study, the building layout has to be defined and the preliminary safety solutions are considered as well in this phase. The radiation protection approach requires that all the radiation fields are well known, even those that are not useful for the treatment itself. In this frame the neutron field due to proton interactions in solid, liquid and gaseous materials has to be analyzed during the design phase in order to reduce this component to its minimum extent and to address the radiation protection program. The injector of the proton accelerator has been installed at the ENEA Research Center in Frascati, Rome and will be used to perform the preliminary low proton energy testing and the benchmarks for the simulations needed to assess the neutron field. In the paper the simulation models and the calculation performed with Monte Carlo codes are described. The related results are presented together with the comparison with the low energy benchmarks and the data found in the literature for similar projects. Considerations about workers and patients protection are issued taking into account different technical options and related advantages and disadvantages.

Introduction
In Italy a new project is close to be launched with the aim of realizing an innovative proton therapy facility. The TOP-IMPLART project is based on the use of a linear accelerator for producing the beam. TOP-IMPLART are the acronym of Terapia Oncologica con Protoni (Oncological Therapy with Protons) and Intensity Modulated Proton Linear Accelerator for Therapy. The project benefits of previous studies, designs

and tests done under the funding of the TOP project carried on in the years 1998 – 2005 by ENEA and ISS (The National Institute of Health). The TOP-IMPLART project has recently been considered suitable for a substantial funding by the Department of Innovation of Regione Lazio. A final decision about this is expected to be taken in the very next months. The work will be carried on in collaboration between ENEA, ISS and IFO (Istituti Fisioterapici Ospedalieri, the most important oncological hospital in Rome). The base of the TOP-IMPLART project is substantially the same as the TOP Project. The accelerator, that constitutes the main peculiar characteristic of this design is a linear accelerator, or , better to say, a sequence of linear accelerators. The low energy part is a commercial 7 MeV proton linac produced from AccSys-Hitachi, that itself is a sequence of a source, a RFQ and a DTL operating at the frequency of 425 MHz.

The project is aimed to develop a proton irradiation facility that could be devoted to different applications taking advantage of the modular nature of the linear accelerators. Using a linear machine instead of a compact circular accelerator (syncrotrons and cyclotrons) permits the possibility to proceed by steps in the construction and operation process and makes it possible the combined use of different irradiation stations at various energies between the minimum (about 7 MeV) and the maximum (about 250 MeV). The sequential setup of each partial irradiation module and its clinical application also before the whole facility has been completed will match the financial support flux that will be discontinue and spread over many years. This process will provide clinical and social advantages in a shorter time than the one that should be required for the construction and operation of the whole facility. The first 7 MeV module of the accelerator, is already installed and has been tested at the ENEA Research Center in Frascati, Rome. Additional modules will be added to the injector leading proton energy to 30, 70 and 150 MeV in a step by step project. The present study is finalized to the neutron field analysis for the radiation protection of the workers involved in the testing activities of the first two modules of the linear accelerator, with a final proton energy of 30 MeV. The main irradiation model considers the proton beam hitting a cell-culture-in-water target. The study has been performed using FLUKA code [1], a powerful computer program based on the Monte Carlo method, implemented to simulate the experimental setup in order to evaluate the neutron field parameters.

Material and methods

The TOP LINAC concept

Usually proton linear accelerators used for research purpose, operate with intense beams, run at low frequencies and must therefore have large apertures. This setup is unnecessary for tumor treatments, where very weak intensities are required (the average beam currents are only about 10 nA), and therefore an high frequency technology is applicable. The idea of using 3 GHz structures with gradient of the order of 15 MeV/m is at the basis of the studies initiated in 1993 by the TERA Foundation. This machine was the first 3 GHz linear accelerator dedicated to proton therapy [2, 3]. It has been designed to produce a continuously variable energy beam, promoting a xyz scanning. This requires a pulse repetition rate as high as possible (400 Hz) to irradiate a single pixel at least twice during a 1 min treatment, and a precise control (2-3 % in a relative intensity range of 50-100) of the dose rate of the single pulse. The fine energy variation is achieved by amplitude variation in the last module still under power, giving a pretty smooth energy variation with a small energy spread (about 0.3%) in the range above 130 MeV. Xyz scanning totally avoids to use passive systems such as absorbers, scattering foils and collimators, whose thickness and shape need to be designed and milled for each tumor shape and volume to provide the desired angular and energy distribution of the beam.

The cost-effectiveness of this facility is a particularly relevant issue. In fact, many cost-effectiveness reviews suggest that at the moment no clear evidence can be drawn either in favor or against proton radiotherapy as opposed to conventional photon radiotherapy. Some authors suggest a net advantage of proton therapy for a limited number of tumor sites, such as melanomas and others ocular tumors, skull base chordomas and chondrosarcomas, medulloblastoma in pediatric patients [4, 5]. For other pathologies such as breast, prostate, head-and neck tumors, similar evidence has been reported for selected patient subgroups [6, 7, 8]. A cost reduction in building proton therapy facilities equipped with robotic systems for patient positioning instead of rotating gantries, is expected to reveal more clearly the clinical advantage of proton versus photon therapy demonstrating improved dose distribution.

IMPLART Frascati test facility and related models

The test facility that will be sited in Frascati will be located inside a narrow, 13 m long shielded room, also referred as IMPLART bunker. The bunker is sized to accommodate the first two accelerating sections up to 30 MeV, with an average beam current of about 10 nA. Geometrical dimensions and shielding material compositions, as derived from the FLUKA database, are shown in the tables from 1 to 4.

Table 1. Shielding materials.

Shielding	Material	Thickness [cm]
Ceiling	Concrete	50
Wall on each side of the beam	Concrete	100
Additional shielding	Lead	10
Wall in front of the beam	Concrete	150
Wall opposite to the beam	Concrete	100

O-Oxygen (Z=8)	0,209235

FLUKA Monte Carlo code has been implemented to simulate a 30 MeV proton beam hitting a cell culture in water enclosed in a Petri's capsule and positioned on the beam axis at about 2 cm from the kapton membrane located at the end of the vacuum accelerating channel. 10^7 particle stories were used in the Monte Carlo execution. The calculation model includes the following main sections:

- Final segment of the accelerating section;
- Petri's-capsule target;
- Shielding walls.

The following kind of results were obtained:

- Neutron fluences inside the bunker, inside the shielding and outside the bunker;
- Neutron dose equivalent inside the bunker, inside the shielding and outside the bunker;
- Double differential neutron fluence spectrum inside the bunker;

These results allow a preliminary assessment of the effectiveness of the existing shielding in relation to the neutron fields. The final segment of the accelerating section has been shaped like a stainless-steel hollow cylinder, with vacuum inside, end-closed by a kapton membrane. The target is a Petri's capsule: a glass or plastic cylindrical box that is the most common container for cell cultures. The simplified model consists of an hollow cylinder containing three layers of material. The hollow cylinder simulate the Petri's capsule with an air-equivalent-plastic (ICRU C-552); the two outer layers simulate the water while the inner layer simulate the cell culture with a tissue-equivalent material, as shown in figure 1.

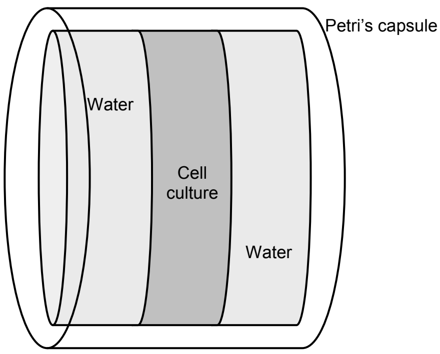

Fig. 1. Schematic view of the target (not in scale).

The tables from 5 to 7 show the FLUKA material composition of the target.

Table 5. Composition of the air-equivalent-plastic (ICRU C-552), ρ = 1,76 g cm^{-3}.

O-Oxygen (Z=8)	0,759414

Results

FLUKA calculations provide results in term of quantity per single source proton that have to be scaled accounting for the actual particles flux in the beam. The data obtained in the following will be than multiplied by the proton-per-hour yield of the Implart modules, that is about 2,25 10^{14} h^{-1}, giving the dose rate in the same time unit.

In the figures from 2 to 5 the final segment of the accelerating section (thin strip) and the target are located at the right, inside the bunker. In the figures 2 and 4, the thin strip below outside the bunker represents the second steel layer. In the figures 3 and 5, the thin sector at the top, inside the bunker, represents the additional lead shielding.

Figures 2 and 3 show neutron fluence due to the proton interaction on the system target as a result of the FLUKA run.

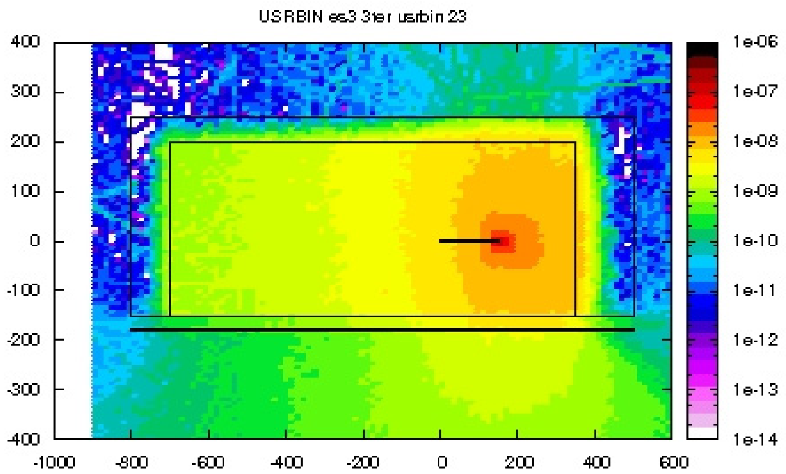

Fig. 2. Spatial distribution of the neutron fluence. YZ plane (vertical section). The abscissas and the ordinates show the linear dimensions in cm, while the spatial distribution is represented by color scale in unit of part/cm^2. The result is normalized per source-particle or primary.

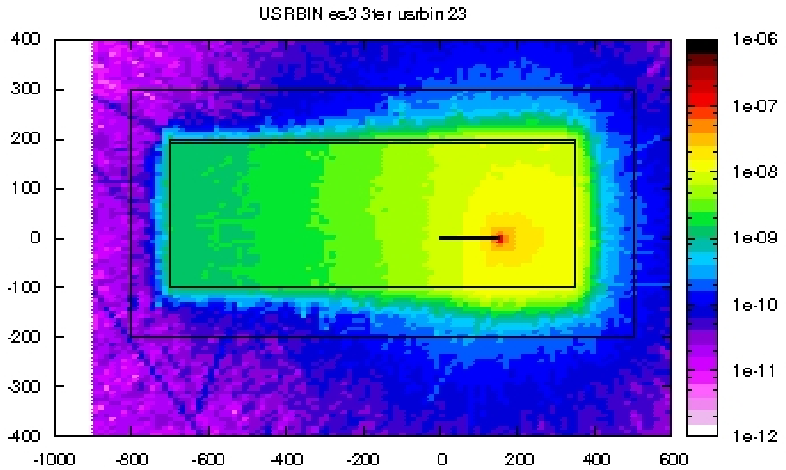

Fig. 3. Spatial distribution of the neutron fluence. XZ plane (orizontal section). The abscissas and the ordinates show the linear dimensions in cm, while the spatial distribution is represented by color scale in unit of part/cm^2. The result is normalized per source-particle or primary.

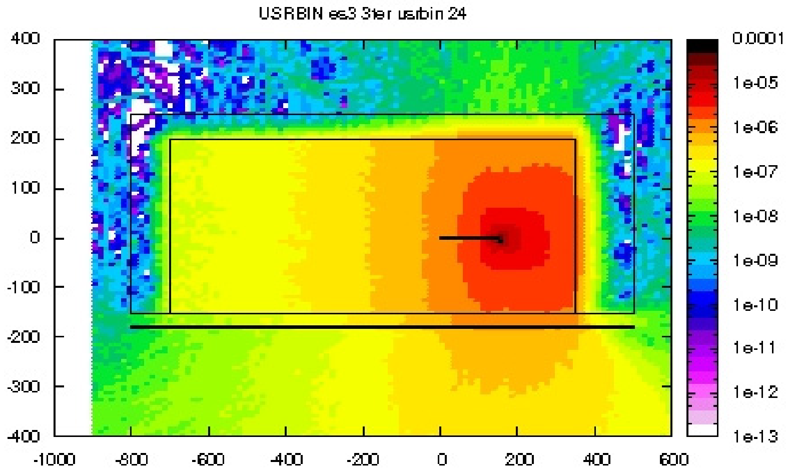

Fig. 4. Spatial distribution of the neutron ambient dose-equivalent. YZ plane (vertical section). The abscissas and the ordinates show the linear dimensions in cm, while the spatial distribution is represented by color scale in unit of pSv. The result is normalized per source-particle or primary.

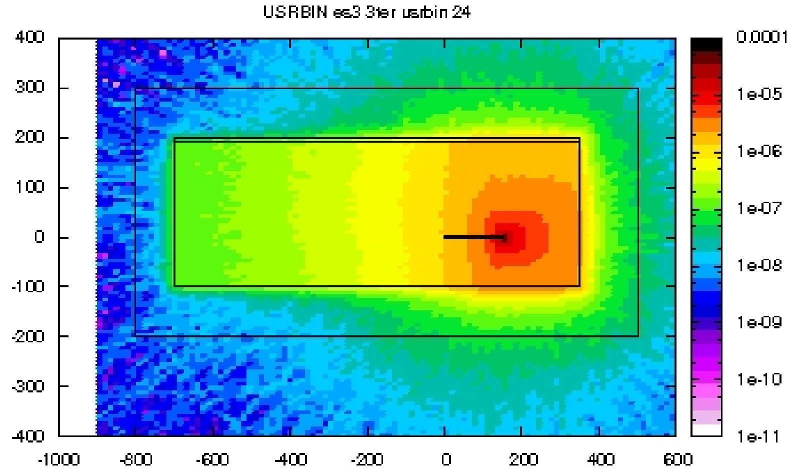

Fig. 5. Spatial distribution of the neutron ambient dose-equivalent. XZ plane (orizontal section). The abscissas and the ordinates show the linear dimensions in cm, while the spatial distribution is represented by color scale in unit of pSv. The result is normalized per source-particle or primary.

In the Figures 4 and 5 the main result of the simulation is shown. The neutron ambient dose-equivalent is normalized to the single source proton. In the chromatic graphs the walls of the bunker are reported in order to assess the related shielding effect.

A general result is represented in Figure 6 showing the neutron fluence spectrum in air, at 10 cm from the target.

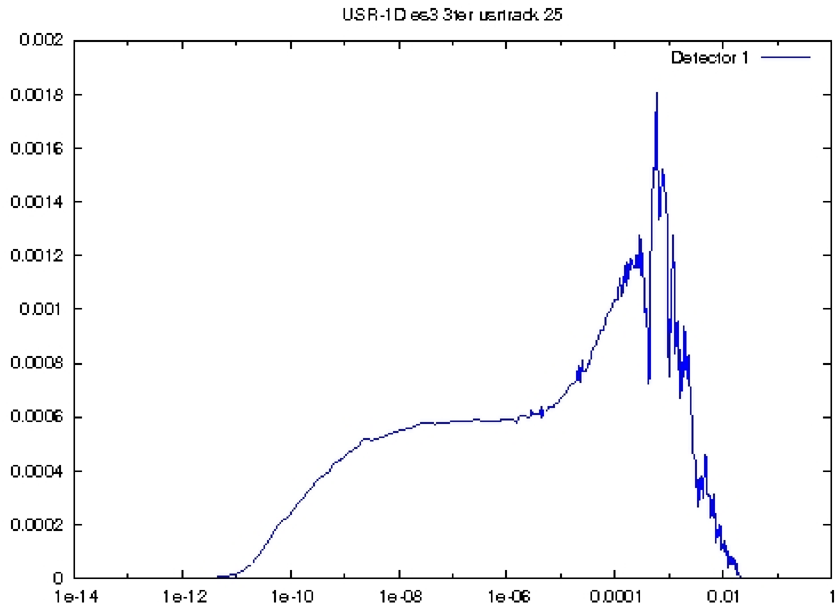

Fig. 6. Differential distribution of the neutron fluence. The abscissas show the energy in unit of [GeV], while the ordinates show the differential distribution of the fluence dΦ/dE in unit of [cm^{-2} GeV^{-1}]. The result is normalized per source-particle or primary.

Discussion

The neutron field is generated by interaction of the proton beam with the nuclei of the target, the air and the shielding. It represents an inevitable and undesirable radiation field which could cause undue dose to the operators.

Figure 2 shows the neutron fluence in vertical projection (YZ plane):

- around the target we have about 1e-07 part cm^{-2};
- inside the bunker it ranges from 1e-08 to 1e-09 part cm^{-2}, depending on the distance from the target;
- outside the bunker it varies from 1e-11 part/[cm^{-2}] beyond the concrete, to 1e-09 part/[cm^{-2}] in the room below the steel layers;

Figure 3 shows the situation in a horizontal projection (XZ plane). The fluence shows a general behavior similar to that shown in the vertical plane, with a slightly lower intensity.

The neutron ambient dose equivalent shown in Figure 4 gives the trend of the field in vertical projection (YZ plane):

- around the target, is about 5e-05 pSv (i.e. 11,2 mSv/h, for a 10 nA current);
- inside the bunker it varies from about 5e-06 to 1e-07 pSv, depending on the distance from the target;
- outside the bunker it can be seen as it varies, in the points of greatest field strength, from about 5e-08 pSv (i.e. 11,2 μSv/h, for a 10 nA current) beyond the concrete, to 1e-06 pSv (224 μSv/h, for a 10 nA current) in the room below the steel layers;

Figure 5 shows the situation in the horizontal projection (XZ plane).

The difference from fluence to dose-equivalent is due to the application of the conversion coefficients that for neutrons are strongly dependent from their energy.

In the case study the neutron energy has the spectral trend shown in Figure 6. The curve shows that the neutron fluence spectrum has the main peak at about 0,598 MeV, then decreases rapidly dying at about 21 MeV and also shows a tail starting from the thermal region at about 4,361 meV with a plateau from about 1e-06 MeV up to 1e-03 MeV. The thermal component could be caused by slowing of fast neutrons in concrete and subsequent backscatter inside the bunker.

Conclusions

The TOP-Implart project could provide important medical applications suggesting the needing of testing the first sections of the accelerator in an existing facility. The current work describes the initial analysis of the neutron field produced by the 30 MeV proton beam provided by the first two accelerating sections.

The preliminary result obtained with the FLUKA simulation shows that the existing shielding walls and structures, effective in reducing the dose rate at an acceptable level for the initial module of 7 MeV protons, have to be improved to keep the dose rate at a similar low level for the upgrade to 30 MeV.

In the simulation wall shielding appears to be able to slow down the dose-equivalent by a factor of about 10 only. A better attenuation seems to occur for the neutron fluence due to the neutron spectrum and the conversion coefficients distribution vs. neutron energy. Anyway the dose rate assessed in the simulation is greater than 10 µSv/h in many areas beyond the shielding walls and this would limit the system workload at less than 1000 hour per year.

In conclusion the simulation model has been setup but further analysis is needed to correctly size the shielding walls or to better define distance and materials. Possible local shielding or beam dumps have to be considered too. If needed, also the accelerator workload and average beam current could be reduced during the testing phase.

Where is Bulgaria in radiation protection in medicine?

Vassileva, Jenia
National Centre of Radiobiology and Radiation Protection, Radiation Protection at Medical Exposure, BULGARIA

Abstract

Medical uses of ionizing radiation are the major man-made source of exposure of the Bulgarian population. The requirements of the International Basic Safety Standards for protection against ionizing radiation and the EURATOM Directive 97/43 were fully harmonized in the Bulgarian legislation and many actions have been undertaken for their practical implementations. In October 2005 new regulation has been enforced for radiation protection at medical exposure. A department for Radiation Protection at Medical Exposure was established at the National Centre of Radiobiology and Radiation Protection in order to lead the practical implementation of the Ordinance. New objective requirements to radiological equipment were set and licensees were obliged to put into operation Quality control program. First Diagnostic Reference doses were given in 2005 based on the limited own experience from the First national survey in conventional performed in 2002–2003 within the Bulgarian-German twinning project. Further enlargement of dose surveys and improvement of RP practice at medical use of radiation were realized within the Bulgarian-Finnish Twining project “Strengthening of administrative structures for radiation protection and safety use of ionizing radiation in diagnostics and therapy”. New radiation protection training programs for medical specialist were elaborated including recent knowledge on patient protection. Several national training courses with international lecturers were performed.

A national system on registration and reporting of medical exposure in Romania

Milu, Constantin; Dumitrescu, Alina
Institute of Public Health-Bucharest, Radiation Hygiene Laboratory, ROMANIA

Abstract

The 97/43/EURATOM Directive was fully transposed into Romanian legislation, starting with the "Norms on radioprotection of the public from medical exposure", which were joitly approved in 2002 by the minister of health and the president of the nuclear regulatory authority (C.N.C.A.N.) and also by other specific regulations regarding radiation protection of the patient. As in most European countries, the medical exposure is the main man-made radiation exposure of the population in Romania. It is now an alarming increase in use of high radiation dose examinations , such as computed tomography (CT) and of X-rays guided interventions (like coronary angioplasty), with similar doses and sometimes even higher (particularly to the skin). As part of the implementation plan of the 97/43/EURATOM Directive, a national system on registration and reporting of medical exposure was recently developed in Romania. The system is establishedby two specific regulations of the Ministry of Health, approved by the ministerial orders No.1542/2006 and No.1.003/2008. It refers to all medical radiological procedures: diagnostic radiology, interventional radiology, nuclear medicine and radiotherapy. The system includes three main parts :

– registration (electronic or on files) of basic data (patient data , exposure parameters and individual patient doses, if available), at the level of each user (X-ray machine, nuclear medicine department and/or radiotherapy facility);
– on-line data reporting to the Radiation Hygiene Laboratory (RHL) , belonging to the local Direction of Public Health and to the specialized network of the Ministry of Health (quarterly);
– on-line reporting of data , by each RHL, to the Institute of Public Health-Bucharest (annually). The Institute of Public Health – Bucharest has to evaluate all data and to issue in June 2010 a first report on data from 2009.

Analysis of doses in x-ray computed tomography

Skrzynski, Witold; Slusarczyk-Kacprzyk, Wioletta; Fabiszewska, Ewa; Bulski, Wojciech
Maria Sklodowska-Curie Memorial Cancer Centre and Institute of Oncology,
Medical Physics Department, POLAND

Abstract

Computed tomography is known to be relatively high dose diagnostic procedure. The need to justify, to optimize, and to evaluate the exposure in tomography examinations is therefore widely accepted. This is especially true for children, who are more sensitive to radiation, and for whom unnecessary overexposure is possible in case of non-optimized scanning protocols. The ALARA principle should, however, be obeyed for all patients.

In this study dose related data were collected for patients examined on several different CT units. The patients included adults and children of various age. The examinations were done either on purpose of diagnosis or for planning of radiation therapy.

Collected data were analyzed in order to establish, whether the parameters of examinations were routinely adjusted accordingly to patient size, especially in case of children. Doses, expressed in terms of $CTDI_{vol}$ and DLP, were compared with reference levels published by the European Commission and by the NRPB. Effective doses were estimated using αconversion factors published by NRPB, and then used for comparison between CT units and groups of patients.

The analysis helped to reveal situations, in which scanning protocols were clearly non-optimized as far as radiological protection of patients is concerned.

Radiographers' safety culture in medical use of radiation

Niemi, Antti[1]; Parviainen, Teuvo[2]
[1] Metropolia University of Applied Sciences, FINLAND;
[2] STUK – Radiation and Nuclear Safety Authority, Radiation Practices Regulation, FINLAND

Abstract

Safety culture is one of the stone basis in medical use of radiation. Safety culture means that organisation and its personnel ways of action and attitudes are so that maintaining and continuous developing of safety is possible. Safety culture in medical use of radiation has been refered mostly theoretically but not empirically. The purpose of this study is to describe and interpret radiographers' safety culture in the medical use of radiation. Another objective is to yield new information and highlight inductively characteristics of safety culture. The data were gathered from two university hospitals and one central hospital. The data consisted of interviews (n = 20), fieldwork, articles in a professional journal (n = 457) and documents used by a radiographer in his work. Focused ethnographic studies and discourse analysis were drawn on to interpret radiographers' shared meanings of safety culture.

Radiographers' safety culture consisted of four shared meanings: challenges of knowledge and skills structuring safety culture, dimensions of cooperation enabling safety culture, disorientation conditioning safety culture and multidimensional professionalism as the foundation of safety culture. The use of technology was considered an essential part of a radiographer's work, contributing to patient care. The radiographers' varied assignments, their conventional opinions, the work and roles of both head radiographers` and physicians, and their responses to current social challenges in modern working life, all were seen as contributing to cooperation.

Protection against radiation was understood to be an important part of the radiographer's standard activities. Radiographers were confused by the different directions and practices in implementing radiation protection. The results of the study can be used in developing and organizing radiographers' work and education. They may also clarify safety culture as a phenomenon and a concept.

Ethical dilemmas in radiographer's work in diagnostic radiology

Paalimäki-Paakki, Karoliina[1]; Henner, Anja[1]; Ahonen, Sanna-Mari[2]
[1] Oulu University of Applied Sciences, FINLAND;
[2] Oulu University, Institute of Health Sciences, FINLAND

Abstract

Purpose: The purpose is to describe ethical dilemmas in diagnostic radiographer's work. The aim of the study is to create new information since there is comparatively little research focusing on this subject.

Methods and materials: Data was collected during spring and summer 2008 and consisted of thematic interviews of diagnostic radiographers (N=8), whose working experience varied from 4 to 31 years. Data was analysed with qualitative inductive content analysis.

Results: Ethical dilemmas were found to consider the use of radiation and radiographer's work community. In the use of radiation, implementation of justification and optimisation principles were found to be lacking. There were problems in the safe use of equipments and especially lacks in referrals. There was neither found common safety culture, because the projections, number of them and dose optimisation was insufficient. Also the use of lead shields varied individually and although it was noticed that some colleges didn't use them, there was no discussion about the common practice. Dilemmas in work community consisted of problems among employees and insufficient practice. Background factors of these dilemmas were found to be both dependent on and independent of the employee, resulting in worsened well-being at work and seek for change. Current processing methods of dilemmas were found to be insufficient, and suggestions for better processing methods were made.

Conclusions: Daily ethical considerations were described by respondents, but not recognised as ethical dilemmas. Ethics in work as a concept may seem separate and distant, despite the fact that in most cases, ethical dilemmas occur in everyday situations. Recognition of dilemmas is important in order to be able to intervene in them. Respondents repeatedly described powerlessness and inability to intervene in ethical problems. Quite many of those problems can be seen as problems or even lack of safety culture.

Effects of Computed Tomography on paediatric patients: towards an understanding of gene expression profiles and the potential role of radiation induced cytokines

El-Saghire, H.[1,2]; Benotmane, R.[1]; Michaux, A.[1]; De Ruyck, K.[2]; Beels, L.[2]; Thierens, H.[2]; Baatout, S.[1]

[1] Radiobiology Unit, Laboratory of Molecular and Cellular Biology, Belgian Nuclear Research Centre, SCK•CEN, Mol, BELGIUM

[2] Faculty of Medicine and Health Sciences, Ghent University, BELGIUM

Abstract

Computed Tomography (CT) is a diagnostic imaging technique that uses X-rays for assessing a variety of disorders in both adults and children. Within the patient population undergoing CT examination, paediatric patients, following interventional cardiac catheterization CT scans, showed low dose hypersensitivity. A recent study showed an *in vivo* induction of γ-H2AX foci, caused by interventional X-rays (Beels et al., Circulation, 2009). It is suspected that the mechanism behind this hypersensitivity is related to non-targeted or bystander effects.

In collaboration with multiple centres, blood samples will be collected from paediatric patients' pre-CT and post-CT; as well as blood samples from volunteers will be irradiated *in vitro*, helping us to understand the kinetics of gene expression and track possible differences between *in vivo* and in *vitro* radiation effects. Using microarrays, we will be able to investigate global gene expression, thus pointing out differential gene profiles before and after exposure to CT scans. This could lead to an understanding of the biological mechanisms behind the low dose hypersensitivity; on the other hand, we might be able to specify certain early radiation induced biomarkers, thus using it to assess the risk associated with CT exposures.

Bystander effect is the induction of DNA damage response in non-irradiated cells that are neighbouring irradiated cells, and is considered to amplify the effects of radiation by increasing the number of affected cells. Potential players that can promote bystander effect are cytokines; these are signalling molecules that are involved in cellular communication during an immune response. We will use multiplex array assay to determine levels of different cytokines following the radiation induced stress.

Part of this project is financially supported by the Federal Agency of Nuclear Control (FANC-AFCN), Belgium.

Radon associated lifetime risk

Laurier, Dominique[1]; Tomasek, Ladislav[2]; Leuraud, Klervi[1]; Tirmarche, Margot[3]
[1] Institute for Radiological Protection and Nuclear Safety, IRSN/DRPH/SRBE, FRANCE
[2] National Radiation Protection Institute, SURO, CZECH REPUBLIC
[3] Institute for Radiological Protection and Nuclear Safety, IRSN/DRI, FRANCE

Abstract

Quantification of the risk associated to radon exposure is a major public health issue. Since the 1970s, 13 cohort studies provided results on the exposure-risk relationship in miner populations. Since the 1990s, more than 20 case-control studies evaluated the risk of lung cancer associated to indoor radon exposure in the general population. Nevertheless, due to variations in the study designs, in the characteristics of the studied populations and in factors that modify the exposure-risk relationship (age at exposure, attained age, time since exposure or exposure rate), it is difficult to verify the coherence of published results. Calculation of lifetime excess absolute risks (LEAR) is a way to compare the results of risk coefficients or models derived from different populations when applied to the same scenario of exposure. We present here some LEAR estimates based on the most recent epidemiological results. Different models are applied, derived from both miner studies (BEIR VI, Eldorado, French-Czech models) and indoor studies (European pooling project). The background reference rates are those proposed by the ICRP. Different scenarios of chronic low rate exposure are considered, including those used by the ICRP. Results illustrate the impact of age and time modifiers on the estimated LEAR. Results obtained using different models derived from miner studies are highly coherent. A good agreement is also observed between LEAR estimates obtained from miners and from indoor studies when applied to adapted scenarios. To conclude, calculation of LEAR allows demonstrating a very good coherence in currently available radon associated risk estimates. These results provide support to the elaboration of radiation protection measures regarding radon exposure.

European atlas of natural radiations: status of the indoor and geogenic radon maps

De Cort, Marc[1]; Tollefsen, Tore[1]; Bossew, Peter[2]; Friedmann, Harry[3]
[1] European Commission, DG JRC, Institute for Environment and Sustainability, ITALY
[2] Unemployed, AUSTRIA
[3] University Vienna, Department of Nuclear Physics, AUSTRIA

Abstract

Based on its political and legal mission, in 2006 the JRC started to design the project of a European atlas of natural radiations. As first step a map of indoor radon was envisaged, given the radiological importance of the related exposure pathway. Since a seminal meeting in Prague, autumn 2006, the indoor Rn map is under way, with contributions from so far (August 2009) 15 countries. Individual measurement data are aggregated into a common grid by the participants. Grid data, which consist of grid cells filled with statistics on individual data, are then further processed by the JRC. In the aggregated dataset, no information on individual houses is available. We present the preliminary results in terms of descriptive statistics and maps, and some further results based on modelling steps, like spatial risk estimate. Indoor radon concentration is controlled by geogenic, climatic and anthropogenic factors. Among the latter are house and room types and living habits. In order to assess the hazard, or potential risk of indoor Rn exposure at a location, independent of anthropogenic factors, one needs a standardized quantity which is only controlled by the geogenic (and possibly average climatic) factors. Since a start-off meeting in Oslo, summer 2008, we are developing a harmonized European Rn index which can be estimated from different input data, as available in participating countries. Among these are indoor Rn concentrations, data on Rn in soil gas, geological classes, geochemical data and external dose rate. Currently algorithms are under discussion to convert such multivariate data, different country by country, into one radon index variable. Future steps of the European atlas of natural radiations may be maps of cosmogenic exposure and geochemical maps of natural radionuclides.

The Austrian Radon Programme – Past and future

Ringer, Wolfgang[1]; Kaineder, Heribert[2]; Friedmann, Harry[3]
[1] Austrian Agency for Health and Food Safety (AGES), Austrian Centre for Radon, Derfflingerstrasse 2, 4020 Linz, AUSTRIA; Email: wolfgang.ringer@ages.at
[2] Federal Government of Upper Austria, Environment, Kärntner Straße 10-12, A-4021 Linz, AUSTRIA
[3] University of Vienna, University of Vienna, Faculty of Physics - Nuclear Physics, Währinger Str. 17, A-1090 Wien, AUSTRIA

Abstract

As early as at the beginning of the 20th century radon measurements in water were conducted in Austria whereas radon measurements in air started in 1949. Several thousand measurements of radon in air in workplaces (caves, mines) and homes were conducted until 1972 by Pohl and Pohl-Rüling. Later measurement campaigns took place in Innsbruck, Salzburg, and Vienna but it was not until 1991 that a systematic and coordinated investigation of the radon situation in Austria began.

The main effort was to establish the Austrian radon map in the framework of a project called The Austrian Radon Project (ÖNRAP) with Harry Friedmann from the University of Vienna as project leader (1992 – 2004). Other main projects were to test various mitigation techniques (SARAH, Maringer, 1996 – 1998) and preventive measures. One project dealt with the influence of building characteristics on the radon concentration and the use of a Blower Door to determine the mean radon concentration of a building (RACODE, Ringer, 1997 – 2001).

Substantial efforts were undertaken to determine the radon exposure in kindergartens, schools, and town halls including the mitigation of the buildings with elevated radon levels.

The knowledge and experience gained by the projects led to the issue of three Austrian standards for radon measurement, mitigation and prevention, and to the issue of a radon information CD and a radon brochure.

In 2006 the Austrian Centre for Radon was established with the aim to better coordinate the radon efforts. Main tasks at present are the setup and maintenance of the official radon website and the design and implementation of the Austrian radon database. Other projects deal with the radon exposure in show caves and tourist mines, the investigation of the house to house variation of radon in a community and the investigation of the causes of that variability, and the determination of radon levels outdoors.

This paper will present and discuss past and future efforts in Austria to determine the radon exposures in homes and workplaces and to reduce the radon risk of the population.

Introduction

"Bergkrankheit" (or mountain sickness), among sixteenth century pitchblende (radium) miners in the Erz Mountains of Germany, was the earliest evidence of the health hazard of inhaled radon and its progeny. However, it was not until the 1920's that the lung disease was attributed to radiation, as opposed to inhaled arsenic (Miller 1990). And it was not until the 1970's that residential exposure to indoor radon began to be considered as a potential public health risk (Nero 1988).

In 1988 Radon was classified as a human carcinogen by the International Agency for Research on Cancer (IARC 1988).

Since the 1980's substantial efforts had been undertaken in many countries to evaluate the radon problem. The annual dose from inhalation of radon gas and its decay products represents typically about one-half of the effective dose received by members of the public from all natural sources of ionizing radiation (UNSCEAR 2008).

This paper describes the studies and projects with respect to radon in Austria in the past, discusses the lessons to learn, and gives a foresight to the future radon strategy.

Radon in Austria until 1991

As early as at the beginning of the 20th century radon measurements in water were conducted in Austria (balneology) whereas radon measurements in air started in 1949. Several thousand measurements of radon in air in workplaces (caves, mines) and homes were conducted until 1972 by Pohl and Pohl-Rüling. Later measurement campaigns took place in Innsbruck, Salzburg, and Vienna but it was not until 1991 that a systematic and coordinated investigation of the radon situation in Austria began (BMGSK 1992).

Radon in Austria after 1991

At the beginning of the 1990's publications from EU, ICRP, WHO, and IAEA gave an international framework to the radon issue (EU 1990, ICRP 1990, WHO 1993, ICRP 1993, IAEA 1996).

In 1991 a project with the aim to evaluate the radon situation in Austria and to provide a concept with respect to a national radon programme was conducted (BMGSK 1992).

Based on EU 1990 and ICRP 1990 the Austrian Radioprotection Commission passed a recommendation concerning 'action levels for indoor radon' in 1992 (BMGSK 1994). Key elements of that recommendation are

- action levels for existing and new buildings (400 and 200 Bq/m^3, respectively)
- the recommendation to set up a radon potential map of Austria
- the recommendation to set up guidelines for mitigation and prevention
- the recommendation to set up a folder to inform the population

In the following legislative matters and the major projects and studies are outlined.

Radon in Austrian legislation and standards

Indoor radon is dealt with in the recommendation of the Austrian radiation protection commission as mentioned above and is not subject to specific legislation.

On the other hand, radon in work places is regimented by the Radiation Protection Law 2006 and the Natural Radiation Sources Ordinance 2008. The Ordinance applies to the following four working areas: water supplies, underground work places in mines, tunnels, etc., show caves and tourist mines, and radon spas. So far, the response of the concerned companies to the legal requirement to induce an evaluation of the radon exposure to the staff was very weak.

A series of Austrian Standards (ÖNORM S 5280 Radon) has been issued dealing with Part 1: Measuring methods and their range of applications, Part 2: Technical precautionary measures in the case of buildings and Part 3: Remedial measures on buildings.

The Austrian Radon Project (ÖNRAP, 1992-2004, Friedmann)

The main project was the establishment of the Austrian radon map (Friedmann 2005). Radon measurements were conducted in about 16,000 living and sleeping rooms in Austrian dwellings. The results were normalised to a standard situation (no basement, ground floor level, …) and therefore the normalised data are an indicator for the radon potential, or in other words, the probability to measure a certain radon level in a specific dwelling in a municipality. Fig. 1 shows the Austrian radon potential map.

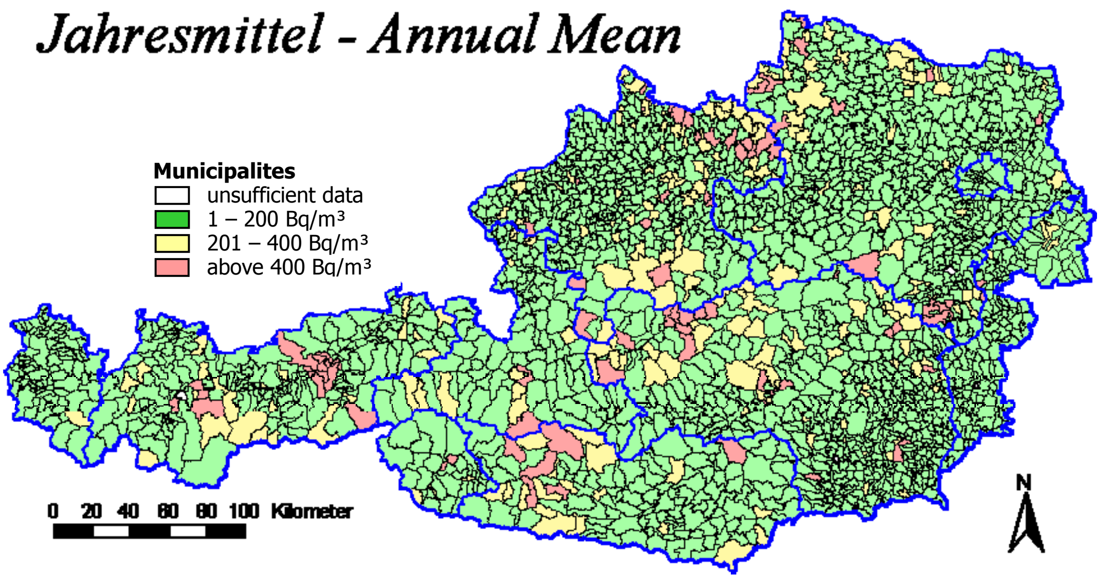

Fig. 1. The Austrian radon potential map.

Radon surveys and mitigations in kindergartens, schools, and town halls

The radon levels in about 800 kindergartens, 350 schools, and 450 town halls have been determined in Austria (mainly in the province of Upper Austria) in the last 10 years. 2,6% of all kindergartens and schools and 1,6% of all town halls showed mean radon levels above 1000 Bq/m³ and 5,9% (kindergartens, schools) and 12% (town halls) above 400 Bq/m³. In total about 130 buildings needed to be mitigated (or are in the process of mitigation since the priority was linked to the radon level) (Ringer 2002, Maringer 2004, Ringer 2004, AOOELR 2009).

Radon in low energy and passive houses (2009-2011, Ringer)

Airtight building shells, low air exchange rates and specific construction and heating technologies like air-soil heat exchanger gave rise to the concern that radon levels may be elevated in low energy and passive houses. A project is currently investigating the effect of those new building types on indoor radon. This project is a subtask of the EU-project "Radon Prevention and Remediation (RADPAR)". (http://web.jrc.ec.europa.eu/radpar/index.cfm)

Complete radon survey in three communities (2009-2011, Ringer)

The aims of the project are to study the dwelling to dwelling variation within a municipality, to evaluate the influence of building characteristics and geology, to verify the results of the Austrian Radon Project, to train local building professionals to mitigate dwellings, and to raise awareness with respect to radon within the municipalities and beyond. For that purpose the radon and thoron concentration of every single dwelling in three municipalities with elevated radon potential is to be measured. Furthermore, the soil gas concentrations in the main geological formations in this area will be determined.

After a public information event and after the distribution of the track etch detectors, presently, the long-term radon and thoron measurements are conducted (January – July 2010).

Mitigation of dwellings with elevated radon levels (SARAH, 1996–1998, Maringer)

This study served to test mitigation methods adapted to typical Austrian houses, to gain experience, and to evaluate typical mitigation costs.

Three dwellings with elevated radon levels were mitigated by applying sub-slab depressurisation, sub-house depressurisation and sub-slab ventilation, respectively, as mitigation method.

The main results are given in Table 1.

Table 1. Main results of the mitigation project.

	Gutau	Königswiesen	Traun
method	sub-slab depressurisation	sub-house depressurisation	sub-slab ventilation
mean radon concentration before mitigation (Bq/m³)	500	900	600
mean radon concentration after mitigation (Bq/m³)	250 (passive) 50 (active)	180	360
cost (EURO)	14000	7000	400
specific radon reduction costs (€/m^{2}Bqm^{-3})	0.23	0.11	0.015

Radon Potential Determination by Controlled Building Depressurisation (RACODE, 1997–2001, Ringer)

In this study a Blower Door (BD) was used to mechanically depressurise houses in a controlled and reproducible manner to determine the radon entry rate. Furthermore, diagnostic tests like "Opening A Door" or "Guard Zone" were carried out to characterise the leakage pattern (i.e. Effective Leakage Area ELA and flow exponent n) of the house. With these data and (simplified) modelling mean indoor radon concentrations are deduced and compared with the results of long term passive radon measurements.

Besides the determination of the mean radon concentration this new method should be useful for the rapid assessment of the effectiveness of mitigation measures if the same kind of measurements at defined pressure conditions are performed before and after mitigation (Ringer 2005).

Radon in work places

With respect to radon exposure in work places major studies – apart from those studies in kindergartens, schools, and town halls as described above – concerned water supplies, tourist mines and show caves.

The results show that the radon concentrations in the water supplies were lower as expected, being in 55% of all measurement sites below 1000 Bq/m³, in 91% below 5000 Bq/m³, and with a maximum value of 38700 Bq/m³. This leads to exposures that are below 2 MBqh/m³ (corresponding to approx. 6 mSv/a) in 42 water supplies. However, for the remaining three water supplies maximal occupational exposures due to radon of 2.8 MBqh/m³ (~ 10 mSv/a), 15 MBqh/m³ (~ 50 mSv/a), and 17 MBqh/m³ (~ 56 mSv/a), respectively, were determined. These water supplies were mitigated. Mitigation measures were: evacuation of the outlet air of the vaporizer by means of a fan, installation of a fan in the exhaust air duct of the compensating reservoir, sealing of drain shafts, mechanical ventilation of the office. In all water supplies the radon exposure was reduced to below 0.8 MBqh/m³ at a cost of approx. € 750,- to € 1.000,- (Ringer 2006, Ringer 2008).

For the purpose of determining the radon exposure of guides and of evaluating the determining factors on the radon concentration, such as climate, structure and geology, long-term time-resolved measurements over 12 months have been carried out in 6 tourist mines and 2 show caves - with 5 to 9 measuring points each - to obtain the course of radon concentration throughout the year. First results are presented in Ringer 2009. The final report is expected by the end of 2010.

Information of the public

A number of folders and brochures has been published to inform the public on the radon issue. One folder deals with radon in water supplies.

Furthermore, a Radon-CD was produced which presents basic information on radon in a multimedia way and a specific radon website was set up by the Ministry for Environment (www.strahlenschutz.gv.at) in addition to the existing Austrian Radon Project website (http://homepage.univie.ac.at/harry.friedmann/Radon/welcome.htm).

Presently, a centralised, web-based radon database is being developed. The purpose is to gather all indoor radon related data like measurements, mitigations, preventive measures, building characteristics etc. in one single database. These data are periodically evaluated to monitor the radon situation in Austria and to provide up-to-date information to the public.

The Austrian Centre for Radon

Based on the Radiation Protection Law the Austrian Centre for Radon was established in 2006 within the Competence Centre of Radioecology and Radon of the Austrian Agency for Health and Food Safety. The principal aim is to coordinate the radon efforts in Austria.

Present tasks are the design and implementation of the above mentioned Austrian radon database and the setup and maintenance of the official radon website. Other main projects are mentioned in this paper (radon in show caves and tourist mines, radon in low energy and passive houses, complete radon and thoron survey in three municipalities).

Discussion

As described in the preceding chapters, an important number of projects and studies has been conducted over the last 20 years in Austria. These efforts served to quantify the radon problem and to find solutions. Radon prone areas were identified, research on the factors determining the indoor radon concentration resulted in a better understanding of the relevant building characteristics, efficient remedial and preventive measures were tested and established, extensive surveys in kindergartens, schools, town halls, water supplies and show caves and tourist mines led to a reduction of the radon risk of the concerned individuals. The knowledge gained was used for legislative matters, for the setup of Austrian Standards, for information material for the public. Finally, the Austrian Centre for Radon was established to better coordinate and concentrate the radon efforts.

But: What was the actual impact on the radon exposure in Austria, how many lives have been saved?

So far, the impact in terms of radon risk reduction was very little. Priority was given to provide help (i.e. information, measurement, mitigation) to those with a high individual radon risk (i.e. high radon levels at home or at work). However, only approximately 0.07 % of the 70,000 buildings which are expected to exceed the action level of 400 Bq/m³ for existing buildings have been mitigated so far! Even worse, due to missing legal requirements to implement preventive measures in new buildings (at least in radon prone areas) the number of radon resistant new buildings is negligible. Bearing in mind that the total building stock increased by over 70 % in the last 40 years in Austria this was clearly a missed opportunity to decrease the collective radon risk.

Finally, despite folders, brochures, websites, and a radon CD public awareness is still very low.

Future tasks

Following the arguments of the previous chapter and with a view to recent publications and drafts on the radon issue (WHO Radon Handbook 2009, ICRP Radon Statement November 2009, EU BSS draft, IAEA BSS draft), the prime future tasks can be identified as:

- There is the need of a binding and executable legislation together with clear assignment of responsibilites to federal and local authorities as this is a prerequisite for an effective radon policy
- Implementation of compulsory preventive measures in building codes as this is an essential and cost-effective measure to reduce the collective radon risk
- Surveys in town halls and other public buildings in all radon prone areas to raise radon awareness of so-called multipliers (local politicians, local administrations)
- Frequent information campaigns to raise awareness of the population
- Extensive measurement campaigns to identify the buildings with elevated radon levels; as a consequence this will require training of building professionals for mitigation
- Integration of the radon issue in school and academic education (builders, engineers, architects, physicians)
- Improvement of the existing radon potential map (further indoor measurements, correlation with geology)

The future tasks should be shaped in a national strategy which also explains its implementation with respect to competent authorities and responsibilities, required financial resources, and evaluation and monitoring of the radon situation.

Conclusions

20 years of substantial efforts led to a widespread knowledge with respect to radon prone areas, factors determining indoor radon levels, remedial and preventive measures, radon in schools, kindergartens, town halls, water supplies, and show caves in Austria. Austrian radon standards and various information material for the public were issued.

However, the impact of these efforts in terms of lives saved or reduction of the mean radon risk was very low so far.

Therefore, in order to convert this knowhow into reduced health risk a number of measures are required like radon specific legislation including the clear assignment of responsibilites, implementation of preventive measures in building codes, further surveys and measurement campaigns to identify high radon buildings, frequent information campaigns, training of builders, engineers, and architects, and the improvement of the existing radon potential map for Austria. A national radon strategy which includes above tasks has to be set up.

Norway’s new national radon strategy

Standring, William; Hassfjell, Christina; Seyersted, Mette; Olsen, Bård;
Rudjord, Anne Liv; Strand, Per
Norwegian Radiation Protection Authority, NORWAY

Abstract
A multidisciplinary working group, including the Norwegian Radiation Protection Authority (NRPA), was initiated in May 2007 by the Norwegian Ministry of Health and Care Services to suggest a coordinated national effort to reduce radon exposure. Their findings were that since radon levels in Norwegian dwellings are log-normally distributed, most of the radon cancers are induced at low levels. They estimated that 70 % of the annual lung cancers in Norway induced by radon occur at levels below 200 Bq/m^3. A successful radon strategy therefore needs to reduce not only high but also moderate radon levels. Radon exposure occurs in all categories of buildings i.e., individual risk comes from the sum of exposures from different buildings; work and leisure. The working group’s findings lead to the Norwegian government publishing a new national strategy for radon in July 2009. The strategy seeks to reduce the sum of all exposures and is directed at all categories of buildings. The national strategy aims to achieve radon levels (a) that are as low as practically achievable and (b) that are below given maximum limits. It is divided into the following sections – radon in: land planning, construction of new buildings; existing dwellings, communities with extreme radon problems, public buildings (including schools and kindergartens) and in work places. The NRPA has been appointed by the Norwegian government to coordinate the implementation of the new national radon strategy in the period 2010–2014. Furthermore, the NRPA has changed its recommendations concerning radon, based on scientific evaluation of the current literature and in accordance with the new national strategy. These changes include ALARA and new action and maximum recommended radon levels of 100 Bq/m^3 and 200 Bq/m^3, respectively. This presentation will present the radon strategy, its justification and the planned implementation.

Introduction
Radon (Rn-222) is a radioactive noble gas produced continually in bedrock material and soils as part of the uranium-238 decay series. Both soil air and groundwater can therefore contain radon. It has a relatively short half-life (3.82 days) and is therefore potentially mobile before it undergoes radioactive decay. Generally, when discussing radon and health effects, one implicitly refers to α-emissions from radon gas and selected daughter nuclides, notably Po-218 and Po-214 (half-lives of approximately 3 minutes and 160 microseconds, respectively).

Increased mortality of metal miners working in the Erz Mountains, central Europe, due to unspecified respiratory illnesses was observed as early as in the 1500s. Recognition that lung cancer was to blame came in the late 1800s, with radon being proposed as the likely cause for the lung cancers in the 1920s. Today, radon is one of the most studied human carcinogens and was recognised as such by the International Agency for Research on Cancer in 1988[1], based on the 11 largest studies on miners (60 000 individuals) which have also been evaluated by the Biological Effects of Ionizing Radiation panel (BEIR VI, 1999).

Radon typically enters buildings from the underlying ground, especially during colder periods as heating a building creates a pressure gradient sucking soil air into the building via cracks and apertures in its foundation. Inhalation of radon and its decay products leads to the deposition of α-particles in the respiratory system. The α-particles have a high linear energy transfer and are quickly stopped by surrounding body tissue. This leads to lots of energy being deposited within very small areas and the inherent high relative biological effectiveness of α-emissions. The final endpoint from received doses is lung cancer; indeed radon is recognised as the second largest cause for lung cancer after active smoking. Strong evidence exists that a single α particle can cause complex clustering damage to a cells DNA and induce major genomic changes e.g. mutation (BEIR VI, 1999). The risk attributed to radon exposure is therefore assumed as a linear relationship with no threshold and no dose-rate dependence.

Several studies have more recently investigated indoor radon and lung cancer, notably three large pooled analyses (Lubin et al., 2004; Darby et al., 2005; Krewski et al., 2006). Importantly, the pooled analyses also made corrections for the smoking habits of study individuals. The pooled analyses show a linear relationship between radon exposure and the risk of developing lung cancer, also at low/moderate exposure levels i.e. applicable to the general population. The risk of radon-induced lung cancer increased with exposure and is proportional to the indoor radon concentration and the exposure time. Moreover, the pooled analyses confirmed there is no lowest threshold radon concentration where no risk occurs. The risk is greatest for smokers and former smokers, though never-smokers can also develop lung cancer as a result of radon exposure. Specifically, the pooled analyses have shown:

- the relative increase in lung cancer risk from a given radon exposure is the same for smokers and non-smokers
- the absolute radon risk is higher for smokers compared to non-smokers
- the majority of lung cancers induced by radon exposure are caused by a synergy effect between smoking and exposure to radon and these lung cancers could have been avoided if the individual either had not chosen to smoke or had not been exposed to radon.

In total, the studies of miners coupled with pooled analyses present strong scientific evidence that exposure to radon leads to an increased risk of lung cancer. Other health effects that have been associated to radon exposure include leukaemia in children, cardiovascular disease, stomach cancer, multiple sclerosis (MS) and skin cancer. However, such studies often rely on differing methodologies producing conflicting

[1] http://monographs.iarc.fr/ENG/Monographs/vol43/volume43.pdf

results and conclusions such that to date there is no scientific concensus for either proving or disproving such health effects are associated to radon exposure.

The Norwegian Experience

Increased focus on radon nationally and internationally led to The Norwegian Ministry of Health and Care Services initiating and leading a multi-sector working group in autumn 2007 to report on the challenges faced and available mitigation measures regarding radon (*arbeidsgruppen for samordnet innsats mot radon*). The working group consisted of delegates from the Ministry of the Environment, the Norwegian Labour Inspection Authority, the National Office of Building Technology and Administration, the State Housing Bank, the National Institute for Public Health, the Norwegian Directorate of Health and The City of Oslo; the Norwegian Radiation Protection Authority (NRPA) acted as secretariat.

Radon concentrations measured in Norwegian homes are approximately log-normally distributed; most Norwegians are exposed to low to moderate radon levels in the home (Fig. 1).

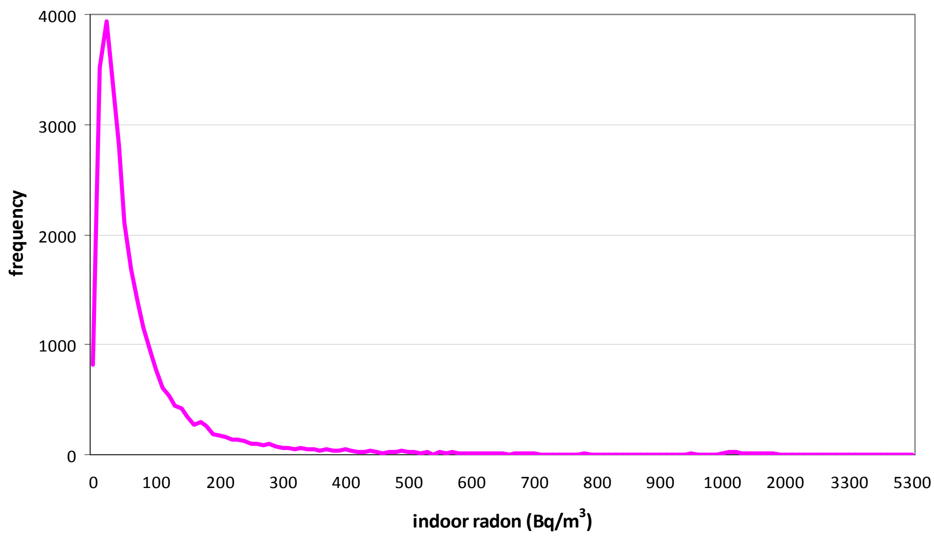

Fig. 1. Results from a national radon mapping campaign in 2000-2001. One radon measurement per dwelling, calculated as the annual average. Notice change of scale intervals on x-axis at indoor radon concentrations >1000 Bq/m^3; Total number of dwellings measured approximately 29 000. [StrålevernRapport 2001:6] available on www.nrpa.no (in Norwegian).

However, preliminary calculations based on the approach used by Darby et al., (2005) adjusted for the difference between the assumed average indoor radon concentrations in the United Kingdom and Norway (59 Bq/m^3 versus 88 Bq/m^3) have shown that approximately 300 people die each year in Norway from radon-induced lung cancer. Due to the distribution of indoor radon concentrations it has been estimated that approximately 70 % of these radon-induced lung cancer deaths occur at indoor radon concentrations below 200 Bq/m^3. To reduce the number of radon deaths substantially therefore requires that radon concentrations are reduced in all buildings, not just in the highest risk areas as all reduction of radon concentration and exposure time will have a favourable impact on health. Taking the population as a whole, health benefits from reducing indoor radon exposure can be considerable, even if only a modest reduction is achieved, so long as the reduction applies to a large number of buildings.

The multi-sector working group ended in the spring of 2009, when it formally submitted its report to the Ministry of Health and Social Care Services. The report and recommendations form the basis the Norway's new national strategy for the reduction of radon exposure in Norway, published 1 July 2009.

The national radon strategy

The national strategy is a tool for management and coordination of radon-prevention work in many sectors and shall be implemented in the five-year period 2009-2014. The strategic goals stated in the strategy are that the Norwegian government will:

- Work towards reducing radon levels in all types of building and premises to below the stated limits
- Contribute to reducing radon exposure in Norway as low as reasonably achievable.

As low as reasonably achievable implies that radon exposure should be reduced as much as reasonably possible, not only to a level just below the stated maximum limit. The choice of strategic goals is based on the knowledge that the risk from radon is proportional to exposure with no lower safe threshold value, such that all reduction of radon exposure will yield a health benefit. Radon can be present in all types of building and premises, and efficient prevention of radon risk therefore implies that radon levels must be reduced generally across society. The strategic goal of achieving as low radon levels as reasonably achievable is supplemented with legally binding limits where appropriate. This will ensure that the authorities have a basis for effective enforcement and compliance.

New indoor radon limits for certain types of building have been adopted (100 Bq/m^3, action required; 200 Bq/m^3, maximum) which are in line with the current recommendations from the World Health Organisation (WHO 2009), the Nordic Radiation Protection Authorities[2] and are supported by the NRPA.

Sub-strategies are proposed for work on:

- Radon in land planning
- Radon and the construction of new buildings
- Radon in existing dwellings
- Norwegian communities exposed to especially serious radon problems
- Radon in buildings and premises to which the general public are admitted
- Radon in the workplace

Stated goals and suggested measures for each sub-strategy are briefly described as follows:

[2] http://www.nrpa.no/dav/a4c7e5d25d.pdf

Radon in land planning

Here, the stated goal is:

- Radon must be emphasised in a systematic and sufficient way in all land planning.

A principal challenge for the work of local authorities in land planning in relation to radon will be to classify the land in relation to the radon hazard. Measures suggested in the national strategy include studying the relationship between radon hazard and geological conditions, as well as which requirements must be set for radon protection of buildings in relation to different degrees of radon hazard. A map-based tool for use in assessing radon hazard when planning land use at local and regional levels is suggested as well as establishing routines and systems that ensure that data concerning the building ground and geology, radon in household water supplies from drilled wells, building construction and radon in the indoor air are collected, both from the public and private sectors. These data should be made available for relevant local, regional and central authorities for administrative/management purposes. Identifying the occurrence of local areas with permeable surficial sediments/deposits and radium-rich bedrock is stipulated, as such areas are of importance with regard to radon levels in Norway.

Radon and the construction of new buildings

Here, the stated goal is:

- New buildings that are being constructed in Norway must have indoor radon concentrations that are as low as reasonably achievable and always less than 200 Bq/m^3.

This target can be achieved by setting specific requirements for anti-radon measures in all new buildings in the technical regulations pursuant to the Planning and Building Act. Specific requirements would include the use of radon barriers (e.g. a membrane), or the required ventilation of the ground below the building. It is difficult to estimate values for indoor radon concentrations in structures before they have been completed and taken into use. However, by setting requirements for preparing the buildings foundations such that it is possible to use active ventilation of the ground, it will be easier to carry out subsequent initiatives with ventilation/pressure modification to reduce the radon concentration to an acceptable level if the indoor radon levels are deemed too high in the finished building. Radon surveys should be carried out in all new buildings when they are taken into use. Specific measures include the possibility of establishing standardised methods/minimum requirements for radon-preventive measures to be used when constructing new buildings and premises. Supplementary guidance material will be necessary, generated by the National Office of Building Technology and Administration in collaboration with the NRPA. Such user-oriented guidelines that describe the regulatory framework and clarify the areas of responsibility for radon when constructing new buildings will be important for both builders and the local authorities supervising development.

Radon in existing dwellings

Here, the stated goal is:

- The proportion of dwellings with indoor radon concentrations exceeding 200 Bq/m^3 must be considerably reduced by 2020. The average indoor radon concentration must be reduced considerably by 2020, and a large proportion of dwellings must have achieved as low radon levels as reasonably achievable.

Different measures other than legal initiatives are the desired option to motivate and encourage homeowners to carry out radon surveys and technical preventive measures in their own homes. One condition for achieving the targets is that the radon-reducing building engineering methods are cost-efficient, safe and reliable. The development of better expertise and increased capacity for carrying out radon-reduction methods within the building industry will also be important. Specific suggested measures include undertaking systematic studies of radon in dwellings situated in all municipalities, the development of standardised radon-reducing measures for existing dwellings and generating campaigns to inform the population about radon: health risks, surveys and the implementation of remedial measures in dwellings. An additional proposal currently under review is the inclusion of radon measurements/status in home buyer reports.

Norwegian communities exposed to especially serious radon problems

Here, the stated goals are:

- All Norwegian communities in ”radon extreme areas” are mapped.
- Acceptable health conditions for the inhabitants of such communities are ensured through the introduction of necessary measures.

Extreme indoor radon concentrations can be measured in some buildings situated in specific areas in Norway. A large proportion of the buildings may have high radon values in such areas, including extreme values up to 50 000 Bq/m^3 in a few cases. Several such areas have been documented, but because the majority of Norwegian buildings have not yet been surveyed for radon, the possibility of finding other radon extreme areas during future surveys cannot be excluded. Such areas require special measures and follow-up, such as intensive information and survey campaigns when indications exist that a high radon hazard is present and assessing the need for individual assessment and medical follow-up, if necessary, of persons who have been exposed to very high radon concentrations over long periods.

Radon in buildings and premises to which the general public are admitted

Here, the stated goals are:

- The proportion of buildings with indoor radon concentrations above the maximum limit (200 Bq/m^3) is to be reduced considerably by 2020.
- The average indoor radon concentration is to be reduced considerably by 2020, and a large proportion of buildings have achieved as low radon levels as reasonably achievable.
- All schools and kindergartens have radon concentrations below the stated maximum limit.

The focus in this sub-strategy has been placed upon schools and kindergartens especially; the combination of obligatory presence and young individuals is deemed as a need for especially stringent requirements. The NRPA has completed an estimation of the costs involved in measuring all schools and kindergartens for radon and completing mitigation measures were appropriate (NRPA report, in press). The cost estimates were based upon the newly drafted legal limits for such buildings (100 Bq/m^3 action and 200 Bq/m^3 maximum), national statistics archive data and cost estimates received from recognised companies in the radon sector. Total costs were estimated as 50 MNOK for all kindergartens, primary and secondary schools [approximately 6.3 million €]. Other categories of public buildings will also be important however, such as hospitals, shopping malls, office buildings, hotels, restaurants, banks, commercial buildings, jails etc. Such buildings are often large and they contribute to the radon exposure of a large number of individuals. Those who are exposed to radon in such areas have no possibility of knowing that they have been exposed, or be in a position to reduce the exposure levels themselves.

Radon in the workplace

Here, the stated goal is:

- Norwegian workplaces shall have building and equipment conditions that ensure radon concentrations are suitable for a fully adequate working environment, based on consideration of employees' health, safety and the working environment.

Radon gas is the greatest source of exposure for ionising radiation amongst all Norwegian employees together. The working environment is already regulated with regard to other potential health risks such as asbestos and indoor climate, and initiatives outlined within this sub-strategy will also have a positive impact by reducing employees' exposure to radon. Together with the previous sub-strategy it is seen as important to study and devise standardised radon measurement techniques and anti-radon measures in different types of building as well as contributing to the development of knowledge about radon measurement techniques and anti-radon measures in large buildings generally.

Implementation of the national radon strategy

To implement the strategy's wide-ranging and ambitious goals the Ministry of Health and Social Care Services appointed the NRPA to establish a coordination group that would follow up the strategy. The coordination group includes participants from sectors that have policy instruments relevant to radon that will be able to suggest and produce radon mitigation measures. The group have met to discuss an overall plan for implementation as well as the establishment of specific working groups which will concentrate on different areas such as: land planning & radon mapping ; radon in existing dwellings; radon in the workplace and radon-related communication & information. This process is on-going.

Three specific pilot studies are also underway. The NRPA are funding a project working together with SINTEF Byggforsk[3] to establish suggested standard practice for a radon measurement protocol in large buildings, specifically schools. The results from this pilot study will enable a more widespread measurement campaign in schools during the 2010-2011 measurement period. The NRPA is also collaborating with the Geological Survey of Norway (NGU)[4] on a project designed to suggest a standardised method for measuring/classifying building raw materials (crushed stone and aggregates are first priority) with respect to their potential to cause elevated indoor radon concentrations, typically when used as fill materials around the foundation of new buildings. One of the goals from this project is to realise the establishment of a national system where radon information is available on-line from the producer, enabling consumers to base their decision on the potential radon risk. Lastly, the NRPA has initiated a pilot radon measurement study in dwellings that previously adopted radon mitigation methods during a 1999–2003 national subsidy campaign, to assess the long term effectiveness of different mitigation techniques used in Norwegian housing.

Regulatory amendments which will contribute to implementing the strategy

Changes have already entered into force 1 July 2009 in the Planning and Building Act (with regard to planning regulations) in which radon risk areas, or areas with potential risk, are to be given special consideration during land planning. Municipal authorities will now be required to include radon risk in risk and vulnerability analyses undertaken prior to new urban development. Furthermore, new radon requirements were adopted in the Planning and Building Act (with regard to building regulations) in March 2010. The new requirements include the introduction of legally binding indoor radon limits for new buildings (100 Bq/m^3, action required; 200 Bq/m^3, maximum). The new regulation also stipulates the use of anti-radon construction techniques, such as inter alia a membrane, and incorporating passive ventilation in the building foundations (which can be "activated" if necessary by installing a suction fan).

Another Norwegian regulation which is important regarding implementation of the strategy is currently in the process of being amended, namely the Radiation Protection Regulations. The new requirements include legally binding limits (100 Bq/m^3, action required; 200 Bq/m^3, maximum) for indoor radon in kindergartens, schools and rented accommodation, and are expected to be adopted in June this year, entering into force in 2014. The first of the pilot projects mentioned above is designed to help establish standard measurement techniques that will enable enforcement of these new radon limits.

Lastly, several other regulations are in the early stages of evaluating possible amendments with regard to radon, notably regulations concerning home buyers/sellers information requirements and radon in the workplace.

NRPA recommendations

The NRPA revised it's recommendations with regard to radon in 2009, the new recommendations are summarized as follows:

All buildings should have radon levels as low as reasonably achievable and within the recommended limits:

- Action Limit of 100 Bq/m^3
- As low levels as reasonably achievable – mitigation may also be relevant under the action limit
- Maximum Limit of 200 Bq/m^3

All buildings should be measured for radon regularly and always following modifications. Radon measurements should be performed as long-term measurements during the winter months using track-etch detectors. Radon mitigation measures in existing buildings should be source specific (aimed at identified radon sources) and seek to achieve as low radon levels as reasonably achievable.

Action Limit of 100 Bq/m^3
The action limit is defined as the threshold over which the NRPA recommends that radon mitigation measures are always initiated. If the annual mean indoor radon concentration is over the action limit, the NRPA recommend that effective radon mitigation measures are implemented as soon as possible to reduce radon levels. It is also recommended that radon measurements are repeated after mitigation, to ensure that the effect of measures is sufficient.

Maximum Limit of 200 Bq/m^3
The maximum limit is defined as the maximum indoor radon concentration that the NRPA considers should exist in all living rooms in all buildings. If the annual mean indoor radon concentration is over the maximum limit, it is recommended that (repeated) radon mitigation measures are implemented, followed up by control measurements, until indoor radon concentrations are as low as reasonably achievable and below the maximum limit.

The term action limit does not define a threshold where one can conclude that radon levels below it are "safe" levels, or where mitigation is not recommended nor has no purpose. If measurements reveal radon levels below the action limit, but where it is considered possible to achieve a substantial reduction of the levels through specific measures, such measures should be implemented to ensure that radon levels are as low as reasonably achievable.

Conclusion

Norway's new national radon strategy has set out wide-ranging and ambitious goals that will require a coordinated, systematic and sustained effort across several sectors in society. The NRPA is interested in sharing experience and keeping good contacts with other relevant authorities with regard to this work.

National measurement database in radon research in Finland

Valmari, Tuomas; Mäkeläinen, Ilona; Arvela, Hannu; Reisbacka, Heikki
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

STUK has carried out indoor radon measurements in Finnish dwellings since 1980s using alpha-track detectors. Our database contains measurements in 70 000 dwellings in detached houses, 17 000 dwellings in semi-detached and terraced houses and 5 000 flats. Residents are asked to fill in a two-page questionnaire form that contains questions on building characteristics, such as foundation type, ventilation type and radon prevention. Measurement activity is affected by location of residence, as people living in high-radon area are more likely to carry out radon measurements. Representative national and regional average concentrations were estimated by calculating the values in 1x1 km cells, and weighting each cell by the dwelling density. The calculated national average radon concentration in dwellings (excluding flats), 137 Bq/m^3, settles in between the representative values of 145 Bq/m^3 and 121 Bq/m^3 obtained in national random sampling surveys in 1990 and 2006, respectively. Municipal-specific radon map of Finland, as well as curves presenting average radon concentration by construction year, calculated using the dwelling-density weighting method, are presented. Until now, random sampling surveys have been necessary to obtain representative information on radon situation in Finland. The dwelling-density weighting approach opens up an alternative method. The database can be utilised, e.g., in radon prevention and mitigation studies.

Introduction

Radiation and Nuclear Safety Authority (STUK) has carried out indoor radon measurements in Finnish dwellings since 1980s using alpha-track detectors (Castren et al. 1992, Weltner et al. 2002). By the summer 2008, our national database contains measurements in 70 000 dwellings in detached houses, 17 000 dwellings in semi-detached and terraced houses and 5 000 flats. Nowadays most measurements are paid by the residents, but the material includes also measurements ordered by local authorities as well as those included in various STUK surveys and research projects.

Large indoor measurement databases can be used for radon mapping and identifying radon-prone areas (e.g. Miles, 1998). In Finland, a national Radon Atlas was published in 1997 (Voutilainen et al. 1997). An updated Radon Atlas will be published in 2010. On the other hand, national and regional radon statistics, such as average concentrations and percentage of houses exceeding the action level, are typically determined by representative sampling surveys. There have been two nationwide random sampling radon surveys in Finland with about 3 000 participants in each. The nationwide mean concentrations were 145 Bq/m^3 in houses and 82 Bq/m^3 in flats during the first survey 1990 - 1991 (Arvela et al. 1993). The respective values were 121 Bq/m^3 and 49 Bq/m^3 in the other survey in 2006 - 2007 (Mäkeläinen et al. 2009; 2010).

This paper investigates the possibility to calculate the national and regional radon statistics using the database material. At present STUK is carrying over 10 000 measurements per year. Utilising the data that is collected in radon measurements in any case would be a cost-effective means to update the Finnish radon statistics. The obvious problem is that the measurement material is highly unrepresentative. Residents in high-radon areas are more likely to perform the measurement, and also the regional campaigns are usually directed to risk areas. The bias is compensated by calculating the values for 1x1 km cells and weighting the values by the dwelling density in the cell. The results are compared to those obtained in the national random sampling surveys.

Material and methods

The radon measurements in the national database in Finland have been carried out using alpha-track detectors. The method has been described by Reisbacka (2010). The detector is posted to the resident together with a two-page questionnaire form that contains questions on building characteristics, such as construction year, foundation type, ventilation type and radon prevention.

The material of the present paper includes measurements in detached, semi-detached and terraced houses by the summer 2008. Apartments in blocks of flats are not considered.

The resident is instructed to locate the detector in the lowest residential floor, e.g. in the living room or bed room. Only measurements in actual living areas (not in cellars, etc.) of dwellings that were normally inhabited during the measurement were included in the material. Two or more detectors used simultaneously in a same dwelling is considered here as one measurement, with the average of the concentrations taken into account.

Measurements were included if the duration was at least 30 days and no more than 25% of the time had taken place outside the official measurement period, 1 November to 30 April. Annual average radon concentration was calculated using a seasonal correction factor of 0.85. The value was determined as the annual average vs. winter-time concentration ratio in the random sampling survey in 2006 (Mäkeläinen et al. 2009). However, also measurements longer than 272 days were included with the result interpreted as the annual average, without using the seasonal correction factor.

Measurements carried out in the same dwelling at different times were identified based on their address or, in case of insufficient address information, by the resident's statement in connection with the later measurement. A total of 87 457 different dwellings, i.e. 6% of all the dwellings in detached, semi-detached and terraced houses in Finland, were identified.

The location coordinates were determined by address using the StreetMap Finland road network material (ESRI Finland Oy), and data from the Population Register Centre and the National Land Survey of Finland. Some of the houses measured prior to 1997 were located from paper maps (Voutilainen et al. 1997). The positions of 75 270 dwellings are known accurately enough so that they could be located in a 1x1 km cell. The database contains 86 182 measurements in these dwellings (average 1.14 measurements per dwelling). There was on average 1.14 detectors used in each measurement.

The national and regional average concentrations as well as percentages of dwellings exceeding 200 Bq/m^3 were estimated by a dwelling-density weighting method. The values were calculated in 1x1 km cells and each cell was weighted by the number of dwellings (not including flats) in it. The dwelling density information was obtained from the Grid Database of Statistics Finland and is based on the situation on 31 December 2005. The grid data contains no detailed information on dwellings in cells that contain only one building. These cells include 1.3% of the Finnish population, and they were assumed to contain one dwelling, if there were inhabitants in the cell. A total of 1.4 million dwellings in 103 004 cells were included in the analysis. There was at least one measured dwelling in 21 258 cells. These measured cells included 73% of all the dwellings. The other cells were given the average concentration and percentage exceeding 200 Bq/m^3 from the nearest measured cell, or average of the values if there was more than one measured cell at the same distance. Each cell was included in the municipality where the centre of the cell is located.

The material of the present paper was compared to the 2 267 dwellings in detached, semi-detached and terraced houses completing the representative random sampling survey in 2006. The newest houses are underrepresented in the present material because the measurement is often made many years after the construction (Figure 1). The main difference in building characteristics is that the material contains clearly more hillside houses than the random sampling survey (Table 1). Other than that, there is no significant difference in the distributions of foundation types. This is assuming that the houses without a basement with an unknown foundation type do have the same percentage of slab-on-ground foundations as the other houses without a basement. There is no significant difference in ventilation types either (Table 2).

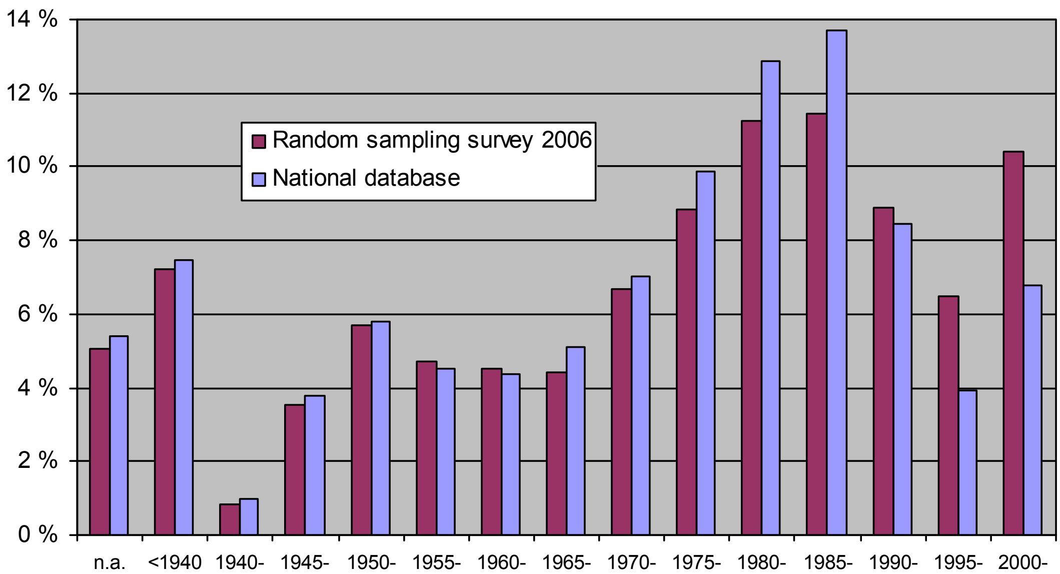

Figure 1. Dwellings in detached, semi-detached and terraced houses by construction year.

Table 1. Foundation types according to the questionnaire form filled in by the resident.

Foundation type	National database	Random sampling survey 2006
No basement, slab-on-ground foundation *	15% (39%)	33% (40%)
No basement, other type of foundation *	7% (18%)	18% (21%)
No basement, foundation type unknown	34%	10%
Cellar or partial cellar	22%	25%
Hillside house	21%	14%
Total (foudation type known)	52 179	2 060

*percentage in parentheses assuming the class *No basement, foundation type unknown* has the same *slab-on-ground* frequency than the other no basement-houses.

Table 2. Ventilation types according to the questionnaire form filled in by the resident.

Ventilation type	National database	Random sampling survey 2006
Natural	62%	58%
Mechanical exhaust	19%	19%
Mechanical supply and exhaust	19%	23%
Total (ventilation type known)	69 499	2 070

All in all, the comparison shows no indication that factors not related to the location of the house would cause significant distortion in the present material.

Results

The average radon concentration of the 75 270 dwellings included in the material is 227 Bq/m^3, if the first measurement in each dwelling is considered (Table 3). The estimated average concentration in all the 1,4 million dwellings in detached, semi-detached and terraced houses, determined by weighting the values calculated for 1 km^2 cells by the dwelling density, is 137 Bq/m^3.

There is 7 703 dwellings with multiple measurements. Typically, the latter measurement is carried out to verify the success of the radon mitigation, initiated by a high concentration in the first measurement. Therefore the average concentration is clearly lower (128 Bq/m^3), if the latest measurement in each dwelling is considered.

Table 3 shows also the results of the random sampling surveys. According to the survey of 2006, the average concentration in houses constructed after 1991 is not any lower as compared to that in older houses (Mäkeläinen et al., 2009). The difference between the surveys (145 Bq/m^3 in 1991 vs. 121 Bq/m^3 in 2006) is partly due to the higher outdoor temperature during the latter survey. Also the houses built before 1991 and having radon mitigation done after 1991 may have contributed to the difference.

The national average radon concentration and the percentage exceeding 200 Bq/m^3 obtained in the present work settle in between those from the two surveys.

Table 3. The average radon concentration and percentage of dwellings exceeding 200 Bq/m^3 in Finland (flats are not included).

Source	Number of measured dwellings	Average, Measured dwellings (Bq/m^3)	Average, All dwellings	>200 Bq/m^3, Measured dwellings (%)	>200 Bq/m^3, All dwellings
Database, highest value in each dwelling	75 270	233	139 [a]	31.5	16.9 [a]
Database, first meas. in each dwelling	75 270	227	137 [a]	31.0	16.6 [a]
Database, latest meas. in each dwelling	75 270	199	128 [a]	28.5	15.5 [a]
Database, lowest value in each dwelling	75 270	194	127 [a]	28.0	15.2 [a]
Random sampling survey 1990	2 096		145		17.9
Random sampling survey 2006	2 267		121		15.1

[a] Calculated by the dwelling-density weighting method.

There are 20 provinces in Finland having 9 000 – 230 000 dwellings each (flats not included). The weighting of the database material (first measurement in each dwelling) by dwelling density results in most cases in slightly higher radon values as compared to the random sampling survey in 2006 (Figure 2). Six provinces with the highest concentrations constitute a continuous high-radon area that is indicated in Figure 3.

Until now, the municipal-specific radon maps of Finland have presented the indoor radon situation concerning the measured dwellings (Figure 3a). On the other hand, the municipal radon averages calculated by the dwelling-density weighting method are shown in Figure 3b. The largest difference between the maps concerns the municipality of Kajaani. The average of the 713 measured dwellings is 405 Bq/m^3, and the estimate given by the dwelling-density weighting method is 120 Bq/m^3. The difference is due to a 3 km^2 local high-radon area that was extensively measured because of the high concentrations found there in the 1980s. This area includes only 5% of the 9 700 dwellings in detached, semi-detached and terraced houses in Kajaani, but as much as 45% of those measured.

The complete data of 75 270 dwellings was divided to smaller subsets to study how the number of measured dwellings affect the result obtained by the dwelling-density weighting method. A total of 376 subsets with 200 dwellings each were created. Any single dwelling was included in only one of the sets. Similarly, 250 sets of 300 dwellings, 150 sets of 500 dwellings etc. were made. The smaller the subset size, the higher the expectation value of the national average concentration calculated from the

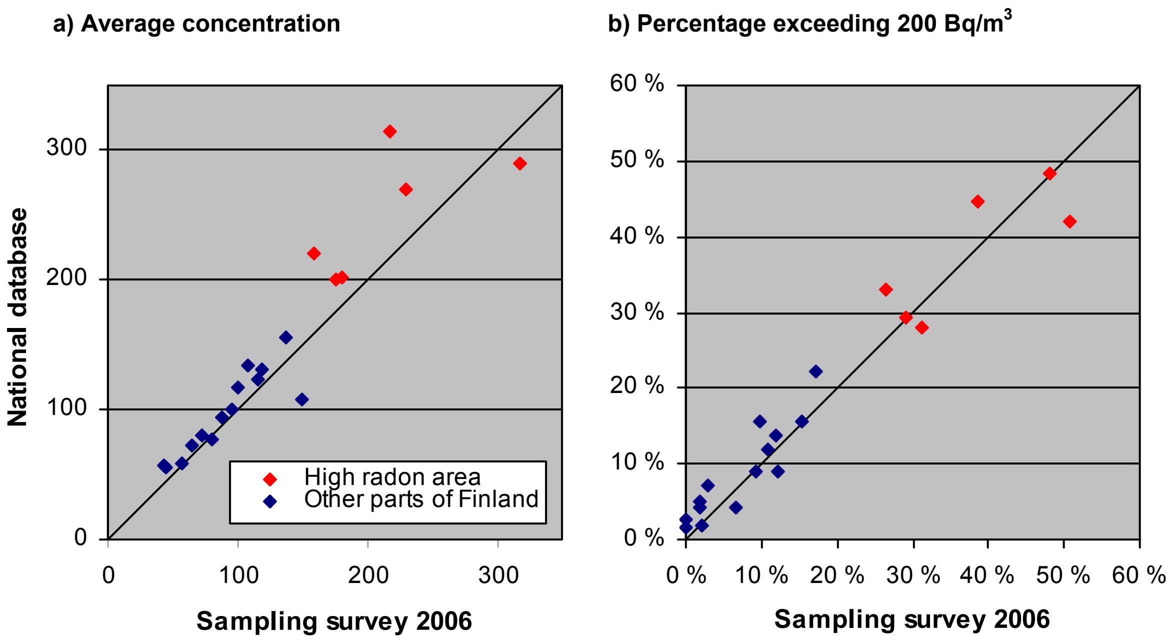

Figure 2. Radon in Finnish dwellings (not including flats). Values obtained from the national database by dwelling-density weighting method (first measurement in each dwelling) compared to the random sampling survey in 2006. Each point represents one of the 20 provinces of Finland.

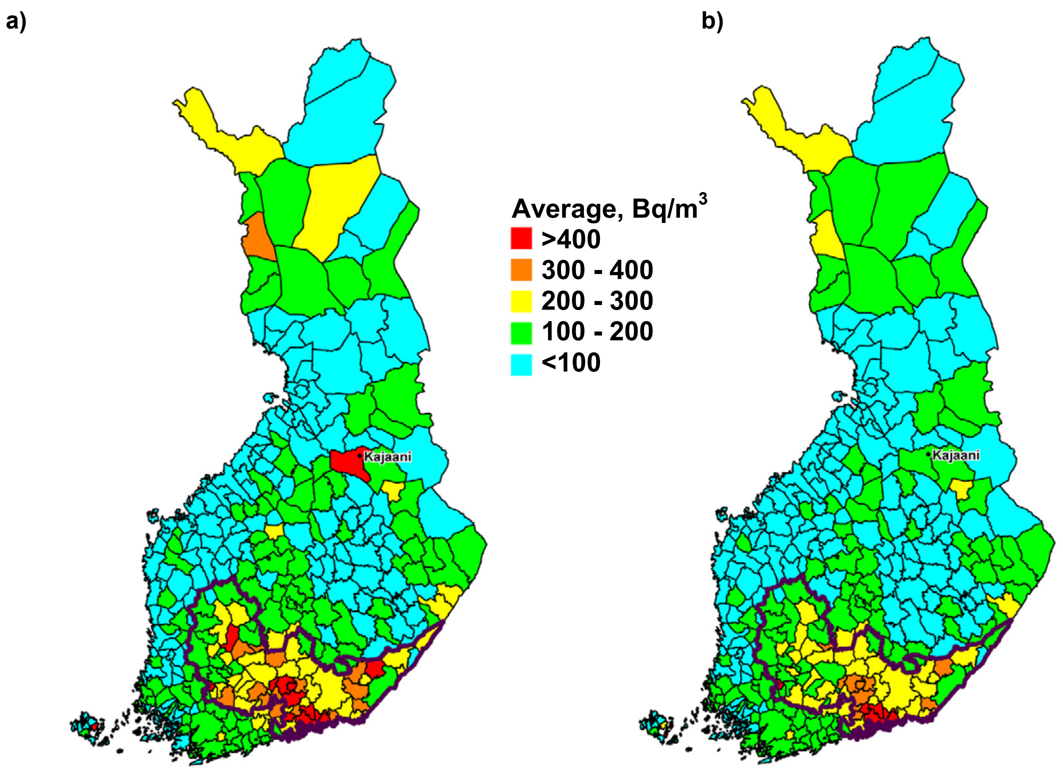

Figure 3. Radon by municipalities in dwellings (not including flats). a) Measured dwellings and b) All dwellings, estimated by the dwelling-density weighting method. First measurement in each dwelling is considered. High-radon area (six provinces with the highest average concentration) is separated by a violet line.

subset (Figure 4). The expectation value deviates less than 5% from the value 137 Bq/m^3 obtained using all the 75 270 dwellings, if at least 5 000 dwellings are included. In an extreme case of making the estimate from one dwelling only, the expectation value equals the average of the measured dwellings (227 Bq/m^3). The relative standard deviation among the concentration averages calculated using the different subsets is $3.6 \cdot n^{-0.6}$, as fitted in the data shown in Figure 4, where n is the number of dwellings used in the calculation. The fitted relative standard deviation is 0.4% for the complete data of 75 270 dwellings.

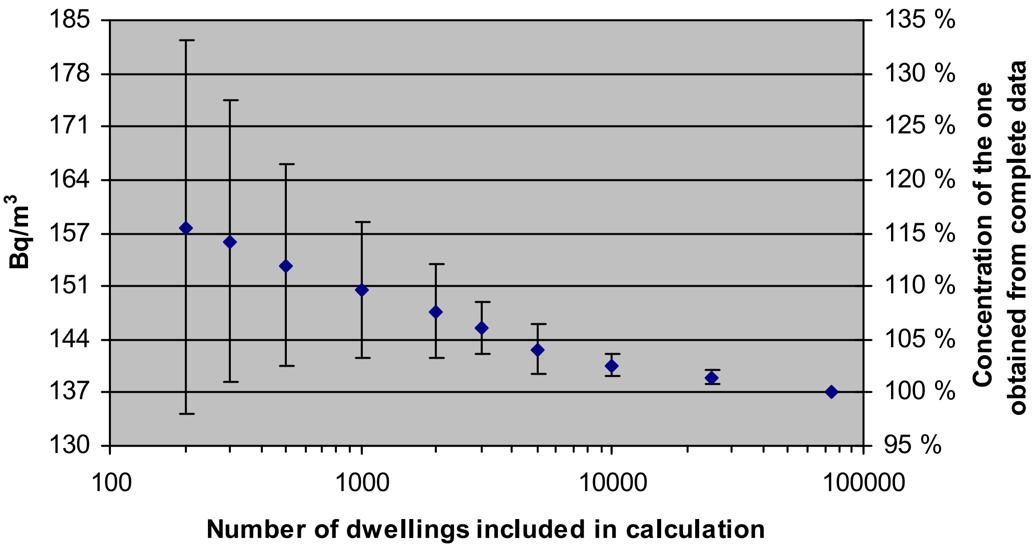

Figure 4. Average radon concentration in Finnish dwellings (not including flats) calculated by the dwelling-density weighting method. Uncertainty is given as ± one standard deviation. First measurement in each dwelling is considered.

The material contains 71 216 dwellings with a known year of construction, indicated by the resident. They were divided to sets of 1 000 (or 3 000) by the construction year. The dwellings with the same year were put in random order. The national radon average was calculated for each set using the weighting factors from the same grid data base (valid December 31, 2005) for all the sets. Thus, the analysis is simplified in a way that it does not consider the fact that houses are not built in the same 1 km^2 cells each year. The concentration trend of recently build houses is rather similar than the one by the random sampling survey in 2006 (Figure 5). The concentrations of older houses follow more closely the random sampling survey in 1990, being clearly higher as compared to the survey in 2006.

The oldest dwellings in the last set of 3 000 measurements were constructed 2002, that is 6 years before the latest measurements included in the material. The time gap between the construction year and the time when the estimate is available can be shortened by using smaller sets, with an expense of decreased accuracy. The oldest dwellings in the last group of 1 000 measurements were constructed 2005.

The national average concentrations calculated from these chronological datasets are 147 Bq/m^3 (1000 dwellings per set) and 143 Bq/m^3 (3 000 dwellings per set). These values are slightly lower respectively, than the corresponding expectation values 150 Bq/m^3 and 145 Bq/m^3 shown in Figure 4 for randomly chosen sets. Thus the chronological subsets overestimate the national average concentration (137 Bq/m^3) slightly less than the randomly chosen subsets.

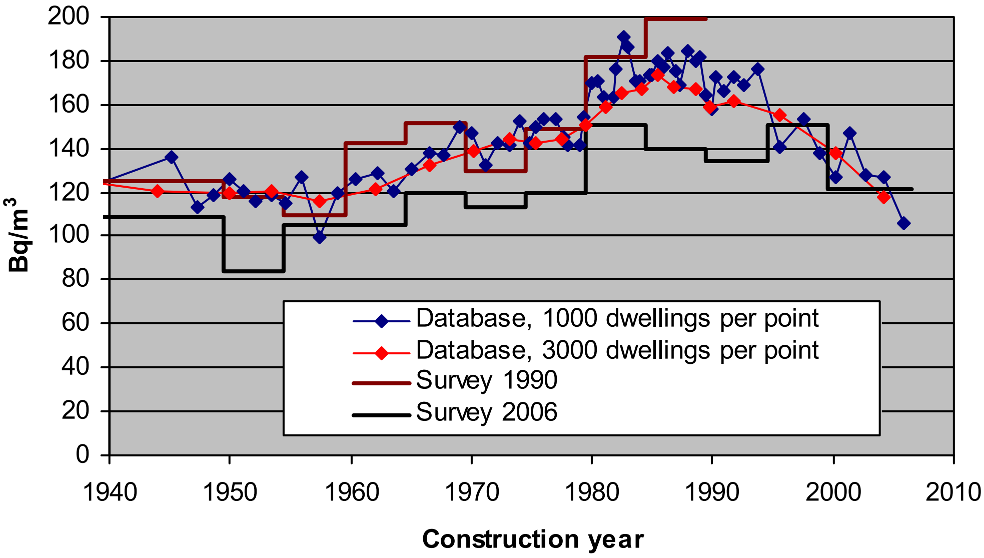

Figure 5. Average radon concentration in dwellings (not including flats) in Finland. The values calculated from the national database (first measurement in each dwelling) using the dwelling-density weighting method are compared to the results of the random sampling surveys in 1990 and 2006.

The average radon concentration of the Finnish houses was the highest in the 1980s and 1990s. The increasing trend before the 1980s was mainly due to the increased popularity of the slab-on-ground foundation type. On the other hand, three main reasons have been identified for the decrease in radon concentrations since the 1990s; i) increased popularity of the crawl-space foundation type, ii) mechanical supply and exhaust ventilation strategy is used in practically all the new houses and iii) radon-safe construction practices have become common (Mäkeläinen et al. 2009). Figure 6 shows, that the recent decreasing trend is the strongest in the high-radon area. This suggests that the radon-safe construction practices, being much more common in the high radon area, are a major contributor to the decreasing trend.

Discussion

The difference in radon concentration between the measured dwellings and the other dwellings seems to be caused mainly by factors related to the location of the house, such as soil gas radon content and soil type. These factors can be compensated for by the dwelling-density weighting method described in this paper. The number of measured dwellings in our database is large enough for producing municipality-specific results, although more work is needed to estimate the minimum amount of measurements needed for reliable results. The material can also be used, e.g., for monitoring radon situation in new houses by construction year. The sensitivity of the results to grid size needs to be studied. There is also a 0,25x0,25 km grid database that can be used, if the 1x1 km grid appears to be too coarse producing significant inaccuracy.

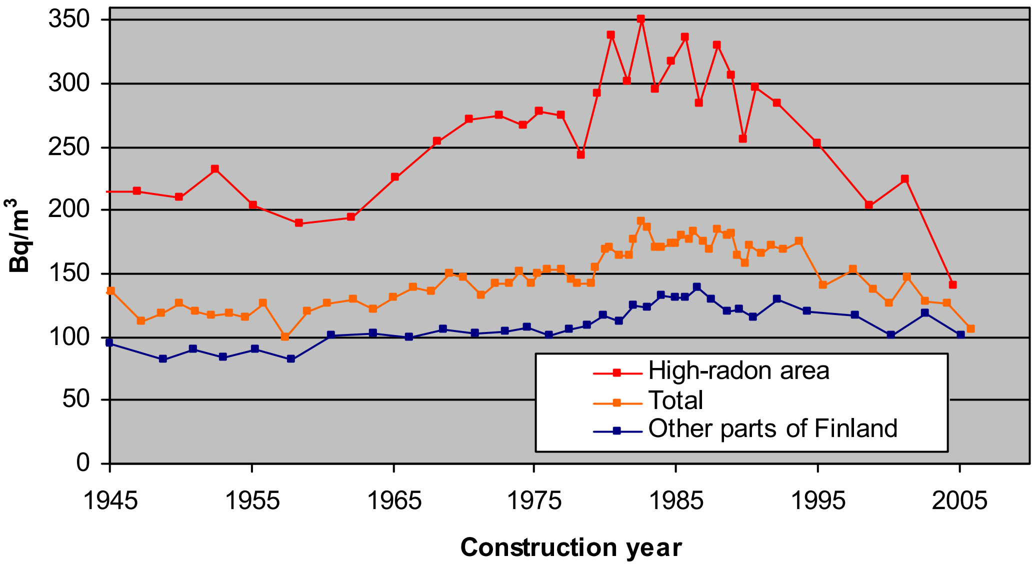

Figure 6. Average radon concentration in dwellings (not including flats) in Finland calculated from the national database (first measurement in each dwelling) using the dwelling-density weighting method. The high-radon area is indicated in Figure 3.

This paper considers only dwellings in detached, semi-detached and terraced houses, but it is important also to study blocks of flats. This is because the average radon concentration in the lowest floor flats with either soil or rock directly beneath them (no cellar etc.) is as high as in houses (Mäkeläinen et al. 2009). Since the number of measured flats is small (4 908), the radon statistics can not be produced with the same elaborateness as can be done in case of houses. The dwelling-density weighting approach requires some modifications when applied to the flats. Measurement is recommended especially for the lowest-floor apartments and consequently they are overrepresented in our material. Another factor causing overrepresentation of high concentrations is that a high value in one apartment often results in measuring also the other apartments in the same building.

Radon measurements are primarily intended to determine if mitigation is needed. Therefore residents are instructed to carry out the measurement in the lowest floor with living areas, because the concentration is usually higher there than in the upper floor. The abundance of lowest-floor measurements was not compensated for in this work. The effect of the radon detector location on the detected concentration needs to be analysed, if the concentration people actually are exposed to is to be accurately determined.

Conclusions

The regional and national average radon concentrations and percentages exceeding 200 Bq/m^3 were estimated by a dwelling-density weighting method using the measurement results in 75 270 dwellings with a known location. The results agree with those from national random sampling surveys with a reasonable accuracy. Until now, random sampling surveys have been necessary to obtain representative information on radon situation in Finland. The dwelling-density weighting approach opens up an alternative method. The new approach is cost-effective, as it utilises data that is collected in any case. The large number of measurements enables also presentation of municipality-specific radon situation.

Our future plans include utilisation of the national measurement database more widely in radon research. Measurement results, combined with the building characteristics data collected by a questionnaire form, can be utilised, e.g., in radon prevention and mitigation studies.

Reducing lung cancer incidence by health campaigns: A review of the uptake, health benefits and cost effectiveness of Smoking Cessation and Radon Remediation Programmes in Northamptonshire, UK

Denman, Antony[1]; Phillips, Paul[1]; Groves-Kirkby, Christopher[1]; Timson, Karen[2]; Shield, George[2]; Rogers, Stephen[2]; Campbell, Jackie[3]

Abstract

The greatest risk factor for lung-cancer is smoking, the second largest factor being raised radon levels at home. Initiatives to stop smoking and reduce domestic radon levels have met with some success, but in both cases a significant proportion of those affected fail to respond. The two risk factors combine, so that those who smoke and live in a house with high radon levels are at higher risk than if exposed to only one of the two threats. There is the potential for combined public health campaigns to better target those affected.

Our group has studied both the smoking cessation and radon remediation programmes in Northamptonshire, UK, considering the costs and health benefits of each, and, using postal questionnaires, recording the demographics of participants. Our analysis suggests that the demographics of the two groups are significantly different. Those who remediate tend to be older, include fewer smokers and have fewer children.

The health benefits from stopping smoking are greater than those from radon remediation, and the smoking cessation programme costs less per lung-cancer averted. In addition, the continuing reduction in smoking prevalence in the UK will reduce the effectiveness of radon remediation campaigns.

This paper discusses the synergy between the programmes, and argues that there is merit in an integrated approach to these health campaigns, and in particular to extending smoking cessation programmes to include advice on reducing the risks from radon.

Introduction

Smoking is the most significant risk factor for lung-cancer. Since this became known, education and health campaigns have been conducted to reduce smoking prevalence. In

England, smoking prevalence has dropped from 45% in 1974 to 28% in 1998, declining further to 21% in 2008 (Dept. of Health, 2010).

Radon, a naturally-occurring radioactive gas, is the second most significant risk for lung-cancer after tobacco smoking. High levels of radon were first identified in uranium mines, but more recently, it has been established that significant levels are found in the built environment, and case-control studies have shown an associated increase in lung cancer in the public from radon in their homes (AGIR, 2009; BEIR VI, 1999; Darby et al., 2005).

Northamptonshire, a county in central England, is one of the areas in the UK where a significant proportion of homes have radon levels over the UK domestic Action Level of 200 Bq·m^{-3} (Bradley et al., 1997). Radon levels can be tested simply, and, if raised radon levels are found, remediation work, usually involving the introduction of a sump and attached pump to extract radon to outside and costing around £750 (around 825€), will reduce radon levels nearly always well below the Action Level. Over the last 18 years, campaigns to measure and reduce radon in homes have been implemented through the local councils' environmental health departments. Despite publicity, only around 40% of householders have tested radon levels in their home, and of those who discover raised levels, only 15% remediate their homes (Chow et al., 2007). Our group has studied the characteristics of those who remediate their homes, and has shown that they are older, have fewer children, and include fewer smokers than the general population (Denman et al., 2004).

The risks from radon and smoking are considered to be sub-multiplicative (BEIR VI, 1999), and so smokers, who are most at risk from radon, are not being targeted by current radon remediation campaigns. This led our group to consider the local smoking cessation initiatives, and whether these might be valuable in reducing radon-induced lung cancers. Our initial work showed that the smoking cessation programme in Northamptonshire has added value compared to cessation programmes in areas with lower radon levels. In addition, there is greater health benefit for a smoker living in a high-radon house from quitting smoking than from remediating the house and continuing smoking (Groves-Kirkby et al., 2008).

In England, smoking cessation programmes are commissioned by the local Primary Care Trust (PCT), part of the National Health Service (NHS), with the assistance of General Practitioners (GPs). Our group has recently studied the characteristics of those who join and participate in smoking cessation programmes.

This paper compares those who remediate and those who quit smoking, and considers the characteristics of each group, and their similarities and differences. It also compares the cost-effectiveness of each programme, and considers the impact of the steady reduction of smoking prevalence in England. These results can inform future public health initiatives to improve the response to both risks.

Material and methods

All houses in the radon remediation series were remediated by a single company following UK Radon Council good practice (The Radon Council Ltd, 1995). In early 2002, additional personal information to make the individual risk assessments was obtained by postal questionnaires sent to all the houses in the study. The questionnaire included questions about all of the residents in the house, including age, occupation, smoking habits and the time each spent inside the house on a recent day; detailed results from this study have been reported previously (Denman et al., 2004).

Participants of the Northamptonshire PCT Smoking Cessation Programme were contacted by telephone in 2007 to ask about their quit status. During the call, participants were invited to complete a written questionnaire, and if they agreed, this was posted to them with a stamped addressed envelope for return. The answers were entered into a bespoke Access database, using double entry and record comparison to ensure data accuracy.

The results from the smoking cessation programme were assessed by examining the bivariate relationships between the main outcome measure (whether the respondent indicated that they continued to have quit smoking), and the socio-demographic factor under consideration, using Chi-squared tests. The results from the remediators were compared to the smoking cessation scheme participants in a similar analysis.

A separate exercise analysed demographic data from 4,626 smokers registering with the Northamptonshire Smoking Cessation Service during 2004-2005 and setting personal quit-dates. Smoking status was validated at 4 weeks by carbon monoxide monitoring, and at 26 and 52 weeks by telephone questionnaire (unvalidated, self-reported). Using age, gender, smoking status and postcode of residence (surrogate for domestic radon concentration) derived from this cohort as input data for the European Community Radon Software (ECRS) tool (Degrange et al., 2000), estimates of the lung-cancers averted in the quitting cohort were generated, permitting preliminary analysis of the relative cost-effectiveness of radon remediation and smoking cessation.

Results

In the radon remediation series, 122 questionnaires were sent, and 73 householders replied (59.8%). The houses contained 162 occupants, an average of 2.22 per house (range 1 to 5). These included 138 adults and 24 children. 1 household did not give personal data on the occupants, leaving 72 houses with 160 occupants suitable for further analysis. Householders had been living in the house for an average of 16.2 years (range 0.8 to 45.9 years). 3 households (6 occupants) had moved in since remediation. 6 households contained smokers, 3 indicated that around 100 cigarettes a week were smoked in the house, 2 suggested 30 cigarettes, while one household smoked 4 cigars a week. In addition, one respondent indicated that only a young adult in their household smoked, but did so only outside the house. 10 of the 160 occupants (6.25%) indicated that they were current smokers. In 2 households, both adults smoked. The remaining 4 households who smoked contained 5 non-smokers who would be subject to passive smoking risk in additional to the radon risk.

In the smoking cessation series, some 482 4-week quitters were identified from the Northamptonshire PCT Stop Smoking Service. These smokers had successfully quit at 4 weeks, as assessed by the Department of Health criteria, during the period 1st July 2006 to 30th September 2006. The sample population had previously consented to be followed up at one year, as part of routine data collection to ascertain their current quit status, and were asked, during this telephone contact if they would provide some further information in a written questionnaire for research. Some 317 questionnaires were sent out. Completed questionnaires were received from 103 quitters (32%), 68 of whom confirmed that they had not smoked since, while 35 had relapsed. 77 lived with a partner, or parent, while 63 had children under 18 living at home, while a further 17 had children over 18 at home.

There are statistically significant differences in family size between remediators, quitters, and the national population. Remediators' family size is smaller, and more likely to be 2, less than that of the national population ($p < 0.001$), while the distribution of family sizes for quitters differs to that of both remediators ($p = 0.006$) and the national population ($p = 0.011$), with the quitters generally having larger family sizes.

The length of time that people had spent in their current house was also studied, and compared to National Statistics. The results are shown in Table 1. Separate data was obtained for <1 year and >40 years but the frequencies were too low for valid statistical analysis and they were therefore combined to form those shown in the Table. Although it appears that remediators have been in their current home longer than the national average, this is not statistically significant ($p = 0.110$). However, it is statistically significant that quitters are more likely to have been in their current house for a shorter time than both remediators and the national population ($p = 0.036$, and $p = 0.033$ respectively).

Table 1. Length of Time in Current Home.

Time in Current House	England, Home Owners 2001/2	Radon	Quitters
t < 3 years	2,755,000	5	18
3< t <5 years	1,424,000	6	15
5 < t <10 years	2,416,000	13	27
10 < t < 20 years	3,525,000	20	19
t < 20 years	4,174,000	26	24
Total	14,294,000	70	103

From the questionnaires, analysis of the ages of responders indicates that the remediators tend to be older than quitters, and for the radon remediators there is a clear peak in the age range 60 to 80 years, which is also seen in Figure 1. However, the difference between remediators and quitters is not statistically significant at the 5% level ($p = 0.185$).

The age distribution of all occupants of remediated houses and of houses with quitters is shown in Figure 1, together with a comparison with the age distribution of the Northamptonshire population. The differences in this case are highly statistically significant (all have $p < 0.001$). This is presumably related to the statistically different family sizes in each group, noted above.

The questionnaire sent to those on the smoking cessation programme also permitted comparisons between those who had remained quitters for a full year, and those who had relapsed since the previous assessment at 4 weeks. Table 2(a) shows that the continuing quitters were more likely to have children under 18 at home. This is statistically significant, with $p = 0.002$. Those who relapsed were more likely to have children over 18 at home, as in Table 2(b). This is also statistically significant ($p = 0.003$). Continuing quitters are also more likely to be living with a partner or parent, see Table 3, with this finding being significant at the 5% level ($p = 0.046$).

Relapsed	14	21
Still not smoking	49	19
Total	63	40

Table 2(b)

Status	Children over 18 at home	
	Yes	No
Relapsed	11	24
Still not smoking	6	62
Total	17	86

Table 3. Association between quit status and living with partner or parent.

Status	Parent or Partner in home	
	Yes	No
Relapsed	22	13
Still not smoking	55	13
Total	77	26

Of the initial cohort of 4,626 quitters participating in the cost-effectiveness study, only 435 remained tobacco-free after 52 weeks. Using the ECRS software, loss of life-expectancy and excess lung-cancer incidence were modelled for each individual in the study, assuming that they: (i) continued smoking, (ii) quit smoking at the time of the study and (iii) had never smoked, in each case for zero radon exposure and the mean annual level in their home imputed from their postcode of residence. Preliminary results are summarised in Table 4. The average life-year saving among ex-smokers in the Northamptonshire radon environment is 1.21, being the difference between the average smoking-attributable life-year losses of 1.93 and 0.72 for smokers and ex-smokers respectively, compared with 1.10 in a radon-free environment.

Table 4. Cost-Effectiveness Comparison.

Smoking Cessation Study		Radon Remediation Study	
Population	462		127
Attributable Lung Cancers	55.22		6.84
Total cost (service+medication)	£1,156,515	Total remediation cost	£746,725
Total cost per quitter	£2,503		
Cost per life-year saved	£2,069		£8,047

Discussion

UK Smoking Cessation Programmes place emphasis on quitting at an early age, as the British Doctors Study (Doll et al., 2004) showed that those who quit successfully by 35 years avoid much of the excess mortality risk due to smoke, those who quit successfully by 50 avoid about half the risk, and those at 60 avoid one third the mortality risk. The age of the occupants when radon remediation is carried out is similarly important, as the degree of risk from radon depends on the total time spent exposed in the home together with the average radon level in the house prior to remediation.

In our study, an analysis of the ages of responders indicates that, although remediators appear to be older than both quitters and the Northamptonshire population, this difference is not statistically significant at the 5% level. However, the age distribution of quitters together with their partners and children has a statistically lower age profile than the population, which is in itself lower than remediators and their families. This contrasts with the relative risk to other occupants in the home, since the reduction in health risk when radon is reduced is similar for each member of the family, while for the smoker, the risk to other family members is the lesser one of passive smoking, assuming they do not smoke, or none, if the smoker smokes outside.

In addition, our study shows that remediators have smaller families than quitters, and have lived in their current homes longer. Therefore participants on the smoking cessation programmes represent a different target population from those who remediate, so there is a potential to extend the reach of a radon remediation initiative.

The questionnaire to quitters also asked about the quitters' knowledge of radon, and whether radon, amongst many other factors, played any role in the decision to quit. These results, reported elsewhere (Groves-Kirkby et al., 2008), showed that few respondents regarded radon as a significant decision factor, and that the direct health concerns as a result of smoking were much more significant as factors affecting the decision to quit.

Smoking cessation programmes have been in operation for longer than radon remediation programmes, and there has been extensive analysis of their efficacy, reflected in many more publications. As a result, smoking cessation programmes have evolved to improve their operation, and to target remaining smokers.

The age profile of UK smokers has changed significantly since 1970 (Dept. of Health, 2010), dropping significantly so that people aged 20 to 24 smoke more than any other age group, which is consistent with the age profile of quitters in our study. There is a considerable literature on other characteristics of smokers, and the relative success of different smoking cessation techniques, and the likelihood of relapse.

Solberg et al. (2007) studied the educational background of young adult smokers (age 18 to 24 years) in the US, and concluded that the level of interest in quitting, number of quit attempts, and relapse rates did not depend on educational level, although higher educational level was associated with a lower proportion of smokers. Macy et al. (2007), studying a similar group, showed that 33% of long-term quitters who had quit for over 1 year, had relapsed by 5 years. They were less likely to relapse if they were married to a non-smoker, had only one parent who smoked, or worked in a smoke-free building. Tucker et al. (2005), also studying young smokers and quitters (23 to 29 years), found that smokers were more likely to have higher rates of substance abuse, illegal activity, poor mental health and victimisation, but these factors were less relevant to quitting than social transitions and interpersonal factors, race, ethnicity, and health status. Other studies have shown that quitters were more likely to relapse if they had higher emotional distress, higher nicotine dependence, higher alcohol consumption, and more medical problems (Augustson et al., 2008), and increased post-quit anger (Patterson et al., 2008). However, Freund et al. (1992) report that recent hospitalisation and a diagnosis of heart disease increases the likelihood of cessation.

Mills et al. (2008) questioned smokers attending US Emergency Departments and found that 37.8% (441/1168) had children. They found that smokers with children were more interested in quitting, and more confident in doing so. Our study supports these findings, with 61.2% (63/103) of those entering the smoking cessation programme having children under 18 at home, rising to 72.1% (49/68) for continuing quitters at one year. Interestingly, our study shows that, if the children are over 18 then the converse is true – that the parent is more likely to have relapsed.

Smoking cessation programmes have developed over the years, but it is proving increasingly difficult to reduce smoking rates further, and Twigg et al. (2009) suggest that a heterogeneous range of different programmes will be required to reach ‘hard-to-engage’ populations. Bauld et al. (2008) compared two types of cessation programme in Glasgow – a group scheme with GP support, and a pharmacy-based scheme – and showed that the demographics of those recruited to each scheme was somewhat different, with a higher proportion of those aged 16 to 40 attending the pharmacy-based scheme. There was also a significantly higher proportion of people with children, whilst the group scheme had an increased percentage of females. The quit rate at 4 weeks was higher for the group scheme. They showed that those who were more socially deprived were less likely to quit, which concords with other studies, which also note that those in socially deprived areas are more likely to smoke (Twigg et al., 2009). Of the factors considered in our study, Bauld et al. (2008) found a significantly higher cessation rate in those with partners/spouses ($p = 0.046$), but only in the group scheme; whereas those with children had a significantly lower cessation rate ($p = 0.003$) but only in the pharmacy scheme. It should be noted that this study was conducted for 4-week quitters, whilst our study was of long-term (1-year) quitters, and many authors note that there is a large relapse rate over the first year. For example Zhou et al. (2008), in a major international study, note a relapse rate close to 80% in the first quarter, with 60% of the remainder relapsing in the next quarter. Zhou et al. also note that relapse rates vary between countries, with subjects in USA and Canada more likely to relapse than those in France, Spain and UK. Others more likely to relapse include those who have failed to quit before, those with cessation-related sleep disturbance, and with heightened anxiety.

Despite these concerns, smoking prevalence in England has steadily reduced over many years, and the Department of Health have published an initiative to reduce smoking prevalence to 10% in 2020 (Dept. of Health, 2010). This target is ambitious, but Canada and Victoria, Australia, both demonstrate falling prevalence rates and already have smoking prevalence below 20%.

Our study indicates that it would be possible to extend the response to the health risks of radon if quitters were provided with safety and remediation information during their interaction with smoking cessation programmes in areas affected by radon.

It should be noted, however, that quitting smoking also saves money, whilst the householder needs to spend money to remediate if raised levels are found. It is interesting to note that, in their questionnaire responses, quitters placed the cost issue as the 7th most significant factor in their decision to quit smoking – below the direct health risks, but above family pressure, and the knowledge of radon (Timson et al., in preparation).

Among smokers in Northamptonshire, individual and population mortality increases with smoking status and radon exposure, with smoking accounting for 5 to 8 times more life-years lost than radon. Quitting smoking is expected to reduce life-years lost to avoidable lung-cancer by 121 years per 100 quitters at a cost of £2,069 per life-year saved. If the same group were to remediate their homes while remaining smokers, the intervention would reduce life-years lost to lung-cancer by 21 years for every 100 remediators at a cost of £8,047 per life-year saved. For ex-smokers and non-smokers with comparable radon exposure, remediation would reduce life lost to lung-cancer by 10 years per 100 remediators and 3 years per 100 remediators respectively, at costs of £17,000 and £62,000 per life-year respectively.

The effect of smoking prevalence is important in radon remediation programmes. For example, AGIR (2009) estimate that, for an annual build of 200,000 new homes in the UK, installation of radon-proof membranes will currently avert 4.4 lung cancers per year. Applying the current relative risks for radon in smokers and non-smokers, this would drop to 2.5 lung cancers per year by 2020 if the UK achieves its 10% smoking rate target.

Conclusions

This study has confirmed that the higher motivation to quit in smokers with children at home, noted by Mills et al. (2008), converts into a higher percentage of smokers with children entering our smoking cessation programme initially and then a statistically significant higher proportion of such smokers continuing to quit at one year. Conversely, the presence of young adults over 18 in the home increases the likelihood of relapse before one year. The presence of a partner or parent in the home decreases the likelihood of relapse.

The study also indicates that those joining a smoking cessation programme differ considerably from remediators, and in particular have significantly larger families, while remediators have lived in the same house for a longer time. Thus they represent a different target group, who do not currently consider radon as a significant risk.

Finally, although the quantitative analysis of cost-effectiveness remains incomplete, it is apparent that in a radon affected area, the cost per life-year saved from a smoking cessation campaign may well be significantly less than that arising from a radon remediation campaign.

There is thus the potential to extend the response to the health risks of radon if provided with safety and remediation information during their interaction with the smoking cessation team in radon Affected Areas.

The approach of radon remediation programmes in England and Wales to date has been through local Environmental Health departments and targeted at remediating the home. However, this analysis suggests that there is scope for the National Health Service to take up this concern, to target smokers and to benefit from the greater experience of running smoking cessation programmes. In addition, the falling smoking rates suggests that the balance between smoking cessation programmes and radon remediation programmes in lower radon areas should be coordinated in order to achieve the best value for money, and highest benefits.

A model describing indoor concentrations of thoron and its decay products

Meisenberg, Oliver; Tschiersch, Jochen
Helmholtz Zentrum München – German Research Center for Environmental Health,
Institute of Radiation Protection, 85764 Neuherberg, GERMANY

Abstract

In the past, the radioactive noble gas thoron (^{220}Rn) was thought to occur only in negligible concentrations. But recently, increased thoron concentrations were found in traditional Chinese and Indian mud buildings, where their contribution to the inhalation dose of the dwellers can be in the order of magnitude of the dose from radon (^{222}Rn). Moreover, the WHO's Radon Handbook of 2009 advises dose reductions also with relatively moderate exposures, for which even average additional thoron concentrations can be crucial. Therefore, a model of the occurrence of thoron and its decay products indoors was developed.

The solution of the differential equations which describe the sources and sinks of the nuclides of the thoron decay chain yielded a theoretical relation between the concentrations of the nuclides in the unattached and the attached state, which are important for inhalation dosimetry. Several differences to existing radon models could be identified. Transfer coefficients occurring in the differential equations were determined experimentally. For this purpose various atmospheric conditions were adjusted in a small-scaled traditional mud dwelling, which had been erected in a laboratory at Helmholtz Zentrum München. Because of the prevalence of increased thoron concentrations in homes with mud as building material, special emphasis was given to study thoron exhalation from mud structures.

To validate the model, model predicted concentrations of thoron and its decay products of real Chinese and Indian mud dwellings were compared to measured concentrations in those rooms. The model makes possible to assess exposures of dwellers to thoron and – combined with a dose model – to calculate their inhalation doses in dependence on their living habits from easily measurable constructional properties of the dwelling. The model predicts significant exposures for residents of buildings with mud construction elements in other countries as well.

Introduction

Need for a thoron model

The radioactive noble gas radon and its decay products have been known as indoor health risks for several decades as they can cause a significant dose to the respiratory tract and other tissue. Only recently, the connection between the exposure to radon and an increased incidence of lung cancer with a linear dose-response relation even below 200 Bq m^{-3} was shown in epidemiological studies (Darby et al. 2005, Krewski et al. 2005). These findings, among others, induced the World Health Organization to advise measures for the mitigation of exposures also with relatively moderate concentrations of radon and its decay products (WHO 2009).

The radon isotope ^{220}Rn (thoron) occurs in most houses mainly from the building material as its half-life is only 55.6 s. For dwellings made of brick or concrete, it contributes to the inhalation dose of the dwellers in the order of 10–20% of the dose caused by all radon isotopes (UNSCEAR 2000). Therefore, previous studies focused on the exposure to the prevalent isotope ^{222}Rn (called radon in the following) whereas thoron was examined only rarely or as a side-aspect of radon measurements (e.g. Stranden 1980, Steinhäusler 1996). In the light of the proposed reduced reference levels (WHO 2009), the dose contribution by thoron gains importance for the total indoor exposure in such dwellings.

Moreover, in the last years occurrences of increased thoron concentrations have been discovered in dwellings made of unfired mineral building materials as adobe and mudbricks (Sreenath Reddy et al. 2004). The contribution of thoron and its decay products to the inhalation dose of people living in the traditional caves which are dug into the loamy soil of the Central-Chinese Loess Plateau has been found to be up to 50% (Shang et al. 2005).

Therefore a characterization of the influence of indoor parameters on the occurrence of thoron and its decay products is required. The model for the calculation of the concentrations of radon and its decay products in mines which was formulated by Jacobi (1972) and was adapted to arbitrary indoor atmospheres by several contributors (Knutson 1988, Porstendörfer 1994) can be used as a base. However, the decay chain of thoron differs from that of radon in several essential properties such as the decay modes and half-lives of the respective nuclides, which causes various significant changes in the model structure. Additionally, several transfer coefficients between the compartments of the thoron model cannot be adopted from the radon model but must be determined separately.

This study presents results from a self-contained indoor thoron compartment model (Meisenberg and Tschiersch 2010) illustrates the reasons for necessary differences to the radon model. Useful instructions for the metrology of thoron are deduced from the model predictions. Types of houses in which increased thoron concentrations can be expected are presented.

Relevant properties of thoron and its decay products

Thoron with its short half-life of 55.6 s cannot penetrate foundations which can usually be found in most modern buildings. On the other hand, a comparatively small thickness such as that of walls and ceilings can be sufficient to cause significant exhalations of thoron. Therefore the building material and thus a part of the building is the major source of indoor thoron. Hence, a thoron model must incorporate the exhalation of the gas and the influences on it.

The spatial distribution of thoron in a room is not homogeneous but features increased concentrations close to thoron exhaling surfaces. Therefore its concentration cannot be specified by a single value but must be characterized depending on the position in the room.

As with radon and its decay products, the dose after inhalation of the radioactive nuclides of the thoron decay chain is mainly caused by their alpha-particle emission. Thus the exposure to thoron can be assessed by the potential alpha-particle concentration *PAEC*, which is the total energy of the alpha-particles emitted by the decay products per volume. Therefore, a thoron model must specify the influence of indoor parameters to this quantity, which can differ from that on the activity concentration of the nuclides.

The contribution of the single decay products to the potential alpha-energy concentration of the thoron decay chain does not only depend on their position in the decay chain but also on their half-life. The long-lived ^{212}Pb ($T_{1/2}$ = 10.6 h) contributes almost the complete portion (91.3%) whereas the contribution of ^{212}Bi ($T_{1/2}$ = 1.01 h, 8.7%) is much smaller but can still be relevant. The contributions of ^{216}Po, ^{212}Po (because of their short half-lives) and ^{208}Tl (only beta-decay) are negligible.

The half-lives of the significant nuclides ^{212}Pb and ^{212}Bi are much longer than that of the nuclides in the radon decay chain. Thus, radioactive decay is less important as a sink whereas possible other sinks such as air exchange influence the concentrations of the nuclides more strongly.

Similar to those of radon, the decay products of thoron originate as single airborne atoms or ions (which cluster water molecules around them) but can also attach to aerosol particles or deposit onto surfaces. The exposure to unattached and attached decay products yields different contributions to the dose in the different parts of the respiratory tract whereas deposited decay products do not add to the exposure of people. Beside the different relevant nuclides, a thoron model must take into account these three states. Additionally, the activity size distribution of the attached decay products is another relevant input parameter for dose calculations.

With these properties, a suitable structure of a model for the indoor occurrence of thoron and its decay products is shown in Figure 1.

Material and methods

Experimental mudbrick room and real rooms

Increased concentrations of indoor thoron have been found in dwellings made of unfired mineral building material such as mud (Sreenath Reddy et al. 2004, Shang et al. 2008). For the determination of the transfer coefficients of the thoron model, a room was erected from mudbricks at Helmholtz Zentrum München. It features dimensions of l = 2.8 m, w = 1.5 m, and h = 1.8 m, a volume of 7.1 m^3, and a semi-cylindrical vault; thus it represents at a reduced scale a type of dwellings which is common on the Central-Chinese Loess Plateau. The mud of the inner plaster, which is commercially

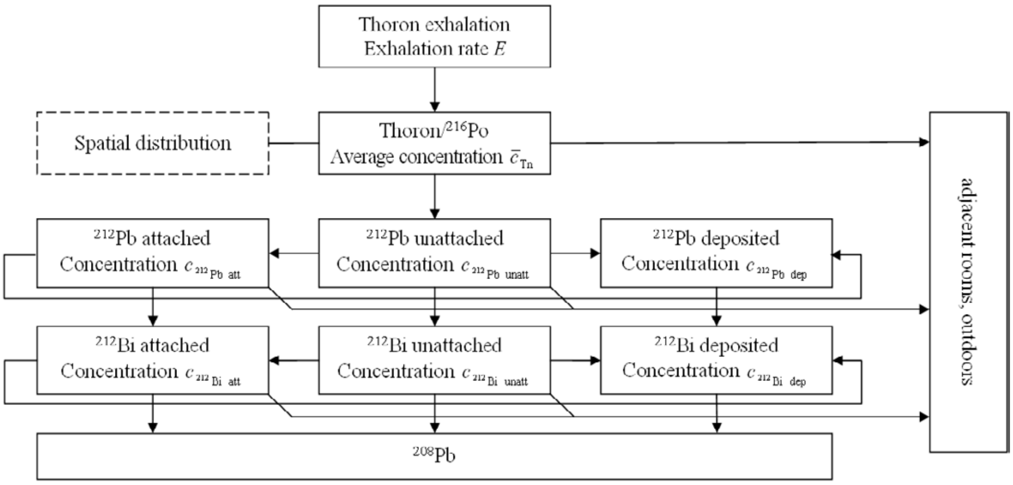

Fig. 1. Structure of the model describing the indoor concentration of thoron and its decay products.

available (Claytech, Germany), was mixed with thorium-rich granite to increase the exhalation of thoron for higher precision of short-time measurements; its specific ^{232}Th activity is about 50 Bq kg^{-1}.

For a validation of the measurement results from the experimental room, measurements were also performed in mudbrick dwellings on the Central-Chinese Loess Plateau and in northern India.

Measurement of thoron concentrations and exhalation rates

Thoron concentrations were measured with the common radon and thoron measurement device Rad-7 (Durridge, USA), which uses the electrostatic deposition of newly formed thoron decay products. It conveys air with a volume flow rate of about 1 L min^{-1} from the end of an inlet tube.

Thoron exhalation rates were measured by means of the equilibrium concentration which is reached in a closed accumulation chamber (Tuccimei et al. 2006). In contrast to radon, leakages and back-diffusion do not need to be taken into account because of the short half-life of thoron. Samples for which the exhalation rate was measured were sealed with thoron-proof lacquer on all sides but one.

Measurement of concentrations of thoron decay products

Working level monitors (commercially available from Tracerlab, Germany; Peter 1994) were used for the measurement of unattached and total thoron decay product concentrations. The decay products were deposited on a sampling substrate with an air flow rate of about 150 L h^{-1}. Their decay was measured online by alpha spectrometry.

For the deposition and measurement of the total thoron decay product concentration, a cellulose nitrate filter was used as the sampling substrate. A wire screen with a mesh size of 625 µm was applied as the sampling substrate for the measurement of unattached decay products (Meisenberg and Tschiersch 2009). With the given air flow rate, this screen features a negligible deposition probability for attached decay products whereas unattached decay products are sampled with an efficiency of about 40%.

Further measurement methods

Specific activities of ^{232}Th in solid samples were measured by gamma spectrometry using its gamma-emitting decay products in equilibrium with it.

Air exchange rates of rooms were measured by one-time release of CO_2 as a tracer gas to the indoor air. The concentration of the homogeneously spread CO_2 decreased by air exchange with clean ambient air. The rate of decrease is the air exchange rate.

Aerosol number concentrations were measured with a condensation particle counter (3022A, TSI, USA) with a lower cut-off diameter of 7 nm and an air flow rate of 18 L h^{-1}.

Results and Discussion

Exhalation of thoron from mud

The exhalation rate E of thoron was measured at various samples of mud such as bricks, plaster, and rammed earth. A dependency on the specific ^{232}Th activity A_{spec}, which can be approximated by a linear function, was found (Figure 2):

$$E = (0.031 \pm 0.003)\,\mathrm{kg\,m^{-2}\,s^{-1}} \cdot A_{spec}\,.$$

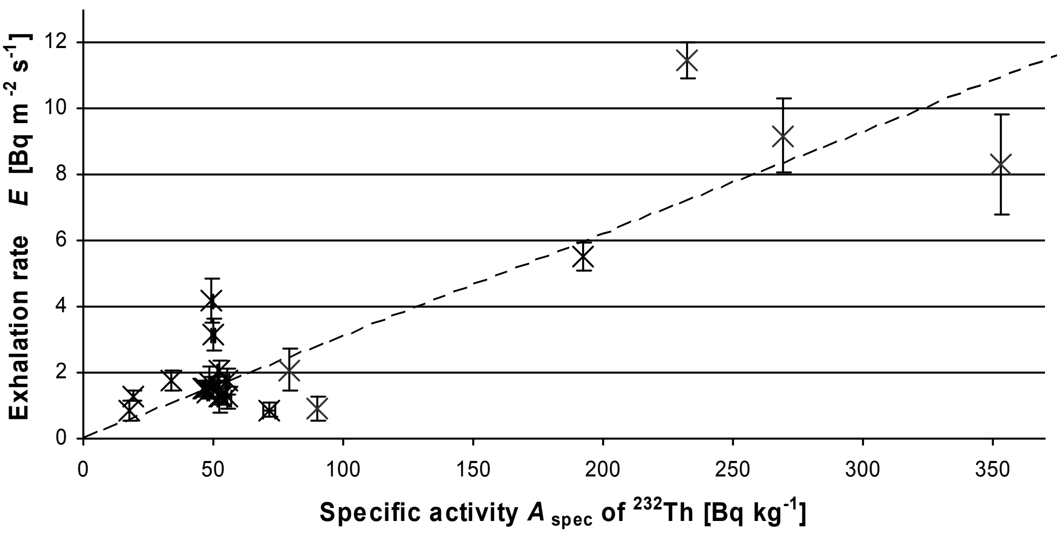

Fig. 2. Exhalation rate of various mud samples from Europe and Asia as a function of their specific ^{232}Th activity as well as the line of linear regression.

For the determination of the diffusion length of thoron in mud, the exhalation rate was measured at two samples from which a few millimeters of mud were removed between each measurement of the series. The exhalation rate remained constant until thicknesses of less than 2 cm were reached.

At several samples of mud, the exhalation rate after firing the sample was compared with that in the unfired state. For this purpose, the samples were fired at a temperature of 900 °C for three days. The exhalation rates were reduced on average to only 6.4 ± 5.1% of the initial value.

Although a distinct influence of the specific ^{232}Th activity in the mud on the exhalation of thoron was observed, even ordinary ^{232}Th activities can lead to increased concentrations of indoor thoron and its decay products: Samples of mudbricks and plaster from the Central-Chinese Loess Plateau featured specific activities of 53 ± 7 Bq kg^{-1} on average, whereas specific activities of 60 Bq kg^{-1} on average (with values up to 310 Bq kg^{-1}) were found in natural building stones from Europe (EC 1999).

The short diffusion length in the mud causes a significant thoron exhalation even from thin layers of mud as plasters. However, fired bricks and clinkers do not seem to be a relevant source of thoron; there, the pores are obstructed by the partly melted minerals.

Spatial distribution of thoron

In the experiment room, the concentration of thoron was measured at several distances from a thoron-exhaling wall. Several measurement series were performed at different air exchange rates. In all measurement series, a decrease of the concentration within a few centimeters was found; with increasing air exchange rates from 0.1 h^{-1} to 4.5 h^{-1} the slope of the decrease became smoother whereas with even higher air exchange rates the gradient increased again. With an air exchange rate of only 0.1 h^{-1} almost no thoron could be found in the middle of the room whereas with higher and still realistic air exchange rates concentrations of up to 15% of the concentration directly at the wall were observed (Figure 3).

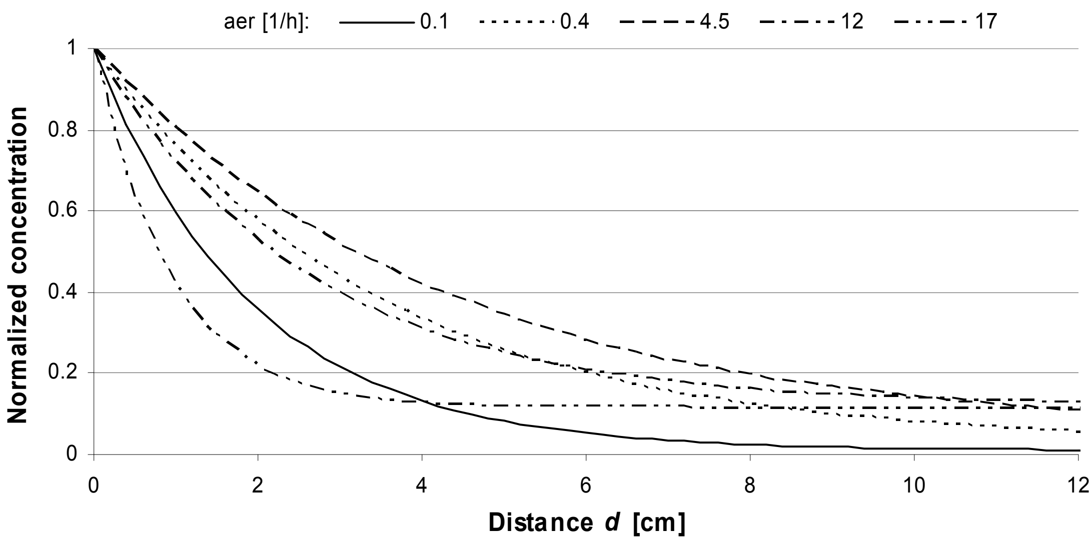

Fig. 3. Concentrations of indoor thoron (relative to the value directly at the wall) as a function of the distance from a thoron-exhaling wall at different air exchange rates aer.

The concentration profile at the lowest air exchange rate is governed by the diffusive transport of the gas. The Gaussian error function describes the spatial distribution of particles which are transported by diffusion if their source spans over one half-space as it is the case with thoron from a wall. When this function is fitted to the measured data, the diffusion length of thoron in air can be determined as 2.6 ± 0.2 cm.

The thoron concentration especially in the middle of the room is strongly influenced by the mixture of the air – in this case caused by air exchange.

Concentration of the thoron decay products

Concentrations of the thoron decay products were measured at different air exchange rates aer in the experimental room. Figure 4 presents the results by means of the equilibrium factor *F*, which is the concentration of the decay products weighted by their contribution to the *PAEC* relative to the average concentration of thoron.

The strong influence of the air exchange on the equilibrium factor and thus on the decay product concentration can be seen; this influence as well as that of possible further sinks is promoted by the small decay constant λ of 0.065 h^{-1} of ^{212}Pb as the most important decay product. The values obey a $\lambda/(\lambda+aer)$ relation. Usual air exchange rates in modern dwellings are in the range from below 3 to about 10 h^{-1} (i.e. *F* in the range from 0.02 to 0.006) with a trend to lower values of less than 1 h^{-1} in low-energy houses ($F = 0.06$). Typical values for the radon decay chain are in the range from 0.4 to 0.2 (Porstendörfer 1994).

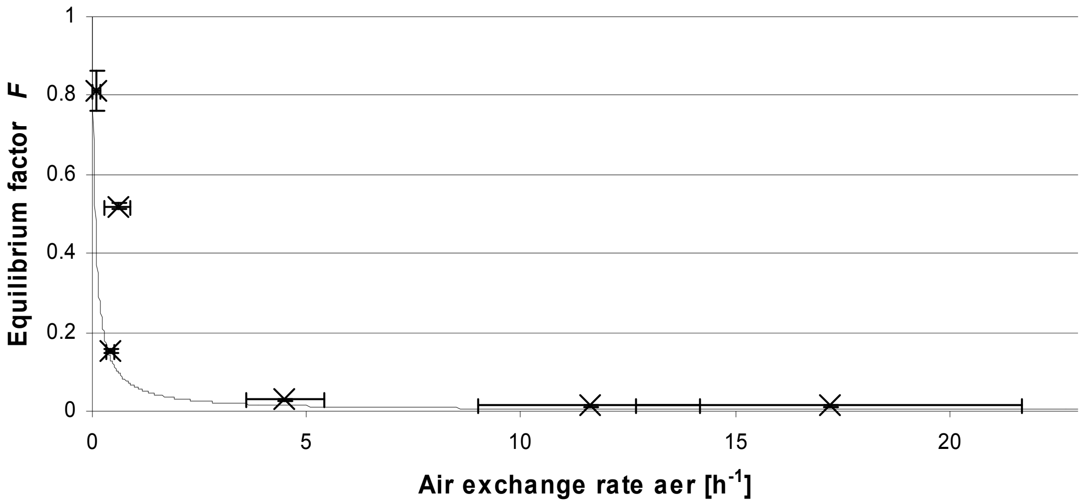

Fig. 4. Equilibrium factor of the thoron decay chain as a function of the air exchange rate: Measurement results from Chinese (X) and from Indian (◊) dwellings and fitted curve.

Unattached fraction of the decay products

The unattached fraction of the thoron decay products was measured in the experiment room at different aerosol concentrations as its most important influence (Figure 5). The air exchange rate during the measurements was 0.1 h^{-1}. Similar to the equilibrium factor, this parameter plays an important role for the unattached fraction because of the long half-lives of the thoron decay products.

The observed values are much smaller than those of the radon decay products with values between 0.05 and 0.20 for usual indoor conditions (aerosol concentrations between 1000 and 20000 cm^{-3}; Porstendörfer 1994). With higher air exchange rates, however, a greater unattached fraction can be expected because of the shorter lifetime of the decay products in the room.

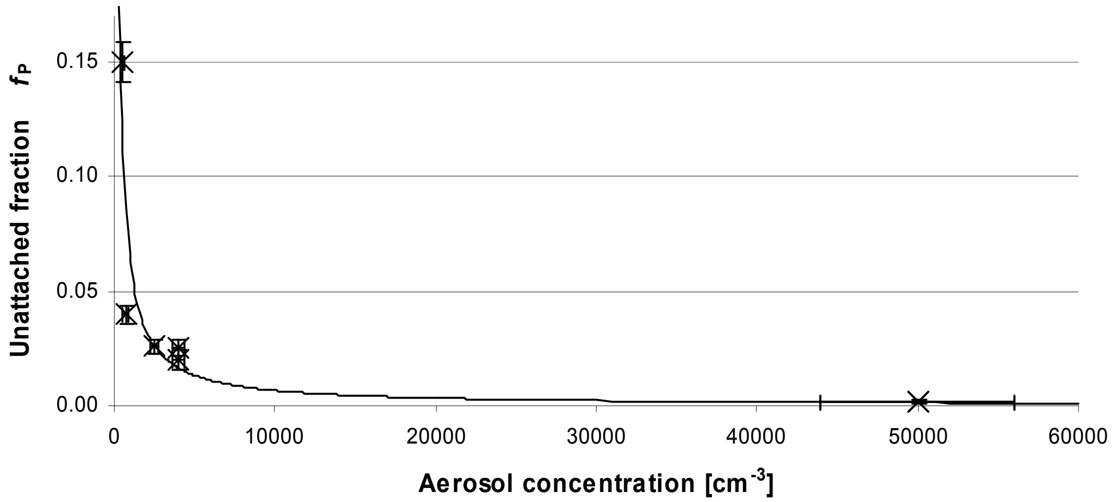

Fig. 5. Unattached fraction as a function of the aerosol concentration and fitted curve.

Conclusions

Consequences on the metrology of thoron exposures

For the assessment of the exposure of people to radioactive gases, the relevant quantities for the calculation of the inhalation dose must be measured. Both for radon and thoron, these are the concentrations of the airborne decay products. For radon, however, a single indoor measurement of the gas can usually provide a satisfying estimate of the inhalation dose.

For thoron, two reasons impede the use of gas measurements for the assessment of the exposure to the decay products: Firstly, the thoron concentration is not homogeneous and does not even feature a constant profile with different indoor atmospheric conditions. Thus, a single measurement at one position cannot give information about the average thoron concentration in the room. Secondly, air exchange plays such an important role as a sink of the long-lived thoron decay products that their concentrations can vary by about one order of magnitude with different air exchange rates. Thus, even the average thoron concentration is not a significant quantity for the decay product concentration if the air exchange rate is unknown.

Therefore, the measurement of the decay product concentration itself is essential. Separate measurements of the concentrations of ^{212}Pb and ^{212}Bi and of the unattached and the attached state are helpful but less important. The development of cheap and simple passive detectors for the decay products is desirable.

Calculation of inhalation doses

Recently, inhalation dose coefficients for the nuclides of the thoron decay chain were published (Li et al. 2008). With these values, their concentrations in mudbrick dwellings of the Central-Chinese loess plateau can yield annual effective doses in the range of up to 2 mSv if a daily indoor stay of 10 h is assumed. Even with a small aerosol concentration of 6000 cm^{-3}, more than half of the dose is contributed by attached ^{212}Pb. Unattached ^{212}Pb and, even less, attached ^{212}Bi add the remaining part.

A calculation of expected concentrations of thoron and its decay products in European mud dwellings shows that they can cause similar doses also there.

Indication for potentially increased thoron exposures

As increased concentrations of thoron and its decay products were found mostly in buildings of unfired mineral building material such as mud, a survey of thoron exposures should initially focus on such buildings. In Europe, unfired mud is a traditional building material for timber-framing buildings but also gains attention as an ecological material in modern indoor architecture. As overviews over the content of ^{232}Th in building materials exist (e.g. EC 1999), indication of areas of mud with high concentrations of ^{232}Th is given.

Air exchange is an effective sink of the long-lived thoron decay products. Therefore, rooms which feature small air exchange rates are prone to high concentrations of the decay products in particular. The refurbishment of traditional buildings aiming at reduced energy consumption might increase the number of rooms where both small air exchange rates and mud as the building material are present.

The concentrations of thoron (averaged over a room) and of the decay products are proportional to the ratio of the area of the thoron-exhaling surfaces to the room volume. Therefore, small rooms, in which this ratio is greater, are more susceptible to increased concentrations than large rooms.

First results of measurements of equilibrium factors *F* and unattached fractions f_p of radon progeny in Czech dwellings

Jilek, Karel; Thomas, Josef; Tomasek, Ladislav
National Radiation Protection Institute, Prague, CZECH REPUBLIC

Abstract

The unattached fraction of radon decay product clusters f_p and equilibrium factor F are dose relevant parameters in all dosimetric approaches to dose calculation. In the past, three year weekly continuous measurements of unattached and attached activities of radon daughter product and air exchange rate were carried out during heating season in thirty occupied typical Czech family houses.

The results indicated significantly different weekly averages of equilibrium factor F and f_p for houses located in towns compared to villages. Due to this fact, approximately 10% average increase of equivalent lung dose rate was estimated in the detriment in towns.

Average values of equilibrium factor F and f_p were 0.40 and 8.6% in urban houses and 0.32 and 10.7%, respectively in rural houses.

Based on measurements of mean values of f_p, average effective dose conversion coefficients per WLM were estimated at 15.0 mSv/WLM in urban houses and 15.9 mSv/WLM in rural houses, respectively.

Introduction

The unattached fraction of radon decay product clusters f_p and equilibrium factor F are dose relevant parameters in all dosimetric approaches to dose calculation. Direct measurements of f_p and F under different ambient conditions allow a comparison of influence of ambient conditions to relative dose contribution [4].

The results of sensitivity analysis applied to the classical Jacobi–Porstendörfer room model [5] generally describing dynamics of both unattached and attached short-lived radon progeny in the room indicate *ACH* (air exchange rate), deposition on surfaces q_f and attachment rate to aerosols X of unattached radon daughter product as the key quantities influencing most strongly the behaviour of observed values f_p and equilibrium factor F in a room. The most important role in processes affecting values of deposition q_f and attachment rate X plays, besides *ACH,* predominantly aerosol size distribution and total aerosol concentration.

In the past, three year weekly continuous measurements of unattached and attached activity concentration of each radon progeny and of *ACH* were performed during heating season in thirty occupied typical Czech family houses.

Primarily, the purpose of the present paper is to introduce the results of direct measurements of F and f_p under different living conditions and to estimate the influence of these conditions to dose contribution.

We also focused on the calculation of the key model parameters X, q_f and *ACH* in measured houses in order to independently estimate the most probable values of F and f_p by means of the room model and to compare them with those obtained from direct measurements.

Since there are well known practical and principal problems arising from long-term measurement of aerosols in occupied dwellings with any SMPC (Scanning mobility particle sizer) caused by evaporating of wide spread butyl alcohol saturator used in particle condensation nuclei counters into the room, aerosol particle size distribution and aerosol concentration were not systematically directly measured. Nevertheless, aerosol concentration Z could be estimated indirectly from measured values f_p by means of Porstendörfer's approximate formula ($f_p = 414/Z$) [3].

Material and methods

All measurements were conducted in thirty occupied typical Czech or two-storey family houses from October to March during heating season. The houses were chosen randomly and they were equipped with central heating system. Originally, we intended to divide them according to assumed different ambient living conditions from the aerosol concentration and its size distribution standpoint in structure as follows: towns – villages, smokers – non smokers. Unfortunately, after finishing all measurements we had to distinguish only basic living conditions according to the house location i.e. town – village and newly according to daily time period.

To detect the assumed influence of different occupant's indoor activities and outdoor changes (traffic density, weather conditions etc.) on behaviour of observed parameters f_p and F we divided each daily 24 hours taking measurement time period into "day" taking from 6 a.m. to 6 p.m. and into "night" taking from 6 p.m. to 6 a.m., respectively. Exposure duration took minimally one week in each house.

Measurement instruments

For measurement of unattached and attached activity concentration of each short-lived radon daughter progeny, we used continuous monitor Fritra 4 (SMM – Prague, CZ). Monitor Fritra 4 has built-in memory buffer allowing more than 4000 records taking each 120 minutes. This measuring interval included ten minutes sampling and 110 minutes taking computational procedure with implemented four alpha counting intervals providing minimum detectable activity (MDA) for each radon progeny in following ratio (^{218}Po: ^{214}Pb: ^{214}Bi) = (1: 0.6: 0.5) stepwise 40 Bq.m^{-3}, 12 Bq.m^{-3}, 15 Bq.m^{-3}. The MDA for measured radon concentration was estimated to about 15 Bq.m^{-3}. Unattached activity concentration of each radon progeny was measured from the screen with mesh 300 and cut-off diameter d_{50} = 4 nm and the attached activity concentration of each radon progeny from the Millipore filter type AA, 0.8 µm placed behind the screen.

The description of monitor Fritra 4 alone in more details and quality assurance from measurement of unattached and attached activity concentration for each radon progeny and from measurement indoor average aerosol concentration standpoint is given elsewhere [2].

Radon measurements were performed by means of well-known continuous monitor Alphaguard (Genitron, D) certified at the German reference chamber at the PTB in Braunschweig. During all measurements, we used its 60 minutes measuring diffusion mode. The both monitors were placed mostly in living rooms at each house.

Theoretical background

i) Equilibrium factor F and f_p as dose relevant parameters

The lung equivalent dose H from inhalation of short-lived radon progeny can be written by means of measured time integral of radon concentration as follows:

$$H = DFC \cdot \frac{T_{\exp}}{170} \cdot F \cdot \frac{a_{\mathrm{V}}}{3700} \tag{1}$$

where

DFC is the dose conversion factor [mSv/WLM],
F is the equilibrium factor,
a_V is the average radon concentration [Bq m^{-3}],
$T_{\exp}$ is the exposition duration [h].

According to calculations by Marsh and Birchall [4] the *DFC* in eq. (1) can be expressed as a linear function of unattached part of equilibrium equivalent concentration of radon progeny f_p as follows:

$$DFC(f_p) = 11.35 + 0.43\, f_p \tag{2}$$

with f_p expressed as the percentage of total PAEC.

Finally, considering eq. (1) and (2) and assuming “the same” breathing rate, the influence of two different ambient conditions to dose can be expressed in terms of relative change of equivalent dose rate H_1/H_0 as follows:

$$\frac{H_1}{H_0} = \frac{F_1 \cdot (k + f_{p,1})}{F_0 \cdot (k + f_{p,0})} \tag{3}$$

with subscripts 0 and 1 representing two different ambient conditions and k - representing the ratio 11.35/0.43 from eq.(2).

ii) Attachment rate X, deposition rate q_f and air exchange rate ACH

The attachment rate X and deposition rate q_f (plate-out) and ACH can be calculated in principle simultaneously from measured unattached and attached activity concentration of each radon daughter progeny by means of an algebraic inversion of the model [2] expressed for room in steady state as follows:

$$
\begin{aligned}
a_{\mathrm{j,f}} &= \lambda_{\mathrm{i\text{-}1}}(a_{\mathrm{j\text{-}1,f}} + R_{\mathrm{j\text{-}1}}a_{\mathrm{j\text{-}1,a}}) / (ACH + \lambda_{\mathrm{j}} + q_{\mathrm{f}} + X) \\
a_{\mathrm{j,a}} &= (ACH.a_{\mathrm{j,o}} + (1 - R_{\mathrm{j\text{-}1}})\lambda_{\mathrm{j}}a_{\mathrm{j\text{-}1,a}} + Xa_{\mathrm{j\text{-}1,f}}) / (ACH + \lambda_{\mathrm{j}} + q_{\mathrm{a}}) \\
a_{0,\mathrm{i}} &= (Q_{Rn} + ACHa_{0,o}) / (\lambda_0 + ACH)
\end{aligned} \tag{4}
$$

with initial conditions $a_{0,\mathrm{i}} = a_{0,i,\mathrm{f}}, a_{0,\mathrm{i,a}} = 0, a_{\mathrm{j,o,f}} = 0$

a_{j} - activity concentration of j-th radon daughter product [Bq m^{-3}]

λ_{j} - decay constant of j-th radon daughter product [h^{-1}]

R_{j} - fraction of recoiled atoms of j-th nuclide from aerosol particles

1$^{\mathrm{st}}$ subscript j = 0, 1, 2, 3, 4 stepwise ^{222}Rn, ^{218} Po, ^{214}Pb, ^{214} Bi, ^{214} Po

2$^{\mathrm{nd}}$ subscript i, o - denotes indoor/outdoor

3$^{\mathrm{rd}}$ subscript f, a - denotes unattached/attached activity j-th radon daughter product

Q_{Rn} - sum of radon entry rates into a house [Bq m^{-3} h^{-1}]

Attachment rate

Under realistic indoor conditions, the observed attachment rate X in a room in „steady state" can be approximately calculated only on the base of measurement of unattached and attached activity concentration ^{218}Po as follows [3].

$$X = \frac{a_{1\mathrm{ia}}}{a_{1\mathrm{if}}}\lambda_1 \tag{5}$$

where

$a_{1\mathrm{ia}}$, $a_{1\mathrm{if}}$ are attached and unattached concentrations, respectively ^{218}Po [Bq m^{-3}]

λ_1 is decay constant ^{218}Po [h^{-1}]

or in case of measurement the proper aerosol size distribution as follows:

$$X = \int_0^\infty \beta(d)\mathrm{Z}(d)\mathrm{d}d \tag{6}$$

where

$\beta(d)$ - attachment coefficient of attached radon progeny to aerosol as a function of particle diameter d [cm^3 h^{-1}]

Z(d) - aerosol size distribution [cm^{-3}]

According to [1] attachment coefficient $\beta(d)$ can be calculated as follows:

$$\beta(d) = \frac{2\pi D_0 d}{\frac{8D_0}{dv_0} + \frac{d}{2\delta_0}} \tag{7}$$

where

D_o is diffusion coefficient 6.8 10^{-2} cm^2 s^{-1}

v_o is mean thermal velocity 1.72 10^4 cm^{-1}

$\delta_o = d/2 + s_o$ with s_o = 4.9 10^{-6} cm is the mean free path of the unattached decay product clusters.

Plate-out

According to the model, the deposition rate q_f, of unattached daughter products can be calculated approximately under realistic indoor conditions ($ACH << X + \lambda_1$) as follows:

$$q_f = \lambda_1 \frac{a_0}{a_{1f}} - (\lambda_1 + X) \tag{8}$$

with all symbols as in previous text.

Air exchange rate

Under the assumptions of the model introduced by the set of eq. (4), the *ACH* can be calculated both by means of an algebraic inversion given previously and by means of numerical iterations applying the set of eq. (4).

On the basis of our previous experiments carried out in the radon chamber of NRPI (National Radiation Protection Institute), we developed the code calculating *ACH* in principle as follows:

Input data for the code were measured lower and upper limit of ratios activity concentrations stepwise Rn/^{218}Po, ^{214}Pb/^{218}Po, ^{214}Bi/^{218}Po and lower and upper limit estimates of *X*, q_f and *ACH*. The code provides stepwise outputs in a form of sets of required parameters *X*, q_f, *ACH* and recoil *R* fulfilling all input conditions. The most probable value of *ACH* was chosen from the set in which the values *X* and q_f matched the best to values *X* and q_f, calculated according to eq. (5) and eq. (8) respectively on the basis measured values of attached and unattached concentration of ^{218}Po. A large number of tests previously performed under the defined *ACH* in the NRPI radon chamber indicated overall agreement of calculated and true values of *ACH* up to acceptable 30%.

iii) Statistical evaluation

The differences between measurements were evaluated using the Student test and assuming log-normal distribution.

Results and discussion

The results of confirmatory data analysis from all measured houses (N=30) in the form of weekly geometric means (GM), corresponding standard deviation (GSD), 95% confidence interval (95% CI) for desired quantities of interest and p-value are summarized in Table 1 and Table 2.

In Table 1 are shown results of the analysis applied to measured data for compared time periods day – night. From Table 1 by means of p-values can be seen that all quantities of interest are not significantly different, except *ACH*.

The observed statistically significant approximate average 30% increase of *ACH* during day compared to night was not surprising. Due to this fact, a higher indoor aerosol concentration coming from outdoor air is assumed and implicitly higher attachment rate *X* (see eq. (6)) is expected and also measured.

The results of attachment rate *X* calculated according to eq. (5) can be approximated by their basic parameters (GM = 24 h^{-1}, GSD = 1.63) for time period day and (GM = 20 h^{-1}, GSD = 1.41) for time period night, respectively. These results agree fairly well with published data. According to [1], attachment rate *X* is ranging from 20 h^{-1} to 50 h^{-1} in poor ventilated houses (ACH < 0.5 h^{-1}) without additional aerosol sources.

Considering eq. (6) and the average attachment coefficient $\beta(d)$ = 0.005 cm^3 h^{-1} published by Porstendörfer in case of poor ventilated houses (ACH < 0.5 h^{-1}) without additional aerosol sources, we can expect average indoor aerosol concentration Z ≈ 4800 cm^{-3} during day and Z ≈ 4000 cm^{-3} during night, respectively.

The results of measured deposition rate q_f calculated according eq. (8) can be approximated by their basic parameters (GM = 23 h^{-1}, GSD = 1.48) for time period day and (GM = 22 h^{-1}, GSD = 1.35) for time period night, respectively. These measured results agree relatively well with published by other authors 40 h^{-1} [7], 10 h^{-1} [3], 30 h^{-1} [10].

According to already cited [1] typical published average values F and f_p in indoor air range between 0.2 - 0.4 and 0.05 - 0.20, respectively for "normal" aerosol conditions Z ≈ (1000 - 20 000) cm^{-3} with mean values of F = 0.3 and f_p = 0.096. These results are in good agreement with our measured results f_p (GM= 0.099, GSD= 1.58), F (GM = 0.35, GSD = 1.31) found for time period day and f_p (GM= 0.107, GSD= 1.47), F (GM = 0.36, GSD = 1.32) found for time period night.

In Table 2 are shown results of the analysis applied to measured data for compared locations town – village. From p-values in Table 2 can be seen that all quantity of interest are significantly different except deposition q_f and the fact that observed mean values F, f_p, X and q_f agree very well with the published data mentioned in previously.

In our opinion, the higher average value F and logically lower average value f_p in indoor air in towns compared to villages are caused mainly by higher average aerosol concentration probably in consequence of different indoor activities. This fact is indicated by dramatically higher values of attachment rate X in towns compared to villages and statistically significant lower average value *ACH* approximately about 30%.

If we consider the above mentioned average attachment coefficient $\beta(d)$ = 0.005 cm^3 h^{-1} published by Porstendörfer, eq. (6) and measured means of attachment rates X from Table 2, we are able to estimate average indoor aerosol concentration Z ≈ 5200 cm^{-3} in case of towns and Z ≈ 3600 cm^{-3} in case of villages. From Table 2 can be also seen that measured average value *ACH* is ranges around (0.3 - 0.4) h^{-1} in case of both towns and villages.

If we consider Porstendörfer's approximate formula f_p = 414/Z mentioned previously (see Introduction) and measured average values of f_p calculated for different observed conditions from Table 1 and Table 2, we can estimate average value of indoor aerosol concentration as follows:

- Z ≈ 4800 cm^{-3} in case of towns and *Z* ≈ 4000 cm^{-3} in case of villages respectively
- Z ≈ 4200 cm^{-3} for time period day and *Z* ≈ 3900 cm^{-3} for time period night.

These results indicate very good agreement of both approaches used to estimate average aerosol concentration *Z* i.e. by means of measured attachment rate X and f_p, respectively and also implicitly a good accuracy of measurements of unattached and attached activity concentrations of radon daughter product by means of monitor Fritra 4.

Since average value f_p in measured urban houses were 8.6 % and 10.6 % in rural houses then with respect to eq.(2) lung dose sensitivity factor DFC= 15.0 mSv/WLM should be applied in case of urban houses and DFC =15.9 mSv/WLM in case of rural houses, respectively. Further, according to [4], the lung dose sensitivity factor DFC contributes to more than 99% of the effective dose per WLM and therefore the above mentioned values of DFC can represent very well the effective dose conversion coefficient per unit WLM.

To verify the Jacobi–Porstendörfer model (see eq.4) from the prediction of *F* and f_p point of view, in Figs. 1 and 2 are illustrated results of comparison of measured values *F* and f_p with those calculated by means of the room model on the basis of input data, i.e. average values *X*, q_f and *ACH* (taken from Table 1 and Table 2) for investigated ambient conditions. For all calculations, average value of recoil R = 0.5 [1] was used. The results indicate a very good agreement between directly measured values of *F* and f_p and calculated by means of the room model.

Assuming "the same breathing rate" the influence of our different investigated ambient conditions (denoted 0 and 1 respectively) to relative changes of the equivalent lung dose rate H_1/H_0 is illustrated in Fig. 3.

In Fig. 3 is seen the average value of H_1/H_0 calculated for proper observed ambient conditions applying eq. (1-3) and combined standard uncertainty acquired by application of the Law of Propagation of Uncertainty to eq.(3).

About 10% significant relative increase of the equivalent lung dose rate in case of towns compared to villages was found. On the other hand, difference in contribution to relative lung dose rate in case of observed conditions day – night was not statistically significant.

Table 1. Results of confirmatory analysis of weekly average values f_p, F X, q_f and *ACH* over time periods day and night.

Quantity (units)	Period	GM	GSD	95% CI		p- value
f_p	Day	0.099	1.58	0.04	0.247	
	Night	0.107	1.47	0.05	0.231	p = 0.494
F	Day	0.35	1.31	0.20	0.60	
	Night	0.36	1.32	0.21	0.63	p = 0.533
X	Day	24	1.63	9	64	
(h^{-1})	Night	20	1.41	10	40	p = 0.130
q_f	Day	23	1.48	11	50	
(h^{-1})	Night	22	1.35	12	40	p = 0.653
ACH	Day	0.41	1.59	0.16	1.04	
(h^{-1})	Night	0.30	1.82	0.09	0.99	p = 0.024

F, f_p denote equilibrium factor and unattached fraction of equivalent equilibrium concentration, respectively
X, q_f denote attachment rate and deposition rate of unattached radon progeny
ACH denotes air exchange rate.

Table 2. Results of confirmatory analysis weekly average values of *fp*, F X, q_f and *ACH* for location town and village.

Quantity (units)	Location	GM	GSD	95% CI		p- value
f_p	Town	0.086	1.58	0.04	0.247	
	Village	0.107	1.40	0.05	0.231	p = 0.003
F	Town	0.40	1.25	0.26	0.63	
	Village	0.32	1.31	0.19	0.55	p = 0.002
X	Town	26	1.61	10	67	
(h^{-1})	Village	18	1.37	10	34	p = 0.001
qf	Town	23	1.41	12	46	
(h^{-1})	Village	22	1.42	11	44	p = 0.661
ACH	Town	0.30	1.91	0.08	1.09	
(h^{-1})	Village	0.40	1.56	0.16	0.97	p = 0.046

The quantities f_p, *F*, *X*, q_f and *ACH* have the same meaning as in previous Tab.1.

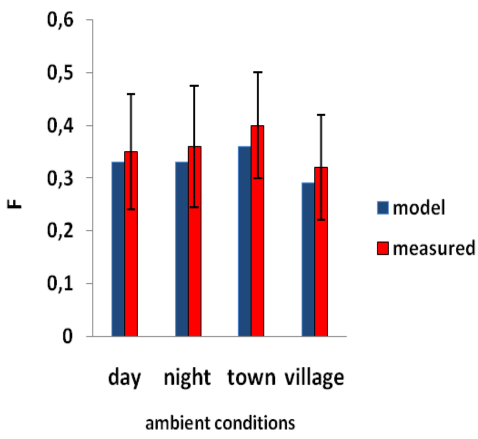

Fig. 1. Results of comparison of equilibrium factor *F* calculated via the room model and directly measured, respectively (with GSD).

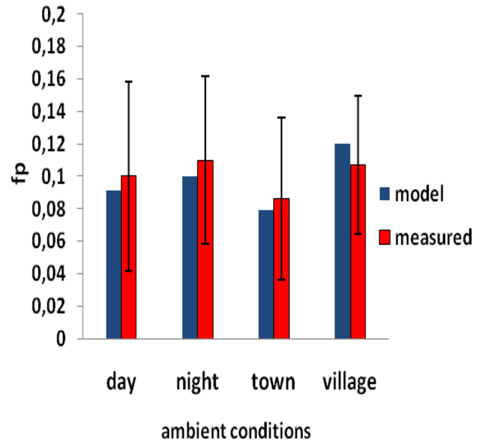

Fig. 2. Results of comparison of f_p calculated via the room model and directly measured, (with GSD)

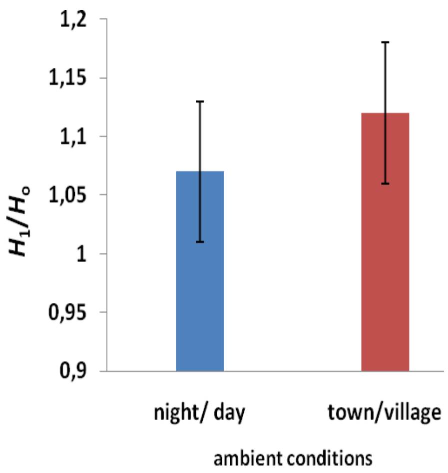

Fig. 3. Average relative contribution to lung equivalent dose rate H_1/H_o under different ambient conditions and the corresponding combined standard uncertainty.

Conclusions

The results of weekly continuous measurements of radon concentration and unattached and attached concentrations of each short-lived radon progeny in thirty randomly chosen Czech family houses during heating season indicated statistically significant difference of weekly averages equilibrium factor F a f_p for urban houses compared to rural. The log-normal distribution of weekly means f_p and F is represented in case of towns as follows: f_p (GM= 0.086, GSD = 1.58), F (GM = 0.40, GSD = 1.25) and f_p (GM = 0.107, GSD= 1.40), F (GM = 0.32, GSD = 1.31), respectively in case of villages. Due to this fact approximately 10% average increase of equivalent lung dose rate was calculated in the detriment of towns.

The difference in mean values f_p and F during observed time period day - night was not statistically significant.

The effective dose conversion coefficients per WLM were estimated to 15.0 mSv/WLM for towns and 15.9 mSv/WLM for villages, respectively.

Both key parameters of the Jacobi-Porstendörfer room model, i.e. attachment rate X and plate -out q_f of unattached radon progeny ranged from 10 h^{-1} to 60 h^{-1} with the mean around (20 – 25) h^{-1}.

The air exchange rate ranged from 0.1 h^{-1} to 1 h^{-1} with the mean approximately around (0.3 – 0.4) h^{-1} and its statistically significant average 30% decrease during the night compared to day was observed.

The average indoor aerosol concentration was significantly higher in towns ($Z \approx$ 5000 cm^{-3}) compared to villages ($Z \approx 4000$ cm^{-3}). On the other hand, difference between mean indoor aerosol concentration during observed time period day ($Z \approx 4200$ cm^{-3}) was not statistically significant in comparison to night time period ($Z \approx 3900$ cm^{-3}).

Abstract

Indoor radon concentrations are subject to high temporal variation that can make short term measurements of radon unreliable and difficult to interpret. Oscillations in radon concentrations can be smoothed by carrying out long-term measurements using CR-39 alpha track detectors, with a typical measurement period of three months or more. Short term radon measurements can be unreliable when used to predict how average long term radon concentrations within a building compare with the Reference Level. Ideally, the measurements would be carried out over a full year as this would provide the most accurate result. However, householders are often reluctant to wait so long for results and detectors left in place for so long are commonly lost. Furthermore, there is evidence to suggest that the sensitivity of a detector may change over such a long period of time, increasing the uncertainty associated with the result. Currently in Ireland, radon measurements are carried out over a minimum period of three months. This is a compromise between the need for a long exposure period to provide a reliable estimate of the long-term mean radon concentration and the problems associated with year-long measurements. The Radiological Protection Institute of Ireland (RPII) have recommended that radon be included in the conveyancing process but recognise that a 3 month measurement period may create too much of a delay when householders are likely to require a radon result in a shorter timeframe. This project compares the results of one month measurements with three month measurements using CR-39 alpha track detectors. Statistical analysis of the results from 662 homes around Ireland are reported.

Introduction

Radon is a naturally occurring radioactive gas which originates from the decay of uranium present in rocks and soils. When radon surfaces in the open air, it is quickly diluted to harmless concentrations, but when it enters an enclosed space, such as a house or any other building, it can sometimes accumulate to relatively high concentrations. In air, radon decays quickly to produce radioactive particles that, when inhaled, are deposited in the airways and in the lungs. These result in a radiation dose which, over a long period of time, may lead to lung cancer. International Agency for

Research on Cancer (IARC) has classified radon as a class 1 carcinogen (IARC, 1988). Worldwide exposure to radon in homes is linked to 3% to 14% of lung cancers, depending on the average radon concentration in the country and method of calculation. (WHO, 2009). In Ireland the average indoor radon concentration is 89 Bq/m^3 which is the eight highest in the world. (Fennell *et al*., 2002, WHO, 2009). When risk estimates for indoor radon are applied to Ireland some radon can be linked to some 10 to 15% of all cases of lung cancer in Ireland and it is the second most significant cause of lung cancer after smoking (RPII and NCRI 2005).

Over 91,000 homes in Ireland are predicted to have radon concentrations above the national Reference Level of 200 Bq/m^3. This equates to over 7% of the national housing stock. (Fennell *et al.,* 2002). In 2006, the RPII recommended that radon measurements, and where necessary, remediation at the time of sale and/or purchase of buildings is an appropriate mechanism to reduce the collective dose from radon in Ireland. (RPII, 2006). There are currently some 4000 radon measurements carried out in Ireland each year and there are 1.9 million dwellings in the country. (Department of Environment, Heritage and Local Government (DEHLG), 2008, RPII, 2009). Therefore it could take over 400 years for the present housing stock to be measured and for those houses predicted to have high radon levels to be identified. In 2007, the number of second-hand homes purchased was almost 38,000 (DEHLG, 2007) therefore if a radon measurement was linked to the conveyancing of houses each house in the country could be tested for radon within about 40 years.

Current radon measurement practice in the RPII is to use CR-39 alpha track detectors over an exposure period of at least three months in conjunction with the application of a seasonal correction factor (Colgan *et al.,* 2008; RPII, 2008). Normal practice is to send two detectors with each measurement pack; one to be placed in a bedroom and one in a living area (RPII, 2008). The average of both rooms is seasonally adjusted and it is this seasonally adjusted average which is compared to the Reference Level. One potential difficulty with linking radon to conveyancing is the need for a three month measurement period as householders are often unwilling to wait so long. Conseqently some countries have introduced shorter ”screeening” measurements for use during conveyancing. (Ibrahimi and Miles, 2009). Extrapolating from shorter measurements to an annual average introduces uncertainties into the result and these will normally be much larger than the uncertainties caused by counting and calibration errors on the detectors [Miles, 2001]. Therefore it is prudent only to use short term screening measurement in selected circumstances, such as conveyancing, and only when the relationship between the short term measurements and the standard long term measurement is known. This study was, therefore carried out to determine this relationship and to investigate possibility of using a one-month “screening” measurement during conveyancing to determine whether a house is above or below the Reference Level.

Material and methods

This project was run in two phases. Phase 1 was carried out during 2008. The RPII contacted 102 customers who had recently applied for a standard radon measurement and invited them to instead participate in this study free of charge. All of those contacted agreed to participate and the households were distributed all over Ireland.

Initial analysis of the detectors revealed that 89% of the three month detectors had radon levels less than 200 Bq/m^3. The dataset did not contain sufficient data for higher radon concentrations therefore phase 2 of the project sought to obtain data on the relationship between three month observations and one month observations at higher radon concentrations. The RPII contacted 840 customers who had previously measured radon levels above 200 Bq/m^3 in their homes. Those contacted were from areas all over Ireland.

In order to make the reply process as easy as possible, the invitation letter had a response slip at the bottom for people who wished to participate, with spaces to add a contact phone number, an email address and a signature. Also enclosed was a freepost envelope to return the response to the RPII. 612 people replied agreeing to participate in the project (a response rate of 73%). This response rate was unexpectedly high. Experience in the UK of response rates to radon surveys has been in the range of 20 – 40%, depending on the areas being targeted (Kendall *et al.,* 2005). The high response rate for this research could be due to how easy it was to respond to the letter.

For both phases of the project, measurement packs were sent to all volunteers. Each measurement pack contained:

- Personalised letter: thanking for participation and setting out instructions for detector placement and return
- Two short-term detectors (labelled: Bedroom 1M; Living area 1M)
- Two long-term detectors (labelled: Bedroom 3M; Living area 3M)
- 1 month record sheet: to record the dates the detectors were placed and removed for the 1 month period
- 3 month record sheet: to record the dates the detectors were placed and removed for the 3 month period
- 2 freepost return envelopes

After the one and three month periods had elapsed, each participant was reminded to return the two relevantly labelled detectors and record sheet. This was done firstly by a phone call; if there was no answer, they were sent either an email or letter instead.

The RPII offers a commercial radon measurement service using alpha track detectors comprising a two part polypropylene holder and a CR-39 (poly allyl diglycol carbonate) detection plastic. Details of detector processing are given in Fennell *et al.,* 2002. The standard radon measurement service offered by the RPII (3 month radon measurement) is subject to stringent quality control procedures and is accredited to ISO 17025 by the Irish National Accreditation Board. Although the one month measurements would not be accredited, they were subjected to the same stringent quality control procedures during this project.

Results

As already described the measurement procedure provided four radon concentration results for each household: living area 1 month, bedroom 1 month, living area 3 month and bedroom 3 month. Mean values for each household were calculated for the one month results and the three month results.

To ensure a high level of confidence in the results, both phases of the study covered all counties of Ireland and contained both high and low radon concentrations. Although the measurement regime was designed to ensure that detectors were in place for set periods of one month and three months, detectors were returned from some households with longer measurement periods. It was decided that observations such as these could mislead the estimation process. In addition for some households useable measurements were not obtained for all four detectors. After eliminating those households with measurement periods greater than one and three months and those with fewer than four results, results from a total of 622 homes were available for analysis. The data consisted of 93 households in Phase 1 and 529 households in Phase 2.

As mentioned the analysis of the Phase 1 data proved to be inconclusive so we will report on two data sets. One formed with all data from Phase 1 and Phase 2. The second formed from merging data from Phase 1 and Phase 2 but with what were deemed to be extreme values that is >9000 Bq/m^3, removed.

A linear regression model was fitted to the data to determine if a useful relationship could be established between one month and three month measurements. It is known that radon concentrations can be modeled well by the lognormal distribution if they have been corrected by subtracting a background average value of outdoor radon concentration and that predictions using this assumption are more accurate than models based on untransformed measurements (Gunby *et al.,* 1993, Fennell *et al.,* 2002 and Murphy and Organo, 2008). Fennell *et al.* (2002) reported 6 Bq/m^3 as being representative of the average outdoor radon concentration in Ireland. Consequently all subsequent modelling was performed on radon levels in which the background level of 6 Bq/m^3 was firstly subtracted from the radon levels before the levels were log-transformed to provide a better fit to a normal distribution.

1.1 Regression analysis

1.1.1 All data from both phases of the project

The merged data set comprised all of the data from phase 1 and phase 2 of the project 622 observations, 529 from phase 2 and 93 from phase 1. As was previously described the measurements in phase 2 were deliberately chosen from higher radon areas. Figure 3.1 plots the background corrected log-transformed results from the one month radon measurements against the log-transformed three month radon measurements for this merged data set. As can be seen in this plot, where the phase 1 measurements are clustered on the bottom left corner of the graph, there was an increased variance among the one month measurements in phase 1 compared to phase 2. However, even with this added variability it is clear from Figure 3.1 that there is still a strong linear association between the one month measurements and the corresponding three month measurements. Indeed the correlation coefficient for this merged data set is r = 0.935.

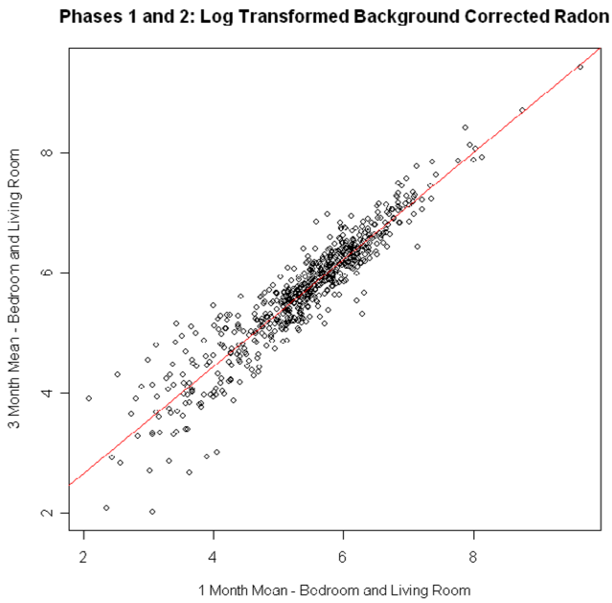

Figure 3.1. Log-transformed household mean 1 month radon concentration vs. log-transformed household mean 3 month radon concentration [all data from both phases of the project].

Table 3.1 describes the fit of the linear regression model that was fitted to this data set. The ANOVA F test P-value which is less than 2.2 x 10^{-16} and the t-tests of the significance of the regression parameters (P-value < 2.0 x 10^{-16}) all indicate that the simple linear regression model is a good fit to the data. The coefficient of determination is R^2 = 87.41% indicating that approximately 87% of the variation in the one month measurements can be explained by the linear association between the one month measurements and the three month measurements.

Table 3.1. Simple linear regression analysis of log-transformed household mean 1 month radon concentration vs. log-transformed household mean 3 month radon concentration [all data from both phases of the project].

	Parameter Estimate	Standard Error	T-statistic	P-Value
Intercept	0.881	0.074	11.86	<2.00x 10^{-16}
Slope	0.891	0.014	65.62	<2.00x 10^{-16}
Source	DF	Sum Sq	Mean Sq	4306.3 <2.2x 10^{-16}
Log 3 month	1	523.62	523.62	
Error	620	75.39	0.12	
Total	621	599.01		
	R-Sq = 87.41%	R-Sq(adj) = 87.39%		

Figure 3.1a contains a Histogram and a QQ plot of the residuals from these plots. While the histogram shows that the residuals are symmetrically distributed, the QQ-plot displays a certain deviation from normality at the two ends of the plot indicating that the regression residuals are somewhat more dispersed than would be expected from a normal distribution. Having said this, a Kolmogorov-Smirnov test of normality on these

residuals gave a p-value of 0.085 thus failing to reject the null hypothesis of normality for the residuals at significance level 0.05.

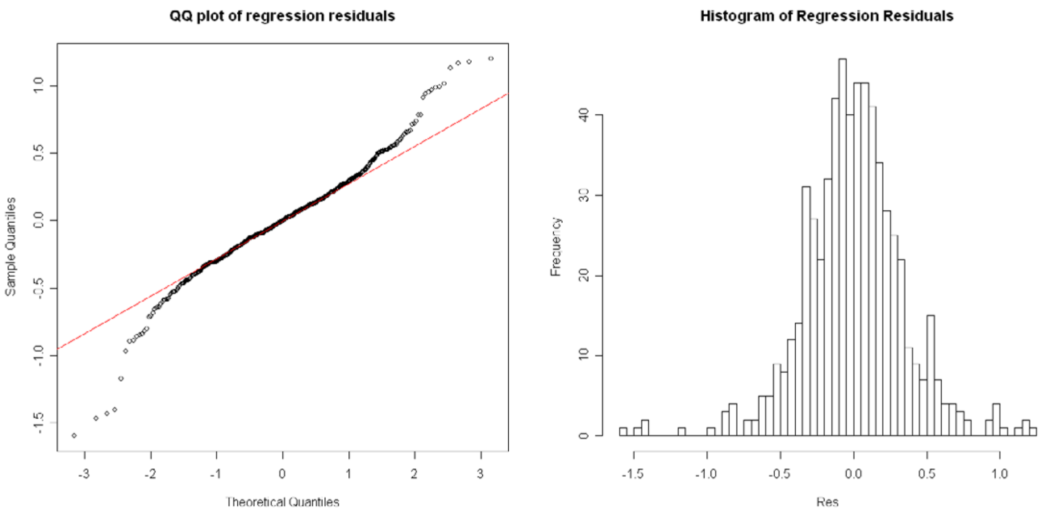

Figure 3.1a. Residuals from the Log-transformed household mean 1 month radon concentration vs. log-transformed household mean 3 month radon concentration [all data from phase 1 and 2 of the project.

1.1.2 Data from both phases of the project with two extreme results (greater than 9,000 Bq/m^3) removed

Two very extreme results (>9,000 Bq/m^3) were removed and the merged data set reanalysed to examine whether these two results had acted as influential observations. Figure plots the background corrected log-transformed results from the one month radon measurements against the background corrected log-transformed three month radon measurements. The correlation coefficient was computed to be 0.932.

Table 3.2 describes the fit of the linear regression model that was fitted to this data set. The ANOVA F test P-value which is less than 2.2 x 10 $^{-16}$ and the t-tests of the significance of the regression parameters (P-value < 2.0 x 10 $^{-16}$) all indicate that the simple linear regression model is a good fit to the data. The coefficient of determination is R^2 = 86.9% indicating that approximately 87% of the variation in the one month measurements can be explained by the linear association between the one month measurements and the three month measurements.

The parameter estimates changed slightly when the two extreme observations were removed indicating that these observations did not unduly influence the model fit.

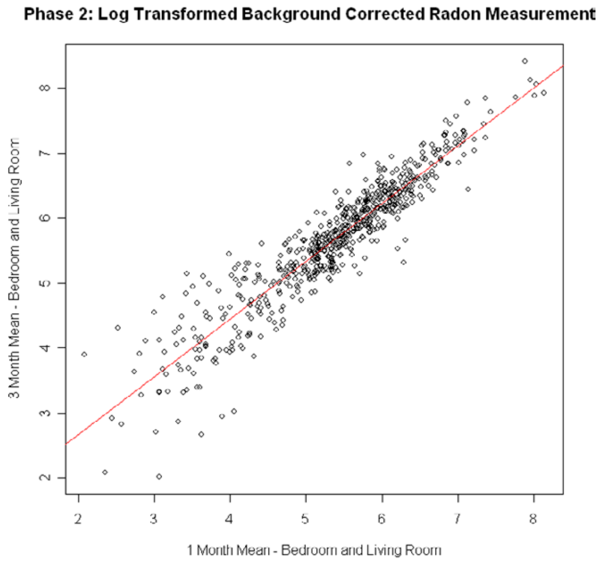

Figure 3.2. Log-transformed household mean 1 month radon concentration vs. log-transformed household mean 3 month radon concentration [data from both phases of the project with two extreme results (> 9,000 Bq/m^3) removed].

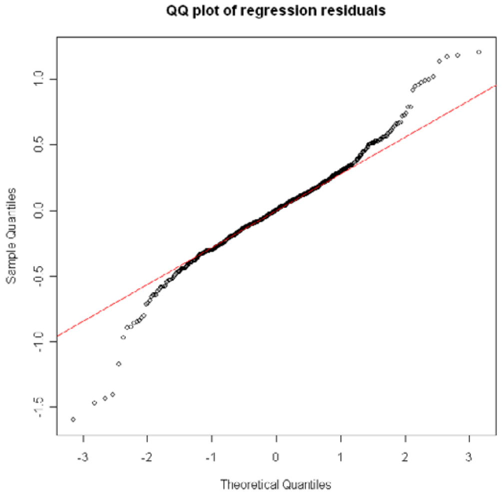
Table 3.2. Simple linear regression analysis of log-transformed household mean 1 month radon concentration vs. log-transformed household mean 3 month radon concentration [data from both phases of the project with two extreme outliers removed].

	Parameter Estimate	Standard Error	T-statistic	P-Value
Intercept	0.880	0.076	11.59	<2.00x 10^{-16}
Slope	0.891	0.014	64.04	<2.00x 10^{-16}
	1.10	0.00502	(1.08, 1.13)	1.10
Source	DF	Sum Sq	Mean Sq	F-statistic P-value
Log 3 month	1	500.25	500.25	4101 <2.2x 10^{-16}
Error	618	75.39	0.12	
Total	619	575.64		
	R-Sq = 86.9%	R-Sq(adj) = 86.88%		

Figure 3.2a contains a Histogram and a QQ plot of the residuals from these plots. The removal of two observations would not greatly influence these residuals and indeed the histogram and the QQ-plot are almost identical to those found on the full merged data set again indicating that the regression residuals are somewhat more dispersed than would be expected from a normal distribution. But once again, a Kolmogorov-Smirnov test of normality on these residuals gave a p-value of 0.087 thus failing to reject the null hypothesis of normality for the residuals at significance level 0.05.



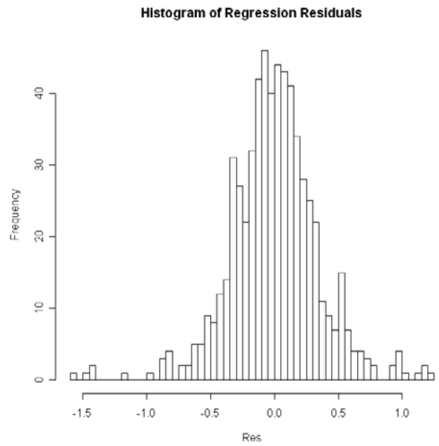


Figure 3.2a. Residuals from the Log-transformed household mean 1 month radon concentration vs. log-transformed household mean 3 month radon concentration [Data from phase 1 and 2 of the project with two extreme observations removed].

1.2 Setting upper and lower threshold levels

The regression models which were fit to the data sets enable us to predict a three month radon concentration on the basis of a one month measurement. We have seen that the regression models fit well so these predictions can be viewed as reliable. The predictions are, however, just point estimates and as such are subject to uncertainty. We can quantify this uncertainty by producing confidence intervals rather than point estimates. The aim of this modelling is to establish two separate bounds on the one month measurement. The first is a lower threshold such that any one month measurement that is below this threshold can be confidently viewed as indicating that a three month measurement taken on the same house would be lower than the 200 Bq/m^3 Irish National Reference Level. The second threshold that must be computed is an upper threshold such that a one month measurement exceeding this threshold would produce a three month measurement exceeding 200 Bq/m^3. The lower and upper thresholds can be computed from the regression model using standard 95% one sided prediction intervals for the background corrected log transformed radon levels which are exponentiated and have had the background of 6 Bq/m^3 added back. Hence to find the threshold levels we solve the following inequalities for the upper threshold (X_U) and the lower threshold (X_L).

$$200 < 6 + \exp\left(\hat{\beta}_0 + \hat{\beta}_1 \log(X_U - 6) - t_{95\%} s \sqrt{1 + \frac{1}{n} + \frac{(\log(X_U - 6) - \overline{X})^2}{SS_{XX}}} \right)$$

$$200 > 6 + \exp\left(\hat{\beta}_0 + \hat{\beta}_1 \log(X_L - 6) + t_{95\%} s \sqrt{1 + \frac{1}{n} + \frac{(\log(X_L - 6) - \overline{X})^2}{SS_{XX}}} \right)$$

where X_T are the upper or lower threshold levels, $\hat{\beta}_0$ and $\hat{\beta}_1$ are the estimates of the intercept and slope from the regression, s is the estimate of the standard deviation of the error terms in the regression model, n is the sample size, $t_{95\%}$ is a one sided 95% critical value of the t distribution $\overline{X}$ is the mean of the background corrected one month measurements and $SS_{xx} = \sum (x - \bar{x})^2 = s_x^2(n-1)$ is the sum of squares of the background corrected one month measurements.

Table 3.3 summarises the lower and upper thresholds (Bq/m^3) of the equivocal result region for the two the datasets described above. Outside of these ranges, one month radon concentrations derived from the datasets can be regarded as definitive indicators of mean annual levels below or above the Irish National Reference Level of 200 Bq/m^3 with 95% confidence. Results falling between these thresholds are regarded as equivocal, and would require a measurement for a three month period in order to estimate a more accurate mean annual level.

Table 3.3 Upper and lower threshold levels (95% CI) for one month radon measurements using alpha track detectors.

Dataset used for analysis	95% Confidence level	
	Lower threshold (Bq/m^3)	Upper threshold (Bq/m^3)
All data from both phases of the project	89	234
Data from both phases with 2 extreme results (>9,000 Bq/m^3) removed	89	235

Discussion

Many international studies have investigated the possibility of reducing the standard radon measurement period with alpha track detectors from three months to a one month period or less (Quindos *et al.,* 1992, Bowring, 1992, Klotz *et al.*, 1993, Chen, 2003, Groves-Kirkby *et al.,* 2006, Ruano-Ravina *et al.,* 2008 and Ibrahimi and Miles, 2009). However, none of these studies were based in Ireland and so cannot be assumed as directly applicable. Climatic conditions, as well as seasonal and dwelling-occupancy factors influence the amount of radon that may emanate from the ground and enter buildings (Sundal *et al.,* 2007). These reasons pointed to the need for an indigenous study covering the whole of the country of Ireland.

Groves-Kirkby *et al.* (2006) found threshold values of 109 - 478 Bq/m^3 for one month alpha track detectors. However, the study had only 18 data-points for the one month measurements and the authors warned that the one and three month results in their study should be treated with caution due to the low number of data-points (Groves-Kirkby *et al.,* 2006). Ibrahimi and Miles (2009) investigated the accuracy of two-week radon measurements using alpha track detectors and found threshold levels of 170 - 300 Bq/m^3. However, their results were based on measurements made in 59 homes in the UK. Although the research suggest a tighter range of threshold levels than what is currently in use for the screening detector service in the UK (current threshold levels are 100 - 400 Bq/m^3), (Ibrahimi and Miles, 2009). In order to ensure a high level of confidence in the results of this study, it covered all counties of Ireland and had a sufficient spread of both high and low radon concentrations. A total of 622 short and long term measurements were available for analysis.

Conclusions

At time of writing this report a formal recommendation has yet to be made on how this study will be used to support the RPII's aim to link radon to the conveyancing of properties in Ireland (RPII, 2006). While the results summarised in table 3.3 are encouraging further work is needed. Before being in a position to recommend a threshold range the RPII will take account of new seasonal correction factors for Ireland. (Burke *et al.,* in press). In addition, the RPII are likely to recommend conservative round numbers for the threshold band.

Radon hazard evaluation based on measurements of indoor air and gamma measurement surveys in combination with bedrock and drift geology mapping

Rudjord, Anne Liv[1]; Smethurst, Mark[2]; Finne, Ingvild[3]
[1] Norwegian Radiation Authority, NORWAY
[2] Norwegian Geological Surveys, NORWAY
[3] Norwegian Radiation Protection Authority, NORWAY

Abstract

During the last 10 – 15 years, The Norwegian Radiation Protection Authority has carried out several surveys of radon in indoor air. These data have been useful for the overall evaluation of radon risks at the local level, and they have been used both for estimations of average radon exposure and, to a certain extent, to identify radon-prone areas. According to the new radon strategy (2009) in Norway, the local authorities will need to consider the radon hazard in connection with area planning, and if necessary impose restrictions or local regulations regarding new building constructions in very high risk areas. The Geological Survey of Norway and the Norwegian Radiation Protection Authority have established a combined approach to mapping of radon in Norway, based on direct measurements of radon in indoor air, bedrock and drift geology, and the mapping of uranium/radium in the ground using airborne gamma-measurement surveys. This work resulted in the release of overview radon awareness maps covering the most densely populated areas in Norway around the capital city Oslo. The performance of the hazard evaluations was tested in an area centered around the municipality of Gran, and was shown to be able to enclose most of the high risk areas. Areas already known to be associated with elevated radon hazards were confirmed, and additional potential high risk areas not yet confirmed by indoor radon measurements were identified. The Norwegian Geological Surveys have recently carried out new air-borne gamma measurement surveys in areas south-west of Oslo. Corresponding datasets on indoor radon are available, and includes areas known to be strongly affected by radon. A test of the combined approach in this area will be independent of the earlier studies, and will be used for additional testing and refinement of the method that has been established. The results of this work so far will be presented.

Indoor radon and construction practices in Finnish homes from the 20th to the 21st century

Abstract

Indoor radon is the second leading cause of lung cancer in Europe. In order to reduce the exposure to radon, it is necessary to understand the structural features of buildings that affect radon concentrations. These features vary with the year of completion of the building.

A population-based random sample study was performed in the homes of 2,882 people. Radon measurements were made using alpha track detectors. Information on the structure of the dwellings was collected using a questionnaire filled in by the residents.

The weighted national mean of indoor radon concentration in single-family and row houses was 121 Bq/m^3 and in blocks of flats 49 Bq/m^3. The national mean was 96 Bq/m^3.

According to our study, the radon concentrations in new single-family and row houses began to rise after the 1960s, and continued to rise until steadying during the 1980s and 1990s, decreasing thereafter to the level of the 1970s. These changes can be explained by changes in building methods.

Before 1965, the prevailing house type was one with a basement with no direct entrance into the living area. This solution reduced the radon entry into the living area. Thereafter, a slab-on-ground foundation, which promotes radon-bearing air entering the house, became the most common foundation. A more radon-resistant foundation, crawl space was popular during 1950s. Its popularity decreased thereafter and increased again after 2000.

Since the year 2000, mechanical supply and exhaust ventilation has been installed in most new dwellings. This reduces the entry of radon due to smaller pressure differences. In addition, the use of radon prevention techniques in new building has become more common because of new building codes.

The changes in the Finnish construction practice from the 20th to the 21st century have had clear consequences, which can be seen in indoor radon concentrations. After a slow awakening to radon awareness in the 1980s, research, guidance and legislation have resulted in the current downward trend in indoor radon concentrations.

Introduction

Indoor radon exposure increases the risk of lung cancer in a residential environment (Darby et al. 2005). The most important reason for high radon concentrations in dwellings is the radon-bearing soil air that flows into the building. Gaps between the slab and foundation walls, permeable materials used in foundations and a high underpressure increase radon concentration. Indoor radon exposure can be reduced by identifying and mitigating dwellings with high concentrations, and by radon prevention techniques in new building.

Regulations concerning indoor radon for the health protection and building control authorities in Finland are working reasonably well and are on a good level on the world scale. According to Decree 944/92 by the Ministry of Social Affairs and Health, the indoor radon concentration should not exceed 400 Bq/m^3, whereas new buildings should be built so that 200 Bq/m^3 is not exceeded (Ministry of Social Affairs and Health, 1992). In addition, Part D2 of the National Building Code of Finland (Indoor climate and ventilation of buildings) sets 200 Bq/m^3 as a reference value for the planning of new buildings (Ministry of Environment, 2004). Since 2004, according to Regulation B3, radon should be taken into account in new building throughout the country (Ministry of Environment, 2004). A radon technical plan should be included in the building licence application. This plan can only be exceptionally ignored when building in areas where exceeding 200 Bq/m^3 seldom occurs.

Material and methods

The results of this study are based on the random sample study by STUK, in which 6,000 Finns were selected using simple random sampling from the Finnish population registry (Mäkeläinen et al. 2009).

The radon measurements were made using alpha track detectors in two half-year periods, the first from April to November 2006 and the second from November 2006 to April 2007. Information on dwelling construction was collected using questionnaires filled in by the inhabitants. Fifty-seven per cent of the selected population accepted the call to participate, and 48 per cent completed a valid measurement; 58 per cent (2,267) of the residents living in houses (single-family and row houses) and 31 per cent (599) of those living in blocks of flats completed valid measurements.

The annual mean of radon concentration for each dwelling was calculated as an arithmetic mean weighted by the lengths of the two measurement periods. The final national statistics were calculated by weighting the annual means using the number of inhabitants of houses and flats in each province.

Results

Annual mean of radon concentration

The weighted average for annual means of radon concentration was 96 Bq/m^3 for all dwellings, 121 Bq/m^3 for houses and 49 Bq/m^3 for flats. The medians were 56 Bq/m^3, 75 Bq/m^3 and 36 Bq/m^3 respectively. Radon concentration notably varies regionally. Häme and South-Eastern Finland (the provinces of Itä-Uusimaa, Päijät-Häme, Kymenlaakso, Kanta-Häme, Pirkanmaa and South Karelia) constitute a continuous high radon area in which a quarter of all Finnish house inhabitants reside. In this area the mean radon concentration in houses was 201 Bq/m^3 and in the rest of Finland 96 Bq/m^3.

Effect of the year of completion of building on the radon concentration

Radon concentrations in new buildings are connected to the construction practices of their time. They were at their lowest in houses built during the 1950s (Fig.1). During the 1960s and 70s the radon concentrations started to rise, being almost double at the beginning of the 1980s compared with houses built during the late 50s. Thereafter, the radon concentrations in new houses have decreased, and since the year 2000 the radon concentrations in new houses has been at the same level as in houses built in the 60s and 70s.

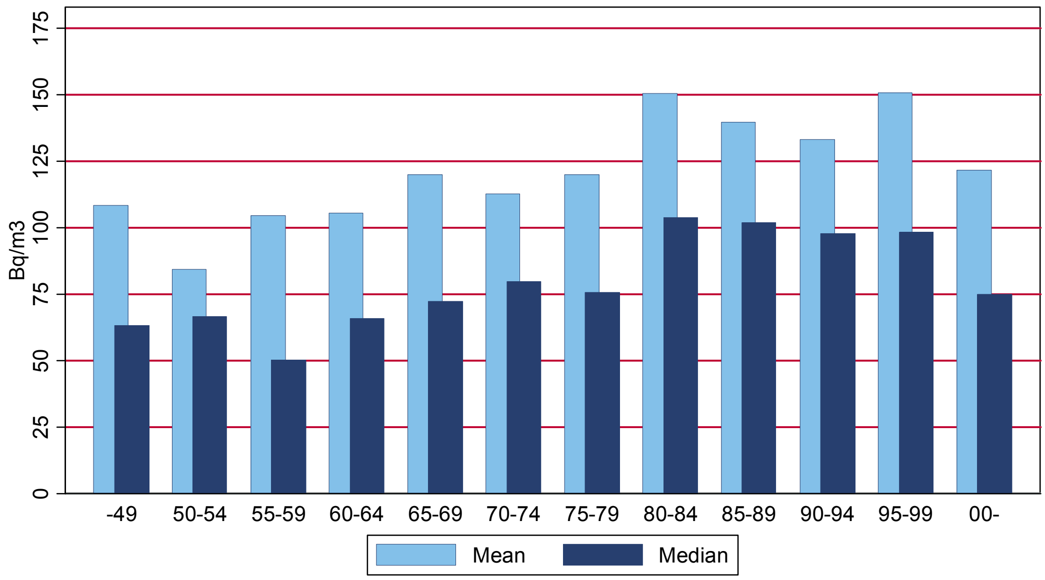

Fig. 1. Means and medians of annual average radon concentration in houses according to the year of completion of the building.

Effect of foundation type on radon concentration

Houses were divided into three types according to the ground contact of the foundations. Both hillside houses and houses with a cellar have basement walls backing onto the ground. In a hillside house, one wall is on ground level and the wall facing it is at least partly backing onto the ground. In houses with a cellar, all walls are ground-contact walls. The third type is a house without a basement that mostly has a slab-on-ground or crawl space foundation. The inhabitants selected the figure most like their house type in the questionnaire.

Until the beginning of the 1960s the most common type was a house with a cellar (Fig. 2). Thereafter, houses without a basement became most common. Since the 70s, a hillside house has been more common than a traditional house with a cellar.

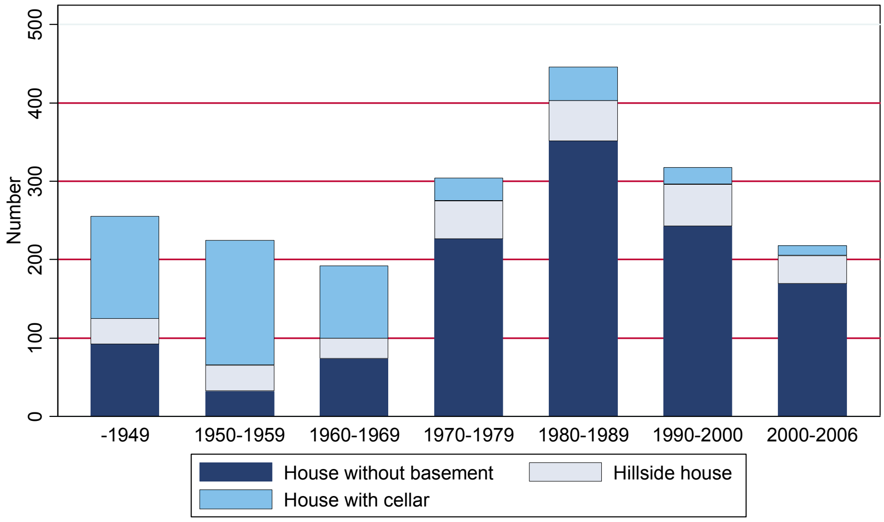

Fig. 2. Numbers of house types in the study data according to the year of completion of building.

The highest radon concentrations are in houses with a basement (hillside houses and houses with a cellar) built in the 1990s and later, having medians of 156 and 152 Bq/m^3 (Table 1). Concerning houses completed before the 1990s, hillside houses have higher concentrations than other types (median 92 Bq/m^3), but houses with a cellar are the lowest (median 66 Bq/m^3). On the other hand, radon concentrations in houses without a basement are almost at the same level regardless of building year (medians 77 and 78 Bq/m^3).

Table 1. Type of house and radon concentration.

House type	All houses*			Built before 1990			Built in 1990-2006		
	Count	Mean Bq/m^3	Median Bq/m^3	Count	Mean Bq/m^3	Median Bq/m^3	Count	Mean Bq/m^3	Median Bq/m^3
House without a basement	1253	119	76	775	118	77	412	117	78
Hillside house	288	156	102	193	143	92	89	191	156
House with a cellar	519	117	66	454	111	66	35	183	152

*Including those with building year missing

In houses with a basement, walls backing onto the ground increase radon leaks into the dwelling without proper sealing. If the staircase to the lowest floor is open, radon-bearing air from downstairs mixes with the air in the rest of the dwelling. On the other hand, if the entrance to the basement is normally closed or the entrance to the lowest floor is only from the outside, radon-bearing air cannot so easily enter the upper floors. This is the case in the older houses with a basement, where only 22 per cent had an open staircase (Table 2). Another factor increasing radon concentrations in new houses with a basement is probably the higher proportion of light-weight concrete blocks used as ground-contact wall material: 71 per cent in the newer houses compared with 16 per cent in the older ones with a basement. In the new houses, the basement floor is also more often used as a living area: 57 per cent in the newer houses and 26 per cent in the older ones. The residents were asked to carry out the measurement on the lowest floor with a living area as the concentration there is usually the highest. This also results in higher concentrations in the new houses.

Table 2. Houses with a basement: Radon and entrance type from the upper floors to the basement level.

Entrance to the lowest floor	All houses with a basement*			Built before 1990			Built in 1990-2006		
	Number	%	Median Bq/m^3	Number	%	Median Bq/m^3	Number	%	Median Bq/m^3
Open staircase	200	28	117	127	22	103	68	64	163
Staircase and door	390	55	65	350	61	65	19	18	179
Only from outside	119	17	78	95	17	76	20	19	117
All	709	100	78	572	100	71	107	100	157

House without basement and radon

A house without a basement has been the most common foundation type in houses since the 1960s. The two most used foundation types in this house type are slab-on-ground and crawl space (Fig. 3). When slab-on-ground laid between the foundation walls is used, radon-bearing soil air gets in through the gap between the foundation wall and the slab unless the gap and feed-throughs are sealed. The crawl space foundation is fairly radon-resistant if radon leaks are stopped by sealing the foundation joints and feed-throughs, and ventilation of the base floor is arranged.

Crawl space as a foundation type was very common before 1960 (Fig. 3). Its popularity decreased thereafter, but, according our data, since the year 2000 it has been getting more popular than ever since the 1950s. Whereas the percentage of crawl space houses was only 4 per cent during the 1970s, it has risen to approx. 20 per cent in houses built after 2000.

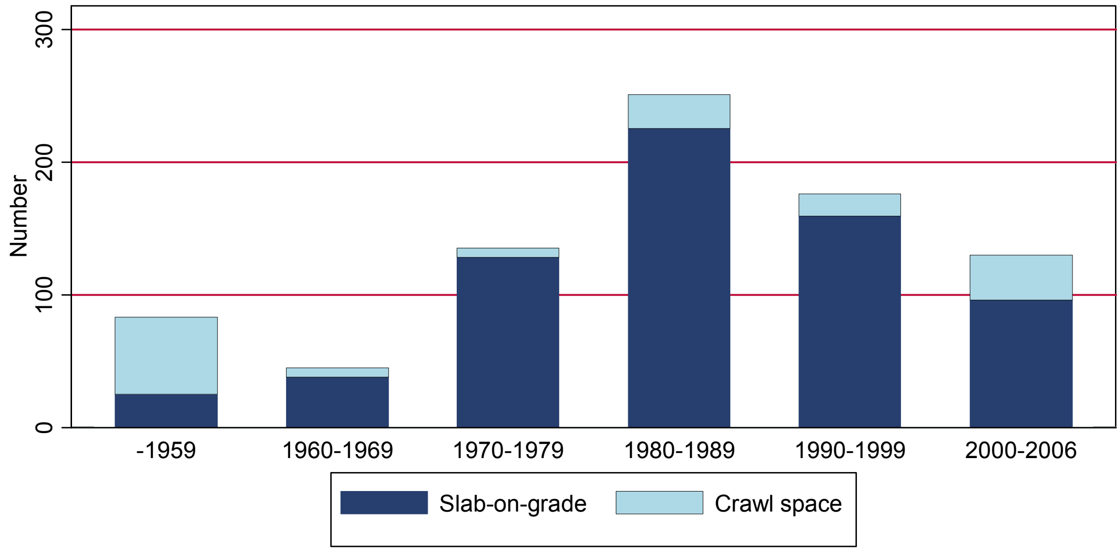

Fig 3. Numbers of slab-on-ground and crawl space foundations in houses according to the year of completion of building.

Differences in radon concentrations between these types are clearly seen (Table 3). Radon concentrations are higher in houses with slab-on-ground foundations built both before and after 1990.

Table 3. Foundation types slab-on-ground and crawl space in houses without a basement.

Foundation type	All houses with a basement			Built before 1990			Built in 1990-2006		
	Count	Mean Bq/m^3	Median Bq/m^3	Count	Mean Bq/m^3	Median Bq/m^3	Count	Mean Bq/m^3	Median Bq/m^3
Slab-on-ground laid between foundation walls	688	132	94	415	134	96	251	130	93
Crawl space	150	61	44	96	59	48	49	60	38

Cast concrete was a clearly more radon-resistant option (medians 75 Bq/m^3 and 58 Bq/m^3) than light-weight concrete blocks (medians 136 Bq/m^3 and 106 Bq/m^3) in both older and newer houses. Light-weight concrete blocks are very permeable, and when used as building material for foundation walls, radon-bearing soil air can easily flow through them from the soil into the dwelling. In houses with slab-on-ground foundations built before 1990, 31 per cent had light-weight concrete blocks used in the foundation walls, but for those built thereafter, the percentage was already 66 (Table 4). Radon concentrations were higher in the older than in the newer houses regardless of the material of the foundation walls. However, because the proportion of foundation walls made of light-weight concrete blocks is smaller in the older houses than in the new ones, the radon concentration in all the houses with slab-on-ground has not changed much (medians 96 Bq/m^3 and 93 Bq/m^3, Table 3).

Table 4. Material of foundation walls and radon in houses with slab-on-ground foundations.

Material of foundation walls	Built before 1990			Built in 1990-2006		
	Number, proportion (%)	Mean Bq/m3	Median Bq/m3	Number, proportion (%)	Mean Bq/m3	Median Bq/m3
Cast concrete	237 (69%)	114	75	74 (34%)	91	58
Light-weight concrete blocks	105 (31%)	158	136	146 (66%)	150	106

Ventilation type and radon

Ventilation types were compared in houses without a basement with slab-on-ground foundations because the group is large enough and does not have temporal confounding factors, as was seen in the last chapter. The data shows that mechanical exhaust ventilation is the most disadvantageous ventilation type with regard to radon (Table 5). This ventilation type increases the underpressure of the dwelling and radon leaks from the soil. The situation in the houses with natural ventilation is only slightly better. The mechanical supply and exhaust ventilation is best with regard to radon. This was as expected: a well-adjusted supply and exhaust system ensures a sufficient air exchange rate, and reduces the underpressure and, consequently, radon leaks into the building.

Mechanical supply and exhaust ventilation has become more popular in new houses. In single-family houses, the change to this system started in the 1980s. In row houses the change has been slower. These changes are one cause of the reduction in radon concentrations observed since 1990 (Table 4).

Table 5. Ventilation type and radon concentration in houses without a basement with slab-on-ground laid between foundation walls.

	All houses			Built before 1990			Built in 1990-2006		
Ventilation type	Count	Mean Bq/m^3	Median Bq/m^3	Count	Mean Bq/m^3	Median Bq/m^3	Count	Mean Bq/m^3	Median Bq/m^3
Natural	284	143	97	244	140	98	28	183	104
Mechanical exhaust	141	148	115	68	136	104	69	163	137
Mechanical supply and exhaust	230	110	76	78	118	81	147	104	75

Radon prevention in new building

Guidance on radon prevention in new building has been available since 1994 (Ministry of Environment, 1994). This first guide was replaced by the RT Building Information File published in 2003 (Building Information Ltd., 2003). The guides recommend sealing the joints between the foundation wall and floor slab and walls backing onto the soil with bitumen felt, sealing the feed-throughs, and installing radon piping as a preparatory measure. The goal is a low radon concentration using only passive sealing. If, however, the radon concentration in the house is measured as more than 200 Bq/m^3, activation of the radon piping by installing a fan on the roof is needed. Activating the fan sucks radon-bearing air from the soil under the slab.

Radon piping has been installed in 64 per cent of houses with slab-on-ground foundations built after 1995 in the high radon areas of Häme and South-Eastern Finland. The percentage of similar houses in the rest of Finland was 14. Sealing of the foundation constructions was not so common: 18 per cent in the high radon area and 14 per cent in the rest of Finland. Both installing radon piping and sealing of foundation constructions were performed in the high radon area and the rest of Finland in 11 and 4 per cent of dwellings respectively.

Radon prevention is clearly more common in the high radon area. The prevention measures showed some reduction in radon concentration, especially in the high radon area, but the numbers of dwellings were too small for conclusions.

Conclusions

Radon concentrations in new houses have increased from the 1950s to the 1980s, and have decreased thereafter, especially since the year 2000. The recent decrease is caused by several reasons, one being the growing percentage of houses with crawl space foundations. Crawl space is a radon-resistant construction if the flow of radon-bearing air into the dwelling is stopped by sealing the base floor and feed-throughs, and by taking care of the ventilation of the crawl space.

Mechanical supply and exhaust ventilation has become the most common ventilation system in new houses, and this has also reduced radon concentrations. The third cause of the reduction in radon concentrations in new dwellings is the use of radon prevention in new building, which has become more popular, especially in high radon areas. The installation of radon piping systems is common in high radon areas; sealing of ground-contact constructions has not been used as often as was expected.

Although radon concentrations in new buildings have decreased, there are also factors that are against the downward trend. Houses with a basement have high radon concentrations. In both hillside houses and houses with a cellar, the proportion of dwellings having living areas on the basement floor has increased, and the entrance from the upper floor to the basement floor is more and more often an open staircase. In addition, the growing use of permeable light-weight concrete blocks as a building material for foundation and basement walls instead of cast concrete has increased radon concentrations.

Part 3 of the National Building code of Finland, which concerns the foundations, came into force in the year 2004. The code requires radon prevention in all buildings. The radon concentration in the completed building should be below 200 Bq/m^3. When the provisions are widely implemented, the reduction in radon concentrations in new buildings is expected to continue.

Abstract

In order to define the naturally-occurring radioactive materials that are source of radon in natural environments, a comprehensive analytical (geochemical, physical and chemical) methodology was employed to study sediment samples from overburden glacial formation in Olkiluoto (W Finland). Techniques such as gamma-spectrometry, emanation measurements, sequential chemical extraction, scanning electron microscopy (SEM), electron microprobe analyses (EMPA) and inductively-coupled plasma mass spectrometry (ICP-MS) were used to determine the potential source of radon. Samples are representing a typical Finnish red-ox profile formed on glacial sediments deposited around 9,000 years ago. In Olkiluoto samples activity concentration of ^{238}U, ^{226}Ra and ^{228}Ra show no significant trend in a function of depth secular equilibrium between ^{238}U and ^{226}Ra occurred only in the samples collected from the reductive zone. In the oxidized horizon higher radium than uranium activity concentration was measured. In this horizon the $^{226}Ra/^{238}U$ is 1.4. In Th decay chain secular equilibrium occurred between ^{232}Th and ^{228}Ra. Radon productions and emanation factors are very low, varying between 0.01 – 0.03 Bq/(kg h) and 0.04 – 0.08, respectively. The uppermost sample collected from the oxidized horizon has the highest radon production and emanation factor. This sample has the highest ^{226}Ra content (52 Bq/kg), as well. The sequential extraction revealed that in the oxidized zone more exchangeable Ra is present than in the reductive zone. In general, more radium was leached (ca. 20% of the total) easily than uranium and thorium, except in the deepest sample, where 30% of the total uranium was leached easily. Monazite, xenotime, zircons, apatite and U-Th-silicates were identified in the samples as the main sources of uranium, thorium and radium. These minerals were partly weathered in the uppermost horizons and mainly fresh in the deeper ones.

The radon situation in Swedish dwellings based on recent measurements

Hjelte, Ingela; Ronquist, Birgitta; Rönnqvist, Tryggve
Gammadata Mätteknik AB, SWEDEN

Abstract

Gammadata has been measuring radon levels in Sweden and abroad since the late 1980´s and is one of the largest suppliers of CR-39 based radon detectors in Europe. Our extensive database includes several hundreds of thousands of measurements. This makes it possible for us to derive several conclusions of the radon situation in Sweden. We present radon levels measured in single family dwellings and their dependence on several factors such as the type of ventilation and foundation of the measured dwellings.

Introduction

Due to the relatively large problem with high radon levels in dwellings in Sweden an examination of which factors increase or decrease the risk for radon levels above the action level is of interest. In the past years radon measurements in dwellings have been available for the general public through offers sent out to all house owners within several municipalities making the selection of measurement locations much more random than previously. This increases the possibility of using data from a measurement database to draw general conclusions concerning radon levels.

We have selected to examine single family dwellings comparing ventilation, foundation, and construction year. The data used is based on the information provided by the person performing the measurement. For single family dwellings we assume that the majority of the information concerning the building is correct.

Since a large portion of the measurements in our database are incomplete concerning information about the building certain combinations of construction year and foundation and ventilation yield very few data. Those results containing fewer than 30 measurement points have been removed from this examination in order to reduce the risk of single measurements of extreme values having a large effect on the result.

In Sweden we have three sources of radon in dwellings, the ground, the building material and the water. Water is the least common source and hence we disregard its effect on the radon level indoors in our analysis. The building material that can provide radon levels above the action level is a light concrete which is based on alum-shale. This material was widely used in the 50´s through the 70´s. In the 50´s and 60´s as much as half the buildings constructed contained some amount of alum-shale concrete (G.A. Swedjemark), The production of this material was stopped 1975 but houses built in the years following can also contain it. Since this material is common only in Sweden we have based our analysis solely on those measurements where there is a notation that the dwelling does not contain alum-shale.

Construction year of the building

Examining the radon levels in single family dwellings can be used as a general quality measurement of the different house constructions in different eras. To examine this we divide into 10 year periods thereby assuming no major reformations in house constructions were made during each time period. A clear relationship between the year a building is constructed and the radon level is evident, see table 1:

Table 1. radon levels in private dwellings depending on year of construction.

Year of construction	Number measured	Average radon level	Highest measured level	Percentage above 200 Bq/m^3
1800-1899	4263	149	6759	16,6
1900-1919	8235	150	>12200	17,7
1920-1929	7826	154	6510	19,5
1930-1939	12949	142	8410	18,5
1940-1949	15174	157	8240	23,5
1950-1959	24866	177	8910	30,0
1960-1969	43229	197	16220	34,5
1970-1979	45412	172	>24500	28,3
1980-1989	21426	111	17050	13,8
1990-1999	10963	71	10960	6,5
2000-2008	12132	59	5050	4,7

In table 1 it is clear that the period ranging from 1950-1979 an increase in the radon level measured is noted compared to previous years. This time period also coincides with an increase in building rate of houses.

Foundation and ventilation

The question arises whether certain combinations of constructions produced in certain time periods are more likely to experience radon problems than others. The house constructions selected for examination includes both the foundation of the house as well as the ventilation type. The four most common foundation types in Sweden are as follows; basement, crawlspace, slab, and split level house, in no particular order. The selected ventilation types are as follows; natural ventilation, mechanical exhaust, and mechanical supply and exhaust air ventilation (most often used together with heat recovery).

In general we find that houses containing basements or split levels in combination with natural ventilation are responsible for the highest radon levels.

Looking at natural ventilation and the radon level dependence for different years and different house foundations it is clear that split level dwellings tend to have the highest radon levels, see figure 1. Until the 1970´s the basement was constructed to contain garage, storage areas, laundry rooms, furnaces etc and were therefore not used as living space. In an annual average calculation only living areas are included. Therefore, in dwellings with the original construction high levels of radon can be present in the basement which are ventilated away before reaching the living space upstairs as it is normally separated from the basement by a door. This is most likely the reason why houses containing basements tend to have lower levels of radon compared to split-level houses where living areas are placed partially underground (C. Boox)

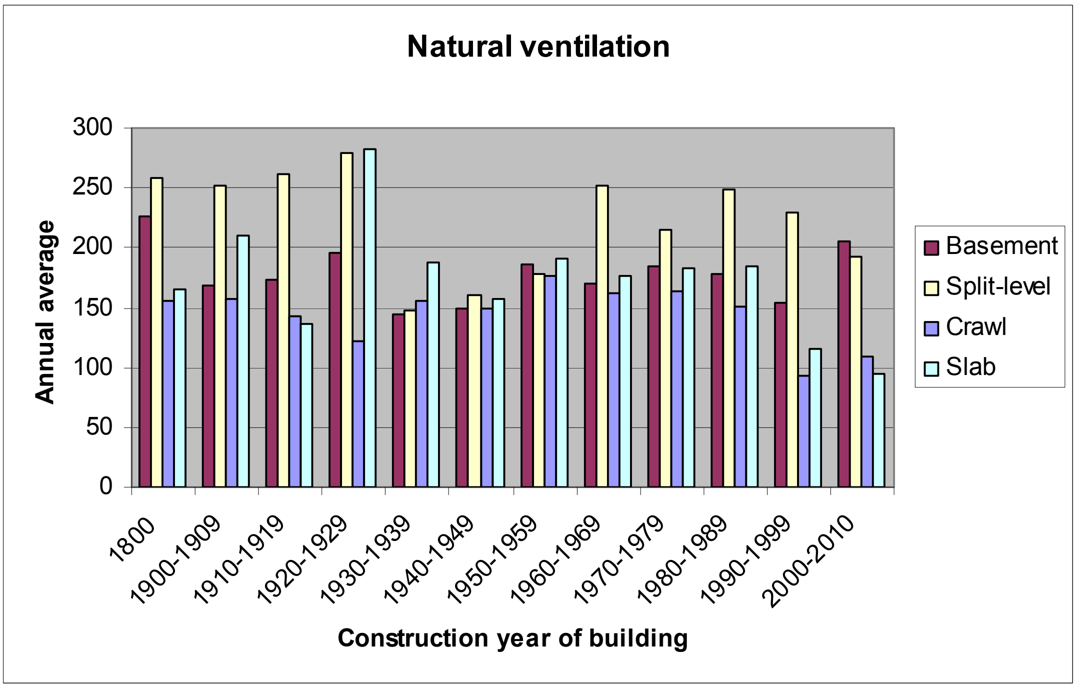

Fig. 1. Annual average radon levels measured in dwellings with natural ventilation which are constructed in the eighteen hundreds until present day and the dependence on house foundation.

For dwellings up until the past 10 years, crawl space tends to have lower levels then the rest. An interesting feature is that slabs as well as crawlspace constructions manufactured in the past 20 years show a marked improvement of radon levels as compared to older constructions and when compared to basements and split-levels of all years. It is disappointing that the same level of improvement is not seen in modern basements and split-levels. Another interesting feature is the increase in radon levels seen in slab constructions of the 1920´s. This may in part be due to the concrete used at this time period, a lack of funds after the first world war tended to increase the dilution of concrete with fillings such as rock which in effect made the material more porous. Also, in the beginning of the 1900´s concrete slabs were not of the same type of construction as today, the main function at those times was to have a more practical floor rather than no floor at all so the slabs were quite thin and not insulated from the ground below.

The same comparison for mechanical exhaust and mechanical supply and exhaust is shown in figures 2, and 3 below.

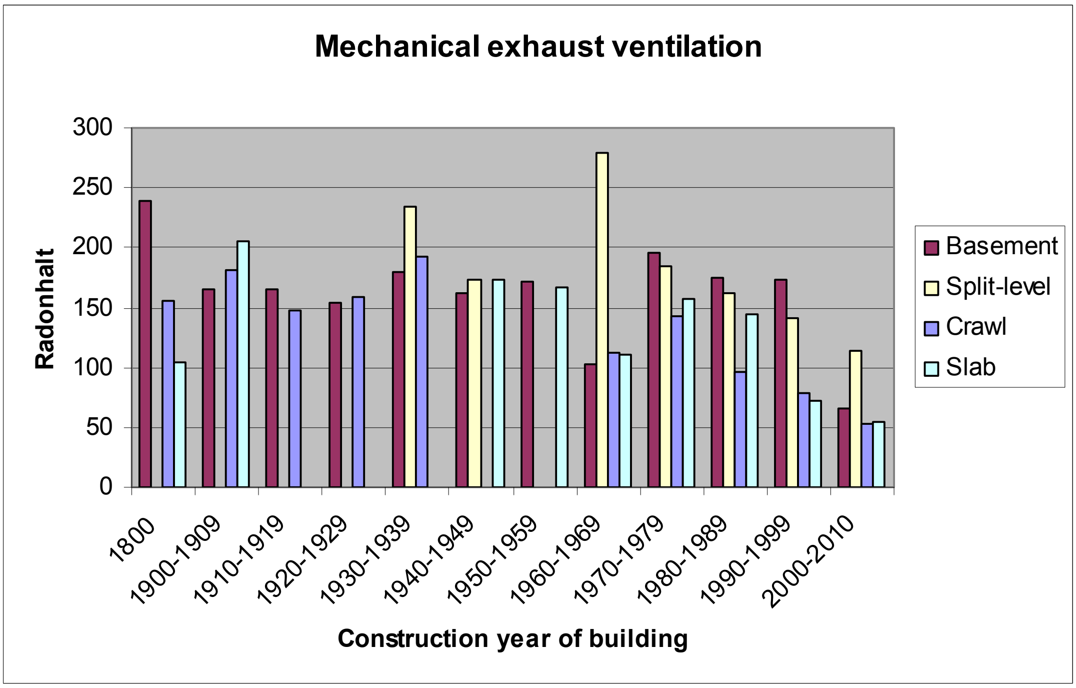

Fig. 2. Annual average radon levels measured in dwellings with mechanical exhaust ventilation which are constructed in the eighteen hundreds until present day and the dependence on house foundation.

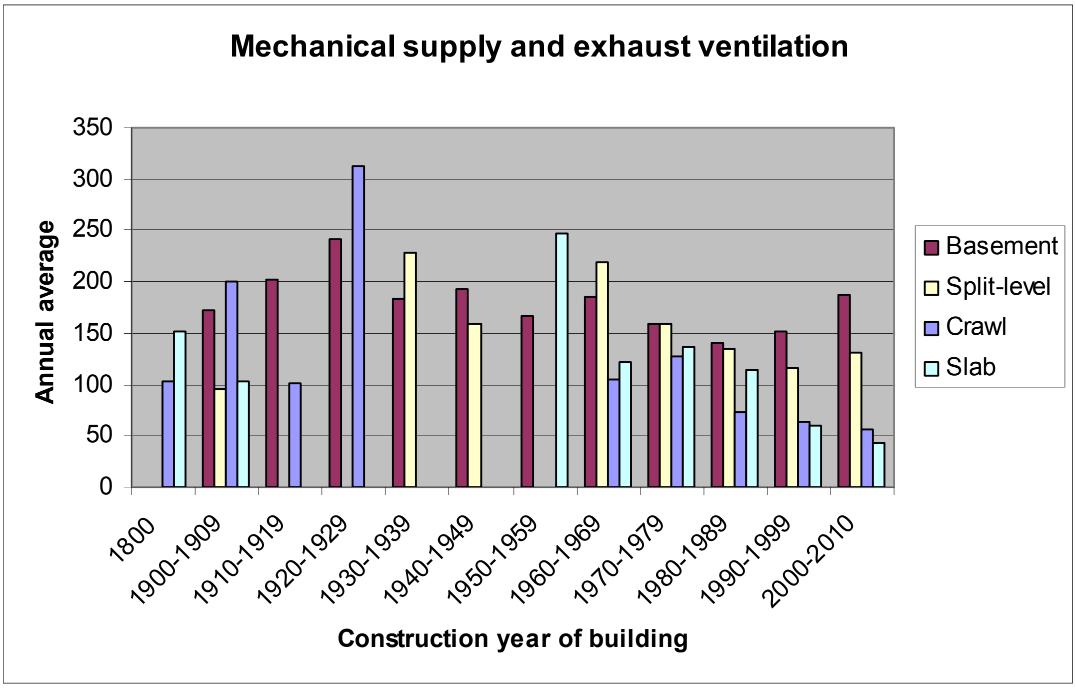

Fig. 3. Annual average radon levels measured in dwellings with mechanical supply and exhaust ventilation which are constructed in the eighteen hundreds until present day and the dependence on house foundation.

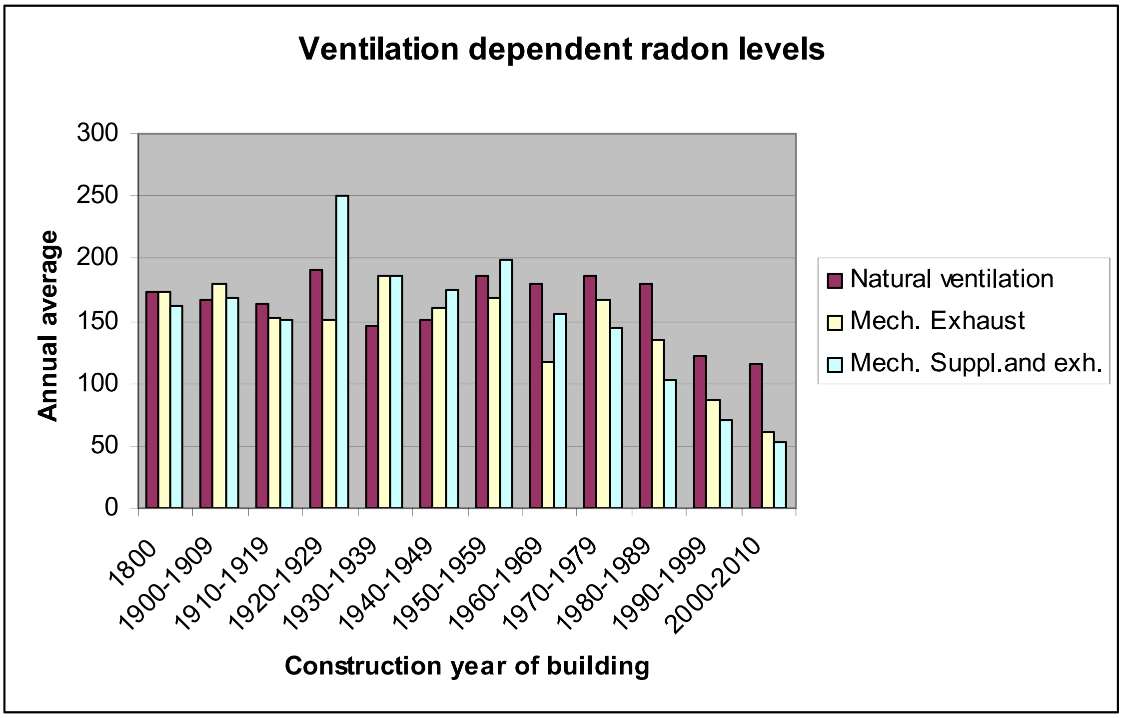

Fig 4. Radon levels in single family dwellings depending on type of ventilation and building construction year.

Mechanically ventilated dwellings have seen a clear improvement in radon levels starting in house constructions in the 1980´s up until the present. Part of the reason may be an increased use of mechanical ventilation in the original building construction. Mechanical exhaust has been used in Sweden starting in the 1930´s while mechanical supply and exhaust air ventilation with heat recovery started being used in the 1970´s (H. Adolphson). For natural ventilation, improvements are seen in buildings from the 1990´s and onward. For mechanical exhaust and supply ventilation this means that in buildings manufactured previous to 1970´s the system was installed afterwards. Although this installation can be assumed to have led to an improved ventilation in the dwelling it has no apparent great effect on the radon level as compared to natural ventilation in these data. In several cases it is evident that mechanical ventilation rather has the opposite effect on the radon level which supports the general notion that using mechanical ventilation does not automatically mean low radon levels (something which our customers informs us of regularly as well). However this does not mean that installation of mechanical ventilation for radon reducing purposes is not effective. As mechanical ventilation is used as a form of remediation it may well be that several of the dwellings included in this data have reduced from an even higher radon.

Another reason that natural ventilation may have a disadvantage over mechanical is that during the energy crisis of the 1970´s the general population was encouraged to reduce their energy consumption by improving insulation in their houses. This is well known to have caused an increase in radon levels (B. Clavensjö) as well as a reduction in ventilation. Therefore it is possible that part of the reason why natural ventilation tends to have higher radon levels is that it no longer is working according to the original construction because the amount of fresh air intake has been reduced.

Conclusions

A modern building with a slab or crawlspace construction together with mechanical ventilation is the best construction according to this study in order to minimize radon levels in single family dwellings. The new WHO recommendations are that radon levels in dwellings should be below 100 Bq/m3. When examining figure 4 above it is noteworthy that the modern buildings with natural ventilation in this study tend to have an average above the WHO recommendation. We therefore propose that mechanical ventilation in combination with slab or crawlspace should be recommended for future construction of single family dwellings

Radon concentrations in newly built homes in Norway

Finne, Ingvild; Kolstad, Anne Kathrine; Rudjord, Anne Liv
Norwegian Radiation Protection Authority, NORWAY

Abstract

Since 1997 requirements on radon in new buildings have been included in building regulations and guidelines in Norway. A large survey of radon in dwellings were carried out in Norway in the period 2000-2001 and the percentage of homes with radon concentration above 200 Bq/m^3 was estimated to 9 % (Strand et al. 2001). These homes were mainly built before the 1997 Building Regulations but little has been known about the effects of the regulations and guidelines on the newly built homes.

During the winter season 2008 the Norwegian Radiation Protection Authority carried out a nation-wide survey including 750 randomly selected dwellings built in the period 2000-2007 to investigate to what extent radon is still a problem in the new housing stock. The survey showed that the 1997 Building Regulations in force at the time of the survey, and the guidelines supporting it, had very limited effect on the radon concentration in the newly built dwellings.

Previous to this study it was assumed that the awareness on radon affected areas could be higher in municipalities strongly affected by this problem. Therefore, another survey was also carried out in seven selected municipalities where extensive radon problems had been found in earlier studies. In two municipalities, 50-60 % of the new dwellings had annual mean radon concentrations above 200 Bq/m^3. In one of the municipalities, all 10 newly built homes had radon concentrations below 200 Bq/m^3. In the remaining 4 municipalities, the fraction of radon concentrations above 200 Bq/m^3 was in the range 10-30 %. The conclusions were that the requirements in the 1997 Building Regulations and supporting guidelines had very little effect on radon concentrations in newly built homes.

New building regulations have been adopted after the finishing of this study and will take effect from 1 July 2010. The new building regulations include specific requirements for the use of radon barriers and preparing the building foundations such that it is possible to actuate active ventilation of the ground, if necessary, after finishing the building.

Introduction

The Norwegian Radiation Protection Authority (NRPA) has carried out several radon surveys during the last twenty years and radon is far the largest contributor to annual radiation dose to the public in Norway. There is no known threshold concentration below which radon exposure represent no risk of developing lung cancer. Exposure to radon in homes has been estimated to cause approximately 300 lung cancer deaths each year in Norway.

Radon gas from the ground enters homes through cracks and openings in the foundation of the building. In July 1997 the building regulations in Norway for the first time required planning of building constructions to avoid enhanced health risk by contaminants in the ground, which included radon. A maximum level for indoor radon concentrations was not given in the 1997 regulations. However, 200 Bq/m^3 was the recommended maximum level in the guidelines supporting the regulations, issued by The National Office of Building Technology and Administration and supported by NRPA.

In 2008 two surveys were carried out by NRPA in order to get knowledge about the radon levels in newly built homes, constructed in the period 2000-2007. In the nation-wide survey, the homeowners were randomly selected. In the other survey all relevant homeowners in seven municipalities, known to have extensive radon problems, got an invitation to take part.

The goal of the surveys was to explore whether the radon concentrations in recently built homes are low, and below the maximum level of 200 Bq/m^3, as recommended in the guidelines. Further, the goal of one of the surveys was to study radon levels in newly built homes in municipalities where previous surveys had shown extensive radon problems.

Material and methods

Indoor radon concentrations can vary considerably due to changes in weather conditions and ventilation rates etc. In Norway, long-term integrated radon measurements during heating season are preferred for assessing the annual average radon concentration. The NRPA recommend a measurement period of at least two months and all results should be seasonally adjusted.

Before building a new home a planning permission is required. Addresses for all estates given planning permission from the year 2000 to the start of the project in the autumn 2007 were ordered from the Norwegian land register. Almost 280 000 addresses were received. Planning permission is also required before reconstruction of homes and construction of other buildings, e.g. tool or car sheds. For this reason a lot of homes constructed outside the period of interest (2000-2007) were also measured. These measurements had to be rejected from the study later in the process.

For practical reasons only addresses which was identical to the homeowners address was included in the surveys, excluding homes hired out.

For the nation-wide survey addresses were randomly selected. For the municipal survey all addresses of newly built homes were selected. The municipalities of Drangedal, Grane, Nes (in the county of Buskerud), Skjåk, Tana, Ullensvang and Ulvik were included in the survey (figure 1).

Fig. 1. The seven selected municipalities with extensive radon problems included in the 2008 municipal survey.

In February 2008, an invitation was sent to approximately 2750 homeowners with an offer to participate in the two surveys; 2500 homeowners in the nation-wide survey and 250 in the municipal survey. Enclosed to the letter of invitation the homeowner could find two CR-39 etched track radon detectors, full instructions for placement of the detectors, a questionnaire and a pre-paid envelope for the return of detectors.

The homeowners were asked to place one detector in the main living area and one in a bedroom. Further they were asked to fill in the questionnaire which should be returned together with the detectors. The questionnaire included detailed information about the point of measurements, building construction, ventilation, etc. The data in this study will be further analysed and published at www.nrpa.no in a NRPA report in English.

The overall response rate in the two surveys was approximately 49 %. However, approximately 36 % of the measurements had to be rejected because the homes were constructed outside the period of interest (2000-2007).

Results and discussion

Nation-wide survey

Measurements from a total of 758 randomly selected homes constructed in the period 2000-2007 were used in the nation-wide survey. The results from the survey are given in table 1.

The mean annual radon concentration for all categories of homes constructed in the period 2000-2007 is estimated to 66 Bq/m^3. 8 % of the homes have at least one measurement exceeding the recommended upper level of radon concentration of 200

Bq/m^3. Taking the uncertainties of the measurements into account this is practically the same result, 9 %, as estimated for the Norwegian housing stock mainly built before the introduction of radon requirements in the 1997 Building Regulations.

The mean annual radon concentration is known to vary for different categories of homes. The results for the different categories for this survey are given in table 1 showing that detached homes have got the highest mean annual radon concentration, and the highest percentage of homes above 200 Bq/m^3. The measured terraced homes have lower mean radon concentration than the measured detached homes.

Horizontally separated dwellings in two-family homes also showed high mean annual radon concentration and a high percentage above 200 Bq/m^3, but based on the result of only 24 homes.

Blocks of flats or multifamily homes have got the lowest mean annual radon concentration, 33 Bq/m^3, and 1 % of the homes above recommended maximum level of 200 Bq/m^3. The reason for this is that most of the flats do not have direct contact with the ground.

Table 1. Results from the 2008 nation-wide survey of homes constructed in the period 2000-2007.

Building category	Number of homes	Mean (Bq/m^3)	Maximum (Bq/m^3)	Homes above 200 Bq/m^3 (%)[1]
All categories	758	66	2670	8
Detached homes	320	90	2670	12
Terraced homes	139	66	1254	9
Horizontally separated dwellings in two-family homes	24	71	782	8
Blocks of flats or multifamily homes	236	33	368	1
Unknown	39	59	823	8

[1]Homes with at least one of the two measurements above 200 Bq/m^3
[2]Annual mean radon concentration

Municipal survey

Measurements from a total of 102 homes constructed in the period 2000-2007 were used in the municipal survey. The results from the survey are given in table 2.

Table 2. Results from the 2008 municipal survey of homes constructed in the period 2000-2007.

Municipality	Number of homes measured	Mean (Bq/m^3) (2)	Maximum (Bq/m^3) (2)	Homes above 200 Bq/m^3 (%)(1)
Drangedal	24	352	1900	58
Grane	10	43	150	0
Nes (Buskerud)	15	167	510	60
Skjåk	20	131	900	20
Tana	12	63	220	16
Ulvik	5	129	330	20
Ullensvang	16	100	420	25

[1] Homes with at least one of the two measurements above 200 Bq/m^3
[2] Annual mean radon concentration

The seven municipalities were known to have extensive radon problems. The mean annual radon concentration for all categories of homes is estimated to 166 Bq/m^3. In this survey, the mean annual radon concentrations were varying between 43 Bq/m^3 and 352 Bq/m^3 for the seven municipalities. All measurements in the municipal survey were made in detached homes (100 homes) or terraced homes (only 2 homes).

For comparison the mean annual radon concentrations for the seven municipalities are shown in the bar graph (figure 2) together with two bars representing all homes and the detached homes, respectively, in the nation-wide survey.

In the municipalities Drangedal and Nes (Buskerud), 58 % and 60 % of the homes, respectively, at least one of the two measurements in the home indicated an annual mean radon concentration above 200 Bq/m^3. However, in Grane no homes were identified as being above the reference level given in the guidelines to the building regulations.

For comparison the percentages of homes with at least one measurement above 200 Bq/m^3 in the seven municipalities are shown in the bar graph (figure 3) together with two bars representing all homes and the detached homes, respectively, in the nation-wide survey.

Further analysis have to be done to get a better understanding of why new homes still have high radon concentrations in areas well known to have extensive radon problems. However, the total results indicate that the building regulations have not had the wanted impact on the radon problem in the majority of the high risk municipalities investigated.

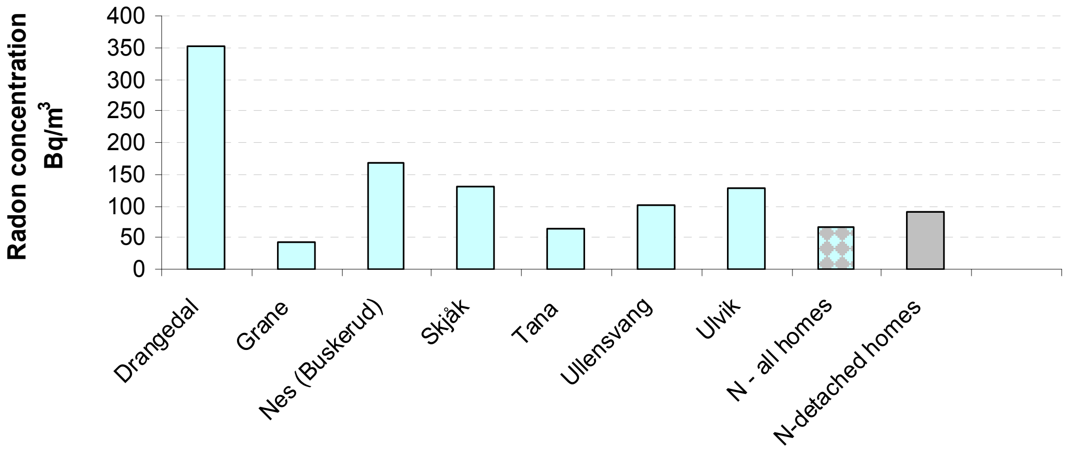

Fig. 2. The mean annual radon concentration in the seven municipalities compared with the mean radon concentration in all the homes and all the detached homes in the nation-wide survey.

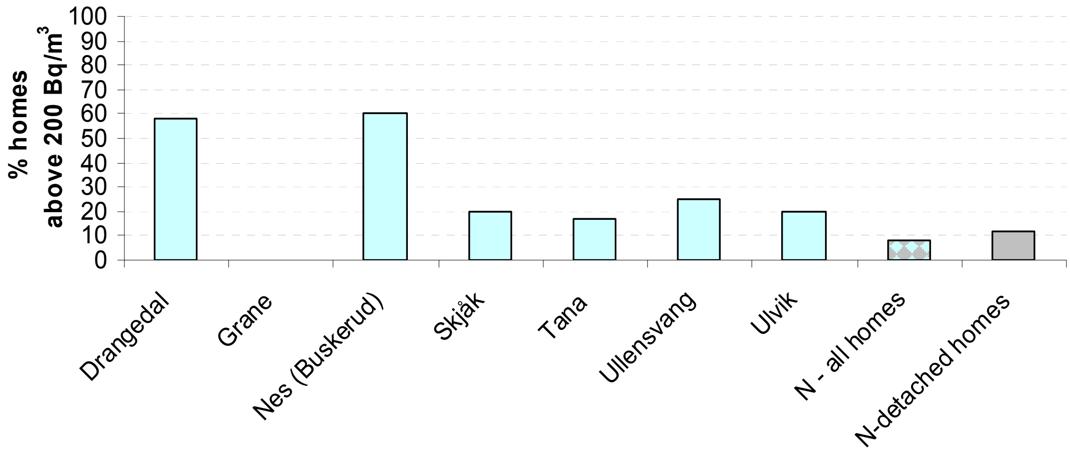

Fig. 3. The percentage of homes with at least one measurement above the maximum upper level of 200 Bq/m^3 compared with the percentage in all the homes and all the detached homes in the nation-wide survey.

Conclusions

Both the nation-wide and the municipal surveys carried out in this study indicate that a significant portion of the newly built homes in Norway have radon concentrations above the recommended maximum level of 200 Bq/m^3. The building regulations, which came into force in July 1997, do not seem to have had any particular influence on the radon concentration in the Norwegian housing stock.

New building regulations have been adopted after the finishing of this study and will take effect from 1 July 2010. The new building regulations include specific requirements for the use of radon barriers and preparing the building foundations such that it is possible to actuate ventilation of the ground, after finishing the building. The new requirements include the introduction of legally binding indoor radon limits for new buildings (100 Bq/m^3, action level; 200 Bq/m^3, maximum). Because the requirements in the new regulations are more specific than the 1997-regulations it will hopefully keep the radon concentrations below the upper maximum level of 200 Bq/m^3 and further reduce the mean annual radon concentration in the coming new housing stock.

Abstract

Radon concentrations in dwellings are known to vary from day to day depending on weather conditions and occupant lifestyle. Consequently, short-term measurements (STM) of a few days are generally less representative of the annual mean radon concentration than long-term measurements (LTM) performed over several months. On the other hand, STM may be used as screening techniques for testing radon levels. The aim of this study was to develop a screening method based on STM to provide fast and reliable indications of radon levels in dwellings.

Radon concentrations were measured in 184 dwellings in Switzerland over a 3 month period using alpha-track detectors (Radtrak). Together with LTM, STM were performed at 3 time points, i.e. at the beginning, the middle and the end of the 3 month period, using activated charcoal canisters (Picorad) exposed during one day. A statistical comparative analysis of LTM and STM in those dwellings was performed to derive the screening method.

Results obtained with STM overestimated, on average, by 35% those obtained with LTM, with a standard deviation of 65%. This was explained by the reduced ventilation applied during STM. The variability of STM at the three different time points was characterized by a standard deviation of 24%. Based on those results, the following screening method was proposed considering an action level of 400 Bq/m^3:

(a) if results of STM are less than 110 Bq/m^3, the annual mean radon concentration is below 400 Bq/m^3 with a confidence level of 95%;
(b) if results of STM are above 970 Bq/m^3, the annual mean radon concentration exceeds 400 Bq/m^3 with a confidence level of 95%;
(c) if results of STM range between 110 and 970 Bq/m^3, LTM are required to determine whether the dwelling is above or below 400 Bq/m^3.

This method was validated for several dwellings. We conclude that STM provide valuable information on radon levels in dwellings to determine if further LTM are necessary. In Switzerland, this STM screening method is primarily used in real estate transactions.

Introduction

Radon exposure is the main component of the radiation dose to the Swiss population and the leading cause of lung cancer after smoking. As part of preventive healthcare, the Radiological Protection Ordinance set in 1994 a yearly average limit of 1000 Bq/m^3 and introduced a guidance value of 400 Bq/m^3 for the concentration of radon gas in Swiss dwellings. A major objective of the ongoing national radon programme is then to identify dwellings where radon concentration exceed the legal limit of 1000 Bq/m^3 and ensure that remediations are performed. To determine radon concentrations, the Swiss Federal Office of Public Health (FOPH) recommends measurements over a 3 month period using dosimeters, during the heating period. Most of the usual dosimeters like alpha-track detectors and electret ionization chambers are used for such long-term measurements (LTM). In Switzerland, those dosimeters are available from approved measuring laboratories.

Since radon concentration fluctuates from day to day depending on atmospheric conditions and occupant lifestyle, short-term measurements (STM) of a few days are less likely than LTM over several months to represent the yearly average radon concentration in dwellings (U.S. Environmental Protection Agency, 2009). Nevertheless, if results are needed quickly, it is widely accepted that STM may be used as screening techniques for a rapid initial testing of radon levels, especially if radon concentration is likely to be significantly higher than the national average value. For instance, there is often limited time to deal with radon in case of real estate transaction and people are asking more and more about radon levels before they buy or rent a home.

The aim of this study was to develop a screening method based on STM to provide fast and reliable indications of radon levels in dwellings. For this purpose, we first aimed at testing STM as compared to LTM that reflect a better average radon concentration. A strategy of screening measurement based on the reliability of STM was then derived and assessed.

Material and methods

As part of a measurement campaign, radon concentrations were measured in 184 dwellings of the canton of Vaud in South West of Switzerland over a 3 month period using alpha-track detectors (Radtrak). The canton is located by the Lake Geneva and at the foot of the Jura Mountain where elevated indoor radon levels were observed. Together with LTM, single STM were performed at 3 time points, i.e. at the beginning, the middle and the end of the 3 month period, using activated charcoal canisters (Picorad) exposed during one day. Each single STM was performed simultaneously with two Picorad detectors in order to assess their reproducibility. Detectors were always placed in the lowest inhabited area in contact with normal breathing air. Areas with a high air circulation rate were avoided (doors, windows). A statistical comparative analysis of LTM and STM in those dwellings was performed.

In order to assess whether electret detectors (E-Perm SST) can be used alternatively to activated charcoal canisters for STM, both types of detectors were exposed simultaneously in a home-made radon chamber during 1, 2 and 3 days. Measurements were limited to a period of 3 days to avoid saturation of activated charcoal canisters. The obtained radon concentrations were then normalized to the reference concentration in the radon chamber measured with an AlphaGuard monitor traceable to the international standard. Moreover, the same experiment was conducted in situ, in a house with high radon levels (~ 1500 Bq/m^3). Performances of both activated charcoal canisters (Picorad) and electret detectors (E-Perm SST) were compared.

Results

Radon concentrations measured with LTM varied between a few Bq/m^3 and 900 Bq/m^3, with an average of 62 Bq/m^3. For STM, the average radon concentration was 85 Bq/m^3. A good reproducibility was found for activated charcoal canisters as showed by the standard deviation of 13% obtained between responses of both dosimeters exposed simultaneously at the same position during a single STM. The dispersion of the three STM performed with both activated charcoal canisters was 24%. Indeed, the Gaussian distribution of the ratio of each single STM to the mean of the three STM given in Fig. 1 is characterized by a mean of 1.00 and a standard deviation of 0.24. This dispersion characterizes the temporal variability of radon concentration and represents the reliability limit of STM.

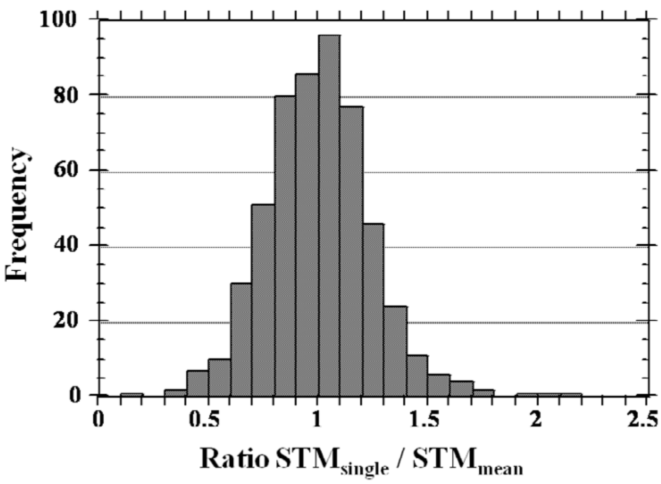

Fig. 1. Distribution of the ratios between the single STM and the mean of three STM (beginning, middle and end of the period). Results of each single STM correspond to the average of radon concentrations measured simultaneously with two activated charcoal canisters.

The distribution of the ratio between each single STM and the LTM was considered Gaussian with a mean (μ) of 1.35 and a standard deviation (σ) of 0.65 (see Fig. 2). The overestimation of 35% obtained with activated charcoal canisters can be explained by ventilation restrictions imposed before and during the STM. Based on this Gaussian distribution (μ = 1.35 and σ = 0.65), it is possible to calculate the probability P that the LTM exceeds a given action level AL using the radon concentration C obtained from STM. The following expressions are then derived:

$$5\% = P\left(\frac{C}{AL} < (\mu - 1.64 \cdot \sigma)\right) = P(C < 0.28 \cdot AL)$$

$$95\% = P\left(\frac{C}{AL} < (\mu + 1.64 \cdot \sigma)\right) = P(C < 2.42 \cdot AL)$$

Thus, considering a given action level AL, the probability that the LTM is below L_{INF}, defined as 0.28·AL, is of 5%. In other words, the probability that the LTM is above L_{INF} is of 95%. Similarly, there is a probability of 5% that the LTM is higher than L_{SUP}, defined as 2.42·AL. Values of L_{INF} and L_{SUP} are given in Table 1 for three different action levels.

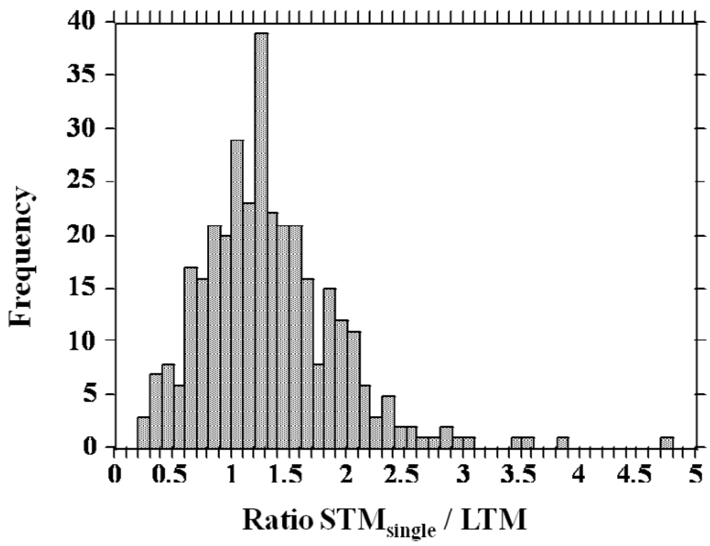

Fig. 2. Distribution of the ratios between the single STM and the LTM.

Table 1. Values of L_{INF} and L_{SUP} according to different action levels.

Action Level [Bq/m^3]	L_{INF} [Bq/m^3]	L_{SUP} [Bq/m^3]
200	60	480
400	110	970
1‘000	280	2’420

Results obtained with electret detectors (E-Perm SST) and activated charcoal canisters (Picorad) are compared in Fig. 3 for both measurement conditions, i.e. in the radon chamber and in the existing house. Each point corresponds to the average radon concentration measured with two dosimeters normalized to the reference concentration obtained with the AlphaGuard monitor during the measurement period (1, 2, 3 or 7 days). A very good agreement was observed for electret detectors, always within ± 10% except for the one-day measurement in the radon chamber (-12%). A relatively good agreement was also found for activated charcoal canisters with a maximum deviation of -22% for the one-day measurement in the radon chamber and +38% for the three-day in situ measurement.

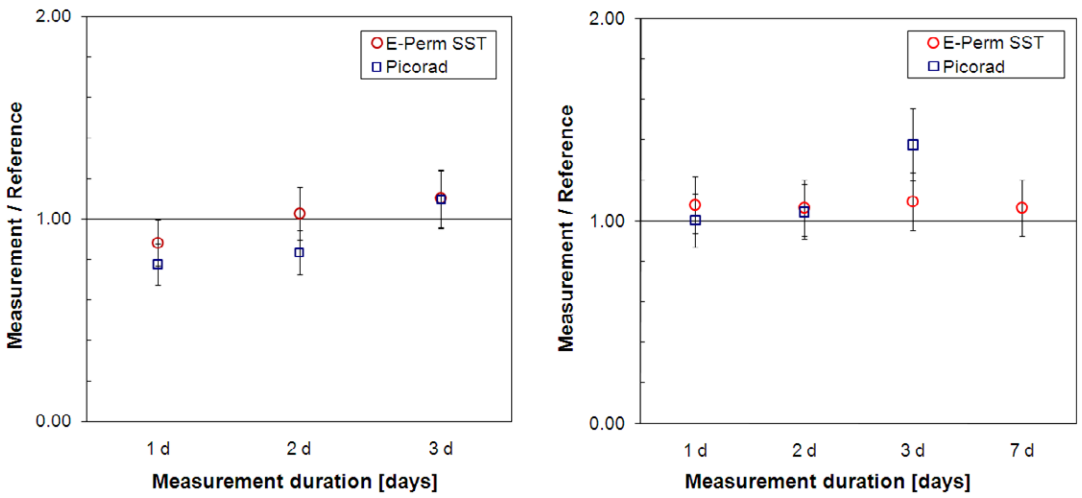

Fig. 3. Comparison of radon measurements with electret (E-Perm SST) and activated charcoal (Picorad) detectors. Measurements were performed in a radon chamber (left) and in an existing house (right) with a radon concentration of about 1500 Bq/m^3. Each measurement corresponds to the average of radon concentrations measured simultaneously with two detectors.

Discussion

Based on these results, we propose a screening method based on STM to provide fast and reliable indications of radon levels in dwellings. For the measurements, windows and doors should be kept closed at least 12 hours before starting the measurement and during the whole measurement period. The recommended duration of measurement is 2 days using activated charcoal canisters (Picorad) and at least 2 days using electret detectors (E-Perm type SST). Note that electret detectors can be quickly evaluated immediately at the end of a measurement and thus are somewhat more appropriate than activated charcoal canisters for STM. Results of STM are then interpreted as follows, for a given action level (values of L_{INF} and L_{SUP} are given in Table 1):

(a) if the result of STM is less than L_{INF}, the yearly average radon concentration is below the action level with a confidence level of 95%;

(b) conversely, if the result of STM is above L_{SUP}, the yearly average radon concentration exceeds the action level with a confidence level of 95%;

(c) while no additional measurements are required in both cases (a) and (b), if STM range between L_{INF} and L_{SUP}, LTM are necessary to determine whether the radon concentration in the dwelling is below or above the action level.

In the UK, a similar study was conducted by the Department for Environment, Food and Rural Affairs (Phillips P.S et al., 2004). STM were based on a period of one week using charcoal detectors, electret detectors and alpha-track detectors. Results of STM were also compared with 3-month measurements performed with alpha-track detectors. For an action level of 200 Bq/m^3, the DEFRA reported similar values of L_{INF} and L_{SUP} as those showed in Table 1, i.e. 68 and 522 Bq/m^3 when activated charcoal canisters were used and 59 and 667 Bq/m^3 using electret detectors.

Our screening method was validated for several dwellings in Switzerland. In our practice, STM are mainly used in the framework of real estate transactions.

Conclusions

Short-term measurements (STM) are appropriate for a rapid screening test of radon levels in dwellings. In this study, a method based on STM, i.e. two-day measurements using electret detectors or activated charcoal canisters, has been developed to determine, with a confidence level of 95%, if an action level (in Bq/m^3) has been exceeded or not and if further long-term measurements are required. In Switzerland, STM are essentially being used in the framework of real estate transactions.

Estimating the health benefits of progeny extraction units as a means of reducing exposure to radon

Denman, Antony; Groves-Kirkby, Christopher; Phillips, Paul
School of Science and Technology, The University of Northampton, UK.

Abstract

Radon exposure to the general public can be reduced by preventing entry of radon gas into buildings using a passive radon-proof membrane or an active sump and pump system. However, a significant majority of the radiation dose delivered is from the decay products of radon rather than from the gas itself. These decay products (also referred to as progeny) are present in indoor air, with an equilibrium factor – a measure of the ratio of progeny to radon gas – of between 0.4 to 0.5. As a result, systems which extract radon progeny from the air by filtering have been promoted as means of reducing exposure to the general population.

The European Community Radon Software (ECRS) offers a means of estimating lung-cancer risk associated with an individual's exposure to radon, and includes the possibility of estimating the health risk from different proportions of radon gas and its progeny by varying the value of the Equilibrium Factor. This software was used to estimate the health benefits associated with reduced decay products in differing concentrations of radon gas. The results were compared to health benefits expected if the risk was reduced by the standard method of reducing the radon gas concentration below the Action Level, which in the UK is 200 Bq·m^{-3} for domestic properties.

These calculations showed that there is the potential for efficient extraction units to provide the necessary dose and risk reduction where initial average radon gas concentrations are up to 800 Bq·m^{-3}. However, above 1000 Bq·m^{-3}, such systems cannot reduce the health risk sufficiently to reach levels comparable to those resulting from radon gas reduction to below the Action Level.

Introduction

The naturally-occurring radioactive gas, radon, is the second most significant risk for lung cancer after tobacco smoking. High levels of radon were first identified in uranium mines but, more recently, it has been established that significant levels are found in the built environment, and case-control studies have shown an associated increase in lung-cancer in the public from radon in their homes (BEIR VI 1999; Darby et al. 2005; AGIR 2009).

Radon decays into other radioactive elements, and two of these, Polonium-218 and Polonium-214, have been shown to deliver a significant proportion of the radiation dose received by occupants of domestic premises. In a sealed system, radon and its progeny exist in secular equilibrium. In the domestic environment, however, secular equilibrium is never maintained, because progeny are continuously being removed from indoor air by surface deposition and ventilation. The degree of disequilibrium between the radon gas and the progeny is represented by the Equilibrium Factor (EF), which is defined as the ratio of the potential alpha energy concentration (PAEC) of the actual progeny mixture to the PAEC of progeny in secular equilibrium with the radon gas. Thus EF is between 0 and 1, and within domestic buildings is typically in the range 0.4 to 0.5. Although they are intrinsically solid materials, radon progeny can exist in suspension in air, either unattached, or attached to aerosol particles. Porstendörfer (1984) has discussed these processes, including plate-out of particles and the influences on the ratio between radon and progeny.

Although technical solutions to the radon problem in domestic properties have been largely based on prevention of ingress of radon gas from the soil under the influence of the climatically-dependent pressure difference between the interior of the dwelling and the external environment, there has recently been renewed interest in the physical removal of radon progeny by direct filtering of the internal air, thereby reducing the equilibrium factor between radon gas and its solid progeny.

A number of studies by our own group (Marley et al. 1998) and others have confirmed that filters can indeed remove radon progeny from air (Ogorodnikov et al. 1962; Busigin et al. 1980) and their efficacy as respiratory filters in mining has been studied (Wake et al. 1992).

Offermann et al. (1985) reported that an air-cleaner used to control the indoor concentration of respirable particles and radon progeny, especially if fitted with a high efficiency particulate air filter (HEPA-filter), was effective in removing radon progeny, a finding confirmed by Li and Hopke (1991), who reported that air cleaners effectively reduce the median dose due to radon and its progeny, and that air-filtration is more effective than electronic air cleaning. However, while air cleaning can be effective in reducing total radon progeny, concentrations of unattached radon progeny, a dominant factor affecting the dose conversion factor, can increase with air-cleaning. Henschel (1994) reviewed techniques for the purpose of reducing indoor radon concentration, commenting that the effects of air-cleaners on health risk were unclear due to the increase in the unattached fraction. Tokonami et al. (2003) noted that use of an air-cleaner enhances the dose conversion factor critically, since the unattached fraction increases significantly due to aerosol removal. Most recently, Kranrod et al. (2009) showed experimentally that radon progeny dose reduction of the order of 50% was feasible by use of a well-configured air-cleaner.

These uncertainties notwithstanding, there are several devices on the market specifically claiming to reduce the risk from radon[1,2]. However, the US Environmental Protection Agency (EPA) does not recommend radon remediation using filters (EPA 2010).

Material and methods

The European Community Radon Software (ECRS) tool (Degrange et al., 2000) performs lung-cancer risk calculations specific to European populations for individual or collective radon exposure profiles. Specifically, the software is capable of generating a range of individual risk-related estimates, including reduced life expectancy and expected age at death, for subjects whose age, sex, smoking habits and domestic radon exposure are known, and can furthermore take into account the equilibrium factor applicable to the environment being investigated. ECRS has therefore been used in the present study to consider whether deploying EF-reducing filtration techniques in homes can produce a significant health benefit to occupants.

In addition to basic demographic, radon exposure and smoking status input parameters, ECRS permits user control of Equilibrium Factor and aerosol parameters. Two Equilibrium Factor tables are provided, attributable to ICRP 65 (ICRP, 1994) and the UK National Radiological Protection Board (NRPB) respectively. Whereas the ICRP parameters, the system default, do not vary with room type, the NRPB data addresses the possible impact of ventilation rate and air smoke content on the equilibrium factor. For the present study, a derivative of the ICRP dataset was used, with identical values of Equilibrium Factor being used throughout the house for each case modeled.

ECRS modeling addresses additional aerosol parameters, representing the overall radon progeny activity-size distribution by a sum of lognormal distributions (modes). For each of these modes, unattached progeny and three attached modes (nucleation, accumulation and coarse), values are given for fraction of total PAEC, dispersion (i.e. geometric standard deviation), and particle size in terms of Activity Median Aerodynamic Diameter (AMAD) for attached particles and Activity Median Thermodynamic Diameter (AMTD) for unattached particles. Two data models are provided, a default Generic House, where the parameters do not vary with room type, and a generalized model, which considers the possible impact of ventilation rate and air smoke content on the aerosol parameters and provides specific room-by-room data. The Generic House option was used in the present analysis.

For the present study, analysis was based on 40-year-old, Non-Smoking and Smoking Males and Females exposed to radon levels of 0, 200, 600 and 1000 $Bq{\cdot}m^{-3}$, for Equilibrium Factors ranging from 1.0 down to 0.02. Using the results from this analysis, iso-risk plots were generated, identifying the effect of reduction of Equilibrium Factor on individual excess lung-cancer risk. The calculated risks of contracting lung cancer were then compared to the risk at a radon level of 200 $Bq{\cdot}m^{-3}$ (the UK domestic Action Level) with an Equilibrium Factor of 0.5.

Results

At all levels of Equilibrium Factor and for both sexes, excess lung-cancer risk is linearly proportional ($R^2 > 0.99$) to radon exposure over the range 0 - 1000 $Bq{\cdot}m^{-3}$ (five times the UK Action Level). Specific Risk factors (incremental risk attributable to 1 $Bq{\cdot}m^{-3}$ exposure) for 40-year-old Non-Smoking Males and Females are themselves linear in Equilibrium Factor (Figure 1), as is loss of life expectancy consequent on radon exposure (Figure 2).

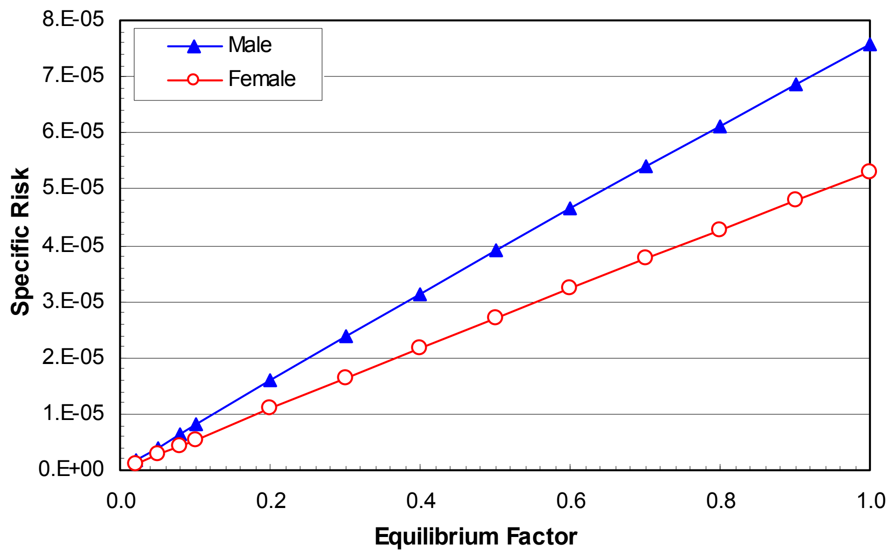

Fig. 1. Variation of excess risk per unit Bq.m^{-3} radon concentration, linear in radon over the range 0 – 1000 Bq.m^{-3}, with Equilibrium Factor for 40-year-old non-smoking Males and Females.

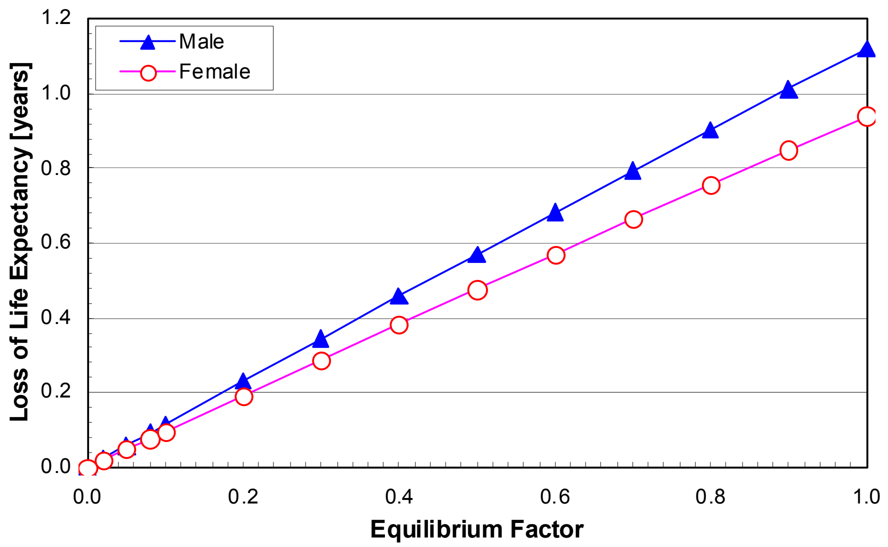

Fig. 2. Loss of Life Expectancy Attributable to Radon Exposure of 1000 Bq.m^{-3} for 40-year-old non-smoking Males and Females.

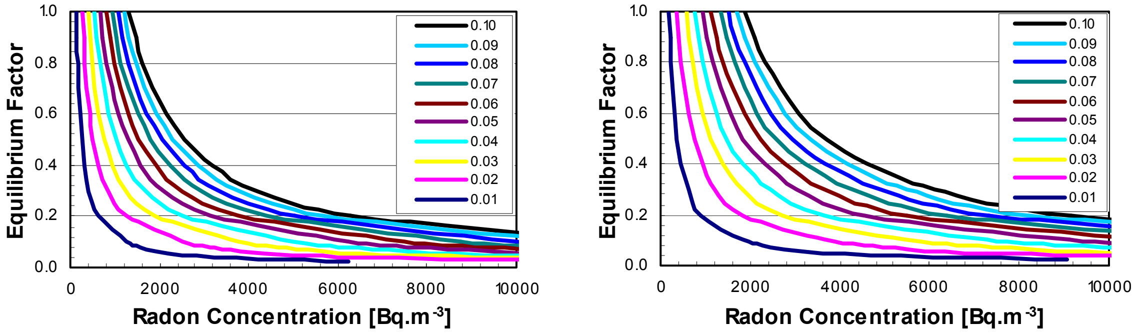
Excess risk represents the additional risk of contracting lung-cancer directly attributable to radon exposure. This is a complex function of age, sex, radon exposure level and duration, equilibrium factor and smoking status. By way of example, Figure 3 shows the set of iso-risk plots in the exposure-level/equilibrium factor domain, generated for 40 year-old non-smoking males and females with whole-life exposure to the indicated radon concentration levels, spanning the range of excess risks from 0.01 to 0.1 (1% - 10%). Similar families of curves can be generated for individuals of other ages, of different smoking status, and with any desired combination of radon exposure and home occupancy. These all have the same rectangular hyperbolic analytical form, the product of radon concentration and equilibrium factor being constant for any given level of excess risk.



(a) Males **(b) Females**

Fig. 3. Iso-Risk Plots for 40-year-old Non-Smokers, Excess Lung-Cancer Risk as parameter.

Discussion

At an exposure level of 200 Bq·m^{-3} with an Equilibrium Factor of 0.5, the current UK Action Level case, the excess risks of contracting lung-cancer are 0.008 and 0.0055 for Males and Females respectively. To facilitate further analysis and discussion, Figure 4 reports the 0.008 risk curve for Male subjects over the typically encountered range of domestic radon concentration levels. A similar curve can be generated for Females, in this case with a risk parameter of 0.0055.

As the figure shows, the iso-risk curves in the EF-radon domain take the analytical form of rectangular hyperbolæ (in this case, characterised by *EF•radon* = 106), a fact readily verified by inspection. Thus, if the Equilibrium Factor in a 200 Bq m^{-3} environment is reduced by a factor of 5 to 0.10, a reduced excess lung-cancer risk situation obtains at all radon levels from zero up to 1000 Bq m^{-3}.

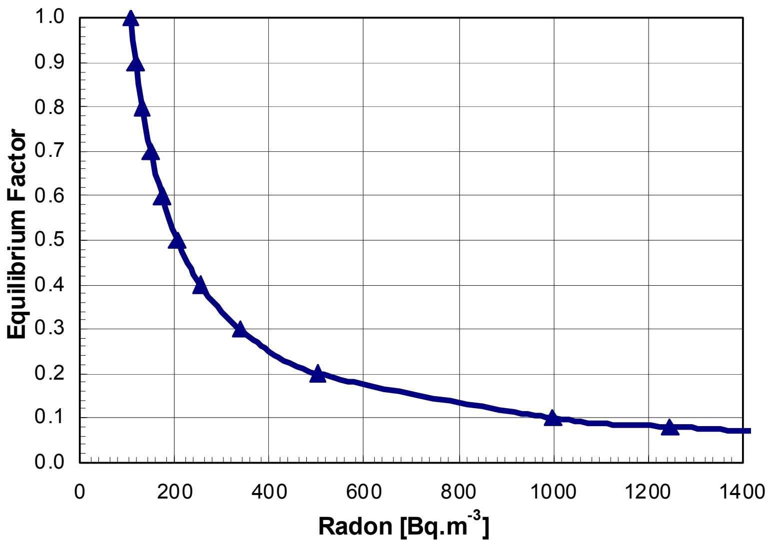


Fig. 4. Iso-Risk Plot (Excess Risk = 0.008) for Males in 200 Bq.m^{-3}, EF = 0.5 Environment.

Curling et al. (1990a) developed an optimization model for filter thickness, solidity, and fibre diameter to minimize inhalation dose from radon decay products, based on modified forms of the Porstendorfer-Jacobi (Porstendorfer, 1984) room model and the Jacobi-Eisfeld (Jacobi and Eisfeld, 1980) lung-dose model. The resulting optimal design, a thin filter of low solidity and large fibre diameter, confirmed that significant reduction in the dose rate could be achieved using a filter system. While the theoretical model predicted 80% reduction in the dose rate, with the inherent assumption of movement of 230 room volumes per hour through the fan, initial experimental trials (Curling et al. 1990b) achieved 50% reduction.

Kranrod et al. (2009) confirmed by measurement that an air-cleaner equipped with an HEPA filter and a deodorizing activated carbon filter preferentially removed the attached fraction of radon progeny from the room air, reducing EF to around 71% of its un-filtered value. Because of the differing contributions to the risk from radon gas, attached progeny and unattached progeny, the 71% reduction in Equilibrium Factor achieved in this way again resulted in a 50% reduction in dose. In the case studied, the initial radon gas level was around 300 $Bq \cdot m^{-3}$ and the risk to occupants was reduced below that at the Action Level of 200 $Bq \cdot m^{-3}$.

Examples in the literature of the Equilibrium Factors achieved in rooms where such filtration systems were operational are limited. Marley et al. (1998) measured F=0.17 in a UK hospital operating theatre, while Li and Hopke (1991) found F=0.134 in a US house. Reduction of the Equilibrium Factor to around this level in any room where the average radon gas level is below 800 Bq m^{-3} would reduce the risk to occupants sufficiently. If an equilibrium factor of 0.1 could be achieved, then the upper limit would be 1000 Bq m^{-3}, and so this could be regarded as an upper limit for such systems.

The performance of air-cleaners will depend on the air volume passing through the filter, and therefore will depend on the size of the room, the air throughput capability of the system and the characteristics of the filter. Thus it would be expected that an air-cleaner will not achieve as significant a reduction in progeny in a larger room. In addition, the movement of radon gas around the building needs to be considered. Additional units may be required in other rooms, if the radon gas moves slowly enough between rooms to decay and create new decay products, or if the source of radon gas and decay products is in another part of the building and reaches the living room and bedrooms independently.

For this reason, such units cannot be installed in any arbitrary room within a dwelling and be expected to achieve significant health benefits throughout the home. The performance of commercial units needs to be tested in standard conditions to ensure that a sufficient reduction in Equilibrium Factor is achieved. Furthermore, when deployed in a home, the performance needs to be checked. Standard track-etch devices only measure radon gas, and so there will be a need to develop simple assessment devices which measure both radon gas and progeny if these sort of units are to be deployed widely.

Conclusions

The theoretical calculations demonstrated in this paper demonstrate that air filtration units can reduce occupants' risk below the limit implied by the Action Level, provided that the radon gas level in the building is moderately raised above the Action Level. At increasing radon levels the air filtration units must be more efficient to achieve the required benefit, and above 1000 Bq·m^{-3}, the unit cannot reduce risk sufficiently to reach the target.

Thus such units may have their place in remediating homes with radon levels up to 800 Bq·m^{-3}, and may also be of value in homes remediated by other means where the level has been brought down, but not below the Action Level. Kranrod et al. (2009) have confirmed that satisfactory performance of such units can be achieved, at least at 300 Bq·m^{-3}.

Several practical issues remain before such units can be widely adopted. Firstly the performance of commercial units needs to be evaluated to assess how far they can reduce the Equilibrium Factor in a range of room sizes. Secondly, a simple monitoring system that can measure both radon gas, and progeny, and is comparable to the simplicity of the track etch systems for radon gas, must be developed, so that the health benefit from such units can be proven.

Abstract

More than 50% of the total absorbed dose from natural radiation sources is attributed to radon gas and its daughters (UNSCEAR, 1993). In the last decades, an increasing regulatory and scientific interest concern radon indoor monitoring, because radon and its daughters produces a risk of lung cancer, by inhalation of high concentrations for a long time. The indoor radon transportation is due principally by two different mechanisms: diffusion from soil and building materials and convection flow. The diffusion mechanism depends on the radium concentration in soil and building materials, as well as on the diffusion coefficient; convective flows are generated by a pressure difference between the inside and the outside of a building. Many external factors can also influence the diffusion process: rainfall, freezing and increasing atmospheric pressure decrease the exhalation rate, while increasing temperature can increase it. In this study temperature, pressure and humidity are monitored together with radon concentrations.

In 2006, for a period of four months between winter and spring, both in soil and indoor radon gas, and meteorological parameters, have been monitored continuously in two buildings at St. Venerina, situated on the low eastern flank of the volcano. This area is crossed by the Timpe Fault System (TFS), that are composed of faults mainly trending towards NNW–SSE and NW-SE. The indoor radon anomalies have been studied trough statistical methodology and they have been correlated with the geodynamic events of volcano Etna, recorded during the investigated period. Its values seems to show variations not due to local meteorology, diffusion or convection mechanisms, instead the predominant effect seems to be the geodynamics of the Etnean area. This study is an example that shows how in the active volcano-tectonic areas, the indoor-radon monitoring, based only on seasonality and floor numbers, is not exhaustive to establish the indoor radon levels, and how radon accumulation may depends on several and complex effects, each one able to generate anomalies of its concentration.

Introduction

During his life, man is constantly exposed to many ionizing radiation sources of natural origin, the most important of whose are ^{40}K and the radionuclides produced by the radioactive families of Uranium and Thorium. These elements have been produced at the time of Earth's creation and their decay products are widely distributed in soil, water and air. Of particular interest from the scientific point of view is the presence of radon gas in the air, in particular the isotope ^{222}Rn, produced by alpha decay of ^{226}Ra, which belongs to the decays chain of ^{238}U. Radon is a noble gas, odorless, colorless and tasteless, seven times heavier than air. Since it is chemically inert, it is characterized by great mobility. The World Health Organization (WHO) through the International Agency for Research on Cancer, included the as a group 1 carcinogen - in a list of 75 substances. The new document that the WHO has recently presented about has raised the level of concentration at the national reference value of 100 Bq/m^3, with an express recommendation to not exceed the limit value 300 Bq/m^3 (WHO HANDBOOK ON INDOOR RADON A PUBLIC HEALTH PERSPECTIVE - 2009), these values should be useful to the national authority to enact the appropriate construction standards. Exposure to radon in dwellings due to the presence of Uranium in soil and building materials is one of the major problems of radio-protection today.

^{222}Rn studies and monitoring showed that this geo-gas can reveal a variety of interesting features, as well as permit a depth comprehension of the Earth's crust.

Relatively recent is a new line of research, that is foretell geodynamic events through the sudden fluctuations of its concentration, the so-called ***radon anomalies***, which can be correlated with the geodynamics of the investigated area (La Delfa et al., 2007; Planinic et al., 2005; Vizzini et al., 2006-2007; Zmazek et al., 2005). The link existing between radon in soil anomalies and seismic events, has been explained by the so-called ***pore-collapse model*** (J.-P. Toutain et al., 1999).

The site

The town of St. Venerina (figure 1) is located on the lower eastern slope of volcano Etna. All the area is exclusively composed of volcanic soils, which refer to lava flows of different ages. From the structural point of view, the territory is characterized, as the entire eastern slope of Mt. Etna, by fault systems with prevailing directions NE-SW and NW-SE, which affect all the area. Some of these tectonic dislocations are well evident by the presence of sharp uneven terrain, the largest of which are called "Timpe".

Based on historical data, some of these faults, are defined “seismogenic”, because they are responsible for seismic activities, both in the recent and historical periods. The seismic activity that is originated from these faults, usually affects relatively shallow crustal levels ($h \leq 7$ km), with generally modest magnitude of earthquakes. However in periods of volcanic eruptions the related seismic events can reach the highest values recorded in all the Etnean area. What previously said was particularly evident in the well-known disaster occurred in October 29, 2002, during one of the most intense eruptions of Mount Etna, when a seismic swarm, and one great earthquake of magnitude 4.4 (Richter scale) and intensity VIII (MCS scale), with epicenter in St. Venerina, was responsible for considerable damages to persons and dwellings.

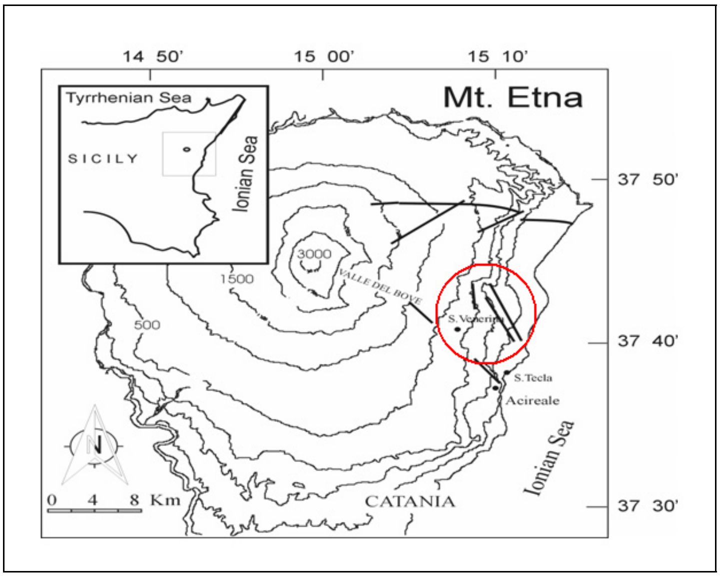

Fig. 1. Map of Mt. Etna and Si.Ge.T. active faults (red circle).

Material and methods

The main contribution of the in soil radon concentrations is due to the emanation process from soil or fractures in the ground. Materials with high Uranium and Thorium contents and which are located near the Earth's surface, can produce a high radon exhalation rate. In this context, Sicily is an island with different specific geological characteristics, offers a variety of lithotypes and therefore of features for building materials. The rocks and soils in all the Etnean area, are characterized by igneous rocks, which have the most Uranium and Thorium contents among the other lithological varieties of the island (metamorphic and sedimentary rocks). Therefore it was considered appropriate to effect a characterization of some rock samples, using gamma spectroscopy, to measure the primordial radionuclides contents. This study, as well as of academic nature, has practical implications on the human exposure to environmental radioactivity, since the rocks sampled in the monitoring sites are those processed and used for the construction of buildings for residential purposes, and this is particularly evident in all the Etnean area and at St. Venerina in particular, where the large part of dwellings are built with volcanic rocks and ash. The samples analysis has been effected revealing the γ-ray emitted by the radionuclides originating from ^{238}U and ^{232}Th decay chains and from ^{40}K, using a HPGe detector with efficiency of 40% and electric cooling. The measurements of radionuclides concentrations are used to determine both the indoor radon concentration and the gamma dose rate (Rizzo et al., 2001).

A benchmark for the radiological risk assessing due to external gamma radiation, is the ***Radium equivalent activity***. The meaning of the Radium equivalent activity is to have a single number or index that can describe the *γ-output* which is originated from different mixtures of Uranium (or Radio), Thorium and ^{40}K in a material. The Radium equivalent activity can be calculated as follows (Beretka and Mathew, 1985):

$$Ra(eq) = A(Ra) + 1.43A(Th) + 0.077A(K)$$

where:

A (Ra) is the ^{226}Ra activity (which is the same as ^{238}U) in Bq/kg

A (Th) is the ^{232}Th activity in Bq/kg
A (K) is the ^{40}K activity in Bq/kg

This equation is based on the assumption that 370 Bq/kg of ^{238}U, 259 Bq/kg of ^{232}Th and 4810 Bq/kg of ^{40}K produce the same dose range. Moreover, the Ra(eq) value of 370 Bq/kg is equal to the annual dose equivalent of 1.5 mSv per year, which represents the highest absorbed dose by a person in a year, caused by the exposure to natural radioactivity coming from building materials. The Radio equivalent activities obtained in the St. Venerina area, oscillate between 221,32 Bq/kg and 246,74 Bq/kg, with an average value of 236,01 Bq/kg, that is well below the threshold limit of 370 Bq/kg.

The Uranium and Thorium contents in rocks in the territory of St. Venerina, don't explain the in soil radon concentrations, more than 20000 Bq/m^3, which were recorded in previous studies (La Delfa et al., 2009; Vizzini et al., 2006-2007), and even more the indoor radon concentration fluctuations, from 2 to 5 times than the seasonal average concentrations, which seems to not be linked with seasonality. The radioactivity based on the primordial radionuclides content is indeed a constant value, characteristic of the lithology of the site. Based on these considerations, a punctual investigation in the territory of St. Venerina has been effected, near tectonic structures in the north part of the town, within the so-called geostructural system of Timpe (Si.Ge.T.), that is a faults system oriented NNW-SSE (red circle in figure 1).

The study of seismicity and the possible correlation with radon concentration fluctuations was carried out during the period between 12th January to 12th April 2006.

This temporal range was conveniently chosen as significant for these studies because a change in the seismic and volcanic styles of the volcano has been detected, while the meteorological parameters, both for indoor and in soil radon monitoring, had not drastic changes of their mean values in all the investigated period.

The in soil radon concentrations collected, showed fluctuations which, as known from the literature, are attributable both to changes in meteorological parameters, and to changes due to the dynamics of the volcano (Planinìc et al., 2005; Shi Yuchun and Xu Yingfeng, 1994; Zmazek et al., 2005). From the radon gas concentrations and the meteorological parameter data (temperature (°C), pressure (mBar) and relative humidity (%)), recorded every 10 minutes from the active monitoring device AlphaGUARD (GENITRON), the daily average values have been calculated. The in soil experimental data of St. Venerina have been collected in order to identify radon anomalies, precursors of seismic events related to the volcano Etna activity.

The results obtained, which are published in La Delfa et al., 2007, showed that there is a close correlation between in soil radon fluctuations and the geodynamic activity of the volcano. This conclusion is even more reliable because during the monitoring period there haven't been drastic changes in the meteorological parameters, which could affect the radon fluctuations of purely geodynamic nature. From these reasons, it became possible to assume that both the in soil and indoor radon concentration fluctuations, recorded and presented in this study, may be associated to the geodynamic activity of the volcano.

Simultaneously with in soil radon monitoring, indoor measurements have been effected, through another AlphaGUARD in modality of natural gaseous spread, put in a confined little room located at the ground floor of an ancient uninhabited building, lacking of windows, and located at a distance of about 7 meters from the in-soil operating instrument. There is a 15-20 cm thickness of concrete separating the room from the soil; the building walls are constituted of lava blocks. This building has been chosen because can be considered as representative of the historical centre of the town.

Indoor radon measurements at St.Venerina have been carried out also in a new building (reinforced concrete) from 12th January to 14th April 2006. In particular measurements have been performed in a basement of one edifice far about 50 meters from the site where in-soil active monitor was operating. It was built with the most current seismic criteria after the famous earthquake of magnitude 4.4 (Richter scale) and intensity VIII (MCS scale) in October 29, 2002, previously described. This dwelling can be considered as representative of the new neighborhoods of the town. In this new site indoor radon has been acquired using ORTEC Charcoal Canisters (CC) technique, following the EPA protocol (Gray and Windham, 1987).

The CC, preliminary weighed, had to be exposed, uncovered, in the confined place for 48 hours. The canister gamma activity (the activity of ^{214}Bi and ^{214}Pb radon daughters) was measured by means of NaI (Tl) scintillation spectrometer. The typical time between the end of the exposition and the beginning of the measurements was about four hours, which is the time needed to reach the transient equilibrium between parent and γ-emitted daughters. The concentration values expressed in Bq/m^3 were determined through the spectral analysis, exposure time and calibration factor known. Humidity sensors, used for all the investigation period to verify the reliability of the CC methodology (Gervino et al., 2004), have ensured that the humidity was always below 70% throughout the monitoring period.

Results and discussion

Both in soil and indoor radon measurements are shown in figure 2 a, b:

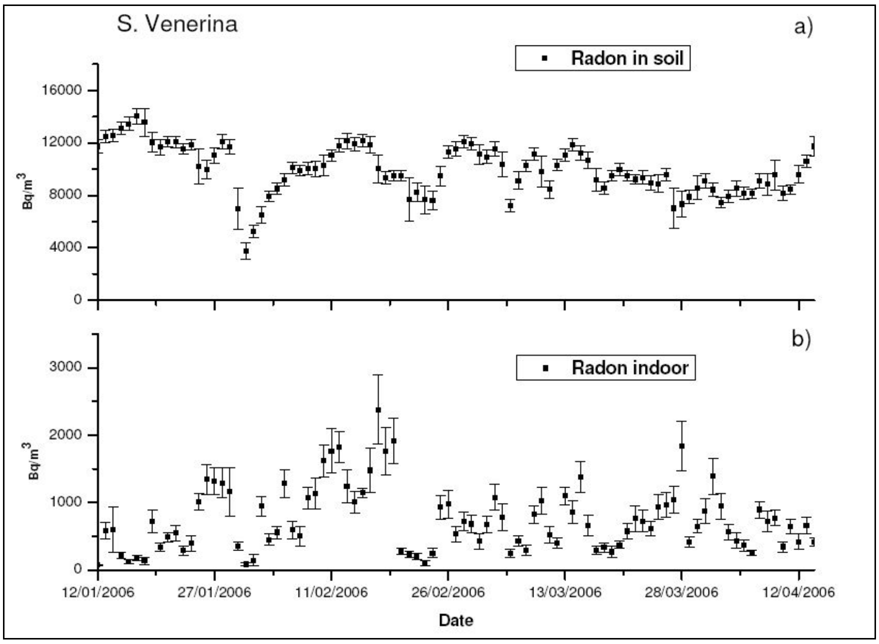

Fig. 2. Both in soil and indoor (old building) radon concentrations.

As it's possible to see, the two trends seems strictly correlated. The indoor meteorological parameters have been also recorded for all the considered period. They are shown in figure 3 as normalized cumulative curves:

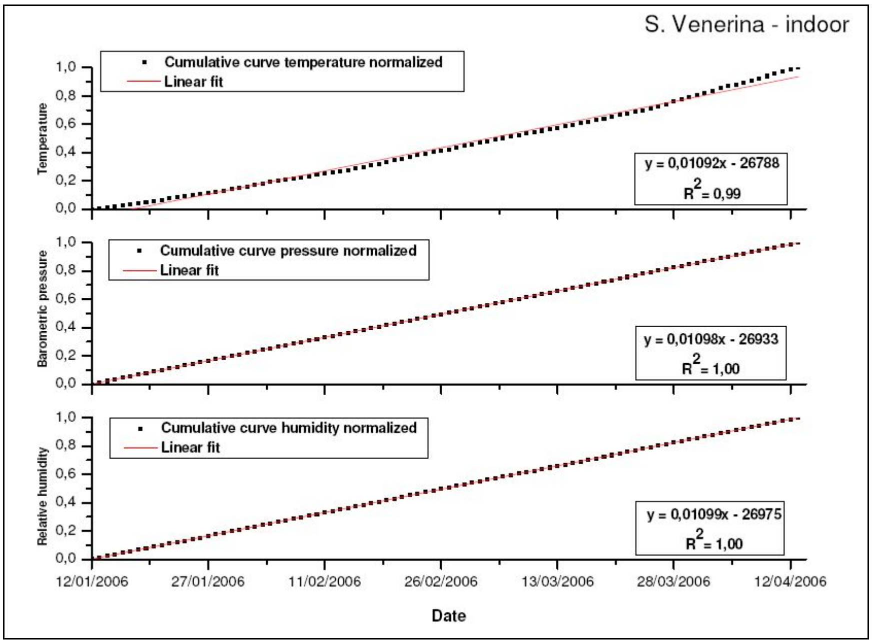

Fig. 3. Normalized cumulative curves of the indoor meteorological parameters.

During the monitoring period, no remarkable variations of meteorological parameters have been observed ($R^2 \geq 0.99$). As it's possible to see, only at the end of the investigation period and at the same time, a little temperature increase and a little humidity decrease have been noticed. These gradual variations are typical of the following spring arrival.

A ***cross-correlation*** analysis was carried out. It is a standard method of estimating the degree to which two series are correlated. Considering the two series the cross correlation r at delay d is defined as the following function:

$$r(d) = \frac{\sum_i [(x(i) - mx) \cdot (y(i-d) - my)]}{\sqrt{\sum_i (x(i) - mx)^2} \sqrt{\sum_i (y(i-d) - my)^2}}$$

Where the two series are indicated with *x(i)* and *y(i)* respectively; *mx* and *my* are the arithmetic means of the corresponding series; $d = 1, 2, ..., N-1$ is the delay in days (the two series represent daily trends).

Result of the cross-correlation is shown in figure 4:

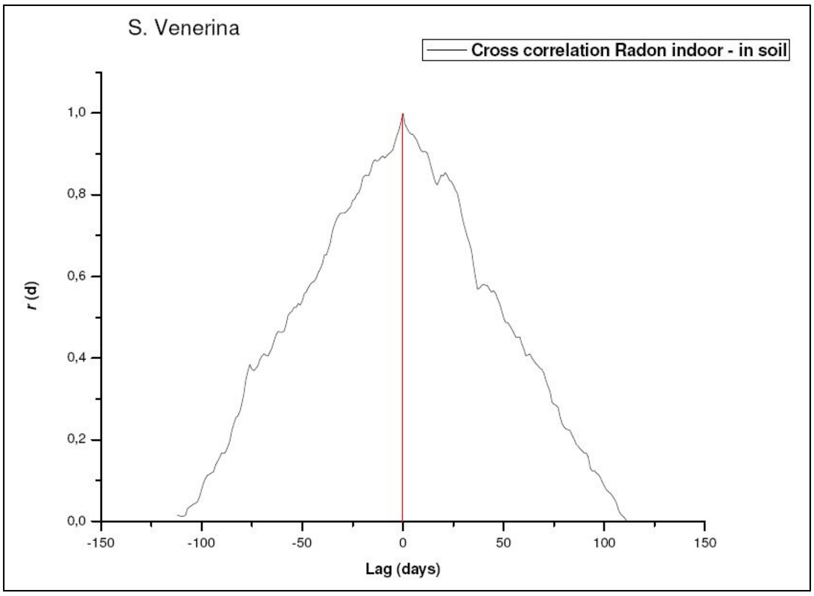

Fig. 4. Normalized cross-correlation between in soil and indoor (old building) concentrations.

As it's possible to see, the maximum correlation is for *d*=0, indicating that indoor and soil radon concentrations have the maximum correlation without delay. Therefore, in old buildings, radon quickly migrates from soil to indoor, reaching values even exceeding those recommended.

Both the indoor radon concentration measurements, that is those detected through the active device AlphaGuard, and those detected through CC, are shown in figure 5 a, b:

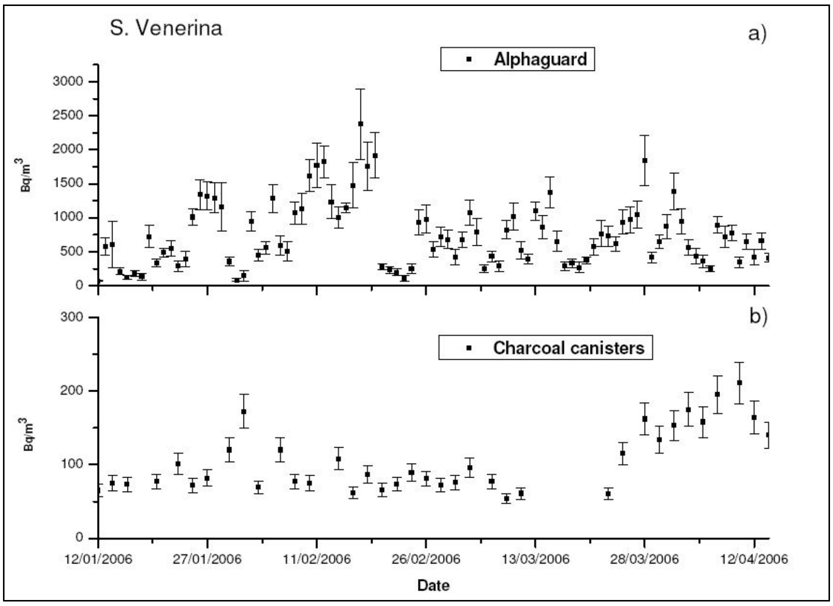

Fig. 5. Both the indoor radon concentration measurements: a) old building, through active device AlphaGUARD; b) new building, through CC detectors.

As previously made for the old building, a cross correlation analysis was carried out. The result obtained is shown in figure 6:

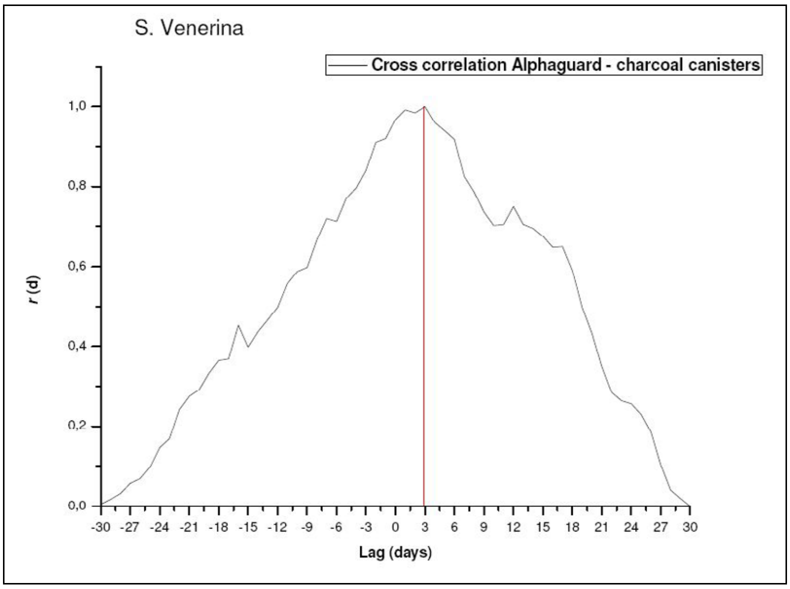

Fig. 6. Normalized cross-correlation between both indoor radon concentrations.

Though one might expect that the new building is able to effectively disperse the radon gas from the subsurface surrounding the building, again in this case, the two trends show a maximum correlation, with a shift of three days, that is inside the radon half-life.

Conclusions

The analysis of rock samples collected throughout the Etna area, have showed that the concentration of primordial radionuclides produce a Radio equivalent activities within the maximum value of 370 Bq/m^3. The values obtained represent the contribution of natural background radiation due to the lithology of the area. These values don't explain both in soil and indoor radon concentration fluctuations recorded in previous studies and, in particular, in the monitoring period considered in this study. It was verified by La Delfa et al., 2007 that the in soil radon fluctuations, showed in figure 2a, are closely linked to geodynamic of the volcano Etna, and this result is even more reliable, because the weather conditions had not undergone drastic changes for all the time interval considered.

Simultaneously with the in soil radon monitoring, indoor radon concentrations in two different types of dwellings have been monitored (figures 2b and 5b), together with the indoor meteorological parameters (figure 3). The indoor weather parameters have stable trends throughout the monitoring period. The cross-correlation analysis have pointed out that the indoor radon concentrations measured, both in the old and in the new building, show the same fluctuations of the in soil radon concentrations. While in the old building, the maximum correlation is without temporal delay, in the new buiding has been obtained a temporal delay of 3 days, however inside the radon half-life. These results show that in active volcano-tectonic areas such as St. Venerina, the geodynamics of the area is strictly correlated also with the indoor radon concentrations, and it seems to be the main external factor of indoor accumulation, in periods of stable weather conditions.

This study wants to point out that in geodynamic settings such as the Etnean area, the indoor radon monitorings (effected to estimate the population exposure to radon gas), which are usually made following a criterion exclusively based on seasonality and floor numbers, should be made considering also the geodynamics of the area of interest, possibly extending the analysis in periods of significant seismic and volcanic activities.

Abstract

Radon gas is generated from radium in soil and rocks. Radon emanation coefficient is regarded as an important factor affecting the generation of radon from soil and rocks and it depends on various environmental factors such as soil particle size, temperature and moisture saturation. In this study, radon emanation coefficient of Japanese soil samples is measured by accumulation method. We have examined experimentally the dependency of radon emanation coefficient on different soil particle size (from < 106 ƒÊm to > 1000 ƒÊm), temperature (5, 25, 40, 55 ‹C) and moisture saturation (from 0 to 0.9).

Evaluation of radon risk using GIS (Geographic Information System) techniques in the Central Hungarian Region

Abstract

A new technique of Wattananikorn et al. (2008) for radon potential mapping based on airborne uranium concentration maps was tested in the Central Hungarian Region. Airborne uranium maps (Tyhomirov, 1965-66 digitalized by Boros, 2009) covering eastern parts of the area were processed and analyzed by standard GIS tools. Soil gas radon concentrations were estimated (Wattananikorn et al., 2008) as well as prospective indoor risk values (Kemski et al., 2001). After the spatial analysis of these data with population maps, the results show different radon risk categories at all settlements (Kohli et al., 1997). GIS analyses were validated by in situ soil gas radon measurements and laboratory analyses of soil samples, as well as radon concentration data in indoor areas. Enough good results were gained proving that tested radon potential estimation method is applicable mainly for selecting settlements needed extended research.

Introduction and objective

Radon (^{222}Rn) is responsible for 48% of the total annual effective dose from natural sources of a man living in average environment (UNSCEAR, 2000). The inhalation of this radioactive isotope and its short lived daughters may cause lung cancer potentially (e.g. Bochicchio, 2008 and references therein).

Generally, mapping of radon risk is based on in-situ soil gas concentration (e.g. Gates & Gundersen, 1992; Kemski et al., 2001) or indoor concentration measurements (e.g. Minda et al., 2009). Both methods are expensive and time-consuming to carry out on extended areas but a crude estimation method for radon risk also exists.

Our main aim was modifying and testing this cost-effective and concise procedure which was published recently (Wattananikorn et al., 2008). Other objective was the classification of all settlements into categories based on the results of tested radon risk mapping/estimation method for gaining which settlements need more extended research.

The studied area

Central Hungarian Region is the most populated area and cultural, educational, financial and political centre of Hungary (Fig. 1A). Hence the idea to predict potentially health deteriorating impacts in the area is widely acceptable. An airborne uranium concentration map (Tyhomirov, 1965-66) of the northern part of the region is available (Fig. 1B) from the middle of the 60's. The digitalized version of this map (Boros, 2009) means the base of the present work.

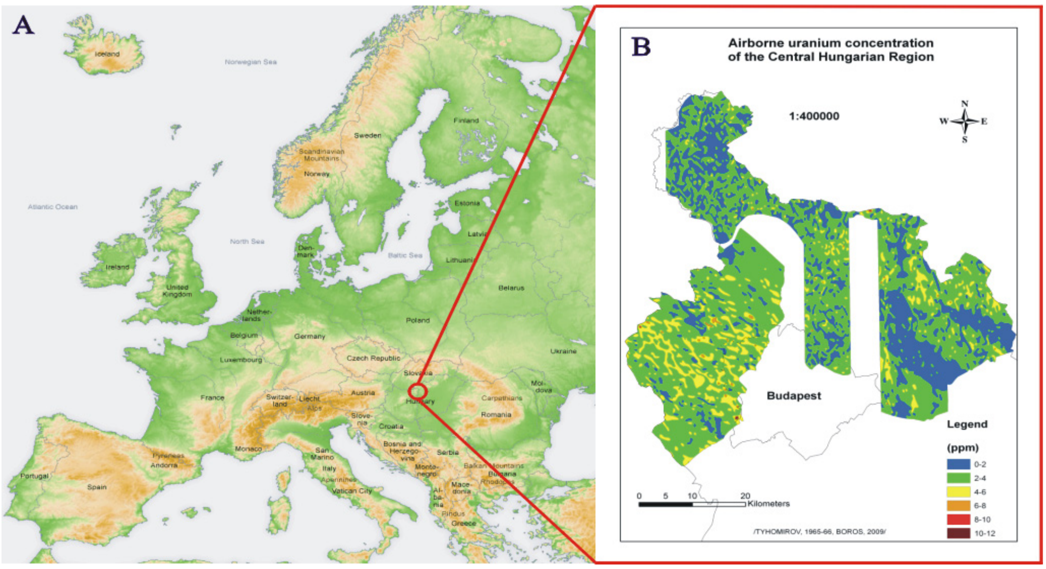

Fig. 1A. Location of Central Hungarian Region in Europe and 1B. Airborne uranium concentration map on the northern part (TYHOMIROV, 1965-66 digitalized by BOROS, 2009).

Methods

Basis of present work is GIS (Geographic Information System) analysis of different databases. The applied software is the ArcGIS 9.3, which can be used for making vector-based maps with geostatistic correction. It also shows the correlation between evaluated and measured databases originated from the following methods (1-4. methods). The complex data processing makes possible testing the estimation of soil gas radon concentration as well as indoor values.

Evaluation of data

1. Soil gas radon concentration was evaluated based on the airborne uranium concentration map of the studied area (Fig. 1B) (Tyhomirov, 1965-66 digitalized by Boros, 2009) and *Eq. 1.* which was published by Wattananikorn et al. (2008).

$$Eq.\ 1.:\ N = 1.92\ u,$$

where N is the predicted soil radon concentration in kBq/m^3 and u is the airborne equivalent uranium in ppm. It is based on measurements in Thailand at 14 areas of 7 test sites of three basins which are covered mainly by Quaternary alluvial and terrace deposits. Correlation between soil radon concentration and airborne equivalent uranium was determined considering the standard deviation of measured values. Hence the upper limit of soil radon concentration can be estimated by *Eq. 1.*. We assumed that this equitation with little changes can be valid in Central Hungarian Region too, although differences in rock type occur. Since differences in permeability values were neglected only a crude estimation can be presented.

2. From the calculated soil gas radon concentration distribution prospective indoor risk values were estimated using *Eq. 2.* (Kemski et al., 2001; Wattananikorn et al., 2008).

$$\textit{Eq. 2.: Indoor radon} = 1.91 \textit{ Soil radon} - 3.3,$$

where indoor radon is in Bq/m^3 and soil radon is in kBq/m^3. Its basis is studying of relationship between maximum ground floor indoor radon and soil radon concentrations in Germany. However, construction features and the age of houses should be also taken into account in further work.

After a spatial and geostatistical analysis of estimated indoor data the results show different categories at all settlements on the settlement map (after Kohli et al., 1997). Most hazardous settlements and distribution type can be studied averaging the values in polygons of settlements' areas (from AGROTOPO digital database) and weighting them by their size. More details on 1. and 2. methods can be found in the references.

Method testing

3. Data on constructed soil gas radon concentration map was compared by data at 28 sites of two types of direct measurements in interest of testing the estimation method based on airborne uranium concentration data. These two types of methods signed by a and b can be found below.

a, In-situ soil gas radon concentration measurements were done using RAD7 radon detector and soil probe at an average depth of 75 cm (according to Gates & Gundersen, 1992).

b, Soil gas radon concentrations were evaluated based on radon mass exhalation rate (similar like Sakoda, 2008) and density, porosity measurements in laboratory by using Eq. 3. (Szabó, K. Zs., 2009).

$$\textit{Eq. 3.: Soil radon} = 100\, E_{mass}\, \rho \,/\, 1000\, p\, \lambda,$$

where soil radon is in kBq/m^3, E_{mass} is the radon mass exhalation rate in Bq/kg/s, ρ is the density of soil sample in kg/m^3, p is the porosity in %, λ is the decay constant of radon in 1/s. A parallel work is supporting the possibility of using this method for soil gas radon concentration estimations (Szabó, Zs., 2009).

4. Indoor radon concentration data were also tested by a few monthly long measurements with Radosys track etched detectors.

Results and discussion

Soil gas radon concentration

Estimated soil gas radon concentration map (1. method) and values of test measurements (3a. and 3b. methods) are presented on Fig. 2.

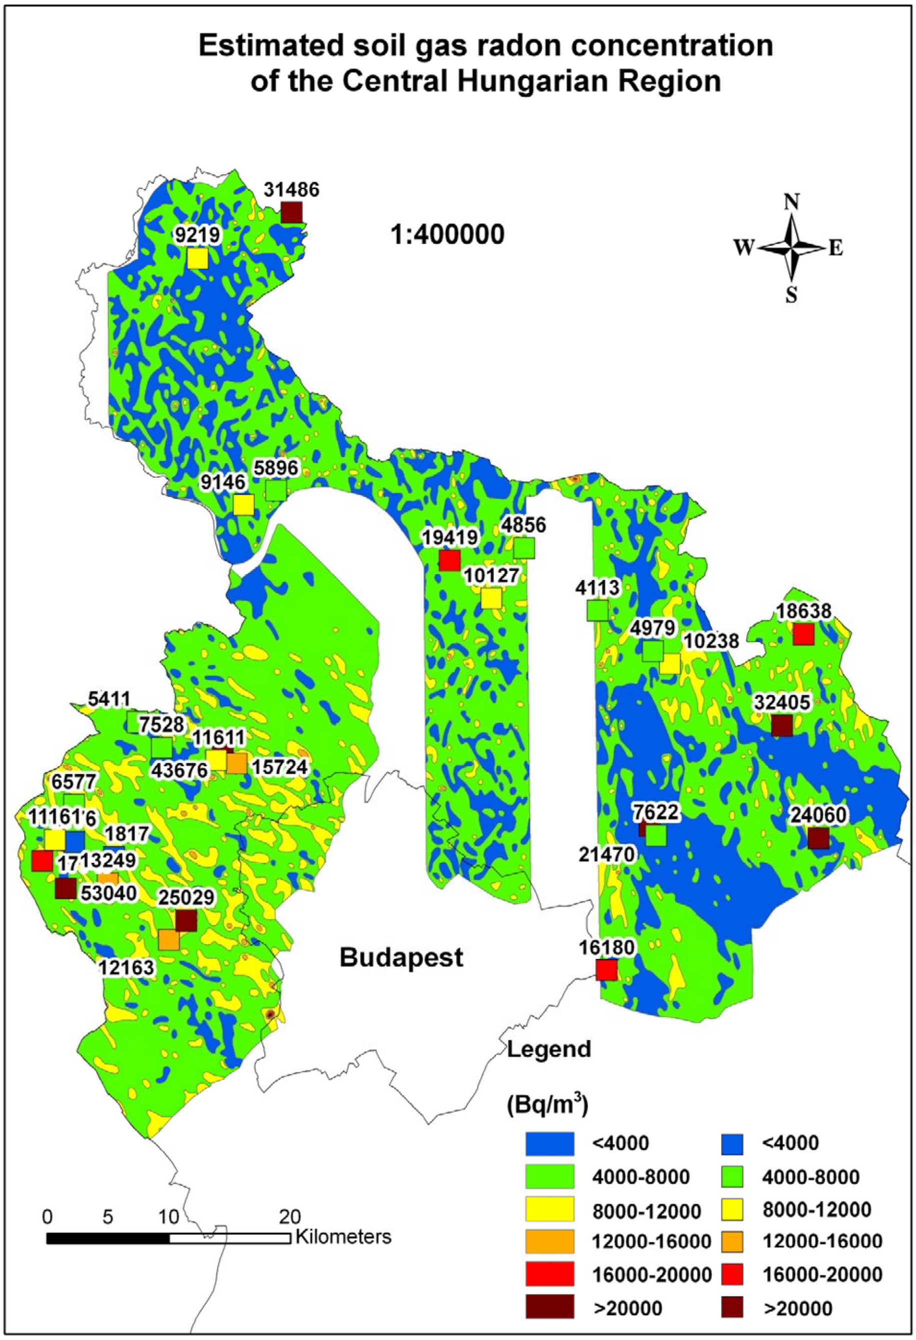

Fig. 2. Constructed soil gas radon concentration map showing the testing points.

The map (Fig. 2.) indicates that the high risk areas are mainly on the limestone and dolomite hills on west side of the region. These areas having higher estimated values of radon concentration should be first explored direct measurements to obtain answer whether they have high risk due to radon. However results of direct measurements show that other areas also can have higher values (e.g. Pesti Plane, Gödöllői hills).

Correlation between estimated and measured values is 0.6 - 0.7 indicating that calculation based on airborne uranium concentration ignores a lot of affecting parameters but can be applied as a crude estimation. However, note that local anomalies cannot be determined.

These results also suggest that a new equation (*Eq. 4.*) should be used instead of *Eq. 1.* in this area (different geological relation) because of the occurred underestimation presumably originated from the differences between permeability values.

$$Eq.\ 4.: N = 2.12\ u,$$

where N is the predicted soil radon concentration in kBq/m^3 and u is airborne equivalent uranium in ppm. Using this equitation most calculated soil gas radon concentration values will be closer to the measured values giving the best estimation.

Indoor radon concentration

Estimated indoor radon risks were calculated for each settlement (2. method). Results are summarized in a histogram on Fig. 3. Number of columns was selected as the *ln[number of settlements (n=95)]*.

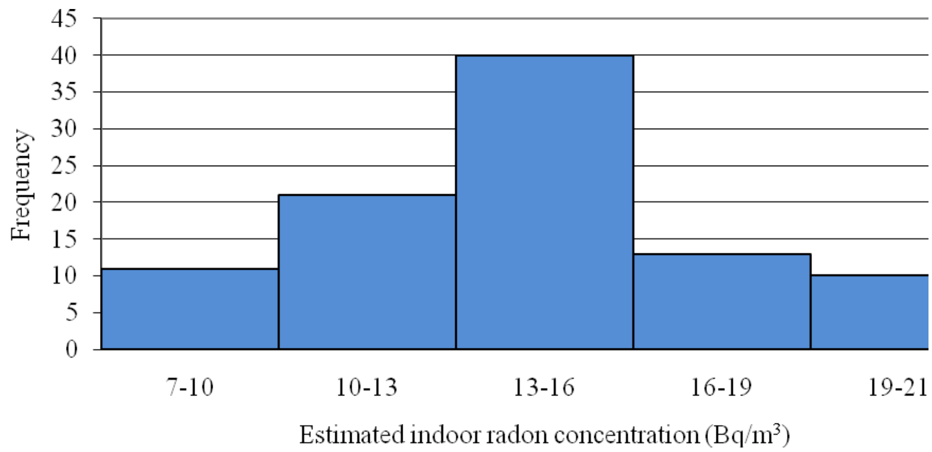

Fig. 3. Histogram of evaluated indoor radon concentrations in dwellings averaged by settlements (n=95).

Values of estimated indoor radon concentration are very low. The procedure has a probability to underestimate indoor radon here as indoor test measurements also indicate (4. method). More direct measurements are necessary to build up a new equitation instead of *Eq. 2.*.

Results originated from estimation indicate a normal distribution (Fig. 3.). This mainly refers to that average airborne uranium concentrations below settlements have a normal distribution and there are not significant average values for one settlement in the Central Hungarian Region. It is again emphasized that it is necessary to determine the realtionship between soil gas and indoor radon concentration at this area too, hence further measurements are needed.

Conclusions

1. A cost-effective method for radon risk estimation based on airborne uranium maps was modified and tested with direct measurements in the Central Hungarian Region.
2. Based on the evaluation high risk areas are mainly on the west side of the region.
3. Since local anomalies cannot be predicted, a correlation of 0.6-0.7 between estimated and measured soil gas radon values is quite reasonable. The calculation based on airborne uranium concentration ignores a lot of affecting parameters but can be applied as a crude estimation. A new equitation (*Eq. 4.*) was also built up for this area.
4. Based on the constructed soil gas radon concentration map, it is possible to select settlements for extended research.
5. Values of estimated indoor radon concentrations are very low. The procedure has a probability to underestimate indoor radon.
6. Average airborne uranium concentrations below settlements have a normal distribution.
7. Further testing and corrections of the procedure are needed.
8. GIS techniques are available and well applicable in radon risk estimation.

Deposition and clearance of inhaled radon progenies in the central airways

Abstract
Most of lung cancers of former uranium miners developed in the central airways. Current computational fluid dynamics calculations indicate high local deposition densities in this region. However, cellular burdens of radon progenies deposited in the deeper regions of the lung and cleared up by the mucociliary escalator may also contribute to the health effects in the large central airways. The surface of airway generations increases with airway generation number, thus, it looks a reasonable supposition that the dose of the deeply deposited and up clearing radon progenies may significantly contribute to the total dose in the large airways.

In this work, the deposition distribution of inhaled radon progenies in the respiratory system was computed by the newest version of the stochastic lung model. A clearance model was developed to simulate the up clearing fractions of attached and unattached radon progenies. The stochastic lung model was applied also to compute the surface of the airways. Finally, the surface activity densities of the primarily deposited and upcleared fractions have been calculated and compared at airway generation level for different breathing patterns.

The main input data of the clearance model are the followings: deposition data, velocity of the mucus in each airway generation, surface area of the airways and the half lives of radon progenies.

Based on the results, the radiation burden per unit surface area in the central airways is the highest in the first few airway generations mostly due to the deeply deposited and up cleared radon progenies. Comparing the amounts of the primary deposited and the up cleared radon progenies in the large airways one can conclude that the burden of the up cleared fraction is higher than that of the primary deposition. The results suggest that a possible reason for the preferential occurrence of radon induced lung cancer in the central airways may be, besides the primary deposition, the contribution of the up clearing radon progenies.

Introduction

Large scale histopathological studies have demonstrated that radon induced lung carcinomas of former uranium miners occurred predominantly in the large bronchi, especially in airway generations 3-5. Computational fluid dynamics calculations yielded high primary deposition density values in this region of the thoracic airways. At the same time, the dose contribution of the deeply deposited and up clearing radon progenies in these large bronchial airways is usually neglected. By the increase of generation number the total surface of airway generations highly increases and the deposition efficiency does not decrease remarkably with generation number, thus the dose contribution of the up clearing radon progenies may be significant in the large airways.

The objective of this study is to compute the generation number specific primarily deposited and the up cleared particle fractions to establish their relative contribution to the resultant surface activity in the large bronchi.

Methods

In the present work, the primary deposition distributions of the inhaled radon progenies were computed in the whole respiratory system by the newest version of stochastic lung deposition model (SLM) originally developed by Koblinger and Hofmann (1990). Particle deposition simulations were performed at four different breathing conditions characteristic of sleeping, sitting, light exercise and heavy exercise physical activities. Functional residual capacity, tidal volume, and breathing cycle times characteristic of an adult man during the four types of activities were derived from ICRP66 (1994) publication.

A new bronchial clearance model has been elaborated to simulate the up clearing fractions of particles deposited in the deeper airway generations. Particles trapped by the high viscosity mucus were assumed to move together with the mucus layer. Mucus velocity values were derived from the available literature. Based on the work of Chopra (1979), the tracheal mucus velocity was supposed to be 1.5 cm/min. Mucus velocity in each generation was 2/3 of the mucus velocity in the preceding higher order airway generation. Based on the ICRP66 data, the halftimes of the transport of the deposited attached radon progenies from bronchial airways to blood is 10 hours. This mechanism was also built into the model.

Figure 1 presents the velocity of the mucus as a function of generation number. In this study only the deposition of ^{214}Pb and the clearance of ^{214}Pb and ^{214}Bi isotopes were simulated, where ^{214}Bi is the decay product of the primarily deposited ^{214}Pb isotope. The applied particle diameter is considered to be 200 nm which is the most frequent aerodynamic diameter in the number distribution of the environment aerosols (Haninger, 1997). The unattached fraction of ^{214}Pb is negligible (Marsh et al. 2008). Regarding attached radon progenies the number distribution is the relevant because usually zero or one radon progeny attaches to an aerosol particle. The ^{214}Pb and ^{214}Bi radioisotopes decay and result in ^{214}Po, which is alpha active with a very short half-life. Finally, the ratio of the up cleared and primarily deposited activity densities has been calculated in each airway generation at the above mentioned four breathing patterns. The main input data of the clearance model are the deposition data, the velocity-distribution of mucus, the airway lengths and the half-lives of radon progenies. The average lengths and the surfaces of the bronchial airways (Table 1) were taken from the newest version of stochastic lung model (Balásházy et al. 2009).

Table 1. The average lengths and total surface areas of the airways in airway generations 1-20 based on the newest version of the stochastic lung model.

Generation number	Length (cm)	Surface (cm^2)	Generation number	Length (cm)	Surface (cm^2)
1		68.88	11		277.6
2		22.35	12		358.5

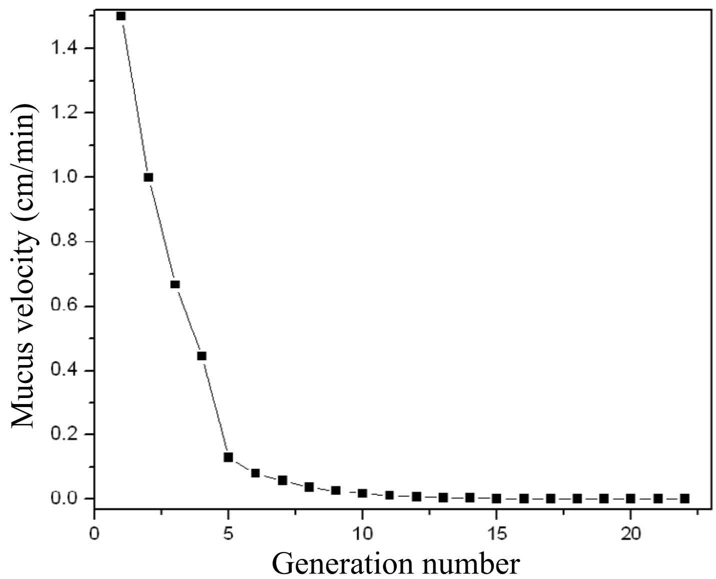

Fig. 1. Mucus velocity as a function of airway generation number.

Results

Figures 2–5 summarise the results of the surface decay density distribution computations. The upper panels refer to the primary deposition, while the lower ones depict the decay density distribution of the up clearing ^{214}Pb and ^{214}Bi isotopes at sleeping, sitting, light exercise and heavy exercise breathing conditions, respectively. The number of selected inhaled particles was always 10^5 at the computation of the deposition fraction distributions.

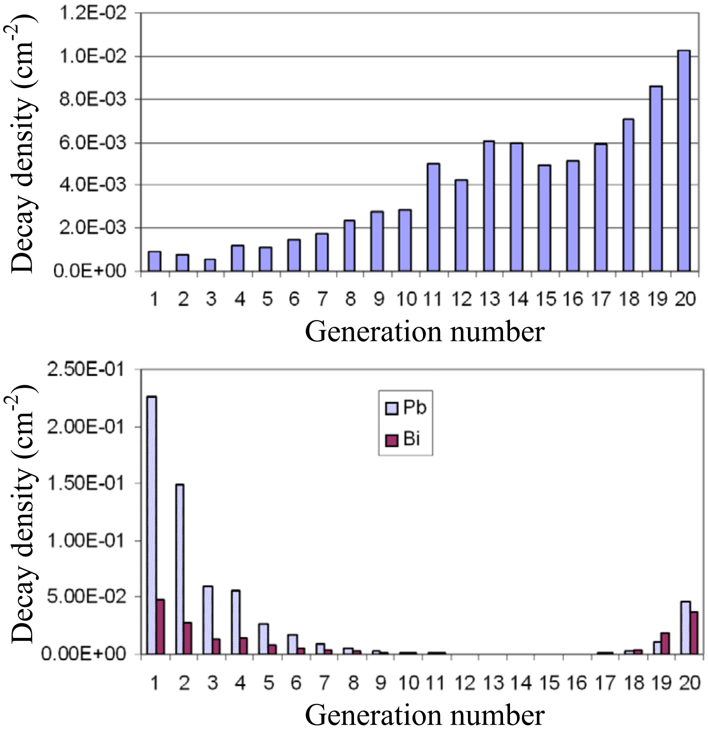

Fig. 2. Decay densities as a function of airway generation number in case of the primarily deposited (upper panel) and up cleared (bottom panel) radon progenies during sleeping.

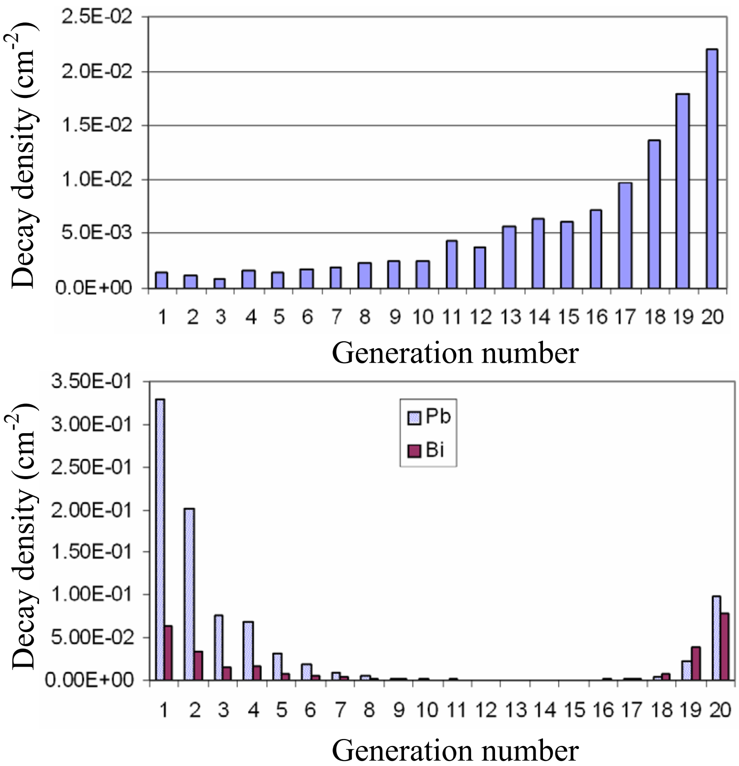

Fig. 3. Decay densities as a function of airway generation number in case of the primarily deposited (upper panel) and up cleared (bottom panel) radon progenies during sitting.

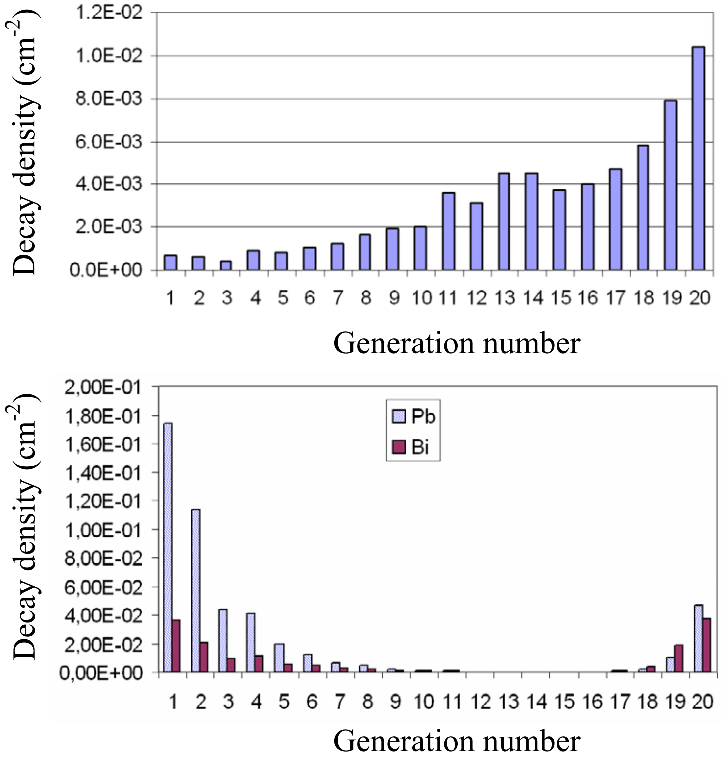

Fig. 4. Decay densities as a function of airway generation number in case of primarily deposited (upper panel) and up cleared (bottom panel) radon progenies during light physical exercise.

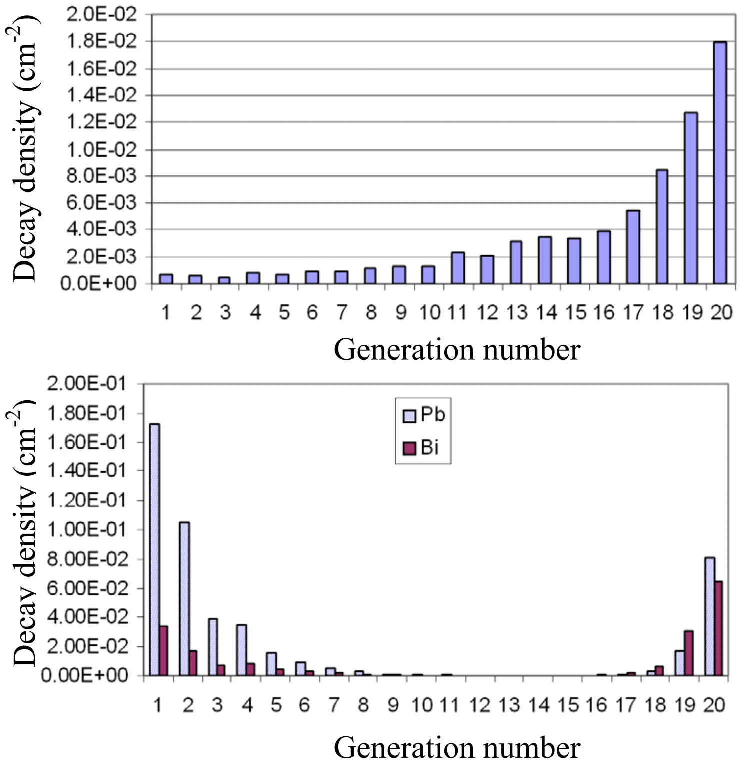

Fig. 5. Decay densities as a function of airway generation number in case of primarily deposited (upper panel) and up cleared (bottom panel) radon progenies during heavy physical exercise.

The figures demonstrate that the decay density due to the primary deposition increases with the increase of the generation number for each type of physical activity.

The decay density originating from the up cleared ^{214}Pb and ^{214}Bi isotopes is significant in the first few generations and slightly in the peripherial regions. This tendency holds for all the studied physical activities. The cumulated decay density, provided by the primary deposition and the up clearing fraction, is the highest in the first few generations, that is, in the large bronchi where most of the radon induced preneoplastic and neoplastic lesions were found. Comparing the relative contributions of the primarily deposited and up cleared isotopes it can be stated that in the most exposed region (large bronchi) the up cleared fraction is determinant. This aspect is usually not considered in current computational dosimetry and risk modelling. Present computations may provide useful input for such models and thus contribute to a quantitatively better estimation of radiation exposures and the related health consequences. Since only about 1 % of the total number of radon progenies is not attached to the aerosols in the mine environment and 5-6 % in homes (BEIR VI, 1999), in the current approach the unattached fraction has been neglected.

Conclusions

Based on the present results, in the central airways, the radiation burden of the deeply deposited and up clearing radon progenies can be up to two orders of magnitude higher than the burden of the primarily deposited fraction in this airways. Physical activity,althogh affects the deposition and the related clearance fractions, does not seem to influence the above tendency. The results demonstrate that one of the reasons of the site specific radon induced lung cancer may be the dose contributions of the deeply deposited and up clearing radon progenies.

In our next publication we will comput the deposition and alpha burdens of all the short lived radon progenies (unattached: ^{218}Po; attached: ^{218}Po, ^{214}Pb, ^{214}Bi).

Reducing the risk to military personnel from radon gas

Williams, Dean; Langridge, Darren
UK Ministry of Defence, Dstl, UNITED KINGDOM

Abstract

Radon is attributable to approximately 1500 deaths a year in the UK alone. It is a naturally occurring radioactive gas that derives from uranium found in rocks and soils, and is therefore a natural environmental hazard. Employers have a legal obligation to assess the radon health risk for all their employees. Recent improvements in the UK radon data set and developing work on the risk of radon gas has made this a priority issue for the UK Ministry of Defence (MOD). The Defence Science and Technology Laboratory (Dstl) were given the challenging task of developing a strategy to address this issue and to implement a monitoring protocol to cover the whole of the MOD estate (thousands of locations) throughout the UK and overseas. The development of this involved:

– Working with and/or obtaining information from the Health Protection Agency and the Health and Safety Executive.
– Utilising the most up-to-date guidance from the Building Research Establishment (BRE) and academia to understand the most appropriate and effective remediation techniques.

The radon monitoring program is now well under way covering thousands of workplaces, with the aim of protecting the health of military personnel now and in to the future. A number of examples are given, including the unusual example of 'working' in caves, where radon levels may be extremely high. A three year research project has been undertaken assessing the radon doses to military personnel in caves in the North Pennines currently used for adventure training activities. The findings from this work not only aid in protecting the personnel directly involved, but also have the potential to inform risks in future caving activities. The data set collected will be invaluable for future theatres of operation and also potential litigation work. Most importantly, the remediation work undertaken will reduce the health risk to MOD employees across the UK and overseas.

An assessment of radon exposure to CR-39 alpha track detectors during postal transit in Ireland

Rochford, Heather; Fegan, Mary; Fenton, David
Radiological Protection Institute of Ireland, 3 Clonskeagh Square, Clonskeagh Road, Dublin 14, IRELAND

Abstract
In many countries, including Ireland, radon measurements are carried out by sending radon detectors to and from customers through the standard postal system. In Ireland, radon detectors are left in place for at least 3 months before the customer returns them by post. The detectors used are CR-39 alpha track detectors and they are sent in standard A5 envelopes with no radon-proof membranes or seals. To date, this has been done on the premiss that the level of radon detected during postal transit was insignificant compared with the much longer period in situ in the customers' premises. This study investigates the contribution made by levels of radon in the Irish postal system to detectors in transit. Thirty one volunteers, located throughout the country were identified for participation in the project. Practically every county in Ireland was represented. Two CR-39 detectors were sent to each volunteer in standard issue envelopes. On receipt of the envelopes, the volunteers immediately posted them back using a similar envelope. Detectors posted close to or during weekends are likely to be in the postal system the longest. For this reason the Radiological Protection Institute of Ireland always issues detectors before Friday. However, there is no control over when customers return them. Detectors were posted to volunteers on a Thursday afternoon to ensure the transit time coincided with at least one weekend. Results from this study conclude that there is no significant radon exposure to Cr-39 alpha track detectors during normal postal transit in Ireland.

Introduction
Radon-222 commonly referred to as radon, is a naturally occurring radioactive gas, formed by the radioactive decay of radium-226, a component of the uranium-238 decay series. Uranium is present in soils and rock. Radon is the largest contributor to the annual radiation dose received by the Irish public, accounting for approximately 60% of all radiation exposure in Ireland (Colgan *et al.,* 2008). Radon has been classified as a class 1 carcinogen by the International Agency for Research on Cancer (IARC 1988, 2001). Inhaling radon and its progeny can lead to lung cancer. It is estimated that in Ireland 150-200 people a year die from radon induced lung cancer (RPII & NCRI, 2005).

Ireland's relatively high radon concentrations were identified during the National Radon Survey (NRS) which was carried out between 1992 and 1999 (Fennell *et al.,* 2002). An average indoor radon concentration of 89 Bq/m^3 was calculated for Ireland, based on measurements made in 11,319 randomly selected homes over a 12 month period. A recent survey by the World Health Organisation (WHO) found this national average to be the eighth highest in the world (WHO, 2009).

Current radon measurement practice in the Radiological Protection Institute of Ireland (RPII) is to use CR-39 alpha track detectors over an exposure period of at least three months in conjunction with the application of a seasonal correction factor (Colgan *et al.,* 2008; RPII, 2008). Normal practice is to send two detectors with each measurement pack; one to be placed in a bedroom and one in a living area (RPII, 2008). These radon detectors are sent to and received from customers through the standard postal system. They are sent in standard A5 envelopes with no radon-proof membranes or seals.

The RPII has made a recommendation that radon measurements, and where necessary, remediation at the time of sale and/or purchase of buildings is an appropiate mechanism to reduce the collective dose from radon in Ireland. However, it recognises that it may not always be possible to complete a three month measurement during the conveyancing process. Hence the RPII has undertaken research on the use of shorter screening measurements for these circumstances (Rochford *et al.*, IRPA 2010). With a shorter measurement period a contribution from radon in the postal system could contribute to and influence the final result.

Thus, this research was undertaken to investigate the contribution made by levels of radon in the postal system to detectors in transit.

Material and methods

Thirty-one volunteers, located throughout the country participated in the project. Twenty three of the twenty six counties in Ireland were represented.

Fig. 1. Location of the volunteers for this study.

The detectors were issued and posted out in accordance with normal procedures. However, on this occassion on receipt of the detectors the volunteer was requested to return them immediately to RPII.

When posting detectors to its customers the RPII avoids weekend and public holidays so as to minimise the time the detectors are in transit. However, there is no control over when customers post back the detectors, which could include weekends. To simulate this, detectors were posted from RPII to volunteers on a Thursday afternoon to ensure maximum time in the postal system.

When the detectors were received at RPII they were subject to the normal practice and procedures in use in the laboratory.

The Radon Measurement Service is accredited by the Irish National Accreditation Board (INAB) to the International Organization for Standardisation and International Electrotechnical Commission (2005) standard ISO/IEC 17025. The scope of accreditation covers radon concentration measurement in air using passive CR-39 alpha track etch detectors for an exposure time of three to twelve months and a minimum detectable concentration of 10 Bq/m^3.

Quality control procedures are carried out on all new CR-39 detectors received in the laboratory: 10% of the unexposed detectors are etched. The subsequent counting determines the background track density ($tracks/cm^2$). If the average background track density of detectors from a sheet (approximately 100 CR-39 detectors) is less than 50 $tracks/cm^2$ the sheet is released for use and if this is greater than 50 $tracks/cm^2$ the sheet is discarded. The average track density for a number of detector sheets accepted for use in the RPII is presented in figure 2. In addition, 5% of the new detectors are exposed in a secondary standard radon chamber. The radon source maintains a radon concentration of 3000 Bq m^{-3}. This is continuously monitored by an ATMOS 12dpx, which is calibrated annually by the manufacturer using a working standard that is traceable to the National Institute of Standards and Technology (NIST), USA.

Detectors are chemically etched in 6.25 M sodium hydroxide at 75 ^{0}C for 8 hours, resulting in uniform tracks ranging from 240 to 340 mm^2. Following the chemical etch, the detectors are measured using the laboratory's Image Analysis System (Quantimet).

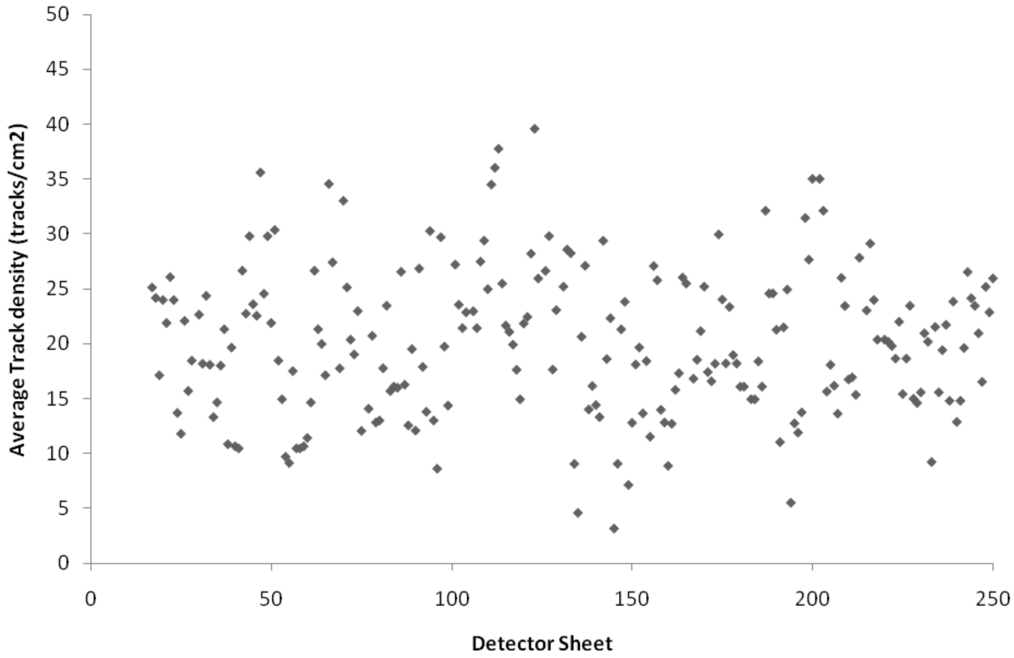

Fig. 2. Average track density of many detectors used by RPII.

Results

It is evident from the data presented in figure 2 that there is considerable variability in background tracks among detectors. The average track density in the set of sheets illustrated in this figure range from 3 to 40 with an average of 21 tracks/cm^2.

The average track density for the two detectors received from each volunteer was calculated and is presented in figure 3.

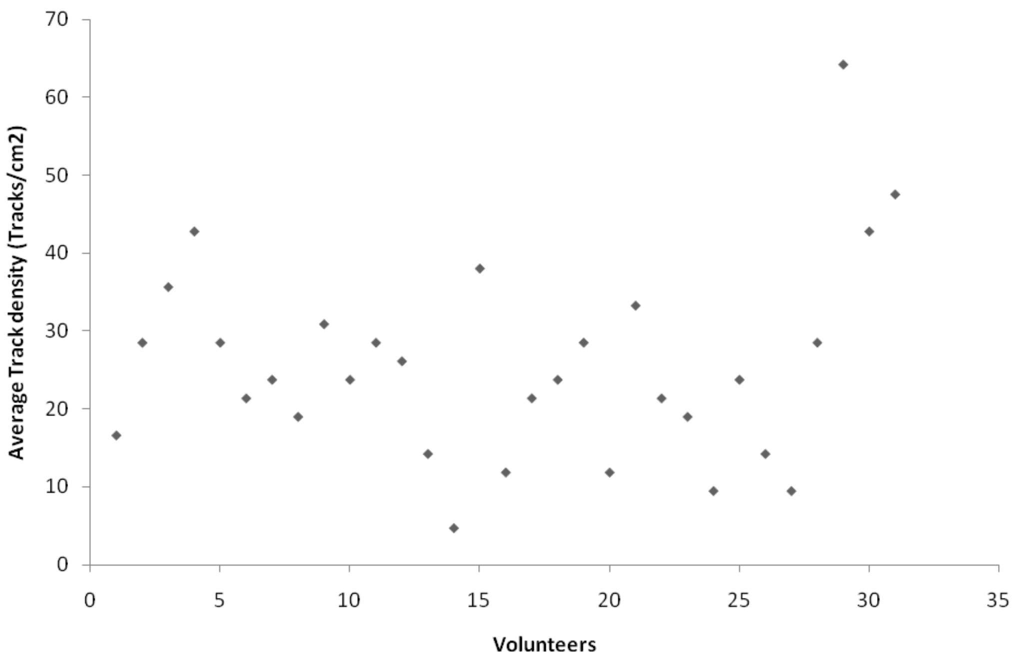

Fig. 3. Average track density of the two detectors.

With the exception of one set of detectors, the average track density for the detectors returned by the volunteers is below 50 tracks/cm^2, the upper limit for background track density at RPII. The range of values is between 5 and 64 tracks/cm^2.

The highest average track density, 64 tracks/cm^2, is from a volunteer address in a county in the west of Ireland. These detectors were in the postal system for six days. This, however, was not the longest transit time.

Two other addresses from this county were also included in this study. One of these recorded the lowest average track density at 5 tracks/cm^2. A similar transit time was recorded for the third detector set from this county which recorded a track density of 29 tracks/cm^2.

The shortest time between detector dispatch and return to RPII for detectors in this study was four days and the longest was seven days. The average time spent in the postal system being five days.

Comparing figures 2 and 3 it can be concluded that there is no significant difference between the detector background track density accepted at RPII and the track density on detectors after a transit time of four to seven days in the postal system.

Conclusions

This study was undertaken to investigate the contribution made by levels of radon in the Irish postal system to detectors in transit.

The result of this study involving thirty one volunteer addresses across the country demonstrates that there is insignificant radon exposure to Cr-39 alpha track detectors during normal postal transit in Ireland.

Abstract

The territory of Campania region is one the most rich of Radon of Italy and presents prone areas of indoor radon because of the characteristics of the subsoil and of the building materials of local origin which is prevalently volcanic. The national survey on indoor radon classifies this region with a mean concentration higher of 30% than national mean value, but other regional surveys on selected building underline the presence of numerous sites where indoor radon levels are very high. In last fifteen years, our work-group has investigated radon levels within dwellings, schools and workplaces. The principal aim of the present work is to summarize the results of about 700 measurements by using a geostatistic approach which has allowed the realization of a Radon distribution map of the region. Each result is the mean value of an entire year and has been performed by the SSNTDs with LR115 films. Data have been normalized respect to the building material and floor location and, then, located on the map. The lognormal distribution of data has allowed the application of geostatistic techniques using spatial interpolators that not require an uniform distribution of data. The analysis has been performed by the Arcview software which allow the selection of the best variogram and furnishes also the map of the variance of results. Different maps have been extracted from different normalization of data. The maps well describe the real situation according to the experimental results.

Radon mapping strategy in the Republic of Moldova

Koretskaya, Liubov[1]; Streil, Thomas[2]; Bahnarel, Ion[1]

Radiation Protection and Radiation Hygiene Centre, MOLDOVA
[2] SARAD GmbH, Dresden, GERMANY

Abstract

Radon is a chemically inert radioactive gas. It is formed by the natural radioactive decay of uranium in rock, soil, and water. Naturally existing, low levels of uranium occur widely in Earth's crust. Radon is responsible for the majority of the mean public exposure to ionizing radiations. Constant exposure to high concentration of radon gas may cause lung cancer. Radon gas from natural sources can accumulate in buildings, especially in confined areas such as basements. The radon concentrations in a building are dependent on the concentration of radium in subjacent ground and surrounding soil, the geological bed rock, the radioactivity of building materials, the ventilation conditions, the meteorological conditions and human activities, also. The results of radon concentrations monitoring in the air samples which have been collected in different buildings placed on the territory of the Republic of Moldova during the period of time since 1991 till 2008 years are given in the paper. Investigations have related, that the ^{222}Rn concentrations (92,0...179,1 Bq/m^3) in most cases do not exceed a maximum permissible level. The establishment of ^{222}Rn concentrations in the air samples collected from Cricova storage of wine undergrounds, Chisinau underground galleries, and Milestii Mici, some mines from Orhei, traced out the values of concentrations (200...1800 Bq/m^3) which exceeded the maximum permissible level. Only 2,1% among all investigated houses in territory of Republic of Moldova exceeds the level of 200/Bq/m^3 for radon concentration. The results require the need of radon concentrations monitoring carrying out in dynamics, with the subsequent elaboration of the radon concentrations maps [1].

[5] Eötvös University, Department of Atomic Physics, HUNGARY

Abstract

The studied former uranium mine is located at the village of Kovagoszolos (S-Hungary). In the area Permian sandstone layers were found to be rich in uranium for mining, which lasted for 40 years. Kovagoszolos has ~350 family houses. At different distances from the surface projection of a mining tunnel radon concentration was measured in 120 houses with passive detector. The average value of the radon concentration is 483 Bq/m^3. Significantly higher radon concentrations (average 667 Bq/m^3) were measured in houses within 150 m from the surface projection of the mining tunnel, compared with the houses further than the 300 m belt (average 291 Bq/m^3). Nine houses were selected for detailed study: short term indoor radon concentration measurement (RAD 7, AlphaGuard); physical (^{226}Ra content, radon exhalation) and geochemical study on collected soil samples from house gardens. From the nine studied houses, in four particular ones the radon concentration was above the recommended level. The radium content in all cases was higher than the world average value. In the studied soil samples the finest fraction is dominated, potential radon source minerals were considered as Fe-oxides and hydroxides. Among the four chosen houses in one house an extrem radon anomaly was recognized. The indoor radon concentration was measured for one month (by active and passive detectors). Outdoor the gamma dose rate, soil gas radon concentration, radon exhalation and air radon concentration were also determined in the surrounded area of the house. In the center of detected radon anomaly (an area 5 m in diameter) the radon concentration of the outdoor air was 1660 Bq/m^3, the gamma dose rate on the soil surface 380 nGy/h, the radon exhalation 20167 mBq/m^{2}s and the soil gas radon concentration was > 2000 kBq/m^3. Based on these results, it is clear that the local geology plays as important role in the development of a radon anomaly as the distance from the surface projection of the mining tunnel.

Radon survey based on home stored CDs/DVDs

Pressyanov, Dobromir; Dimitrova, Ivelina; Georgiev, Strahil; Mitev, Krasimir
Faculty of Physics, St. Kliment Ohridski University of Sofia, BULGARIA

Abstract

This work presents results from a pilot radon survey based on retrospective measurements by CDs/DVDs. A short description of the CD method for retrospective measurements of integrated radon concentrations is given. The results of the survey are presented, demonstrating that the method allows measurements representative for the risk assessment with uncertainty better than 20 %. The survey includes private homes and public buildings. A large percent of the measurements were organized remotely using disks sent by mail, which clearly demonstrates the serious potential of the method for large-scale radon surveys.

Introduction

At present radon (^{222}Rn) is considered the second most important cause for lung cancer after smoking (WHO, 2009). When the contemporary risk from radon is assessed, it is necessary to reconstruct the historical exposure of the subjects. This goal is targeted by the retrospective methods. The majority of them are based on measurements of the long-lived radon progeny ^{210}Pb/^{210}Po implanted in hard surfaces (Samuelsson, 1988) or trapped in spongy materials (Oberstedt and Vanmarcke, 1996). The first approach gives results that are highly dependent on the complex behaviour of the short-lived radon progenies in the air, while the second involves elaborate and costly radiochemical procedures. A principally different approach for retrospective measurement of radon by compact disks (CDs) was proposed (Pressyanov et al. 1999, 2001). Since then substantial experimental and theoretical work has been devoted to tests of the CD method (Pressyanov 2009, 2010; Pressyanov et al. 2001, 2003, 2004). The aim of this work is to present results from a pilot study organized in Bulgaria that demonstrates the practical potential of the method for large-scale radon surveys.

Description of the CD method

The CD method is based on the remarkable ability of the material from which CDs and DVDs are made to absorb ^{222}Rn. This material is the same type of polycarbonate from which some track-etch detectors for alpha particles (Makrofol®, Lexan®) are produced. The basic idea of the method is to combine the absorption ability and the track-etch properties of the material of the disks. When a disk is exposed to air, ^{222}Rn from the air is absorbed in the polycarbonate (Fig 1.). The alpha particles emitted by the absorbed ^{222}Rn and its short-lived progenies form latent tracks inside the disk. The number of those tracks is proportional to the activity concentration of ^{222}Rn in the air, integrated over the exposure time. However, near the surface, tracks are also formed by ^{222}Rn progenies existent in the air or plated-out on the disk's surface. In such way, a "noise" signal is formed, which is hard to correlate to the activity concentration of ^{222}Rn (due to the complex behaviour of radon progenies in the air). To avoid the "noise" signal, tracks are developed at depths greater than 79 µm below the disk surface. This depth is enough to ensure that no tracks are formed by progenies of ^{222}Rn (and ^{220}Rn) plated-out on the surface or present in the air (Pressyanov et al. 2000).

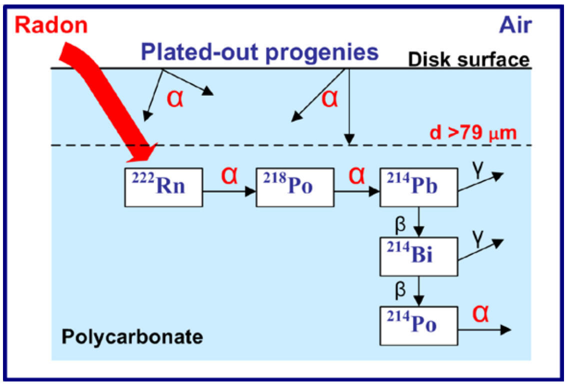

Fig. 1. Principle of the CD method - radon is absorbed in the polycarbonate and the tracks at d ≥ 79 µm are only due to the absorbed ^{222}Rn and its progenies.

At a depth greater than 79 µm below the disk surface the net track density $\boldsymbol{n_0}$ (number of tracks per unit area) is only due to radon absorbed in the polycarbonate and is proportional to the activity concentration of radon in the air $\boldsymbol{A_V}$, integrated over the exposure time $\boldsymbol{T_{exp}}$:

$$n_0 = CF \int_{o}^{T_{\exp}} A_V \, dt \qquad (1)$$

where ***CF*** is a calibration factor. Experimental studies (Pressyanov 2010; Pressyanov et al. 2000, 2003, 2004) have shown that for a given depth of etching the following factors have negligible influence on ***CF***:

- ^{222}Rn progenies in the air or plated-out on the disk surface;
- ^{220}Rn and its progenies;
- ^{210}Po, generated inside the polycarbonate by absorbed radon for reasonable exposure times;
- fading and aging of the polycarbonate material;
- storage of the disks in enclosed (but not hermetic) space, like jewel cases or cabinets;
- cigarette smoke and dust;
- atmospheric pressure in the range 57 – 148 kPa;
- humidity in the range 0 – 100% RH.

In addition, theoretical estimates indicate that no effect on the track density could be expected from the laser light used to write and read data from the disks (Pressyanov 2010).

The only factor known so far to have significant influence on the calibration factor is the ambient temperature. However, as shown in (Pressyanov et al. 2003), a correction for the ambient temperature could be made after the exposure. If such a correction is not applied, the expected bias of the result is within 12% for etching at 80 µm. It is estimated for the interval 10 ÷ 30^0 C and for reference temperature of 20^0 C (Pressyanov 2010). Considering that the average room temperature varies in an even narrower interval, the bias for disks exposed indoors should be even smaller.

The applicable range of the method for 10 years exposure time is from a few $Bq.m^{-3}$ to over 20 $kBq.m^{-3}$ (Mitev et al. 2010; Pressyanov et al. 2003, 2008). The upper range is reached by etching at higher depths, where the track density is smaller. On the other hand, a disk exposed as shortly as one year might give statistically significant signal above 30 $Bq.m^{-3}$. The method is applicable for the whole range of activity concentrations of ^{222}Rn indoors that are of practical interest.

Principle steps of the CD method

Exposure

It is assumed that the exposure continues from the day the disk is obtained by its owner till the day the disk is processed in the laboratory. Any tracks formed before the owner obtains the disk are considered “background”. To estimate an average value for the background track density in CDs and DVDs a large number of new disks were etched. They were bought from different places and were of different brands. The individual background track densities varied from 2 to 40 $tr.cm^{-2}$. The average background track density was estimated at 6,3 $tr.cm^{-2}$ with standard deviation 2,3 $tr.cm^{-2}$.

In order to make retrospective measurements which are representative for the risk from exposure to radon, the analysed disks have to be more than 5 years old. Our experience shows, that in most households disks which are at least 10 years old and whose age could be determined with accuracy better than 1 year are found. However, in case “old” disks are not available, disks that are less than 5 years old are analysed. Such disks could also detect an existing radon problem, but would have limited value for estimates of the long-term past exposure.

Gathering disks

A major advantage of the CD method over other methods for retrospective radon measurements is the fact that no visit to the studied homes is necessary. Disks could be sent by mail, which allows large-scale surveys to be organized very efficiently.

Calibration

Another advantageous feature of the method is the possibility for *a posteriori* calibration. This means that the individual ***CF*** of each disk could be determined after it is taken for analysis (i.e. after the exposure). To do this two pieces are cut from the disk (usually two quarters). One of them is processed right away and the “original” track density in the disk ***n*** is found. The other piece is additionally exposed to known activity concentration of radon. Then ***CF*** is determined as:

$$CF = \frac{n_C - n}{I_V} = \frac{\Delta n}{I_V} \tag{2}$$

where $\boldsymbol{n_C}$ is the track density in the additionally exposed piece and $\boldsymbol{I_V}$ is the integrated activity concentration to which it was exposed. Note that $\boldsymbol{n}$ and $\boldsymbol{n_C}$ should be determined for the same depth.

In our laboratory the calibration is performed using the set-up shown in Fig 2. (including 50 L hermetic box, certified ^{226}Ra source and AlphaGuard® radon monitor). At initial activity concentration of 2 $MBq.m^{-3}$ 10 hours of exposure are enough to provide an increase in the track density of over 400 $tr.cm^{-2}$. After the exposure, the disks are left to degass in radon-free atmosphere for about 4 weeks, so that all absorbed radon could decay or desorb. Further the two pieces are processed together in an identical way.

Any bias due to difference in the properties of the disks is avoided by *a posteriori* calibration. Our experience shows that even disks of the same brand might have somewhat different ***CFs***. The average ***CF*** determined for 34 disks is 0,020 ± 0,03 $cm^{-2}/kBq.h.m^{-3}$. The biggest difference we have observed between the individual ***CF*** of a disk and this value is –45%. That is an argument in favour of the *a posteriori* calibration of each studied disk. The procedure increases the time needed to obtain the final result, but is quite simple and could be applied simultaneously on many disks.

(a) **(b)**

Fig. 2. Set-up used for calibration of CDs. a) Tracebility is provided by a certified ^{226}Ra source and AlphaGuard® radon monitor. (b) The exposure is carried out in 50 L hermetic box.

Pre-etching and electrochemical etching

A surface layer is removed from each disk, so that the tracks at a certain depth below the surface (d ≥ 79 μm) could be developed. This is done by chemical pre-etching (CPE) using an aqueous solution of 52% KOH (m/v) and 40% methanol (m/v) at 30^0 C. At this regime the bulk-etch velocity is about 1 $\mu m.min^{-1}$. The depth of the removed layer is determined by measuring the disk thickness before and after the CPE by micrometer.

The tracks at the studied depth are revealed by electrochemical etching (ECE). The ECE process is performed at effective electric field of 3.0 $kV\ mm^{-1}$ with frequency of 6 kHz. The temperature is 25^0 C. The etching solution is a mixture of ethanol with

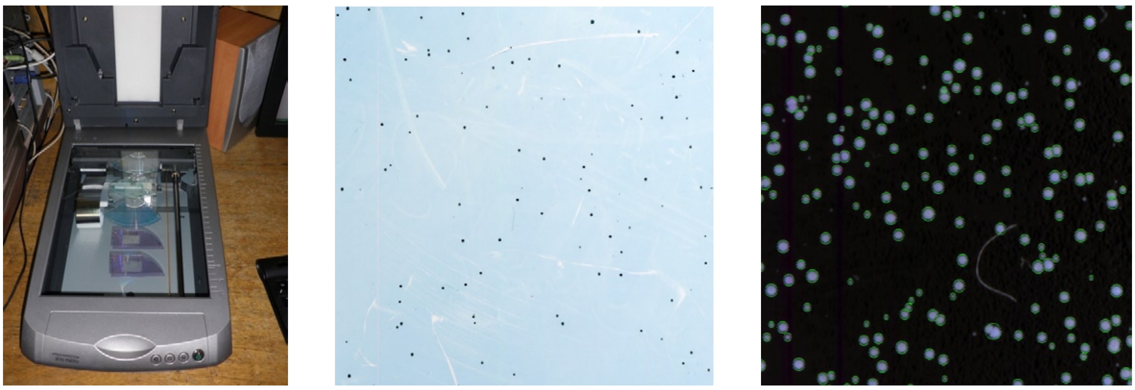
6N KOH solution with 1:4 volume ratio (Vanmarcke and Janssens 1986). The process is preceded by a 30 min pre-etching with the same solution. After this the electric field is applied for 3 hours. The equipment available in our laboratory (shown in Fig. 3.) allows us to process about 30 disk quarters daily.

(a) (b)

Fig. 3. Set-up used for CPE and ECE. a) Disks prepared for etching. (b) Injecting the etching solution (front) and ECE in progress (back).

Track counting

The tracks are counted automatically after the disk is scanned by a commercial computer scanner (Tsankov et al. 2005) as shown in Fig.4(a). An example of a scanned image is shown in Fig. 4(b). A computer program (DGTrack) developed specifically for counting ECE tracks in CDs/DVDs is used to process the image (Mitev et al. 2010). The program has the ability to discard artefacts (like scratches that are common in used disks) and to separate overlapping tracks (as can be seen in Fig.4(c)). Scanning and counting 30 disks by DGTrack takes up to 60 minutes and most of this time is consumed by scanning (Mitev et al. 2010).



(a) (b) (c)

Fig. 4. (a) Scanning CD/DVD pieces for automatic counting of tracks. (b) Scanned image of the etched area of a CD. (c) ECE tracks in a CD counted by DGTrack (Mitev et al. 2010).

Estimating radon activity concentration

After the track density at a certain depth in the disk $\boldsymbol{n}$ is determined along with the corresponding $\boldsymbol{CF}$, the average radon activity concentration for the period for which the disk was stored is found as:

$$A_V = \frac{n_0}{CF.T_{\exp}} = \frac{n - n_b}{n_C - n} \frac{I_V}{T_{\exp}} \tag{3}$$

where $\boldsymbol{T_{exp}}$ is the length of this period (i.e., the age of the disk) and $\boldsymbol{n_b}$ is the background track density. The relative uncertainty of $\boldsymbol{A_V}$, $\boldsymbol{\delta(A_V)}$ is given by:

$$\delta(A_V) = \sqrt{\delta^2(stat) + \delta^2(I_V) + \delta^2(T_{\exp}) + \delta^2(temp) + \delta^2(d)} \tag{4}$$

where the first term accounts for the statistical uncertainty in the track densities, and $\boldsymbol{\delta(I_V)}$ and $\boldsymbol{\delta(T_{exp})}$ are the relative uncertainties of $\boldsymbol{I_V}$ and $\boldsymbol{T_{exp}}$ respectively. The term $\boldsymbol{\delta(temp)}$ accounts for any difference between the temperature of exposure of the original disk and the temperature during the calibration exposure. The term $\boldsymbol{\delta(d)}$ accounts for the uncertainty in the depths of etching – this uncertainty might mask small differences in the depths at which the two pieces are etched. The last two terms in Eq(4) are evaluated theoretically, using a model given in (Pressyanov 2009). The typical and extreme values of the components of the uncertainty of $\boldsymbol{A_V}$ are shown in Table 1.

As it could be seen, in most cases the average radon activity concentration could be determined with uncertainty better than 20%. Higher uncertainty is usually due to the high relative uncertainty of the exposure time when one or two year-old disks are used.

Table 1. Typical and maximum values of the components in the relative uncertainty of radon activity concentration determined by retrospective measurements with CDs/DVDs.

Relative uncertainty	Typical, %	Maximum, %	Notes
δ(stat)	5	10	-
δ(I_V)	5	10	-

Results

A blind test of the method was performed in 2009 in the frames of an international intercomparison of passive radon detectors organised by the Health Protection Agency (HPA), UK. Compact disks were exposed at HPA and were sent to us by mail. A good agreement between the referent values and the results obtained by the CD method was found within the stated uncertainties. The results confirmed that the method could detect elevated radon levels even for short exposure times.

A pilot survey started in Bulgaria aiming to test the potential of the method for large-scale measurements. Around 200 disks were collected from 88 buildings. The disks were provided by their owners and varied in brands and age (from 1 to 15 years). The regions from which disks were collected include the cities Sofia and Varna, the town of Eleshnitsa and the region of the town of Bouchovo. In the last two regions uranium mining and milling had been in progress in the past and they are considered areas with high radon risk. The distribution of the activity concentrations in the studied buildings in these regions are shown in Fig.5(a). Although the number of buildings is small, it is clear that in many of them radon poses a problem. For comparison, the distribution of the activity concentrations in the studied buildings situated in Sofia, Varna and some other locations is presented in Fig.5(b). The obtained average is close to the average reported by UNSCEAR (UNSCEAR 2000). The averages and the medians for the studied buildings in the 3 regions, from which most of the disks were collected, are given in Table 3. The 95% confidence interval (CI) for the median was determined using non-parametric statistical analysis (Conover 1980). Moreover, it should be noted that CDs were taken from some of the homes in Eleshnitsa in which prospective measurements had been made in the past. As shown in (Pressyanov et al. 2010) the results obtained by CDs correlate very well with those obtained by the independent past measurements.

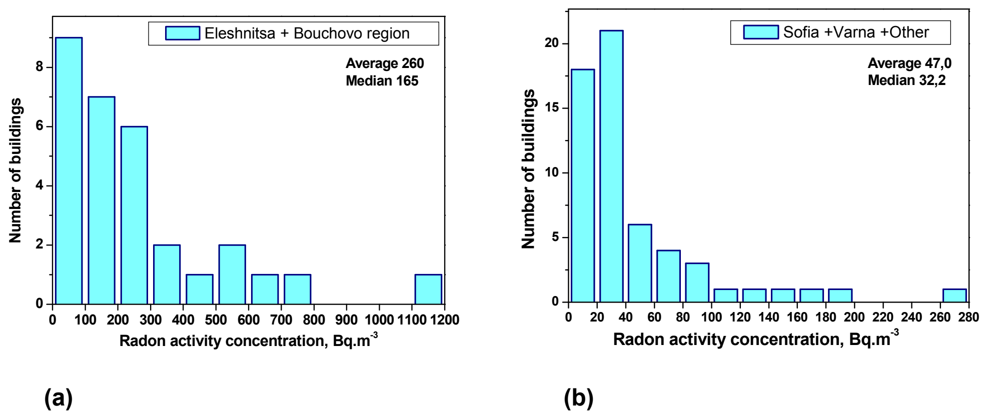

Fig. 5. Distribution of the activity concentration of radon obtained by measurements with CDs/DVDs in buildings in (a) risk areas (Eleshnitsa and in the region of Bouchovo); (b) areas considered "normal" (Sofia, Varna and some other locations).

Table 2. Values of the average and median of the activity concentrations of radon in buildings in three towns in Bulgaria obtained by measurements with CDs/DVDs.

Area	Number of buildings	Radon activity concentration , Bq.m^{-3}	
		Average	Median (95% CI)
Sofia	24	41,1	29,5 (19,0; 38,7)
Varna	17	38,5	17,3 (13,8; 29,7)
Eleshnitsa	22	166,1	123,4 (78,4; 210,0)

Most of the disks used in the survey (75) had been stored in homes, while the rest of them had been stored in different public buildings – four schools, a kindergarten, a hotel and several workplaces. Elevated radon concentrations were found in the kindergarten (about 500 Bq.m^{-3}), which had since been successfully remediated by an active suction system. An interesting result was obtained in one of the other buildings (Fig.6). The analysis of a 3,5 year-old disk (CD1) lead to an estimate for the radon activity concentration about two times higher than the analysis of a 1,9 year-old disk (CD2). It turned out that before the second disk was bought, passive mitigation of the building had been installed. Subtracting the integrated activity concentration estimated by CD2 from the one estimated by CD1 allowed us to determine the average radon activity concentration for the period before the remediation (Fig.6). In this way, using CDs we determined a reduction factor of 3,7 ± 1,4 (at the level of 1σ). For comparison, conventional measurements showed about 3 times reduction in radon concentrations after the remediation. The example illustrates the ability of the CD method to roughly detect substantial changes in radon concentrations. In addition, the same approach could be used to exclude the last few years, which do not contribute to the present risk. This application of the CD method is useful for case-control studies and will be explored further.

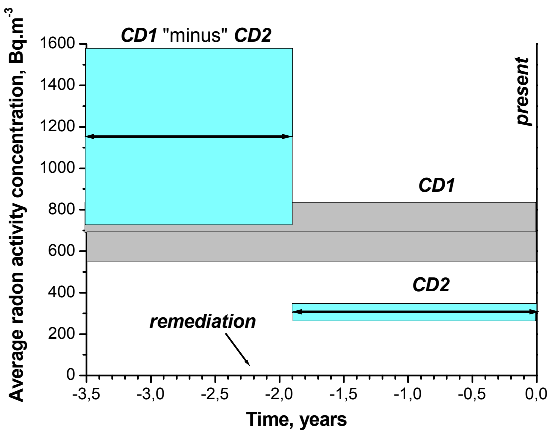

Fig. 6. Estimate of the average radon concentration for a past period by using two disks of different age. Remediation of the building has been made before CD2 was bought. The filled regions mark the estimated concentrations ± 1σ.

Conclusion

The conducted survey, however small, demonstrates that the CD method:

- allows precise retrospective measurement of the activity concentration of ^{222}Rn with uncertainty potentially better than 20 %;
- allows individual calibration of each disk after the exposure;
- could be widely applied – CDs and DVDs are available in homes, work places, schools, etc.;
- could provide results representative for risk estimation – in many households disks as old as 10 ÷ 15 years are available;

- pinpoints buildings with radon problem even with disks less than one year-old;
- could detect significant changes in the activity concentration of ^{222}Rn in the past by etching disks of different age;
- allows to monitor the individual exposure of the occupants even when they change residencies often;
- allows to organise measuring campaigns remotely by asking the participants to send disks by mail;
- is fast, simple and inexpensive.

The above features of the CD method make it appropriate for large-scale radon surveys. The method gives results that are representative for the risk from exposure to radon and could prove useful in case-control studies.

Radon measurement method with passive alpha track detector at STUK, Finland

Reisbacka, Heikki
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

In Finland, Radiation and Nuclear Safety Authority (STUK) has performed approximately 5 000 – 20 000 indoor radon measurements per year. The detector material is polycarbonate and the holder model is STUK's own. After at least a two-month measurement in the heating period, the polycarbonate films are electrochemically etched in order to see the alpha tracks. Tracks are calculated with image processing and analysis system. Research and Environmental Surveillance of STUK is an accredited testing laboratory T167 (EN ISO/IEC 17025) by the decision of the Finnish Accreditation Service (FINAS). Airborne radon concentration is one of the accredited fields of testing performed at STUK and verified by FINAS. STUK's Health Risks and Radon safety laboratory also makes comparison measurements every second year with primary standard of Physikalisch-Technische Bundesanstalt (PTB), the national metrology institute laboratory in Germany. STUK's Health Risks and Radon Safety laboratory sends its reference measuring device to PTB for calibration. This is to conserve the measurement standard at STUK.

Introduction

The first passive radon detector that STUK used was STUK's own making. It was an open Kodak LR-115 detector, used from 1980 to 1984 (Mäkeläinen, 1984). In 1984 STUK started to use closed passive radon detector. The detector holder was made from clear plastic and the detector was a 300 - µm thick Makrofol polycarbonate film. The other side of the detector was clear and the other side was matt (Mäkeläinen, 1986). In 1989 the detector holder material was replaced with an electric conductive (carbon fibre reinforcement) ABS plastic and 250-µm thick polycarbonate was used as the detector.

Material and methods

The present day passive detector is used for dwellings and workplaces. The detector holder is STUK's own design, closed and with a filter, 17 mm high and 45 mm in diameter. It is made from ABS plastic including 10% carbon fibre. There are six holes in the holder cover, and below the cover there is a paper filter disc, Whatman / Schleicher & Shuell 589/3, diameter 45 mm. STUK's detector is shown in Figure 1.

Figure 1. STUK's detector.

The detector is made of 250 - µm thick polycarbonate sheet, Bayer Makrofol DE 1-1 CC. Both sides of the detector are clear. STUK gets the film directly from factory in 610 x 915 mm sheets, clear cover plastic on one side and green cover plastic on the other side. Finnish company die-cuts the Makrofol to keep the clear cover plastic as one piece and the green one will be removed just before packing it into the detector holder. Cover plastic prevents the detectors from scratching. The background was three tracks per cm^2 for the new detector and today it is five tracks per cm^2. STUK performs control tests for background in every three months. Roughly one out of 5 000 detectors breaks down because of high voltage. Also the track density can vary in one or two per 5 000 detectors so that they must be rejected.

In the detector holder there is a 19-µm thick aluminium-metallized sheet of polyester, Hostaphan RNK 19. The surface resistance for the aluminium coating is 2 ohm/m^2, and the thickness of the aluminium coating is less than 0,05 µm. Inside the holder steel spring keeps the parts in their places. The detector holders, detectors and questionnaires are identified using bar code labels. The bar code type Interlieved 2/5 is suitable for small detectors like in our case.

The pre-etching time is 1 h 12 min and the electrochemical etching time is 2 h 22 min. Etching temperature is 36 ºC, frequency 2 kHz and field 28.8 kV/cm. The etching solution is potassium hydroxide, KOH and ethanol. For the KOH solution we take 385 ml saturated potassium hydroxide and 620 ml distilled water, and compound it with ethanol 1:1. On the other side of the detector, we use sodium chloride solution, 61 g NaOH in 1 l water, as a conductive liquid. Control unit takes care from etching times. Fluke 87 True RMS Multimeter stores ranges of voltage, average, maximum and minimum. Etching chambers in constant temperature cabinet are shown in picture 2.

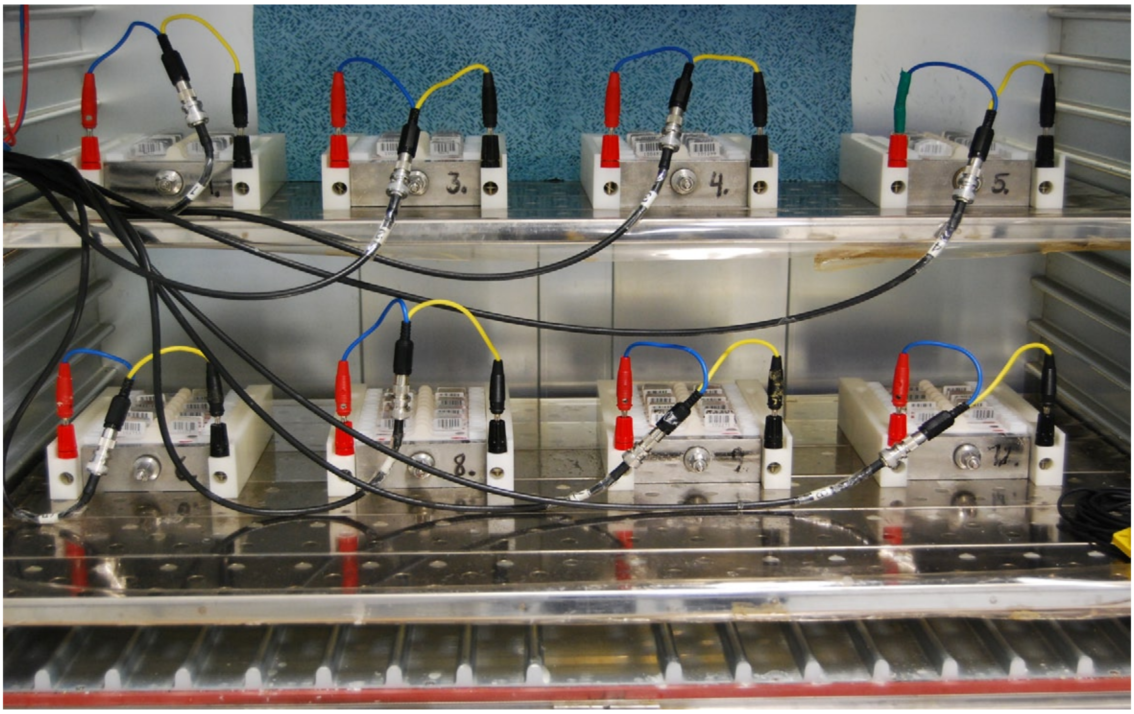

Figure 2. Etching chambers in constant temperature cabinet.

Track counting is made with Leica image analyze system. The software is Qwin, the microscope Mz6 and the camera DC 300. The counting area used is 1.52 cm². We take one picture from the detector and the program will divide it into 16 sectors for calculation. If the amount of tracks differs significantly in more than three sectors, the system rejects the detector for hand control. STUK makes every other month verification to the counting system by re-counting the same test detectors.

The main testing system is to use test detectors. 300 - 600 test detectors are exposed to the same radon concentration. At least every twentieth detector is a test detector and they will go through every stage daily.

Laboratory information system RAMI includes the customer register and the measurement register. RAMI takes care of result calculations, result letters and invoices.

Research and Environmental Surveillance of STUK is an accredited testing laboratory T167 (EN ISO/IEC 17025) by the decision of the Finnish Accreditation Service (FINAS). Airborne radon concentration is one of the accredited fields of testing performed at STUK and verified by FINAS. STUK participates in intercomparisons of passive radon detectors. STUK's Health Risks and Radon Safety laboratory also makes comparison measurements every second year with primary standard of Physikalisch-Technische Bundesanstalt (PTB), the national metrology institute laboratory in Germany. STUK sends its reference measuring device, Alpha Guard, to PTB for calibration. This is to conserve the secondary measurement standard at STUK.

In Finland, Radiation and Nuclear Safety Authority has performed approximately 5 000 – 20 000 indoor radon measurements per year. Amount of annual radon measurements is shown in figure 3.

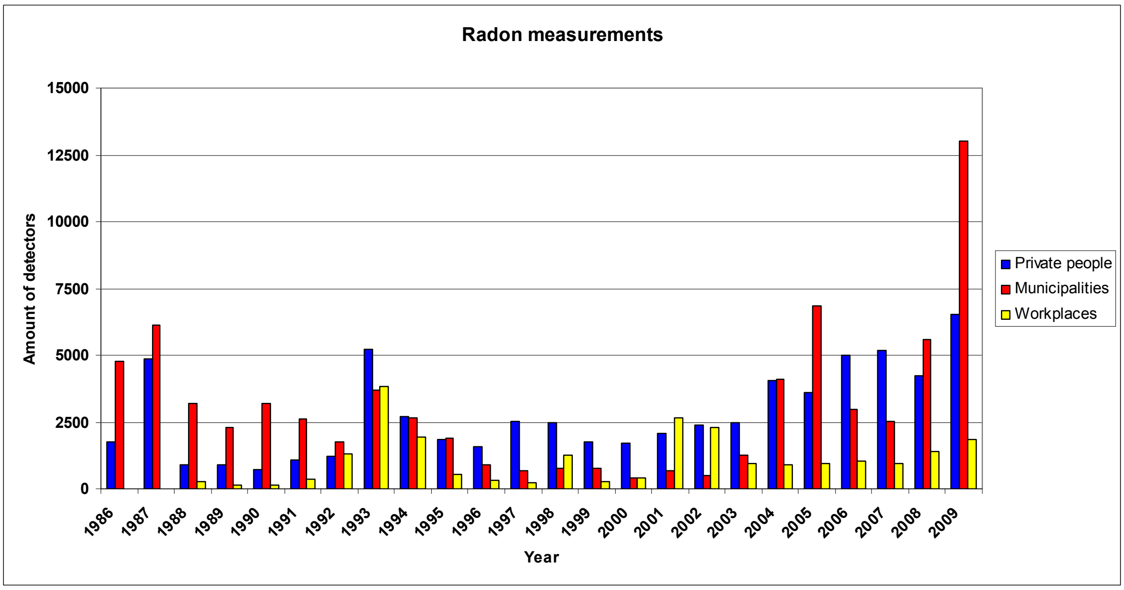

Figure 3. Amount of annual radon measurements in Finland.

Abstract
This paper presents the following results: (i) Realization of the metallic radon standard system; (ii) Quantitative extraction of radon from the radium source; (iii) Absolute standardization by liquid scintillation counting and relative measurements of radon activity, by using the HPGe gamma-ray spectrometry method and the reentrant ionization chamber. The final purpose of the work is to calibrate adequately the secondary standard systems, for using them in the measurement of the working standards, glass vials containing radon gas standard, in order to assure the traceability. A method for modeling the radon transport in various matrices was also elaborated, with reference to the simulation of the radon detectors containing active charcoal. It will be validated experimentally, with radon gas standards.

Introduction
The necessity to create a primary Romanian ^{222}Rn standard system and the general concept of such a system to be established at IFIN-HH, Radionuclide Metrology Laboratory were presented at IRPA 12 Congress by Sahagia et al. (Sahagia et al. 2008). A preliminary variant of a glass circuit was realized and used for the extraction of radon. It contains a vacuum system for the circulation and recovery of radon and a Pylon solid source of ^{226}Ra, http://www.pylonelectronics.com/pylonradioactive.php, type RN-1025-250, flow-through, with the activity: $A_{\mathrm{Ra\text{-}226}}$= (259 ± 10)kBq, on 21 August 2008, traceable to the NIST, USA. The method for absolute standardization of ^{222}Rn in equilibrium with its daughters by liquid scintillation counting (LSC) was first used by a common French-Romanian team at the Laboratoire National Henri Becquerel (LNHB), France, such as presented by Cassette et al.(Cassette et al. 2006). The method was developed at IFIN-HH, with some original aspects, referring to the correction for the decay of the very short half life daughter ^{214}Po during the extendable type dead time

of the LS counter. The results obtained in the absolute standardization of radon were published by Sahagia et al.(Sahagia et al. 2009a)

This paper presents the following results:(i) Realization of the final metallic system, provided with all the necessary control gauges and the preparation of sources by the quantitative extraction of radon from the radium source. (ii) Absolute standardization by LSC and relative measurements of radon activity, by using the HPGe gamma–ray spectrometry method and the CENTRONIC IG12/20A ionization chamber. The final purpose of the work will be to calibrate adequately these secondary standard systems for using them in the measurement of the working standards, glass vials containing gas radon, prepared with the radon facility. These standards will be used for the calibration of equipments of various laboratories involved in radon measurement. A method for modeling of the radon transport in various matrices was also elaborated. One part of it refers to the simulation of the radon detectors containing active charcoal, a particular case of a purely diffusive transport in a medium with constant saturation. It will be validated experimentally, with radon gas standards produced with the standard radon system.

Material and methods

1. Presentation of the system and the preparation of sources

The new variant of the system was constructed from stainless steel and contains all the necessary gauges for the control of the pressure inside the circuit. It allows the extraction of large activities of radon from the Pylon source. At the same time it can be used in several modes of work, as it contains two ways of access to the circuit: (i) the concomitant extraction in two recipients; (ii) the extraction of radon in a single recipient and the transfer into another. Both these types of operation were intended to prepare the final (iii) mode, consisting of the sequential extraction and quantitative transfer from a recipient to another, in order to establish the traceability chain. This mode of operation is treated in an internal IFIN-HH Report (Report, 2009). Photograph 1 presents the two variants of installations

Fig. 1 (a) Glass system.

Fig.1(b) Metallic system.

Several sources were prepared in glass ampoules or vials, in both modes of work, (i) and (ii).The pair of sources 9 - 10 were prepared in the manner (i), and the pairs 13-14, 15-16 and 17-18 were prepared in the manner (ii). The sources 9,13,15 and 17 contained the radon as gas, while the sources 10, 14, 16 and 18 were prepared by adsorption/ dissolving of radon in liquid scintillator (LS) type OPTIFLUOR O, a Perkin Elmer product. The recovery of radon in the recipients was done at the 77 K temperature, by using Dewar vessels with liquid nitrogen. The pressure in the metallic variant of system was fully controlled and allowed for the preparation of high activity sources by the recovery of the main part of radon exhaled by the Pylon source. Figure 2 represents both types of radon ampoules, flame sealed.

Fig.2. Flame sealed ampoules: left – LS; right - gas.

All the operations were performed in a radionuclide fume cupboard, coupled to the ventilation circuit. The radon concentration in the laboratory was permanently measured with a monitor, Radon Scout, SARAD GmbH, Germany product, coupled to a personal computer. Figure 3 shows the registrations for a 24 h period of the radon concentration in the laboratory, during the preparation of sources.

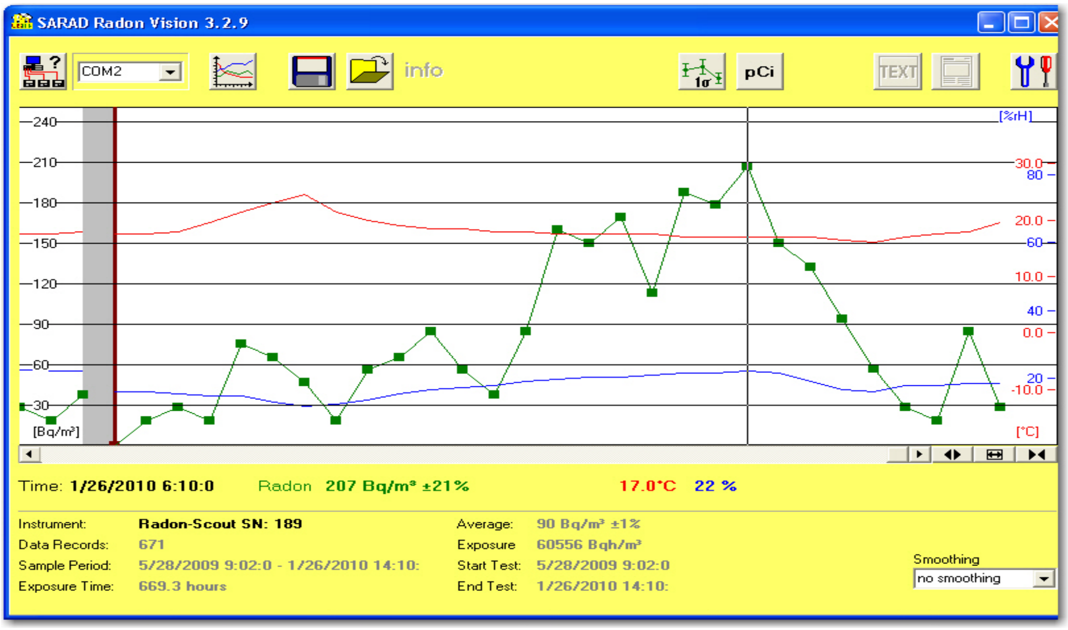

Fig. 3. Radon concentration in the laboratory.

Such as it can be seen from the figure, the maximum concentration values are registered during the night time, when the laboratory ventilation is not working; the marked, 210 Bq/m^3, is at 6 h in the morning. During the working time the values are less than 90 Bq/m^3, showing that no contamination occurs.

2 . The measurement of activity

The measurements were performed by the absolute LSC method with the ampoules prepared in LS, and relatively, by the gamma–ray spectrometry using a high resolution HPGe system and by the measurement in a CENTRONIC IG12/20A well type ionization chamber, with all types of recipients.

2.1. Measurement by the LSC method

The method was described in the above cited papers. The method consists basically from the measurement of the whole sequence of short lived nuclides of the ^{222}Rn decay chain in a LS counter. The main correction is due to the disintegration of ^{214}Po during the dead time of the LS counter. The formula for the calculation of the ^{222}Rn from the counting rate R_0 is:

$$R_0 = 5.0242 \cdot A_{\mathrm{Rn222}} \tag{1}$$

In relation (1), R_0 represents the corrected counting rate for the ^{214}Po decay. The approximate relation for this correction is:

$$R = R_0\left[1 - 0.0008576\,\tau\left(1 + \frac{\tau}{2}(\rho - \lambda)\right)\right] \tag{2}$$

In this relation, R is the registered counting rate, corrected for background; τ is the fixed dead time of the counter, in μs, $\lambda = 0.00427$ (μs)$^{-1}$ is the decay constant of ^{214}Po and ρ is the true counting rate.

A method based on the precise determination of the fixed counter dead time τ = (40.07±0.06) μs and the repetition of measurements for several days, with the extrapolation to the source preparation time was applied, such as described by Sahagia et al.(Sahagia et al. 2009a). The extrapolation is correct, and the data are correctly used, when the linear extrapolation equation is accomplished:

$$[R_0] = [R_0]_0\, 2^{-\frac{t}{T_{1/2}}} \quad or \quad \log[R_0] = \log[R_0]_0 - \frac{\log 2}{T_{1/2}}t \tag{3}$$

$[R_0]_0$ is the extrapolated counting rate, corresponding to the source preparation time, and $T_{1/2} = (3.8232 \pm 0.0008)$ d is the half life of ^{222}Rn according to Monographie BIPM-5. (Bé et al.2008). Contrary to the previous measurements, when low ^{222}Rn activities were extracted from the Pylon source (a maximum 1572 Bq at the preparation time), in this case higher activities were extracted and had to be measured. It was necessary to wait for longer periods the decay of radon, in order to be measured. As the extrapolation was extended on longer time intervals, more measurements and checks of the correct extrapolations were necessary.

2.2 The measurement by gamma-ray spectrometry

The measurements were performed with gas and LS recipients. A gamma-ray spectrometer, provided with a high efficiency HPGe detector was used. The sources were measured at a distance of 44.2 cm from the detector surface, in order to diminish the influence of the recipient geometry. The measurements were made on the two main photopeaks: 352 keV (Pb-214) and 609 keV (Bi-214). The emission intensities for the two quanta, $I,(\gamma s^{-1})/Bq$ were respectively: 0.3560(7) and 0.4549(19) (according to Bé et al 2008). Various models for calculation of efficiency, leaving from point source approximation and the GESPECOR programme (GESPECOR, 2007) were used. More details are given in the Internal Report IFIN-HH, 2009.

2.3 Measurements with the ionization chamber

The laboratory disposes of a well type ionization chamber type CENTRONIC IG12/20A, provided with an electrometer type Keithley 6517A, which was calibrated for a number of 18 different radionuclides. The results were validated during our participation in key and supplementary comparisons, Sahagia et al.(Sahagia et a. 2009b). The calibration factors were expressed in terms of the ratio between the ionization current and the activity of the measured sources.The measurements were performed with both types of recipients by registering the obtained ionization current. In the case of the gas ampoules, the measurements based on the HPGe were taken as reference. In the case of the LS ampoules, both methods of activity measurement, LSC and HPGe, were used. The measured activities were considered as the arithmetic mean of the two photopeaks' results.

3. Modelling methods

A conceptual and mathematical model describing the migration of the radon generated from the radium existing in the soil was elaborated. The experience gained in various modeling situations, such as presented by Toro et al. (Tora et al. 2008) was used. The radon transport is produced first of all due to the diffusion which occurs as a consequence of the radon concentration difference between the two phases: gas and liquid. Leakage of the transport fluids, air and water, drives to an advective - dispersive transport. The description of this biphasic emanation process is complicated also by the physic-chemical properties of the porous medium; more equations must be written both for the transport and leakage, coupled by the degree of saturation and physic-chemical processes. The modelling consists in several types of activities: (i) Definition of a conceptual model, containing the work hypotheses; (ii) Elaboration of a mathematical model, containing the sets of equations which describe the physical processes; (iii) Elaboration of the numerical model for solving the equations. A particular case of the model application is the simulation of the transport of radon inside the detectors containing active charcoal, a pure diffusive transport in the medium with a constant saturation. The calculation results follow to be compared with those experimentally obtained with the use of radon gas standard vials.

Results

The radon prepared sources activity measurement results, obtained by using the three methods, are presented in Tables 1, 2 and 3.

1. Measurement of activity by the LSC method

A number of 4 LS ampoules were measured and the results, in terms of total decay chain activity $[R_0]_0$, radon activity, $[A_{Rn\text{-}222}]_0$ on the source preparation time and the optimum calculated half life, $T_{½}$, are presented in Table 1.

Table 1. LSC measurement results.

Amp. no	Time from the preparation date, d / no of points	$Y_0 = A_0 + B_0\, t$, $\tau = 40.07$ μs
10	(20.8403 – 28.9062)/ 5	Y_0 = (5.7411 ± 0.0074) – (0.07793 ± 0.00028) t $[R_0]_0$= (550 883 ± 9 475) Bq; $T_{1/2}$ = (3.8628 ± 0.0138) d $[A_{Rn222}]_0$= (109 646 ± 1 886) Bq, k=1
14	(8.8125 - 14.8611)/ 5	Y_0 = (5.0762 ± 0.0087) – (0.07868 ± 0.00014) t $[R_0]_0$= (119 182 ± 2 395) Bq; $T_{1/2}$ = (3.814 8± 0.036) d $[A_{Rn222}]_0$= (23 721 ± 477) Bq, k=1
16	(19.0556 - 26.0208)/ 2	Y_0 = (5.7725 ± 0.0066) – (0.07868 ± 0.00014) t $[R_0]_0$= (592 243 ± 8 943) Bq; $T_{1/2}$ = (3.8274 ± 0.036)d A_{Rn222} = (117 878 ± 1 780) Bq, k=1
18	(12.9410 – 30.000)/ 3	Y_0 = (5.4486 ± 0.0053) – (0.07855 ± 0.00068) t $[R_0]_0$ = (280 931 ± 3 425) Bq; $T_{1/2}$ = (3.8232 ± 0.033) d $[A_{Rn222}]_0$ = (55 916 ± 671) Bq, k=1

2. Measurement of activity by the HPGe gamma-ray spectrometry

A number of 2 gas and 2 LS ampoules were measured and the results are presented in Table 2.

Table 2. Results of measurement by the HPGe Gamma-ray spectrometry.

Discussion

The measurement results, such as presented in Tables 1, 2, 3 and 4 reveal the followings.

Regarding the absolute, liquid scintillation method, it is the primary method, to be taken into account for the realisation of a primary radon standard. The LSC method assured a good precision of standardization, combined standard uncertainty situated between 1% and 2%, even in the case of these high activity sources. The calculated radon half life values from the extrapolation procedure are in agreement with the theoretical value $T_{1/2} = (3.8232 \pm 0.0008)$ d.

Regarding the HPGe gamma-ray spectrometry,Table 2 results, one may comment. The theoretical ratio of the ^{214}Pb and ^{214}Bi activities is $A_{Bi} / A_{Pb} = 1.00363$. The determined ratio values, column 6, is much higher for the point source approximations in efficiency calculation; the ^{222}Rn activity values, column 7, differ significantly from a photopeak to another and consequently the model is not adequate for efficiency evaluation. The GESPECOR variant applicable only to the LS sources is much better, as the values agree and also they agree with the values measured absolutely by the LSC (sources 10 and 14). This program is not applicable to the gas recipients, maybe because the volume distribution of the ^{214}Pb and ^{214}Bi inside these sources is not known. The conclusion is that the only possibility to determine the activity of gaseous sources is to achieve a quantitative transfer of radon from the gas to LS recipients, to measure them by the LSC method and to establish the traceability chain.

Table 3 and Table 4, ionization chamber measurement results discussion. The calibration factors obtained with 2 gas ampoules, leaving from the gamma-ray spectrometry measurements are not consistent in terms of their combined standard uncertainties. On the contrary, for a number of 4 different LS sources the calibration factors agree, once as individual results with reference to the LSC method, and twice as compared with those determined taking as reference the activity measured by the HPGe gamma ray spectrometry method, based on the use of the GESPECOR program for efficiency calculation. This result has the same conclusion, that the main problem is to develop the method for the transmission of activity unit from the LSC method to the gaseous sources, in order to assure the traceability chain.

Conclusions

- The radon system was used to prepare recipients containing radon extracted from a radium source, both as gas and dissolved in liquid scintillator.
- The activity of all radon recipients was measured by various methods: the LS ampoules were measured absolutely by the LSC method; all recipients, gas and LS, were measured relatively by using the gamma-ray spectrometry and the reentrant ionization chamber.
- The comparison of results revealed that in the case of the LS ampoules a model for gamma–ray spectrometry efficiency calculation is adequate, such as the agreement of results demonstrated, while for the gas recipients no model can be used.
- The general conclusion is that a traceability scheme for the transfer of activity unit from primary to secondary standards is needed.

Estimating lung cancer risk due to radon exposure in the radon-prone areas of Belgium

Dehandschutter, Boris; Sonck, Michel
Federal Agency for Nuclear Control-Health & Environment, Brussels, BELGIUM

Abstract

Radon exposure in Belgium is particularly pronounced in the southern part of the country, characterized by a sub-surface composed of highly deformed and fractured (black) shale, schist and quartzite of the Ardenne massif. A national indoor radon measurement campaign (1995-2000) showed that all of the high radon risk areas (where more than 5% of the measured buildings exceed the current Belgian action-level of 400 Bq/m³) were situated within the Ardenne massif, affecting a population of about 380 thousand. For this reason, detailed information, measurement and prevention campaigns have been organized for the local population and municipal authorities. Whereas the national average indoor radon concentration is about 50 Bq/m³, this average increases to about 130 Bq/m³ in the high risk areas. Here, 13% of the houses exceed the action level, affecting more than 50 000 people, and 4% of the houses exceed 800 Bq/m³, affecting more than 15 000 people. In 33% of the dwellings, the design level for new buildings (200 Bq/m³) is exceeded. According to the risk estimates from international epidemiological studies, about 18% of the occurring lung-cancers in the high risk areas (~43 cases on 240 per year) would be due to radon exposure. About 38% of the radon-induced lung-cancers (LC) would occur in the population exposed to more than 400 Bq/m³ (about 30 lung-cancers per year). Comparison of these theoretical values with actual LC statistics of the Belgian Cancer Registry shows a good match between the total number of annual LC in the high risk areas (239 calculated to 240 observed in the period 2004-2005). The correlation between LC incidence rate and average radon concentration however is obscured by the high number of influencing factors (migration, age-distribution, life-habits,…) and the relatively limited population and LC incidence rate. Radon campaigns aim at stimulating house owners and building responsibles to mitigate the radon affected buildings and to apply preventive measures in new buildings. In the high risk areas, preventive reduction of radon exposure to below 200 Bq/m³ should lead to a reduction of the LC incidence rate with 7%.

Introduction

For the general population, radon is usually the most prevailing source of radiation exposure in the indoor environment (ICRP 60, 1990). The link between radon and lung cancer has been first recognised through miner cohort epidemiological studies (BEIR

IV, 1988; BEIR VI, 1998; UNSCEAR 2000). More recent case-control studies highlight the linear no-threshold relation between lung cancer risk and indoor radon-concentration in dwellings (Darby et al., 2005). In order to efficiently manage the radon exposure, most European countries have adopted a radon action plan, setting out the criteria, strategies and practical aspects of radon controlling activities. The Belgian radiation protection regulation (ARBIS, 2001) foresees the control of radon exposure in workplaces and in dwellings in radon prone areas. A national radon measurement campaign during the 1990's highlighted the occurrence of radon prone areas (defined at that time as municipalities where more than 1% of the dwellings exceed the action level of 400 Bq/m³) in the southern part of the country (Poffijn and Vanmarcke, 1990; Zhu et al., 1998). Ongoing indoor radon measurements led to the classification of the territory into radon regions (Fig. 1) on a national scale and into radon classes on a local scale (Fig. 4). Within the radon prone areas, a specific region shows a high risk of having high indoor radon concentrations. This is the high risk area (HRA, Radon region 2 on figure 1), where more than 5% of dwellings exceed the action level. It is characterised by the occurrence of highly deformed metamorphic rocks of Lower Palaeozoic age. The HRA affects a population of about 380 thousand. If the national action level would be brought to 200 Bq/m³, the population living in the HRA would increase to more than 1.1 million. The measurement campaigns also allowed assessing the radon exposure of the Belgian population (Table 1).

Material and methods

The Belgian Cancer Registry containes LC incidence data on a municipal scale starting from the year 2004. The most recent data concern 2005. These data show the variability in LC incidence rate between men and women as well as some regional variation. Table 2 shows the annual LC incidence rate for the period 2004-2005 in Belgium. For this period, about 7000 LC per year have been registered.

Table 2. Observed annual LC incidence rate in Belgium in the period 2004-2005.

Region	population	men	women	total
Belgium	10584534	5361.5	1539.5	6901.0
Wallonia	3435879	1744.0	521.5	2265.5

Brussels	1031215	404.0	174.0	578.0
HRA	376568	180.0	61.0	241.0

Table 3. Observed annual LC incidence rate in the HRA in the period 2004-2005.

District	men	women	total
Verviers	127.5	46.5	174.0
Bastogne	21.5	6.0	27.5
Neufchâteau	31.0	8.5	39.5
Total	**180**	**61**	**241**

The linear increase without threshold of the relative risk with indoor radon concentration has been estimated in various recent studies (Baysson et al., 2004; Darby et al., 2005). In this paper, the value of 16% increase of relative risk per trench of 100 Bq/m³ has been used following Darby et al., 2005. This leads to the estimation of LC incidence rate based on the average (GM) radon concentration for each region (Table 4). The obtained values show a good correlation between the observed values (table 2) and calculated LC occurrence. This estimation uses a smoker population of 1/3, which is justified taking into account the importance of the long term exposure of the population.

Table 4. Estimated annual LC incidence rate in Belgium for smokers (S) and non-smokers (NS). Lifetime LC risk (0.16% increase per Bq/m³)* expressed per thousand. Lifetime =70 y.

	LC risk NS (promille)	LC risk S (Promille)	LC NS	LC S	total	Without radon	due to radon
Belgium	4.487	110.534	452	5571	6023	5504	520 (9%)
Wallonia	4.651	114.574	152	1875	2027	1787	240 (12%)
Flanders	4.389	108.110	256	3149	3405	3181	224 (7%)
Brussels	4.389	108.110	42	521	563	536	38 (7%)
HRA	4.999	123.139	18	221	239	196	43 (18%)
No radon*	4.100	101.000					

**After Darby et al.. 2005*

A more refined estimate of LC occurrence can be obtained taking into account the variability of the radon exposure within the HRA. This estimate gives a slightly higher LC incidence rate.

Table 5. Estimated annual LC incidence rate in the HRA for smokers (S) and non-smokers (NS).

Exposed to (Bq/m³)	Ref used (Bq/m³)	Population in the HRA	annual LC				
			NS	S	total	without radon	due to radon
>800	800	18828	2	20	22	10	12 (56%)
400 to 800	400	30125	2	24	25	16	10 (39%)
200 to 400	200	86611	4	54	59	45	14 (24%)
<200	100	241004	11	133	144	124	20 (14%)
total		**376568**	**19**	**232**	**250**	**194**	**56 (23%)**

Results

The number of calculated LC (Table 4) corresponds well to the number of observed LC (Table 2). On the national level this would mean that about 8% of the LC incidence rate would be due to radon. whereas this incidence rate due to radon increases to 18% in the HRA. The calculated incidence rate within the HRA depends largely on the exposure class, where for the highest (lifetime) exposures of more then 800 Bq/m³ 56% of the LC incidence rate could be attributed to radon.

When looking at the scatter plot of lung cancer incidence rate and radon concentration per district, no statistical correlation can be observed. For the data per municipality, the LC incidence rates for the observed period are so low that no correlation whatsoever can be observed. When looking at the (age standardised) LC incidence rate among women, however, a vague trend can be observed (Fig. 2).

Figure 3 shows the age standardised LC incidence rate among women per district. This figure shows that the HRA contain some of the highest incidence rates in the country, except for one district (District *Marche*) with very low LC incidence rates.

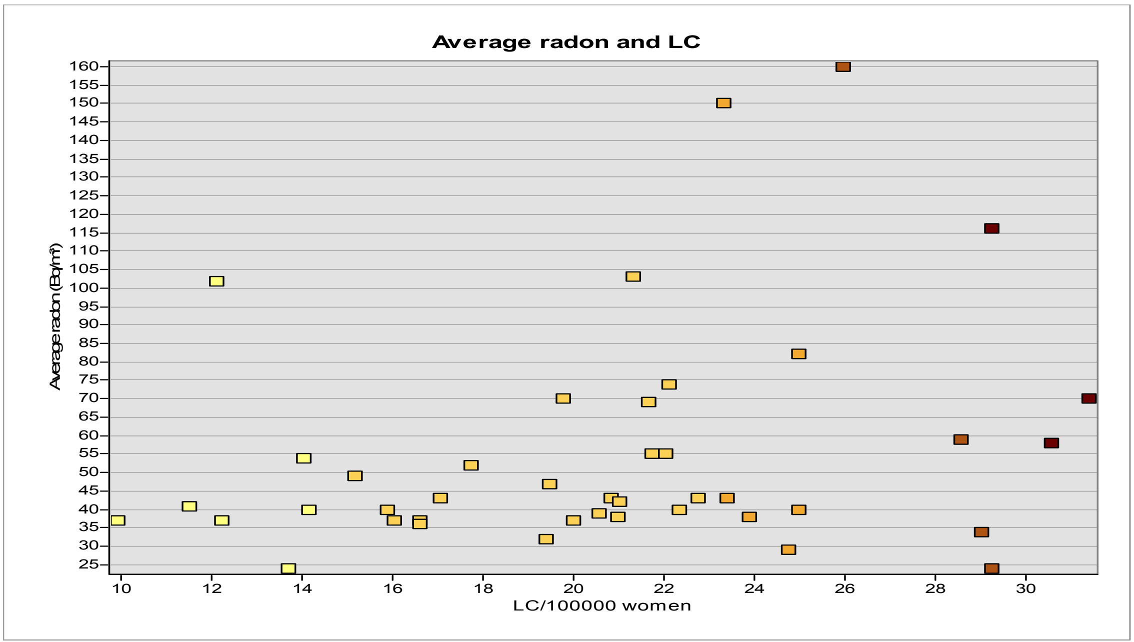

Fig. 2. Scatter plot of the average (GM) radon concentration per district versus LC incidence rate among women.

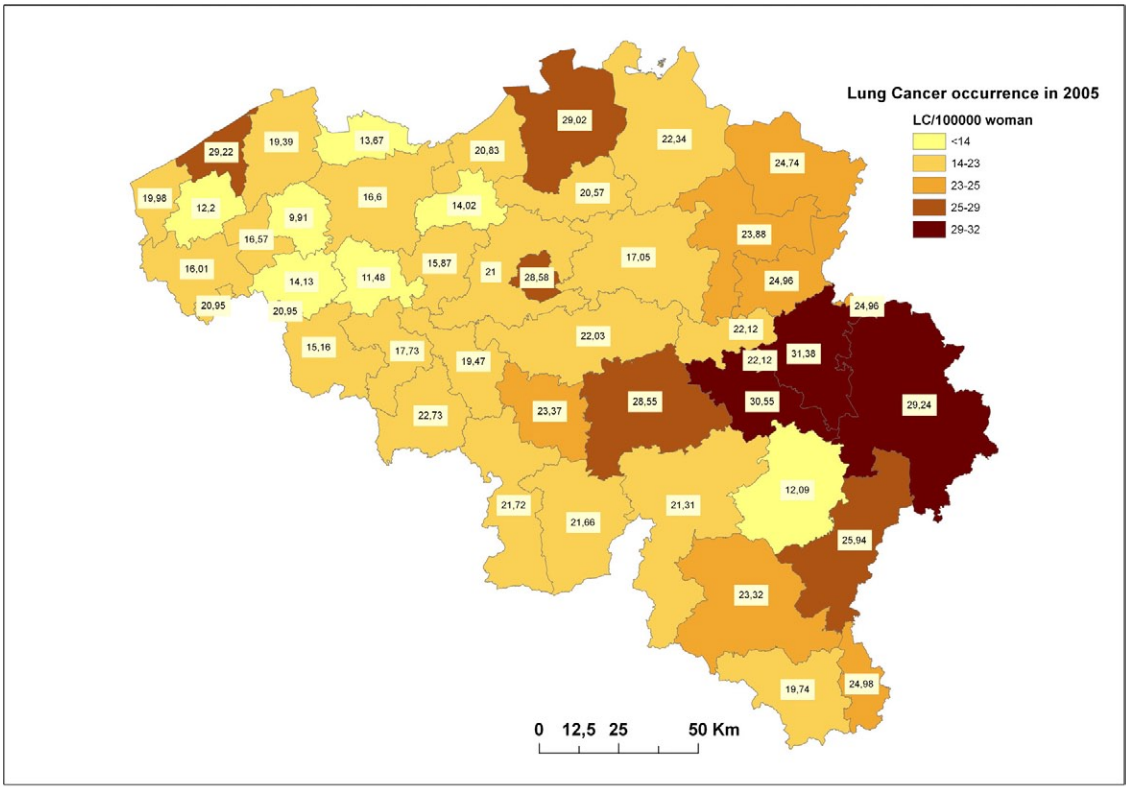

Fig. 3. Distribution of age standardised LC incidence rate among women per district.

Figure 4 shows the radon distribution per municipality on the Belgian territory. This figure shows that, in the case of the district 'Marche', partly covered by the HRA, only 4 municipalities, representing only 22% (12368) of the population of the total district (53123) actually are within the HRA.

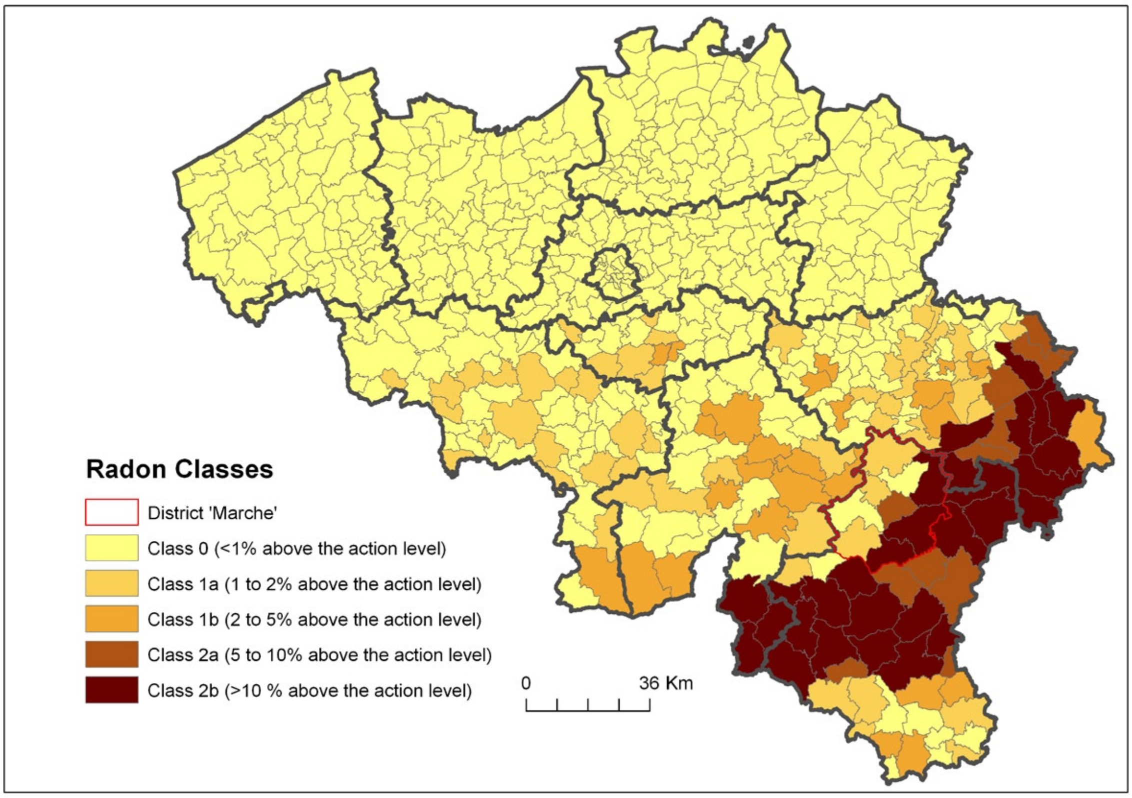

Fig. 4. Radon distribution per municipality.

Discussion

The LC incidence for 2004-2005 contained in the National Cancer Registry correlates well with the data calculated from the radon risk studies. Comparing the observed number of lung cancers to the calculated number of lung cancers, there is a better match for the high risk areas then for the other areas. Part of the explanation could be that much more radon measurements have been made in the HRA than in the less affected regions. improving the accuracy of the calculated LC incidence values.

A slight trend can be observed when looking at the distribution of radon on the territory and LC incidence rate for women per district. A remarkable deviation from this general trend (district 'Marche' on fig. 4) could be due to the discrepancy between the district boundaries and the HRA limits. Refining the resolution of the LC incidence rate data to the municipality scale, however, leads to too few cases to allow statistical correlation. A possible trend in the LC incidence rate data among man, from the other hand, seems not at all suggested by the data. Smoking habits and occupational exposures might be a reason for this.

Conclusions

A reoccurring question among the population in the high risk areas concerns the link between regional variations in LC incidence rate and increased indoor radon concentrations in their region. The current preliminary study investigates the risk estimates based on the recently published international epidemiological studies of radon and LC, applied to the high radon risk areas in Belgium, and compares them to the observed number of LC in this region as available from the Belgian Cancer Registry. Although the Belgian Cancer Register contains until today only data for the years 2004-2005, some preliminary conclusions can be drawn from the present analysis.

LC incidence rate correlates well with LC estimates taking into account radon, based on the most recent international epidemiological studies (Baysson et al., 2004; Darby et al., 2005). For areas with a better estimation of radon concentration distribution, the fit between the observed and calculated LC incidence rate is better. This confirms the quality of the used epidemiological studies and their ability to estimate the influence of radon on the general LC incidence rate and hence to allow a risk reduction policy based on the epidemiological findings.

This preliminary study indicates that the correlation between the regional variation of LC incidence and the regional variation in radon concentration is statistically weak and remains until now unproven. This is partly due to the very low number of cases, and due to the high uncertainty about other influencing factors, such as smoking/living habits and migration of inhabitants. Once the Cancer Registry data set will be extended and contain the LC incidence rate data of most recent years, a statistical study could possibly reveal this correlation, as is suggested by the weak trend already observed for LC incidence rate among women.

Estimation of seasonal correction factors – a new model for indoor radon levels in Irish homes

Burke, Orlaith[1]; Long, Stephanie[2]; Murphy, Patrick[1]; Organo, Catherine[2]; Fenton, David[2]; Colgan, Peter Anthony[2]

[1] School of Mathematical Sciences, University College Dublin, Dublin 4, IRELAND

[2] Radiological Protection Institute of Ireland, 3 Clonskeagh Square, Clonskeagh Road, Dublin 14, IRELAND

Abstract

Indoor radon concentrations have been shown to vary considerably with season. Many countries account for this by applying a correction factor to radon measurements of less than one year. To date, Irish radon measurement services have used correction factors based on data collected during a UK national survey of radon in 2000 homes in the 1980s. In the absence of similar data for Ireland at the time, these were considered suitable for use due to the similarities between the climate, house types and lifestyles in both countries. In order to better estimate the long term radon concentration in Irish homes from measurement results, a dataset comprising measurements from 5640 Irish homes was analysed and used to derive a set of correction factors specifically for Ireland. These were generated by means of Fourier decomposition analysis and the new correction factors compared, using 95% confidence intervals, to those derived in the UK using the same analysis and to those currently in use in Ireland. In both cases, differences were found between 10 of the 12 monthly seasonal correction factors. The results of this analysis will be given along with an overview of the methods used.

Introduction

1.1. Background

Radon is a naturally occurring radioactive gas which originates from the decay of uranium present in rocks and soils. When radon surfaces in the open air, it is quickly diluted to harmless concentrations, but when it enters an enclosed space, such as a house or any other building, it can sometimes accumulate to relatively high concentrations.

In air, radon decays quickly to produce radioactive particles that, when inhaled, are deposited in the airways and in the lungs. These result in a radiation dose which, over a long period of time, may lead to lung cancer. Exposure to radon in homes is linked to between 150 and 200 lung cancer deaths each year in Ireland. This represents 10 to 15% of all cases of lung cancer in Ireland and it is the second most significant cause of lung cancer after smoking (RPII and NCRI 2005).

Indoor radon concentrations can vary significantly due to a large number of factors which include the local geology, soil permeability, building and lifestyle characteristics and climate (Gunby et al 1993). Ireland's relatively high indoor radon concentrations were established during the National Radon Survey which was carried out between 1992 and 1999 by the Radiological Protection Institute of Ireland (RPII 2002). An average radon concentration of 89 Bq/m^3 was calculated for Ireland, based on the 11,319 homes measured during this survey. This national average has been shown in a recent survey by the World Health Organisation to be the eighth highest concentration in the world (WHO 2009). Since 1989 the Radiological Protection Institute of Ireland (RPII) has worked to raise awareness of this issue and provides a measurement service to encourage home-owners to measure and, where necessary, remediate their homes.

To measure indoor radon concentrations the RPII use a passive alpha track-etch detector which consists of a two-part polypropylene holder and a CR-39 (polyallyl diglycol carbonate) detection element (RPII 1992). The annual average radon gas concentration for a home is determined using two detectors; the first is placed in the main living area and the second placed in the main bedroom for at least three months. This three month measurement is then converted to an annual average radon concentration by applying a seasonal correction factor. The seasonally adjusted annual average radon concentration for the home may then be compared with the National Reference Level of 200 Bq/m^3.

1.2. Seasonal correction factors

The temperature difference between indoors and outdoors combined with the effect of wind on a building result in a lower atmospheric pressure indoors relative to that in the ground. This results in a pressure-driven flow of radon from the ground into the building, once an entry route exists (Wrixon et al 1988). Consequently, external changes in temperature between seasons can result in significant variation in indoor radon concentrations. For this reason it is important to apply seasonal correction factors to radon measurements of less than one year. In Ireland, the seasonal correction factor applied to any three month measurement is the mean of the three individual monthly correction factors for the measurement period (RPII 1994). These were derived from data collated for the UK national survey by Wrixon et al (1988). As mentioned in Organo and Murphy (2007), the suitability of these Irish factors has not been assessed until now, as it was assumed that the seasonal characteristics of both the UK and Ireland are similar.

The use of seasonal correction factors is a complex issue and has been much debated in the literature. Miles (2001) has shown that, for homes of "atypical" construction, factors such as wind speed and direction may have more influence on radon levels than the external temperature. He pointed out that a significant minority of homes (maybe 10 to 20% in the UK) have no substantial seasonal variation or followed a different seasonal pattern to that for typical homes. However, he showed that for a "typical" home, i.e., a home that responds to the weather in a manner typical to many Northern European homes, the application of seasonal correction factors improved the accuracy of estimates of the annual average radon concentration. Denman et al (2007) agreed that such correction factors improve the accuracy of predictions of long-term risks for measurements of at least three months.

It has been shown that one of the most significant effects on indoor radon concentrations is rock type (Gunby et al 1993) and that the type of geology can impact on seasonal variation. For example, it has been shown that radon-rich sedimentary geologies show a high degree of seasonal variation, while radon-rich igneous geologies result in relatively constant radon concentrations (Groves-Kirkby et al 2009). Consequently, a number of studies advise against the use of a single seasonal correction factor for a wide range of geologies. Pinel et al (1995) initially raised concern regarding this while more recently, Gillmore et al (2005) also advised caution in applying a single set of seasonal correction factors to regions with complex geologies. Pinel et al's study calculated correction factors using a series of measurements made in southwest England. However, despite the very different geology in this part of the country and different time-scales over which the measurements were made, the correction factors derived agreed closely with the original correction factors based on nationwide data (Wrixon et al 1988).

Due to this concern regarding the application of general seasonal correction factors to specific regions, a number of studies have derived regional seasonal correction factors. A study by Denman et al (2004) in an area with uniform geology showed that the seasonal variation observed did not match the "average" seasonal correction factors derived by the National Radiological Protection Board (NRPB) for use across the UK (Wrixon et al 1988). This study was carried out on a small sample size (34 homes) and over a limited geographical area and consequently, it is not surprising that the correction factors differ from those derived by the NRPB. The UK Childhood Cancer Study Investigators (2000) also derived region specific seasonal correction factors and concluded that the use of these improved the accuracy of their data. However, other studies have derived regional seasonal correction factors and found either that there was no statistical difference between these correction factors and the "average" correction factors (Grainger et al 2000) or that the differences were minor (Baysson et al 2003).

On balance, it is clear that the use of seasonal correction factors will result in a better estimate of the long term indoor radon concentration. On this basis, a collaborative study was carried out between the RPII and the School of Mathematical Sciences at University College Dublin to derive seasonal correction factors specifically for Ireland.

Material and methods

The statistical methodology used to estimate seasonal correction factors for Ireland is based on that described in Pinel et al. (1995). This makes use of the lognormality of background-corrected indoor radon concentrations and describes the data using Fourier decomposition. The data is transformed appropriately and a linearization is used to maintain approximately normal errors for least squares regression. The Fourier parameters are estimated by least squares regression and used to compute the appropriate seasonal correction factors.

This methodology results in two equations. The first is used to calculate “three month seasonal correction factors” which may be applied to correct radon measurements of three months (equation 1):

$$\hat{f}_i = \frac{3\sum_{k=1}^{12}\hat{m}_k}{12\sum_{k=i-1}^{i+1}\hat{m}_k} \qquad (1)$$

The second equation is used to calculate “one month seasonal correction factors” and may also be applied to a radon measurements of greater than three months. The mean of the individual monthly correction factors for the measurement period is calculated and applied to the radon result.

$$\hat{f}_i^{(1)} = \frac{\sum_{i=1}^{12}\hat{m}_k}{12\hat{m}_i} \qquad (2)$$

Application of this method to 5,640 background-corrected, lognormally distributed data from the RPII’s home measurement database results in two sets of seasonal correction factors for use with future radon measurements in Irish homes. This statistical methodology is described in full detail by Burke et al. (2010).

Results

3.1. Comparison with UK factors

Table 1 reports the three-month seasonal correction factors (equation 1) calculated for Ireland using the Fourier decomposition analysis alongside the factors calculated by Pinel et al. (1995) for the UK using the same analysis. It should be noted that the convention adopted in reporting the seasonal correction factors means that the UK factors reported below are in fact the reciprocals of those presented by Pinel et al.

A simulation study was carried out – simulating 10,000 datasets, each consisting of monthly data with 1,000 observations in each of the twelve months. This allowed the calculation of the empirical 95% confidence intervals for the Irish factors.

Table 1. New Irish seasonal correction factors compared to UK factors.

Measurement Month (i)	New Irish Factors	New Irish Factors: Standard Error	New Irish Factors: 95% Confidence Interval	UK factors (Pinel *et al*, 1995)
1	1.14*	0.00627	(1.12, 1.17)	1.35
2	1.14*	0.00633	(1.12, 1.17)	1.27
3	1.10	0.00502	(1.08, 1.13)	1.10
4	1.04*	0.00220	(1.02, 1.07)	0.91
5	0.97*	0.00217	(0.94, 0.99)	0.75
6	0.89*	0.00728	(0.87, 0.92)	0.65
7	0.86*	0.01106	(0.83, 0.88)	0.64
8	0.86*	0.01123	(0.83, 0.88)	0.74
9	0.89	0.00769	(0.87, 0.92)	0.89
10	0.96*	0.00259	(0.93, 0.99)	1.09
11	1.04*	0.00189	(1.01, 1.06)	1.25
12	1.10*	0.00485	(1.08, 1.13)	1.35

Note:
Correction factors apply to a three month period, centred on measurement month i
A significant difference between factors is indicated with *
The standard errors were calculated using the Delta method (Pawitan 2001)

It is clear that all of the factors are significantly different with the exception of the factors associated with the third and ninth months (March and September). These months correspond to the time points close to where the graph of the two sets of factors intersect (Figure 1).

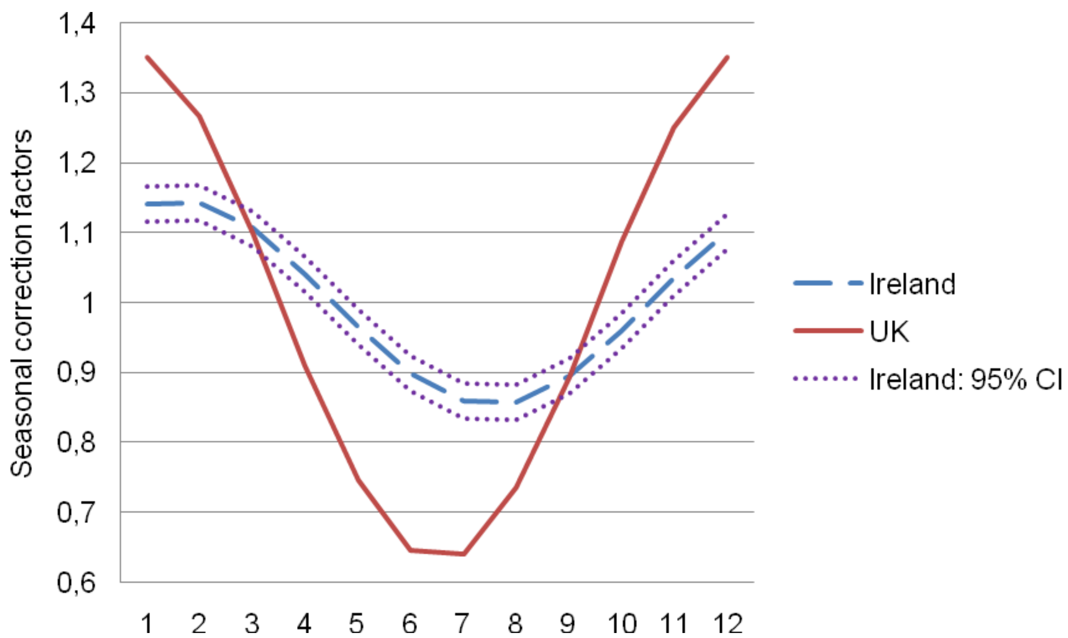

Fig. 1. Comparison of new Irish seasonal correction factors with UK factors for months 1 - 12

3.2. Comparison with seasonal correction factors currently used in Ireland

The seasonal correction factors currently in use in Ireland (RPII 1994) are one month factors based on the Wrixon et al. moving average analysis of UK data. The seasonal correction factor that is presently applied to any three month measurement is the mean of the three individual one month seasonal correction factors for the measurement period. These are given in Table 2 where they are compared with the one month seasonal correction factors that have been calculated in this study using equation (2).

The Irish seasonal correction factors calculated in this study are significantly different from the current factors in ten of the twelve months (Table 2). The two sets of factors associated with measurement months 4 and 10 (April and October) are not found to be significantly different (Figure 2).

Ideally, in order to fully validate the newly calculated seasonal correction factors, we would compare seasonally corrected observations to true annual measurements for each dwelling. Unfortunately, since this was not a designed experiment, we do not have access to both short term and corresponding annual measurements on a house-to-house basis and this validation analysis cannot be done. However, we can provide some evidence to support the robustness of the new Irish seasonal correction factors. In particular, we have examined the year-to-year variation of the factors by analysing data from two three-year subgroups (1999-2001 and 2003-2005) and found that the pattern of the seasonal correction factors remains stable across the years.

To illustrate the application of these factors in practise, an example may be useful for the reader. Consider a January measurement of 130 Bq/m^3. The RPII estimate the total measurement uncertainty to be 27% (Hanley et al 2008). The 95% confidence interval on the measurement is therefore (94.9 Bq/m^3, 165.1 Bq/m^3). The January factor (1.16) with corresponding 95% confidence interval (1.14, 1.20) is then applied to each end of the measurement confidence interval (94.9 Bq/m^3, 165.1 Bq/m^3). This allows us to create a 95% confidence interval for the seasonally adjusted value (108.19 Bq/m^3, 198.12 Bq/m^3).

Table 2. Comparison of new and current seasonal correction factors for Ireland.

Measurement Month	New Irish Factors	New Irish Factors: 95% Confidence Interval	Current Irish Factors
1	1.16*	(1.14, 1.20)	1.35
2	1.16*	(1.14, 1.20)	1.30
3	1.12*	(1.10, 1.16)	1.20
4	1.05	(1.02, 1.08)	1.05
5	0.96*	(0.93, 0.99)	0.90
6	0.89*	(0.85, 0.91)	0.75
7	0.85*	(0.80, 0.86)	0.60
8	0.84*	(0.80, 0.86)	0.65
9	0.88*	(0.85, 0.90)	0.80
10	0.96	(0.92, 0.98)	0.95
11	1.04*	(1.01, 1.07)	1.10
12	1.11*	(1.10, 1.15)	1.20

Note:
Correction factors apply to a one month period
A significant difference between factors is indicated with *

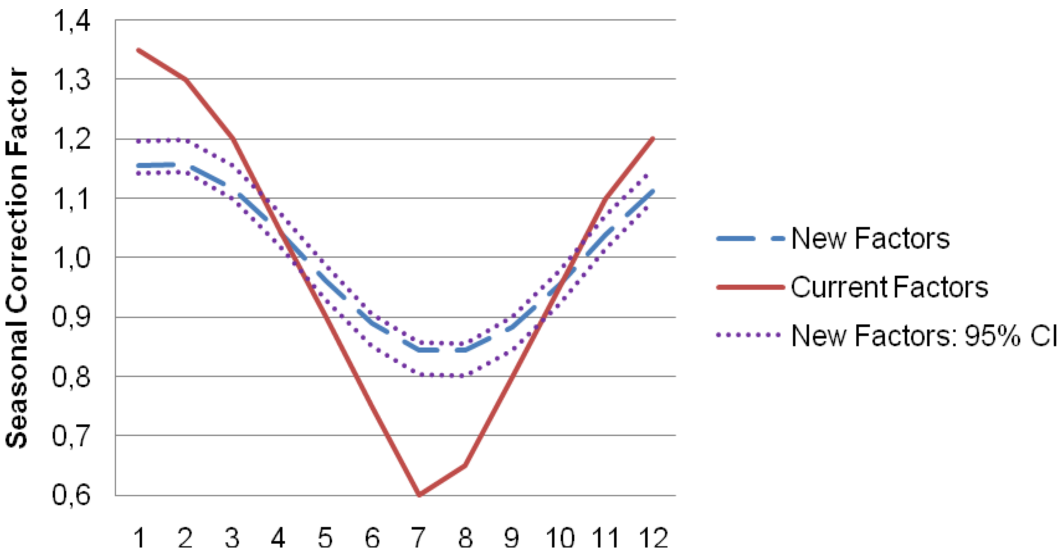

Fig. 2. Comparison of new and current one-month seasonal correction factors for Ireland for months 1 to 12.

Discussion

The "three month" correction factors have been generated from three-month data so ideally, if all measurements were exactly three months duration, these correction factors would be applied to future radon measurements. However, in reality, many measurements exceed three months, making use of "three month" correction factors impractical. In this paper we also have estimated a set of "one month" correction factors. For measurement periods differing from three months, the use of the mean of the individual one month correction factors for the measurement period is more practical and flexible. Use of these factors has shown that there is negligible difference in the correction factor that is applied, whichever set of correction factors are chosen.

Both the "one month" and the "three month" correction factors differ from the equivalent factors derived by Pinel et al. and Wrixon et al. There may be a number of reasons for this observed difference. It has been shown that monthly mean radon concentrations correlate strongly with the monthly mean outdoor temperature during the measurements (Miles 1998). Overall, there are larger extremes of temperature in the UK, most likely due to the climate moderating influence of the Atlantic Ocean on Ireland. This may account for some of the observed differences in seasonal correction factors. As discussed earlier, seasonal variation in indoor radon concentrations may also be affected by other external factors such as local geology, the structure of the dwelling or climate and may vary from year to year. In addition, it may not be appropriate to apply correction factors for measurements of less than three months, to homes of atypical construction or those built on unusual geology. Analysis, to investigate the effects that these external factors may have on the seasonal correction factors derived, is currently ongoing in University College Dublin.

Conclusions

The main aim of this paper was to produce, for the first time, a set of seasonal correction factors for indoor radon levels in Ireland derived from Irish data. Prior to this the factors used in Ireland were based on UK data.

The new set of seasonal correction factors for Ireland is calculated using a Fourier decomposition procedure recommended by Pinel et al. (1995) as an improvement on the Wrixon et al. (1998) procedure. The new seasonal correction factors for Ireland are statistically significantly different from the current factors in use in Ireland and the UK.

As discussed, we are aware that there are other external factors that influence the seasonality of radon emissions. However, the set of factors reported here is that which best summarizes the position for a typical Irish home and their use will provide a better estimate of long-term radon concentrations in Irish homes.

Abstract

A condensation monodisperse aerosol generator has been used in NIRS radon-aerosol chamber; aerosol particles are generated by the evaporation–condensation method and supplied into the chamber through the sampling port. Carnauba wax is used as the aerosol material. This study describs the generation and measurement techniques for radon and its progeny, in order to make available an accurate calibration facility for radon concentration and to allow investigations covering fundamental questions of physics with regard to the behavior of radon and its progeny as a function of the environmental parameters. Furthermore, we try to control the monodisperse aerosol with a differential mobility analyzer.

The study of behaviour of radon and its decay products in the low layer of the troposphere

Burian, Ivo; Otahal, Petr; Merta, Jan
SÚJCHBO, v.v.i., CZECH REPUBLIC

Abstract

Radon and its decay products are often used like tracers of dynamic processes in the atmosphere. They are used to study climatic phenomena and to produce climatic models scores of the time.

The source of radon in the atmosphere is the bedrock. The transport of radon from soil could be characterized by radon flux; UNSCEAR (2000) presents the estimation of the worldwide average of radon flux 0.016 Bq·m^{-2}·s^{-1}. The value of radon flux in one place isn't in the time constant - it is influenced by three fundamental parameters: the concentration of radon in bedrock, the soil moisture and permeability of soil. Methods of determination of radon flux are very sensitive on interpretation of gained results in the dependence on the atmospheric condition for individual measurement.

The concentration of radon and its decay products isn't in the low layers of the atmosphere constant - it is strongly influenced by dynamics of the atmosphere. The main factors which influence the concentration of decay products are dry and wet depositions. Generally it is possible to observe differences between concentrations in the day and in the night and in cold and warm parts of the year. The mean concentration of radon outdoor are about 10 Bq·m^{-3} according to UNSCEAR (2000).

The research in this area was supported by project of SUJ 200402, investigation of a vertical and horizontal distribution of radon and its decay products in the atmosphere was realized among others.

Dose

Only a minority of mankind could be characterized as workers of category A (B) and a negligible number of workers is employed in waterworks and other NORM workplaces; therefore, we take into account the remaining men and women.

It is estimated [1], that the inhalation of radon decay products (RnDP) represents an essential part of human irradiation (dose).

The "radon" influence greatly differs for individual states. Our detectors for radon measurement were applied in Kuwait and the concentrations were many times lower than European results. Values in ships cruising to the South Pole were also one one-hundredth of the values measured in Central Europe.

Not only do thousands of kilometers or miles play a role, an Austrian village Umhausen is split due to different geological structures in two radon levels.

Czech Masiff

A very small country in Central Europe, the Czech Republic – CZ, "suffers" due to an influence of tectonic processes ending 5.10^6 years ago. Many years after (1985) it was organized representative research led to a mean of indoor EER (energy equivalent radon concentration connected with RnDP) of 55 Bq·m^{-3}. It could be transformed to a year's average of radon concentration of 140 Bq·m^{-3}; probably the largest mean in the world.

The method of this estimation was very simple – an application of a solid state nuclear track detector (SSNTD): Kodak LR115 it this wave "bare" without the diffusion chamber. The choice of application in dwellings was governed by electricity consumers list.

The Task

The question:
When values of radon in dwellings are so high in Central Europe, what happens to the concentration outside? The indoor concentration is influenced not only by bad insulation of houses, but mostly by intensive radon flux from the Earth's surface.
(It has been published that radon concentration outdoor in Masiff Central in France is sometimes more than 1000 Bq·m^{-3}!)

Therefore, this is one of the reasons why the Czech State Office for Nuclear Safety (SONS) supported our outdoor measurement (the project SUJ 200402).

For this reason we developed methods for the estimation of instantaneous values of EER ("grab sampling" – called BUHS), pseudocontinuous measurement (TS96), and integral month mean estimation (STANTOM).

The output – distance

The results of measurement were interesting in some cases:

The distribution of instantaneous EER was estimated in heights of 0.3 m to 20 m as homogenous (measurement on a crane, on a view-tower). After the application of SSNTD, the radon concentration is seen as decreasing - see results after SSNTD application in diffusion chambers in heights of up to 40 m.

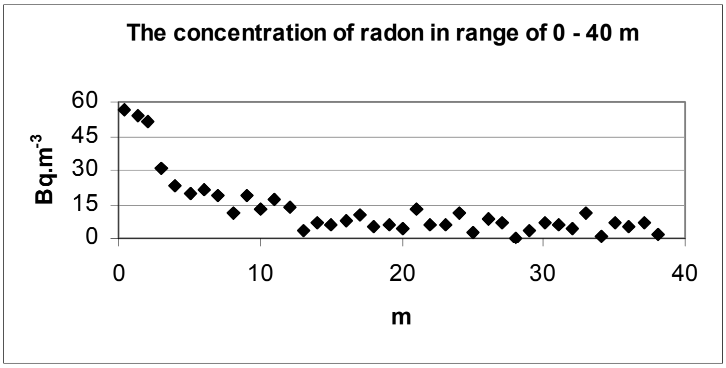

Fig.1. The concentration of radon in range of 0 – 40 m.

The distribution in the dimension of thousands of kilometers does not differ fundamentally – in Braunschweig (western Germany), the morning values were lower to compared to values in our country (the other points), but not dramatically:

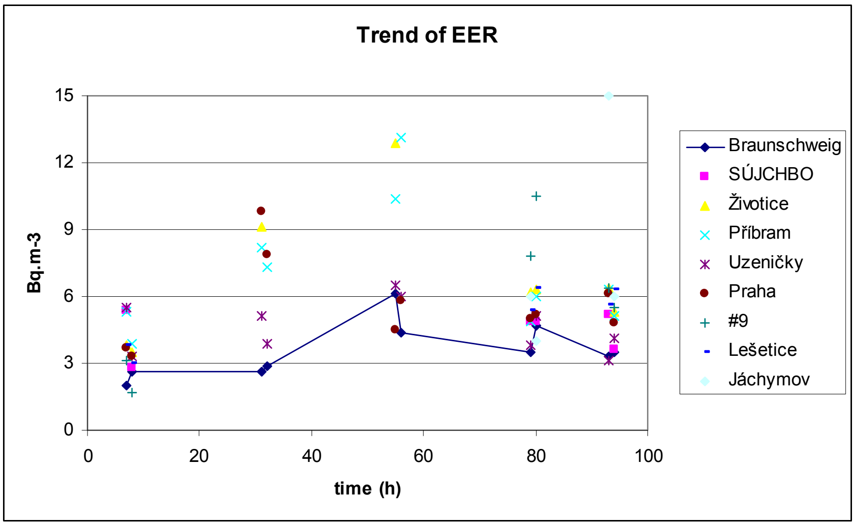

Fig.2. The trend of EER.

We didn't have an opportunity to measure in the Bering strait as our Japanese colleagues, but by chance we measured in Indianopolis (USA), on the coast of Finland and in central Romania. In most cases, the values and tendencies were similar. Of course, in the coastal regions the concentrations were lower due to negligible radon flux from the sea's surface. This hypothesis was supported by a more frequent number of measurements realized by the Dutch, when the influence of wind direction was seen as very important. The North Sea as well as other bodies of water are surely a big anti-source of radon.

We realized measurements around some radon sources or around absent source: old dump tailings originated in the Marie-Sklodowska era and ended up in the 1950s; the largest Czech lake; sludge beds near a reproducing plant. In these cases, no influences of radon sources or their absence were observed. Surprisingly, the mixing of air is probably a prevailing process. There is only one exceptional case – the neighborhood of active uranium mine exhaust, where radon (EER) is higher.

The output – time

Time (which is not always money) plays a role. The daily trend has been published many times. Only in the case of valleys (e.g. in Spain [2]), the tendencies are not typical. In all the cases of our location, there were only two systems observed:

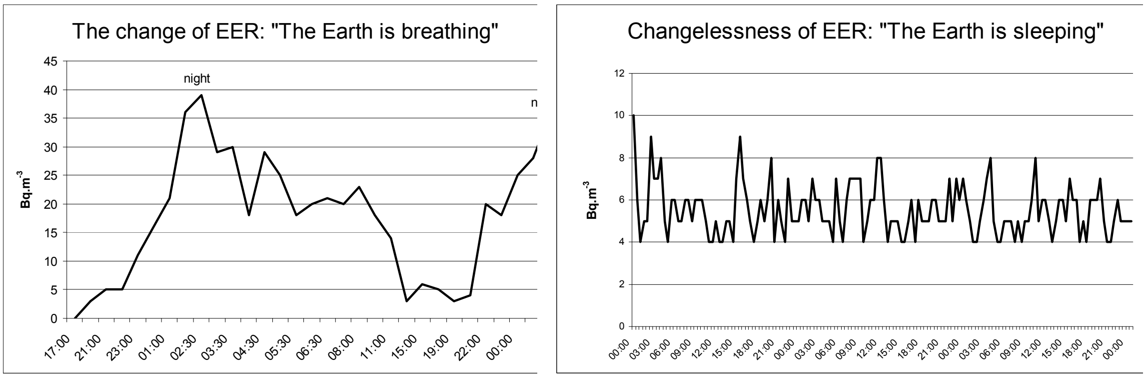

Fig.3 Different behavior of the Earth.

Appendix 1

Other radionuclide concentrations were measured, but the accuracy here is not sufficient for estimations with sufficient uncertainty:

- Concentration of thoron (^{220}Rn) daughter products is less than 0,3 Bq·m^{-3}
- Concentration of long-lived alpha-emitting radionuclides. The mean result published by the State Institute for Radiation Protection – SURO [3] after a huge volume sampling is 0.5 mBq·m^{-3}, and our results are lower - 0,2 mBq·m^{-3}.

Preliminary results of F (ratio of EER and radon concentration) show to values near to 0.3. The ratio of RnDP unattached to aerosol to total RnDP is approximately 0,1.

Appendix 2

There were about 200 000 miners employed in the uranium industry and the registration of their lung cancer incidence and their intake was relatively accurate. This is a reason for including Czech data into metastudies

The described differences between parts of our country also allow us to realise epidemiological studies between inhabitants.

Appendix 3

In 1985 the Organization for Economic Cooperation and Development organized a world-wide comparison to define reference laboratories [4]. As far as we know, more of them do not yet exist (the Australian ARL Yallambie is the only one). One can see again some international intercomparison tendencies. One of them [5] showed us that our measurement could be compared to most results of European laboratories.

Appendix 4 – opinion

Theories exist that radon outdoor is possible to estimated after gamma dose measurement. Our experiences showed us that the correlations between measurable units (gamma dose - radium concentration – radon in soil – radon flux – radon outdoor – EER outdoor) are very weak. These hypotheses were supported by many field measurements.

Appendix 5 – time spent indoors

In our country only 0.03 of inhabitants are involved in agriculture and forestry.

Are there countries around the world where the whole population does not stare at the TV most of evening? After our sociological mini-research, the time spent outdoors in the CZ is 0.07 - lower than the global mean published by ICRP.

The problematic question is the duration of stay in cars and trucks. After commented research, an individual spends 0.05 in vehicles. Of course, due to air-condition, the EER is reduced by factor 2.

Conclusion

It is not surprising, that the intake (and therefore the contribution to dose) for an inhabitant outdoor is not very important.

Taking into account the usual transformation 6 nSv/ ($Bq \cdot h \cdot m^{-3}$) – [6], the dose for inhabitants being indoor is 3 mSv per year and for being outdoors only 0.015 mSv per year. The facts of lower radon concentration of an afternoon were included into the calculation and other sources were not impacted.

Another important fraction of the effective dose is of course the photon irradiation - 1 mSv per year is a rough estimation of this part of the effective dose. We did not see any essential difference between the situation outside and inside buildings.

Abstract

In support of epidemiological studies involving pooling of data for German, French and Czech uranium miner studies, the individual annual doses from the year of first employment to 1999 were required. The annual absorbed doses to regions of the lung, red bone marrow, liver and kidney of each individual miner within the cohorts were calculated. The annual absorbed doses arising from the alpha radiation alone were calculated as well as the absorbed doses arising from the mixture of alpha, beta and gamma radiation. The doses arising from exposure to radon progeny, and to the long-lived radionuclides in the uranium ore dust have been calculated with biokinetic and dosimetric models developed by the International Commission on Radiological Protection. The organ doses arising from the inhalation of radon gas alone have been evaluated using published dose coefficients that were calculated with a specific pharmacokinetic model. The external gamma dose has also been measured and is included in the calculation of the total absorbed dose to specific organs. In this paper the methodology and the parameter values chosen for different exposure scenarios are presented as well as the results of organ dose calculations.

Abstract
This paper presents estimates of doses from external exposure and intake of radionuclides for a cohort of about 20,000 offspring, whose parents were exposed in the early 1950s from discharges of liquid radioactive wastes into the Techa River (Southern Urals, Russia). Bone-seeking ^{90}Sr was the main contributor to the internal haemopoietic tissue doses received *in utero* and during infancy following maternal ingestion of the radionuclide before or during pregnancy and breastfeeding as well as postnatal exposure from direct ingestion. To provide reliable estimates of doses from ^{90}Sr, biokinetic models developed by the International Commission on Radiological Protection in Publications 88 and 95 were specifically adapted to the Techa River populations to describe strontium transfer to the foetus and breast milk. These models were validated by direct measurements of ^{90}Sr in the foetal skeleton, breast milk and maternal skeleton. To refine dosimetric model for the *in utero* and infant periods, a series of hybrid computational phantoms were developed for the 10, 20, and 30-week foetus and a newborn, from computed tomography (CT) and magnetic resonance imaging of preserved foetal specimens of similar gestational ages and a 6-day neonatal female cadaver. MicroCT imaging of autopsy specimens of the newborn skeleton allowed consideration of the 3D microstructure of marrow cavities and bone trabeculae across the newborn skeleton. Features of *in utero* haemopoiesis were considered and taken into account in dose estimates. Doses from postnatal exposure were evaluated with the Techa River Dosimetry System TRDS-2009D, taking account of ingestion of $^{89,90}Sr$ in breast milk and ^{137}Cs intake in cows' milk. Improved assessments of *in utero* and postnatal doses will be used in epidemiological studies to evaluate risks from chronic exposures in early life.

This work has been funded by EC (contract FP6-516478) and the US DoE Office of Health Programs.

Application of the new ICRP reference computational phantoms to internal dosimetry

Abstract

In nuclear medicine, radiopharmaceuticals are incorporated into the body and distributed through biokinetic processes. Thus, each organ can become a source of radiation delivering a fraction of emitted energy in tissues. Therefore, internal radiation dose must be calculated accurately and realistically. Until now, the absorbed doses were derived from standard mathematical phantoms, in which different regions are defined by complex equations. An alternative class of anatomical models called voxel phantoms was then developed to offer realistic geometries of the human anatomy.

In this context, the International Commission on Radiological Protection (ICRP) has chosen to adopt voxel models to represent the reference adult. Consequently, the Specific Absorbed Fractions (SAFs), first step allowing the absorbed dose calculations, has to be re-evaluated for the new ICRP reference phantoms.

SAFs were thus evaluated for monoenergetic photon and electron sources using OEDIPE software and MCNPX Monte-Carlo code. The SAFs values were then validated by a comparison with those obtained by the German Center for Environmental Health (HelmholtzZentrum München) using EGSnrc Monte Carlo code.

The results show a general agreement for photons and high-energy electrons with differences lower than 8% between both laboratories. Nevertheless, significant differences were found for electrons at lower energy.

Given these results, the impact of the new ICRP reference phantoms on the absorbed doses per incorporated activity to patients from radiopharmaceuticals was estimated. Absorbed doses were calculated for the [^{18}F] FDG and [^{99m}Tc] ECD in 25 organs for the new ICRP reference computational phantoms. The dose estimates are overall similar to those of the mathematical phantom except for some particular organs (urinary bladder or uterus) where observed differences can be up to a factor of 2.

Introduction

In nuclear medicine, internal radiation dosimetry specifically deals with the deposition of radiation energy in tissue due to the incorporation of a radionuclide within the body. However, unlike external radiation dose (which can be measured), internal radiation dose must be calculated accurately and realistically either for diagnostic or therapeutic applications.

Until now, the method to calculate absorbed dose was based on the MIRD formalism and standard mathematical phantoms, which different regions are defined by complex equations. Then, through the evolution of computers' power, an alternative class of anatomical models called voxel phantoms was developed. They are based upon three-dimensional images techniques such as magnetic resonance imaging or computed tomography and provide detailed information about human anatomy.

Therefore, the International Commission on Radiological Protection (ICRP) has chosen to adopt voxel models, based on realistic images, to represent the reference adult. Consequently, the different dosimetric parameters must be reevaluated. Prior to the determination of absorbed doses, the Specific Absorbed Fractions (SAFs) need to be calculated for the new ICRP reference phantoms.

In this context, a fruitful collaboration between the French institute of radiological protection and nuclear safety and the German center for environmental health allowed the evaluation and the comparison of the SAFs for monoenergetic photon and electron sources using the Monte-Carlo codes MCNPX and EGSnrc, respectively.

Material and methods

1. The new ICRP reference phantoms

Both dose assessments due to radionuclides and SAF calculations for monoenergetic photons and electrons were performed using the ICRP reference adult male computational phantom (RCP-AM) and reference adult female computational phantom (RCP-AF) (Zankl et al. 2007, ICRP 2009). These models developed by the HelmholtzZentrum München are based on existing voxel phantoms (REX and REGINA) derived from CT tomographic data of real individuals. Each of RCP-AM and RCP-AF has 141 organs and tissues whose dimensions and masses are consistent with the ICRP reference anatomical and physiological parameters of ICRP publication 89 (ICRP 2002).

2. OEDIPE

The software OEDIPE was used in order to perform the calculations. OEDIPE is the French acronym for "tool for personalised internal dose assessment". It was developed at IRSN on the basis of a friendly graphic interface developed using the Interactive Data Language (ITT Visual Information Solutions, USA) (Chiavassa et al. 2005, 2006). The main purpose of this software is to estimate, in case of internal contamination or administration of radiopharmaceuticals, the personalised dose delivered by associating voxel phantoms and the MCNPX Monte-Carlo particle transport calculation code (LANL, USA) (Waters 2002). It can provide either the dose distribution at the organs' level or at the voxel level.

3. SAFs calculation

The RCP-AM and RCP-AF phantoms were integrated in OEDIPE to create automatically the MCNPX input file. Monoenergetic photon and electron sources were uniformly distributed in the source organs. In all the simulations, 5 million histories were generated and 15 energies of emission were chosen ranging from 0.01 to 10 MeV. The transport of secondary particles was taken into account. The tally *F8, energy deposit tally, was used to score absorbed energy in selected target organs. The SAF values were then derived for each source and target region using equation 1:

$$SAF(r_k \leftarrow r_h) = \frac{E_k / E_h}{m} \qquad (1)$$

Where r_h is a source organ, r_k is a target organ, E_k is the energy absorbed in r_k, E_h is the energy emitted from r_h and m is the mass of the target organ.

SAFs for the different source and target organs and for both, photons and electrons, were calculated and compared with those of the HMGU using the EGSnrc Monte Carlo code (Kawrakow and Rogers 2003). A comparison was also made between photon SAFs calculated using the new ICRP voxelized reference phantoms and those previously calculated for the ORNL male and female stylized phantoms. Finally, electron SAFs were compared to the former assumptions used by the ICRP and MIRD committees (Snyder et al. 1978, ICRP 1978). Indeed, for electrons, if the source and target regions are the same, the radiation is assumed to be entirely in the source organ. If the source and target regions are different, the specific absorbed fraction is reduced to 0. And in the particular case of walled organs, it is assumed that the Φ_i is equal to half the mass of the source organ.

4. Dose assessment

As it will be discussed further in the result section, the use of the new ICRP voxelized phantoms had led to differences in the photon and electron SAFs. Thus, it was interesting to study if the same influence could be observed for the dosimetry of radiopharmaceuticals.

When incorporated radionuclides are considered, biokinetic processes cause a distribution of the substance in the body, and, consequently, several organs of the body become source organs.

For a given radionuclide, the absorbed dose D_{rk} to a target region r_k from radiation emitted from a source region r_h is defined by the MIRD Committee (Loevinger et al 1991) and calculated using the following equation:

$$D_{rk} = \sum_h \tilde{A}_h \, S\,(r_k \leftarrow r_h) \qquad (2)$$

Where $\tilde{A}_h$ is the cumulated activity in source region (mCi h or MBq s) and equal to the total number of nuclear transformation in r_h; $S\,(r_k \leftarrow r_h)$ is the S factor which is defined by the following equation:

$$S = \frac{\sum_i k\,(n_i\, E_i\, \phi_i)}{m} \qquad (3)$$

In the MIRD equation 3, the factor k is a proportionality constant (rad g/mCi h MeV or Gy kg/MBq s MeV); n_i= number of particles with energy E_i emitted per nuclear transition; E_i=energy per particle (MeV); ϕ_i= fraction of energy absorbed in the target; **m**=mass of target region (g or kg).

In our present work, the organ absorbed doses were evaluated using OEDIPE software. OEDIPE takes into account the spectra data of several radionuclides derived from the publication 38 of the ICRP. The former assumptions used for electrons were not therefore considered.

Using OEDIPE, the sources of radiations were uniformly distributed in the organs of the voxel phantoms proportionally to the cumulated activity of the radionuclide, published in the publication 106 of the ICRP. An input file is then automatically created and is ready to be run with MCNPX. After the Monte Carlo calculation, the output file is processed by OEDIPE to obtain the absorbed doses per unit activity (mGy/MBq). Knowing the initial activity incorporated, absorbed doses are consequently obtained for 25 selected regions. Effective dose E was calculated from the estimated organ doses and tissue weight-factors, according to the formula set out in CIPR 60.

The absorbed and effective doses were calculated for 2 commonly used radiopharmaceuticals: the [^{18}F] FDG and [^{99m}Tc] ECD according to the following procedure:

For a contamination due to the administration of the [^{18}F] FDG, the activity is distributed in the pre-defined source organs: lungs, heart wall, brain and the liver as described in the publication 106 of the ICRP. The remaining activity is uniformly distributed in the other organs and tissues. Our definition for “Other organs and tissues” excludes the colon contents, the stomach contents, the small intestine contents, the gall bladder contents, the urinary bladder contents, the air inside the body and the skin at top and bottom, in addition to the defined regions.

The same assumption is also done for the [^{99m}Tc] ECD concerning the distribution of radioactivity in the “Other organs and tissues”.

Absorbed and effective doses calculated for the 2 radiopharmaceuticals using voxel phantoms were finally compared to those assessed using the mathematical phantoms.

Results and discussions

1. SAFs calculation

a. Photon SAFs

The source organs chosen are the lungs, the thyroid and the liver. The colon wall, the stomach wall, the liver and the breasts were selected as target organs. Some selected examples are given to illustrate our results.

An overall good agreement was obtained between SAF values assessed by MCNPX and EGSnrc. Figure 1 shows that, for photon sources in the liver, SAFs in the lungs agreed within 4 % between the two Monte Carlo codes. Similar results are obtained for all the sources and targets studied.

The SAF (Lungs ← Liver) values estimated by MCNPX and EGSnrc using voxel phantoms are also compared in figure 1 with those calculated for ORNL phantoms. Figure 1a shows that SAFs calculated in the new reference male computational phantom diverge from those calculated by Cristy and Eckerman (Cristy and Eckerman 1987) for mathematical models. Indeed, for energies below 300 keV, the ratio between the SAFs calculated for voxel and mathematical phantoms can reach 25. For higher energies, this maximum ratio is reduced to 1.5. Over the entire energy range, the results show that SAFs calculated with mathematical models are underestimated, especially at low energies. As it is shown in figure 2b, MCNPX and EGSnrc estimations for the female reference computational phantom are also different from those of the stylized model of Stabin (Stabin et al.1995). The difference can reach a factor of 18.3 at 10 keV and is reduced to 1.2 at 100 keV.

The observed discrepancies are due to the different shapes and distances between the organs of the mathematical and voxel phantoms, whose influence is predominant at low energies. Indeed, the interorgan distances are larger in the mathematical phantoms than in reality, due to the simplified organ shapes of the stylized phantoms that were required owing to the limited computational capacities available at the time when these models have been developed.

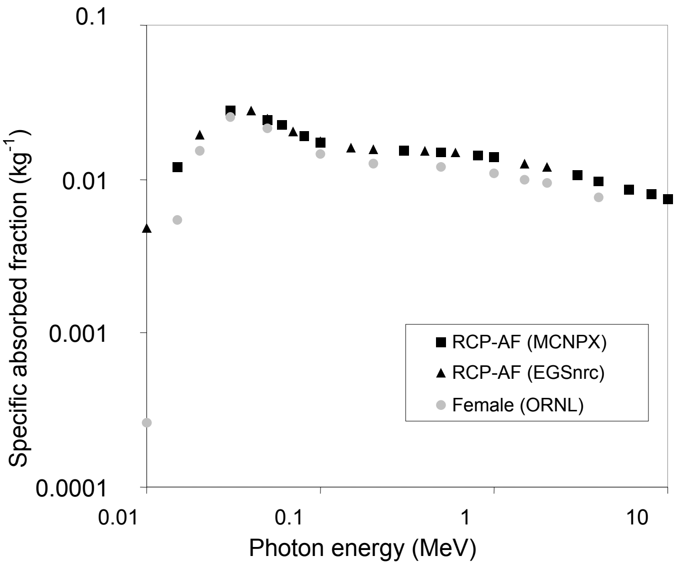
(b)



(

Fig. 1. Photon SAFs (Lungs ←Liver) for the adult (a) male and (b) female voxel (MCNPX / EGSnrc) and stylized (ORNL) phantoms.

b. Electron SAFs

Figure 2 illustrates the comparison of the electron SAFs calculated at HMGU and IRSN for RCP-AM and RCP-AF in the case where the source organ is the lungs and the target is the breasts. A good agreement is obtained for energies higher than 500 keV. Nevertheless, for distant source and target regions, SAFs calculated by the HMGU and IRSN can differ by several orders of magnitude for energy electrons lower than 500 keV. In some cases, variations exceed 100 % at 50 keV and 60 keV. The discrepancies between the SAFs for the low energy electrons are mainly attributed to the different low-energy electron transport algorithms used by EGSnrc and MCNPX due to high Monte-Carlo statistical uncertainties for energies deposited in distant organs.

Even though electrons are considered as weakly penetrating radiation, another simulated result shows that irradiation of adjacent regions cannot be always neglected. Indeed, in figure 2, when former ICRP and MIRD approximations were applied, SAFs (Breasts ← Lungs) were supposed to be equal to 0 over the full energy range. However, Monte Carlo simulation demonstrates that, for energies ranging between 6 MeV and 10 MeV, SAFs would not be negligible in the reference computational phantoms (about 0.02 for the male phantom and 0.034 for the female phantom at 10 MeV).

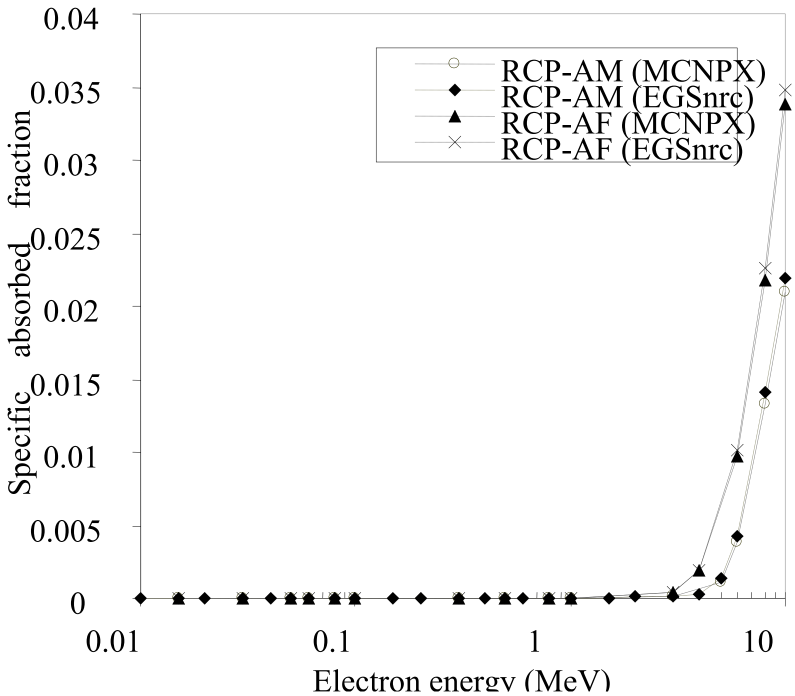


Fig. 2. Electron SAFs (Breasts <- Lungs) for the adult reference computational phantoms. With the former MIRD and ICRP approximation of non-penetrating electrons, this would always be 0.

2. Dose assessment

As an example of the results, figure 3 shows comparative values of some organ-absorbed doses and effective dose for the adult computational and mathematical reference phantoms for the [^{18}F] FDG radiopharmaceutical. Absorbed doses evaluated using the new ICRP reference phantoms were quite similar to those calculated in the ICRP 106 using mathematical models. Nonetheless differences were noticed for some particular organs. Indeed, the dose absorbed by the bladder of the mathematical phantom is higher by a factor 2.4 to the dose calculated for the male voxel phantom and by a factor 2.3 to the one evaluated for the female voxel phantom.

The same observation is valid for the absorbed doses due to the incorporation of [^{99m}Tc] ECD. In fact, the dose absorbed the urinary bladder shows significant differences by a factor 2 between the absorbed doses calculated for the mathematical models and those calculated for the adult computational phantoms.

The discrepancies observed in the absorbed dose values are mainly due to differences in the geometry and organ distances between the mathematical and the voxel phantoms and to the approximations previously used by the MIRD committee.

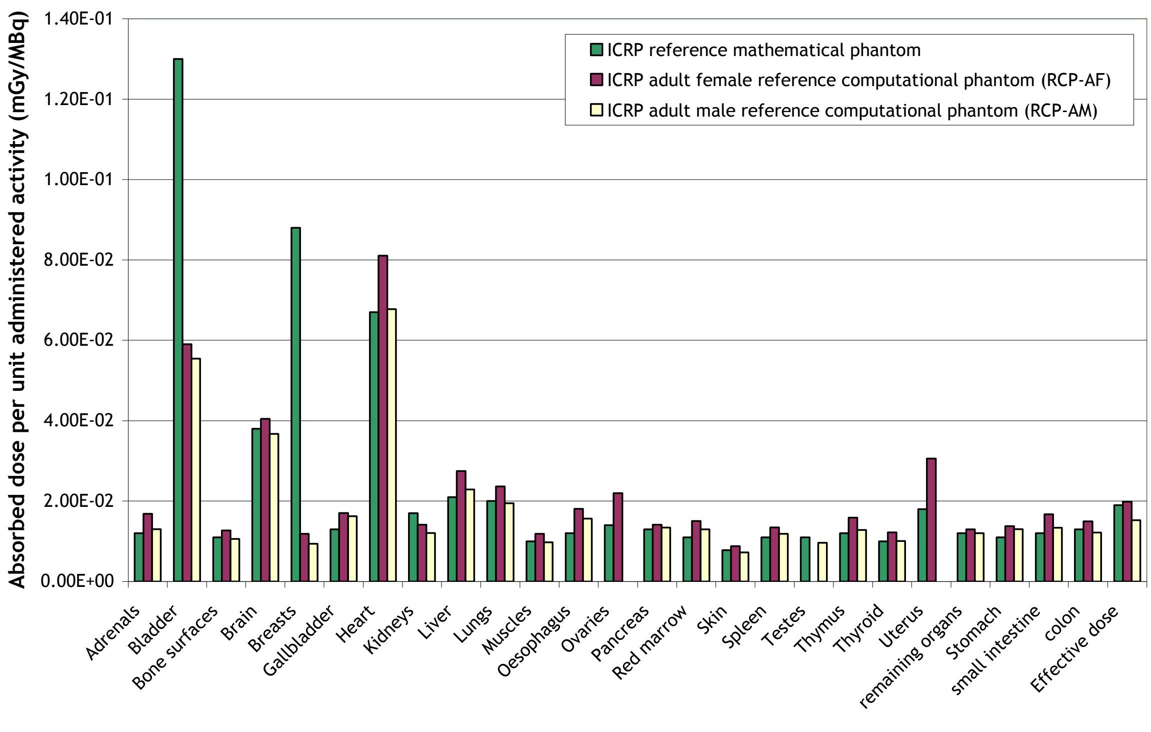

Fig. 3. Organ-absorbed doses per unit activity administered for [^{18}F] FDG.

Conclusions

The aim of this study was to show the effect of the new reference computational phantom recently adopted by the ICRP in internal dosimetry. First, a comparison between photon and electron SAF values calculated at the HMGU and IRSN was achieved for the male and female reference voxel phantoms with two different Monte-Carlo codes (EGSnrc and MCNPX respectively). Photon and high energy electron SAFs evaluated for many source-target organ pairs agree well between the 2 institutes. However, larger differences are noticed for low energy electrons (<500 keV) due to different physical models and algorithms used in the Monte Carlo codes. Furthermore, absorbed doses per unit administered activity were calculated for both [^{18}F] FDG and [^{99m}Tc] ECD in 24 defined organs and the remaining ones for the new ICRP reference computational phantoms. The dose estimates are overall similar to those of the mathematical phantom. However, differences are found between doses absorbed in particular organs. Indeed, for the urinary bladder, the absorbed doses published in the ICRP publication 106 are almost 2 times higher than the dose evaluated for the voxelized phantoms. Differences are also noticed for the uterus where the absorbed dose calculated using the computational phantom is 70 % higher than the dose calculated using mathematical models. The reasons of such discrepancies may be due to the different geometries of the organs in the 2 phantoms and to the approximations used in the past for mathematical phantoms. Careful investigations will help to explain the observed discrepancy.

The guidelines for internal dose assessment after “malevolent use” incidents presented in TMT Handbook

Etherington, George
Health Protection Agency, CRCE, UNITED KINGDOM

Abstract

The main objectives of internal contamination monitoring after a malevolent use incident are to quantify absorbed doses to organs for people who may be subject to deterministic health effects because of very high exposures, and to quantify committed effective doses for people with lower levels of internal contamination. Rapid assessments of monitoring measurements are likely to be needed for two reasons. First, urgent decisions on follow-up actions may have to be taken (e.g. on therapeutic treatment of life-threatening radiation exposures, or on the need for more accurate monitoring to allow decisions on decorporation measures to be made). Second, assessments of internal dose may be needed to support treatment and decorporation measures and to provide information to individuals and others on potential effects on health. The simple action level scheme proposed in TMT Handbook (published in 2009) is described. The action levels are related to dose, but are expressed in terms of measured quantities so that direct comparison with monitoring results can be made, allowing rapid decisions to be made on follow-up actions. The use of the simple “look-up” tables provided in TMT Handbook for quantitative assessment of internal doses is also described These tables allow the direct determination from monitoring measurements of both committed effective dose and absorbed doses to lungs, red bone marrow and the colon. The biokinetic and dosimetric model parameter values assumed for the calculations of the data contained in these tables are discussed. Dose assessment look-up tables are a potentially useful resource, particularly during the early stages of the response to an incident, but users should be aware of their limitations. The potential uncertainties in assessed dose arising from the use of default values for model parameters such as inhaled particle size, absorption type and gastro-intestinal uptake factor are discussed.

Improving ingestion dose modelling for the ARGOS and RODOS decision support systems: A Nordic Initiative

Abstract

A Nordic work group under the NKS-B activity PARDNOR has revised the input parameters in the ECOSYS model that is incorporated for ingestion dose modelling in the ARGOS and RODOS decision support systems. The new parameterisation takes into account recent measurement data, and targets the model for use in Nordic preparedness. The importance of some of the revisions is illustrated.

Introduction

Most European countries have integrated either the ARGOS or the RODOS decision support system in their preparedness against nuclear accidents. The ingestion dose module in both of these two systems is based on the ECOSYS model, which was developed shortly after the Chernobyl accident. ECOSYS default parameters (see, e.g., Müller & Pröhl, 1993) are generally applied in dose calculations without much consideration of their applicability and representativeness for the particular case. However, the default values reflect southern Bavarian conditions with respect to for instance dietary habits, food import patterns, farm animal feeding regimes and crop growth seasons, and are far from representative of for instance Nordic conditions. Another problem with the ECOSYS default data is that much of the generic data describing the processes of mobility of contaminants is rather old, and does not reflect the current state of knowledge, e.g., following the host of post-Chernobyl investigations. This affects the quality of parameters such as deposition velocities for different types of particles, leaching rates, fixation rates, desorption rates, resuspension enrichment factors, natural weathering rates, transfer factors and biological half-lives for farm animals. It is also problematic that crop transfer factors have so far not been linked to a soil classification. Many of these shortcomings may greatly impinge on ingestion doses, and the parameters have therefore been revised by a Nordic work group under the NKS-B activity PARDNOR. This paper gives examples demonstrating the importance of both generic and location-specific parameter changes.

Methods and results

The text below gives a few examples of the work that was carried out to improve the quality of some generic parameters used in the ECOSYS model, as well as to accommodate specific Nordic values for location (country or region) specific parameters.

Dietary habits

Dietary habits can vary widely between countries, depending on, e.g., the climate and local tradition. For inclusion in the ECOSYS model (and thereby in ARGOS and RODOS) it is essential to obtain recent location-specific data for the consumption pattern, so that proper estimates can be made of the doses received by a local population in the event of an incident leading to contamination in food production systems. A survey was first made in all the Nordic countries to assess which data would be available for different age groups on the dietary composition. In-line with the outcome of this and to address as wide a range of discrete age groups as possible, thereby also complying with the methodology used in the ECOSYS model, it was decided to consistently focus on four age groups: infants and young children 1-4 y, teenagers <15 y, young adults (ca. 30 y), and more senior adults (ca. 60 y). For all countries, except for the Faroe Islands, fairly recent survey data are available for such age groups. For some countries separate data for each of the two genders are available. In some cases gender deviations of some significance have been noted, but such differences are not readily accommodated in the framework of the ECOSYS system.

Figure 1 shows a comparison of the consumption of wheat and rye flour in the different Nordic countries. Here it is seen that a typical Danish adult consumes about 3.3 times as much rye flour as does the typical Norwegian adult. Such traditional differences in diet are important to take into account in optimising efforts to reduce doses after a contaminating incident. However, as this relationship is 4.3 for the senior adults, but only 2.9 for teenagers, this particular difference between Norwegian and Danish diets seems to be declining, stressing the need for recent dietary data for the modelling. Fairly recent dietary data is available for most Nordic countries. The exception is the Faroe Islands, where the latest, and not very detailed dietary survey was conducted in 1981-82. Anyway, in the Faroe Islands and Iceland, these grain products are imported from abroad. It is also seen from Figure 1 that due to differences in climate, in the northernmost countries (Norway and Finland), practically all wheat used for consumption by humans is spring wheat, whereas in Denmark, Sweden and Germany, the majority of the wheat produced/consumed is winter wheat. This means that if a contamination occurs in the spring, the wheat plants will in Finland and

Norway have undergone very little development, whereas in the more southern countries, where sowing took place already in the previous autumn, and the warmer weather would lead to a more rapid plant development, the wheat plants could be quite mature, and receive a comparatively considerably larger contaminant deposition. This would greatly affect wheat flour contamination levels in the first year harvest.

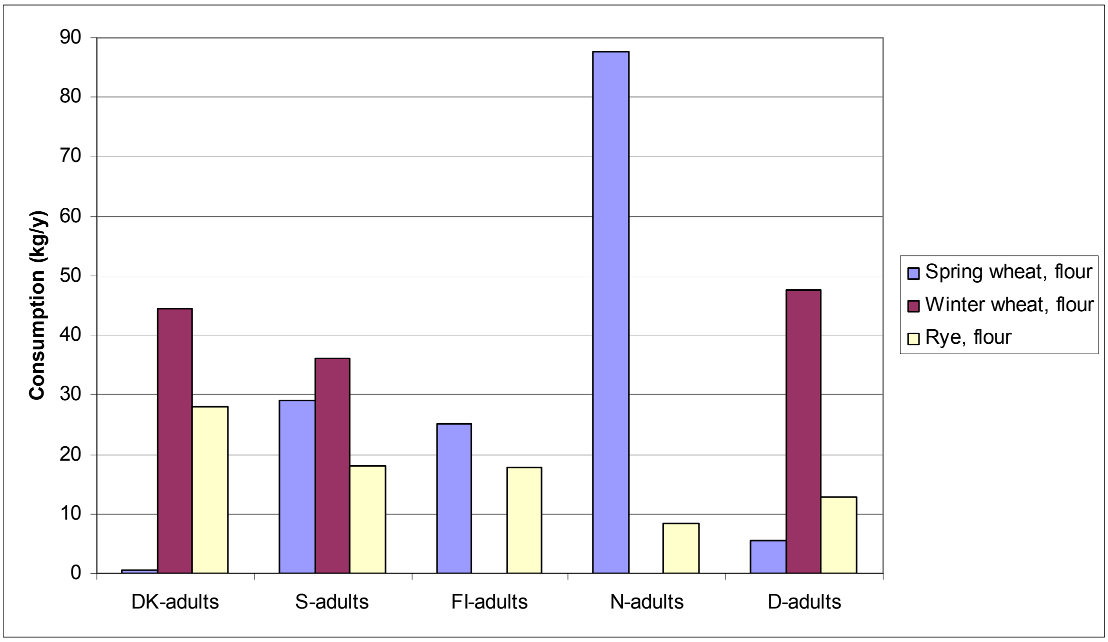

Fig. 1. Consumption of wheat and rye flour in the Nordic countries, compared with the German ECOSYS defaults (average figures for adults - ca. 30 y). DK=Denmark; S=Sweden; FI=Finland; N=Norway; D=German defaults.

Figure 2 shows a comparison of the consumption of potatoes, leafy vegetables and root vegetables in these countries. Also here there are great differences, as it would seem that the average Faroese adult consumes about 3 times as large amounts of potatoes as the average Icelander. Since the best available Faroese data is rather old (for these particular products from an estimate made in 1962), this difference should be considered with some caution. However, a new, unpublished rough estimate of the average for all age groups would be of the order of 70 kg per year (Bjarnason, 2007), indicating that this consumption is still comparatively very high. It is also seen that Danes consume relatively large amounts of root vegetables (particularly compared with Swedes), whereas Swedes and Germans seem to consume much larger quantities of leafy vegetables than do the inhabitants of the other considered countries. It should of course here be noted that consumption of directly contaminated leafy vegetables can give very high early phase doses.

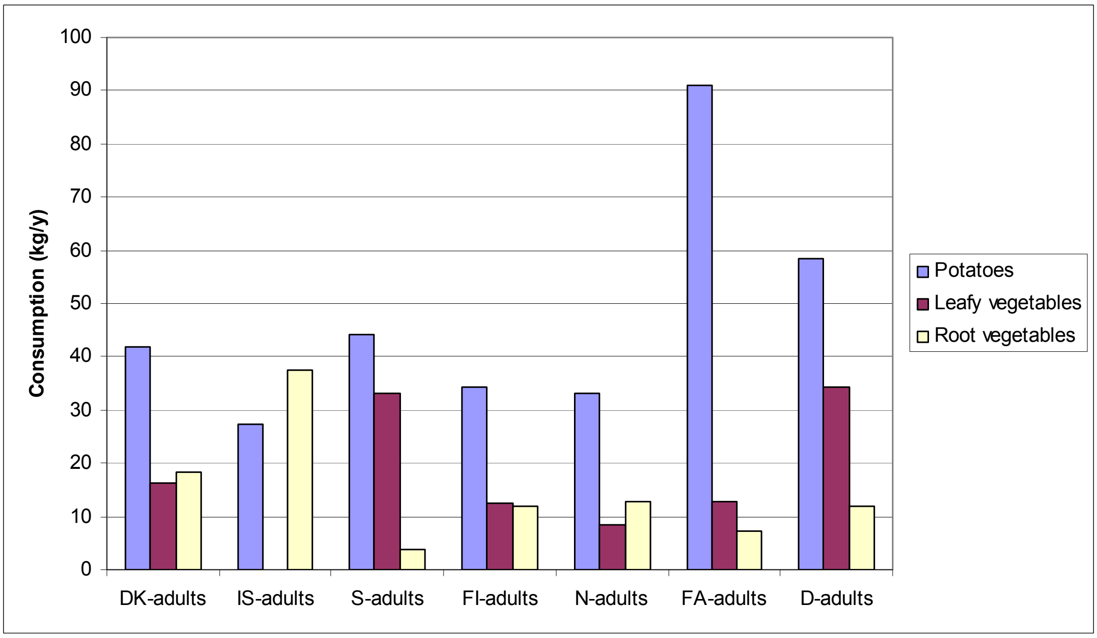

Fig. 2. Consumption of potatoes, leafy vegetables and root vegetables in the Nordic countries, compared with the German ECOSYS defaults (average figures for adults - ca. 30 y). DK=Denmark; IS=Iceland; S=Sweden; FI=Finland; N=Norway; FA= Faeroe Islands; D=German defaults.

Leaf area index

The leaf area index (LAI) is the factor in ECOSYS which determines the state of growth of all vegetation. This can have great bearing on the deposition (dry and wet) to crops, and thus also greatly influence ingestion dose in general. Since LAI depends strongly on the climate (soil temperature variation), it is essential to identify LAI data that adequately represent the location to be modelled. For instance, the Danish Institute of Agricultural Sciences has, based on large amounts of measurement data, developed a simple empirical model / data set describing the seasonal variation of LAI for a number of different crops (Plauborg & Olesen, 1991; Olesen, 2006). The key variables are here the sowing time, soil temperature and harvest time. Values are given for normal and low fertilisation status. The model may thus be applied for different climates, and should be applicable also for other Nordic conditions, where the variation over the year in soil temperature is known. An example of a temperature sum and LAI data set is given in Table 1 for spring barley, with normal fertilisation level. TSum represents a summation over days multiplied by the average daily values of temperature (degree days). Based on the time-variation of TSum at a given location, a date can be associated with each TSum in the table below.

To test the general validity of the model for description of LAI development in Nordic areas, an annual soil temperature variation measurement dataset was obtained from the Swedish University of Agricultural Sciences in Uppsala (SLU, 2008; Kyllmar & Johnsson, 2006). Compared with a Danish data set for the location Herfølge, the Swedish temperatures are over the entire year some 1-5 °C lower. The results of applying the soil temperature data from Uppsala in the Danish model for barley can be compared with measured values of LAI for barley in Uppsala, at two different times of the year: the 18th of June and the 13th of July, 1995 (Thorgeirsson & Søgaard, 1999). Fig, 3 shows the development of LAI over a season, modelled on the background of the Danish dataset and the soil temperature data reported for Uppsala, assuming respectively normal and low fertilisation status. As can be seen, the model curves are in good agreement with the measured LAI data for the Uppsala location (denoted by the triangles in Fig.3), indicating that the Danish model dataset may also be applied for other localities with (slightly) different climates. However, it should be noted that in the northernmost areas of the Nordic countries, crop sort varieties are sometimes specially selected to give rapid development, to make the most of the short growing season. Data for the soil temperature development over the year were compiled for localities in all Nordic countries.

Table 1. Relationship for spring barley at normal fertilisation level between TSum and LAI-total, according to the Danish empirical model.

	TSum	LAI-total
Sowing time	0	0
	110	0
	210	0.41
	310	1.16
	410	2.53
	509	5
	1180	5
	1590	2
After harvest	0	0.3

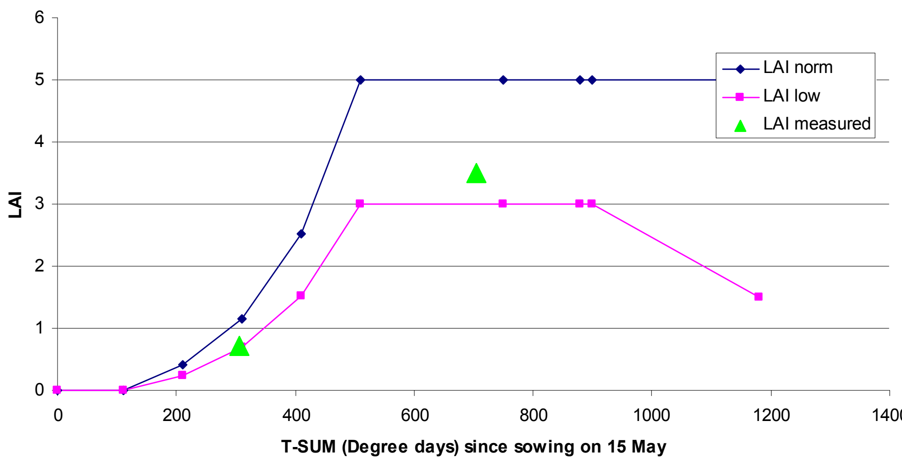

Fig.3. Seasonal variation in LAI for barley at Uppsala, Sweden. Model curves compared with two measured data points.

Fixation rates

In ECOSYS, fixation rate is a generic parameter governing the loss of bioavailability of the contaminants due to strong attachment of radionuclides particularly to clay minerals. Fixation half-lives are generally (with the exception of caesium and strontium) set to very high values (mostly 1000 years), to reflect the low tendency of fixation in soil of most radionuclides considered in ECOSYS. This seems reasonable, and dose estimates over 50 years (the longest period over which accumulated ingestion dose can be estimated in the excel version of ECOSYS) would not be affected much by refining these parameter estimates. Specifically for caesium, the selective fixation in clay minerals gives a much shorter fixation half-life. Here, the ECOSYS default value is 8.7 years. Like other ECOSYS parameters, this is based on old assessments, not adequately taking into account the many assessments made after the Chernobyl accident, in which the physicochemical forms of the contaminants are representative of those that can be expected in connection with a future large nuclear power plant accident.

Applying a modified version of the sequential extraction technique described by Tessier et al. (1979), it was suggested by Oughton et al. (1990) that the 'strongly fixed' fraction of a contaminant in soil could be defined as the part of the contamination that can not be extracted with the most inert solutions, but requires addition of strong acid to go into solution. Such modified Tessier extractions have also been applied by other workers, and it has become a standard technique for sequential extractions to assess the mobility in soil and sediments of contaminants like ^{137}Cs and ^{90}Sr. If it is assumed that the mobile (easily extractable) fraction decreases exponentially over time, sequential extractions carried out by various workers at different times after the contamination from the Chernobyl accident took place (e.g., Salbu et al., 1994; Andersson & Roed, 1994; Bunzl et al., 1997; Shand et al., 1994) on soil samples from Nordic, Ukrainian, Russian and other European areas with different characteristics, suggest that radiocaesium fixation half-lives would typically range between about 1.3 and 2.7 years for most soils with significant mineral phases, and some 4-5 years for very sandy or organic soils.

Consider an ECOSYS example scenario, where dry deposition of ^{137}Cs occurs on the 1st of January, and diets, import fractions and feeding regimes reflect Danish conditions, whereas the rest of the parameters are ECOSYS defaults. If the fixation half-life for caesium is here changed from 8.7 years to 2 years, ECOSYS would estimate the influence on ingestion dose components as shown in Table 2.

Table 2. Percentage change in ingestion dose contributions to adults integrated over resp. 2 and 50 years, by setting the ^{137}Cs fixation half-life to 2 years (scenario described above).

	Winter wheat flour	Fruits	Cow's milk	Beef (cow)	Total
2 years	18.5 %	23.7 %	0.5 %	0.5 %	0.5 %
50 years	67.6 %	69.9 %	7.7 %	8.0 %	9.5 %

The figures in Table 2 show that particularly some of the long term dose contribution estimates could be rather far off if a fixation half-life value of 8.7 years is used for a mineral soil.

The data for sequential extractions of strontium is sparser, but investigations by Oughton et al. (1990), Oughton et al. (1992) and Salbu et al. (1994) suggest a fixation half-life of respectively 20 years, 11 years and 23 years for soils with mineral content. This is in good agreement with the default fixation half-life of 20 years applied in the ECOSYS model.

Conclusions

A review of the ECOSYS model and its default parameters identified a number of points where elaboration is deemed necessary before ECOSYS should be applied for Nordic emergency decision support. For each of the Nordic countries, a dataset has been established describing the typical diets for four different age groups, ranging from young children to senior adults. Large dietary differences were found (also due to different food production conditions in the different Nordic countries), which could influence ECOSYS consumption dose estimates considerably. The applicability of a simple Danish empirical model for calculation of leaf area index as a function of soil temperature was positively tested for use for Swedish conditions (Uppsala soil temperatures) by comparison with a few reported measurements of leaf area index and corresponding soil temperature sums. Representative soil temperature sum values were collected for different locations in the Nordic countries, which could be applied to improve ECOSYS leaf area index parameterisation. The ECOSYS default value of the rate of radiocaesium fixation in soil was compared with a new estimate, taking into account more recent experimental data. The difference in this value could have considerable influence on long term consumption dose estimates. Also a large number of other ECOSYS input parameters have been examined, and improvements and targeting of these for Nordic conditions have been suggested by the same Nordic work group (see, e.g., Hansen et al., 2010)

Abstract

The introduction of new technologies in radiation therapy aimed at improving the dose distribution to the tumour volume, calls for the development of innovative devices able to assure the quality of radiation beams and in-vivo real time dosimetry measurements.

This work describes the use of a novel glass composite fibre dosimeter for the characterization of different types of radiotherapy beams. The dosimeter is based on the radioluminescence emission of a small portion of SiO_2 fibre doped with cerium prepared by means of the sol gel and powder in tube techniques. The doped portion is connected by fusion splicing to a commercial optical fibre which is optically coupled to a photomultiplier tube operating in photon counting mode. The signal is processed by a circuitry and software properly designed. In order to subtract the Cerenkov contribution to the signal response a double optical fibre geometry is adopted.

The system was tested by using conventional radiotherapy photon and electron beams, as well as stereotactic fields generated by a 6 MV linear accelerator equipped with cone stereotactic collimators. Characterisation measurements were also performed using 138 MeV proton pencil beams at the Center for Proton Therapy of the Paul Scherrer Institute (PSI), using the discrete spot scanning technique.

The system showed interesting dosimetric properties in terms of sensitivity, reproducibility, linearity, energy and angular dependence. Moreover, the small dimension of the fibre and the possibility to perform real time measurements of the dose rate, proved to be particularly useful for a reliable evaluation of the output factors of small stereotactic fields and for resolving different scanning sequences of proton pencil beams.

Introduction

The development of new technologies for external radiation therapy has been impressively fast during the last few years. Intensity Modulated Radiation Therapy (IMRT) has become the standard methodology in many countries; the number of tomotherapy machines operating thought the world is continuously increasing as well as the centres and facilities dedicated to hadrontherapy. In fact, the introduction of novel concepts for radiation beam delivery can lead to an improvement of the treatment outcome by means of a dose distribution which more strictly conforms the tumour volume.

These progresses call for a corresponding improvement of instruments and methodologies employed for the maintenance of a satisfactory quality assurance system. Furthermore, the possibility to perform prompt checks of the delivered dose through in-vivo dosimetry measurements become more and more important when treatments involving dose escalation to target volume are planned.

This work reviews the characteristics of a novel radioluminescent (RL) dosimeter based on a glass composite optical fibre. The system was tested with photon and electron beams used in conventional radiotherapy, as well as with small stereotactic fields. The luminescent and dosimetric properties of the fibre were investigated also with proton beams through an active scanning irradiation regime.

The small dimensions, together with the possibility to perform real-time measurements of the dose, make the system an useful tool for assuring the quality of different types of radiation beams and for in-vivo dosimetry measurements.

Material and methods

The dosimetric system

The core of the dosimetric system consists in a portion of silica optical fibre doped with cerium, obtained by combining the sol-gel and powder in tube techniques. The synthesis procedure, developed at the Department of Materials Science of the University of Milano Bicocca and explained in detail elsewhere (Chiodini et al. 2003; Vedda et al. 2004), is here briefly summarised.

The sol solution was obtained with Tetraethoxysilane (TEOS) and Ce (III) nitrate as precursors in a solution of water and ethanol. The sol was placed in a thermostatic chamber at a temperature of 40 °C to activate the sol–gel transition. Xerogel powder was obtained by rapid drying in rotating evaporator and by further grinding in agate mortar to improve the grain size uniformity. Slow sintering up to 1100 °C in a quartz chamber gave the final glass powder, which was then treated in vacuum at higher temperature (1500–1600 °C) for some minutes in order to improve the rare-earth scintillation efficiency and eventually remove the OH content excess. The glass powder was finally introduced in a vacuum-sealed quartz tube (10^{-4}-10^{-5} mbar) and heated in a furnace at 2100 °C, applying a proper pulling speed to obtain the portion of doped fibre of the required diameter (range: 100- 200 μm). This portion was connected by fusion splicing (Starlite S.r.l, Italy) with a commercial optical fibre, which was optically coupled (Fraen Corporation S.r.l., Italy) to a photomultiplier tube (PMT) (Hamamatsu, R7400 P) operating in photon counting mode. The signal was processed by an acquisition unit properly designed (EL.SE S.r.l., Italy), mounting a secondary PMT for the subtraction of the Cerenkov light produced in an undoped fibre stretched parallel to the doped one. A picture of a prototype of the acquisition unit with the fibre sensor is shown in Fig. 1.

Fig. 1. Picture of a prototype of the acquisition unit (ELSE S.r.l., Italy) with the RL fibre.

The characterisation tests

Detailed descriptions of the set up and measurements performed to characterise the dosimetric system under different irradiation conditions has been reported elsewhere (Mones et al. 2006 and 2008; Veronese et al. 2010). Briefly, all the tests performed with radiotherapy photon and electron beams where performed at the Radiotherapy Department of the Hospital of Novara (Italy), using two medical linear accelerators: a Clinac 2100 CD and a DBX (Varian, USA) equipped with cone stereotactic collimators. The main properties investigated with these machines were:

- reproducibility and stability of the RL signal,
- dose response,
- dose-rate dependence,
- energy dependence,
- angular dependence,

Moreover, depth-dose profiles (PDDs), transverse profiles (TPs) and output factors (OFs) measurements of small beams were performed.

Irradiations with proton beams were carried out at the Center for Proton Therapy of the Paul Scherrer Institute (PSI), using a scanned proton pencil beam. Basic properties like reproducibility and dose response were tested also with protons; afterwards, the measurements were focussed on the capability of the system to resolve different scanning sequences and to measure the PDD of a mono-energetic proton beam.

Results and discussion

Fig. 2 shows typical RL signals versus irradiation time, and their reproducibility under the same experimental conditions. Typically, a reproducibility better than 1% can be obtained. The height of each curve (expressed in counts per seconds, cps) is proportional to the dose rate; the integrated area (corresponding to the total counts registered during the irradiation) is proportional to the dose. Consequently, the intensity of the RL signal increases with increasing the dose rate, as shown in Fig 3, but, for a fixed dose, the total counts remain almost constant, indicating that the dosimeter enables a reliable evaluation of the absorbed dose, independently of the dose rate used.

A linear increase of the total counts with increasing dose was observed, independently of the type and energy of the radiation beam. An example of dose-response curve is given in Fig 4. Moreover, the detector proved to be particularly suitable for the measure of PDDs and TPs, as shown in Fig. 5 and 6 respectively. In particular, the small dimensions of the doped fibre enable the correct assessment of the OF of small fields, like those employed in stereotactic radiosurgery. Fig. 7 shows the OF of circular fields measured with the doped fibre, compared to the results obtained using a micro-ionization chamber (Exradin A16, collecting volume 0.007 cm3*)*. A satisfactory agreement between the two sets of data was obtained, with a maximum discrepancy of the order of 1% in correspondence of the smallest field of 12.5 mm diameter.

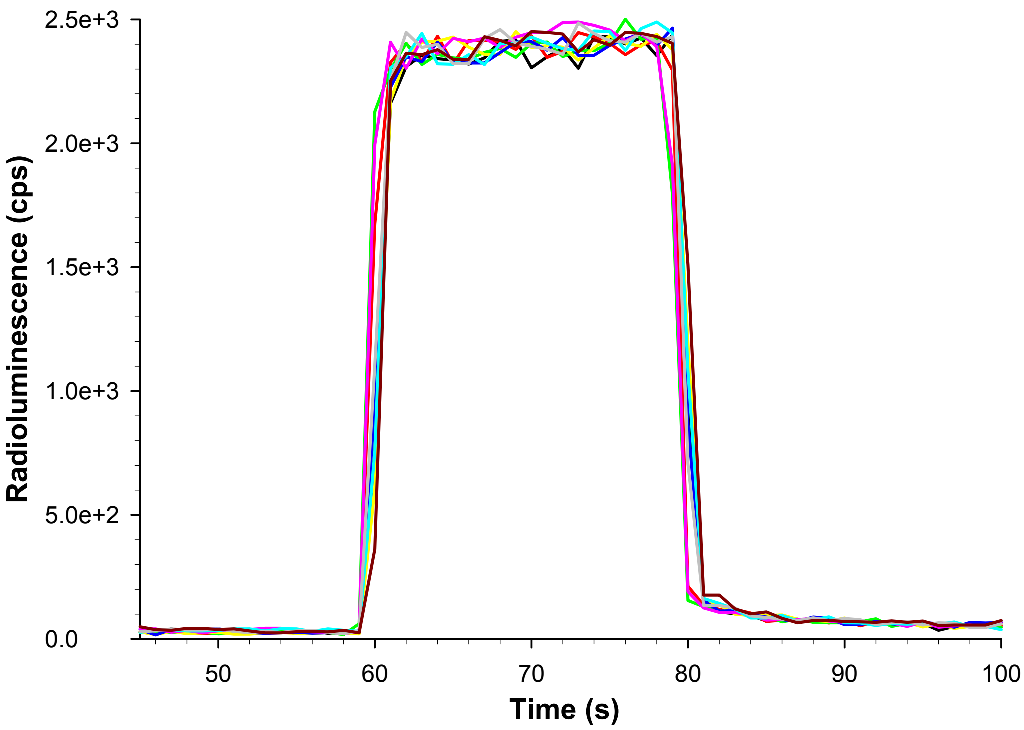

Fig. 2. Series of RL signals versus irradiation time measured with the doped fibre irradiated with 6 MV photon beams.

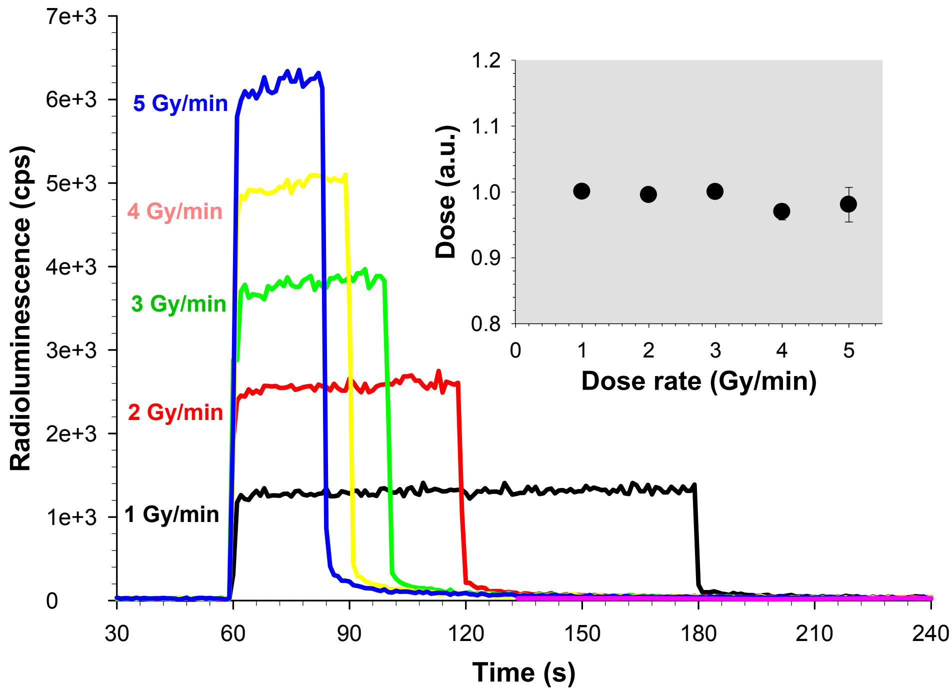

Fig. 3. RL signals versus irradiation time measured with the doped fibre irradiated with 6 MV photon beams, using different dose rates. The integrated areas proved to be independent of the dose rate as shown in the inset, where the measured dose is plotted versus the corresponding dose rate.

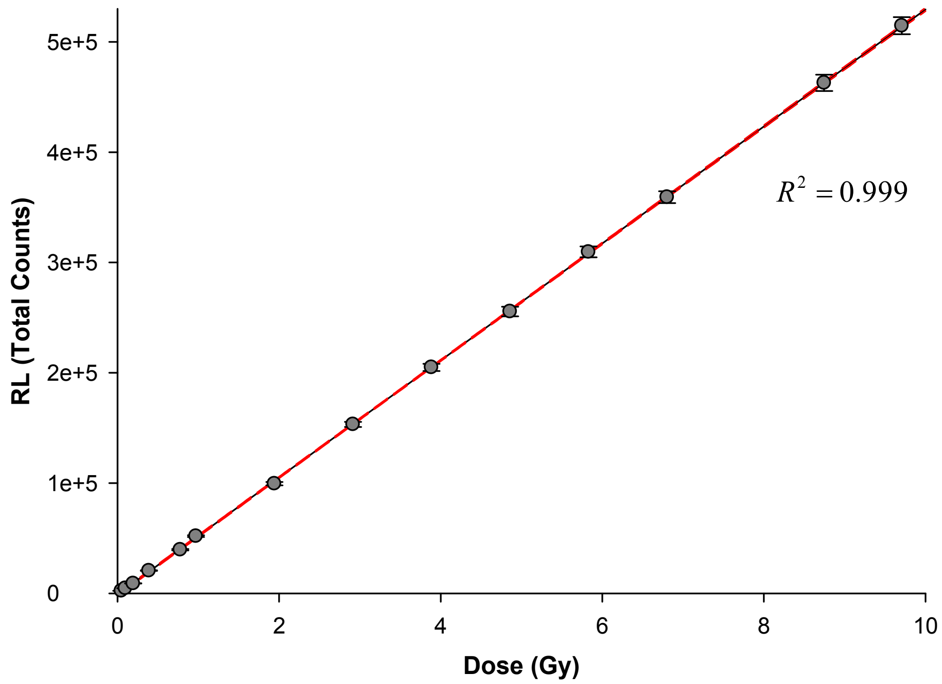

Fig. 4. Example of linear dose response of the fibre dosimeter.

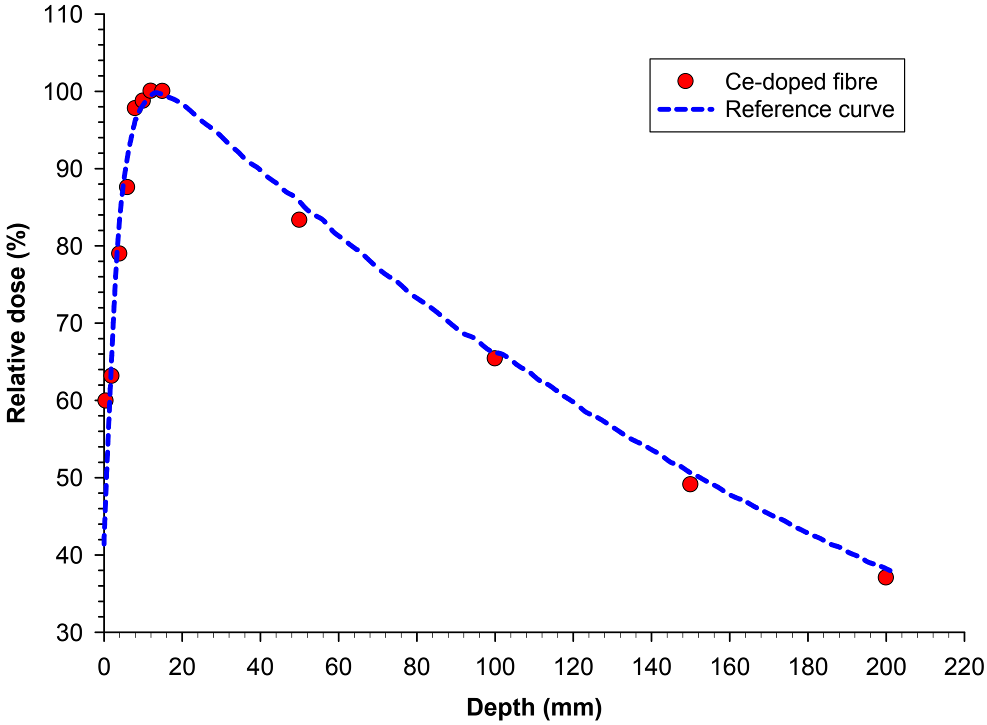

Fig. 5. Depth dose profile of a 6 MV photon beam in water measured with the doped fibre and compared with the reference curve obtained with a diode.

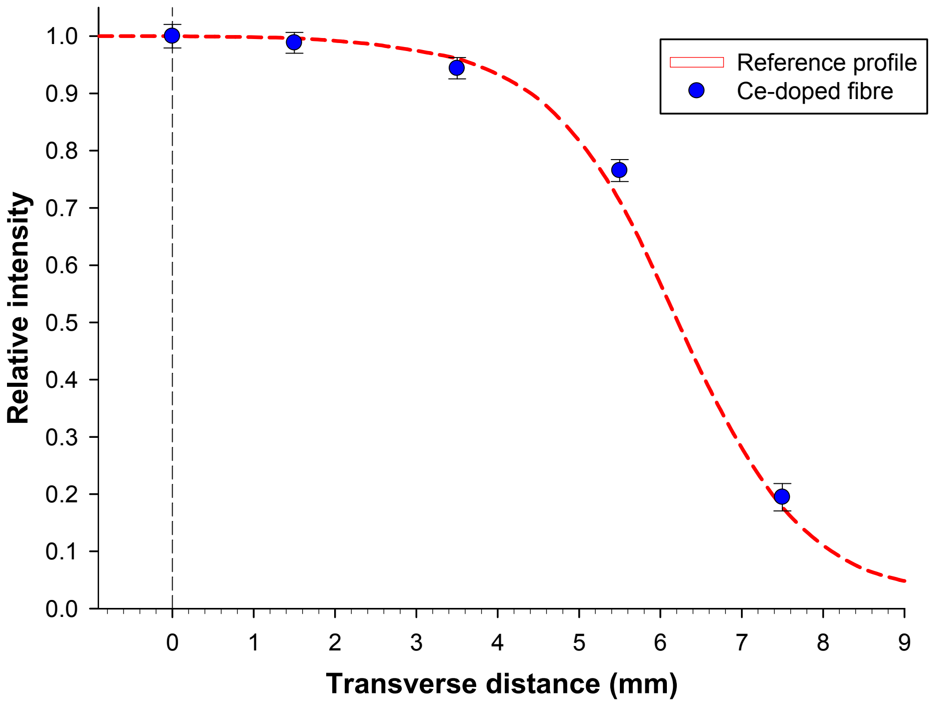

Fig. 6. Transverse profile of stereotactic field (12.5 mm diameter collimator) measured with the doped fibre and compared with the reference curve obtained with a diode.

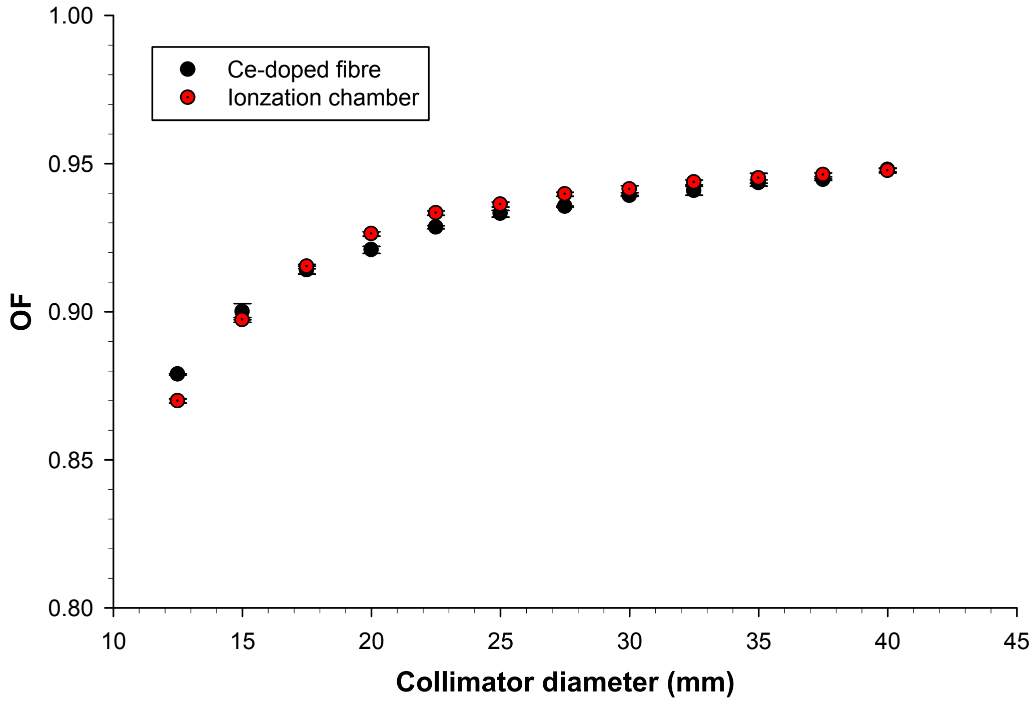

Fig. 7. Output factors of stereotactic fields measured with the doped fibre and compared with OF obtained using a micro-ionization chamber.

An interesting property of the system observed during the tests performed with proton beams is the possibility to discriminate the dose contributions due to the various spots composing the irradiation scanning sequence. An example of signal obtained by irradiating the doped fibre placed in the centre of a cubic irradiation volume (6 cm side) is shown in figure 8, where the modulation of the signal intensity reflects the temporal and spatial characteristics of the scanning sequence. Further tests attested the capability of the system to assess the total dose in one point independently of the sequence and spot duration used to deliver such dose.

As many other scintillators (Safai et al. 2004), also silica doped fibres suffer of a progressive decrease of the RL efficiency with increasing the Linear Energy Transfer (LET) of protons. This quenching effect is evident by comparing the PDD of a 138 MeV proton beam measured with the RL detector, with the corresponding curve obtained using a standard ionization chamber. The results of this analysis is shown in figure 9, where an underestimation of the dose of approximately 10% can be observed at the depth of the Bragg peak.

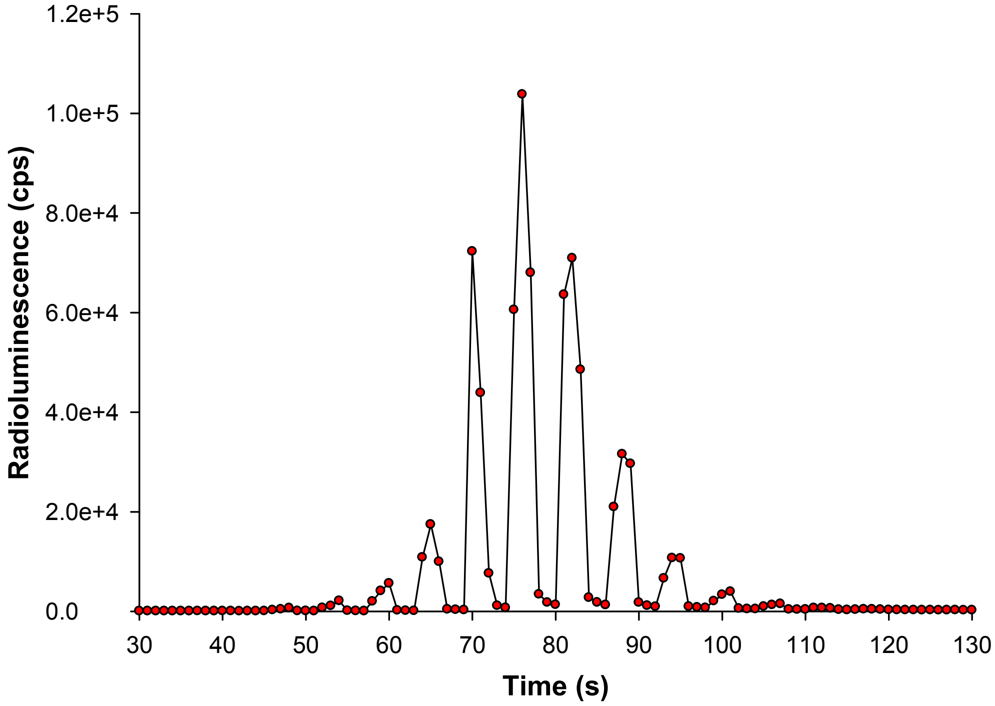

Fig. 8. Example of RL signal versus irradiation time measured with the doped fibre irradiated with a 138 MeV proton beam using the spot scanning technique.

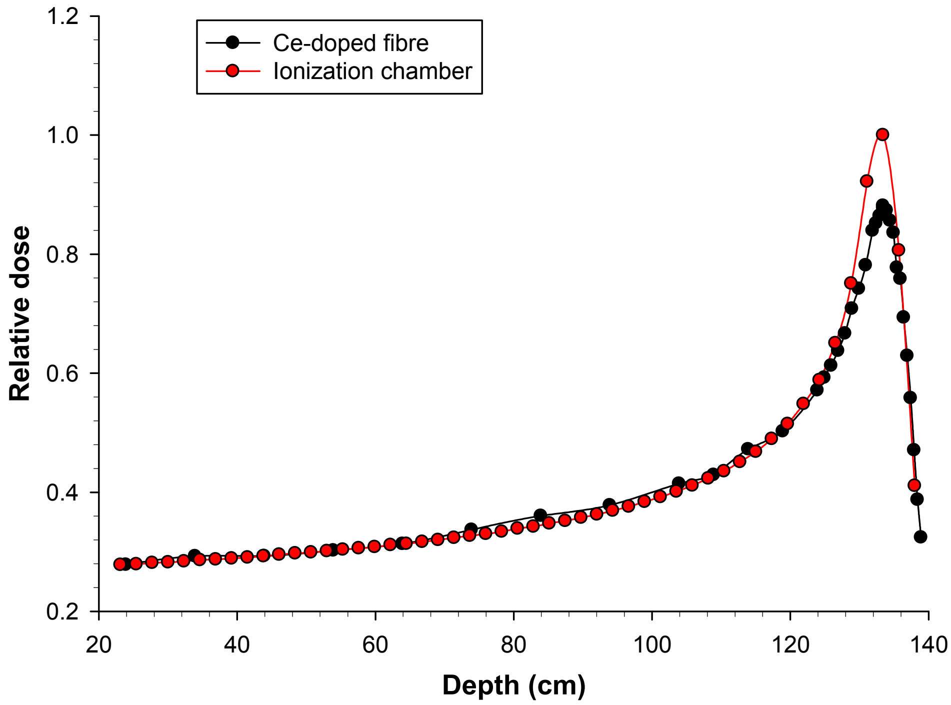

Fig. 9. Depth dose profile of a 138 MeV proton beam in water measured with the doped fibre and compared with the reference curve obtained with an ionization chamber.

Conclusions

The results of the various tests performed using different radiation beams attested the promising properties of the dosimetric system. On the basis of these outcomes, a pre-industrialization agreement was signed between the inventors of the system and EL.SE S.r.l., an Italian Company specialized in the development and sale of radiation technology devices for medical applications.

Abstract

The optimization of the use of active personal dosemeters (APDs) in interventional radiology (IR) is performed by one of the work packages of the ORAMED project, a Collaborative Project (2008 – 2011) supported by the European Commission within its 7th Framework Program. Due to the specificity of the X-ray fields used in IR (low energies, pulsed fields), the current technology of APDs is inadequate, notably in terms of energy detection threshold and dose rate response. The work presented in this paper consists in establishing guidelines related to the use of APDs in IR. The guidelines are divided in three parts. The first part presents the real radiation field characteristics encountered in IR. The dose rate in the direct field at the level of the table (i.e. above the patient) ranges from 2 to 360 Gy.h-1. The dose rate in the scattered beam at the level of the operator ranges from 5.10 – 3 to around 10 Gy.h-1.Finally, the energy of the scattered spectra ranges from 20 to 100 keV. The second part describes the results of tests performed in laboratory conditions and in hospitals. All APDs present a linear dose response and most of them a satisfactory response at low energies (down to 20 keV). However, some present dose rate and angular responses that do not always fulfil the ISO 61526 standard requirements. Tests in pulsed mode show that limitations of several APDs are mostly due to high dose rates rather than to pulse frequency. This point was confirmed by tests in hospitals. The last part of the guidelines proposes advices in the choice of the APD type and some methods to correct the response of the devices depending on the IR procedure type.

Radiation protection in radiotherapy: primary standard dosimetry of high-energy photon beams in Austria

Baumgartner, Andreas[2,3]; Steurer, Andreas[1]; Tiefenböck, Wilhelm[1]; Gabris, Frantisek[1]; Maringer, Franz Josef[1,2,3]

Abstract

The Austrian absorbed dose to water primary standard is a graphite-calorimeter. It was developed by the Federal Office of Metrology and Surveying (BEV) in cooperation with the Research Centers Seibersdorf. The BEV is the National Metrology Institute (NMI) of Austria. The graphite-calorimeter is a Domen-type calorimeter and in operation since 1983. The realization of the unit absorbed dose to water is based upon absorbed dose to graphite measurements. The absorbed dose conversion is done by two independent methods based on the photon fluence scaling theorem. The graphite-calorimeter was originally designated for determination of absorbed dose to water in ^{60}Co gamma ray beams. The progress in radiation therapy within the recent years required for extension of the graphite-calorimeter application range to enable primary standard dosimetry of high-energy photon beams. The development of the primary standard is based upon Monte Carlo simulations with PENELOPE code and measurements with the graphite calorimeter and ionization chambers. Furthermore the graphite calorimeter and its corresponding components had to undergo a refurbishment and modernization process. This paper presents the results of the energy range and application enhancement of the primary standard. The determined correction and conversion factors for high-energy photon beams and a detailed uncertainty budget of the primary standard is given. Furthermore the re-evaluated correction factors for ^{60}Co gamma ray beams are presented. To validate the results the BEV participated the international key comparison for absorbed dose to water in ^{60}Co gamma radiation at the Bureau International des Poids et Mesures (BIPM). Moreover the BEV planned and coordinates the EURAMET Project 1021 intended for direct comparison of absorbed dose to water primary standards. The accomplishment of the BEV high energy calorimetry project was promoted by the Physico-technical Testing Service (PTP), which is an entity of the BEV.

Introduction and overview

The Austrian absorbed dose to water primary standard is a graphite-calorimeter. It was developed by the Federal Office of Metrology and Surveying (BEV - Bundesamt für Eich- und Vermessungswesen) in cooperation with the Research Centers Seibersdorf. The BEV is the National Metrology Institute (NMI) of Austria. The graphite calorimeter is a Domen-type calorimeter and is in operation since 1983. The realization of the unit of absorbed dose to water is based upon absorbed dose to graphite measurements. The graphite calorimeter is designed for quasi-adiabatic and quasi-isothermal mode of operation. The absorbed dose conversion is done by two methods based on the photon-fluence scaling theorem. These methods are: conversion by calculation and conversion with an ionisation chamber.

In Austria the calibration and verification of therapy dosemeters is done in ^{60}Co gamma radiation. The applied secondary standards, e.g. used in hospitals, are traceable to the primary standard graphite calorimeter. The conversion of the ^{60}Co chamber factor to the chamber factor for high-energy photons and high-energy electrons uses the code of practice of the Austrian standard ÖNORM S 5234-3. The improvement of the absorbed dose to water primary standard directly leads to an improvement of quality assurance measurements in Linac radiotherapy, i.e. directly related to the radiation protection of patient. Further the accurate knowledge of the applied dose is a main factor influencing the success of a radiotherapy and therefore from great importance for the treatment planning.

The graphite calorimeter was originally designated for determination of absorbed dose to water in ^{60}Co gamma ray beams. The progress in radiation therapy within the recent years required the extension of the graphite-calorimeter application range to enable primary standard dosimetry of high-energy photon and electron beams. The accomplishment of the BEV high-energy calorimetry project was promoted by the Physico-technical Testing Service (PTP), which is an entity of the BEV.

To enable the graphite calorimeter for primary standard dosimetry of high-energy photon and electron beams a set of beam quality dependent conversion and correction factors was required. Additionally the graphite calorimeter, the graphite phantom and all corresponding components had to be adapted to the measurement requirements for high-energy photon beams. This was done within a refurbishment and modernization process intended to ensure the quality and reliability of the primary standard and to maintain the primary standard at an international level. The correction and conversion factors were obtained via Monte Carlo simulations with PENELOPE code, measurements - with the graphite calorimeter and ionization chambers - and with the use of published factors.

First of all measurements and simulation studies for the estimation of correction factors were carried out for ^{60}Co gamma rays to achieve a well-founded basis. This lead to the re-evaluation of the BEV absorbed dose rate to water reference value for ^{60}Co gamma ray beams. To validate those results the BEV participated the international key comparison for absorbed dose to water in ^{60}Co gamma radiation at the Bureau International des Poids et Mesures (BIPM). Subsequently measurements and Monte Carlo studies for selected high-energy photon beam qualities were performed.

To achieve beam quality specific correction factors it was necessary to consider the radiation field characteristics of irradiation facilities used for measurements. This included the Monte Carlo modelling of the BEV ^{60}Co teletherapy unit and of Varian Linac treatment heads. Thereby photon energy spectra were determined. These spectra constitute the basis of beam models used for the graphite calorimeter specific Monte Carlo simulations to obtain the required application specific correction factors. For high-energy electron beams concepts were developed for the realization of primary standard dosimetry. Nevertheless the practical implementation requires adaptations of the graphite phantom.

A confirmation of the energy range and application enhancement of the graphite calorimeter and thus of the implemented correction and conversion factors is done in the framework of the project 1021 of the European Association of National Metrology Institutes (EURAMET). This project is intended for the direct comparison of primary standards for absorbed dose to water in ^{60}Co and high-energy photon beams. The participating NMI's are: BEV, the Federal Office of Metrology (METAS - the NMI of Switzerland) and the Physikalisch-Technische Bundesanstalt (PTB - the NMI of Germany). For the comparison exercise the BEV transported the graphite calorimeter primary standard to METAS and PTB for operation in the accelerator radiation fields.

The advance of the graphite calorimeter provides the methodical fundamentals to enable the BEV for the accomplishment of primary standard dosimetry of high-energy photon and electron beams.

ETAM
Method for Exposure Conditions Reconstruction

Marinkovic, Olivera[1]; Spasic Jokic, Vesna[2]
[1] Serbian Institute of Occupational Health "Dr Dragomir Karajovic", Belgrade, SERBIA
[2] Faculty of Technical Sciences, University of Novi Sad, SERBIA

Abstract
Laboratory for personal dosimetry in the Serbian Institute of Occupational Health, Belgrade, is using LiF TLD nearly twenty years. Equipped with Harshaw TLD Reader Model 6600 (12^{th} serial unit), REMSMENU software and Computerised Glow Curve Deconvolution (CGCD - DOS version) has prepared calibration for elapsed time estimation.

Recognizing importance of more information in personal dosimetry practice, Laboratory developed criteria for estimation exposure conditions named **ETAM – Exposure Time Assessment Method.**

ETAM is based on LiF fading and difference between low temperature peaks half-life. The main values are calculated using CGCD Programme which gives: *FOM* (Figure of Merit), *peak2*, *peak3* and *peak5*. Then using laboratory's calibration curves is possible to calculate elapsed time T_2 and T_3. Ratio *peak2/peak5* and *peak3/peak5* are linear functions of logarithms of elapsed time T_2 and T_3 respectively. So, even for one LiF crystal estimation is based upon two sets of parameters. One TLD for personal dosimetry usually has two or more LiF crystals.

ETAM recognizes three types of exposure conditions: one-shot exposure (O), repeated exposure (R) and continuous exposure (C).

It is crucial to analyse together all main values. For example: if deconvolution *FOM* is too high it does not mean that method is inapplicable. Contrary, it could be argument that exposure was not type O. ETAM criteria is discussed in the paper supported with numerous illustrations from real practice results. Laboratory has about 2000 users monthly. They are working in different exposure conditions, but mainly type C and R.

Introduction
Serbian Institute of Occupational Health (SIOH) "Dr Dragomir Karajovic" is the newest name (from 2009) of the institution established in 1953 with the aim to develop occupational medicine, to investigate all occupational hazards, radiological as well. Since 1959 the Institute was organized in five centres. The Radiation Protection Centre has three departments: Dosimetry, Radioecology and Medical Department.

Dosimetry Department (DD) consists of two parts: sector for radiation protection measures and Laboratory for Personal Dosimetry (LPD). Very often personal dosimetry is performed for users who engage DD for radiation protection measures. So, plenty of data from both sides: from “in situ” measurements and corresponding personal dosimetry results is big advantage in the case when it is necessary to prepare a special report for user (comments for doses above investigated levels or limits).

LPD has used different techniques during fifty years: film dosimetry until early 80’s; then TLD - MgB_4O_7, Toledo 654 Reader; and Harshaw TLD Reader Model 6600, LiF crystal, from January 1992. LPD has more then 2000 users with monthly frequency.

ETAM – Exposure Time Assessmnet Method

Exposure Time Assessment Method (ETAM) has been developed for analyzing TLD, type 100 (LiF:Mg,Ti), for benefit of users, occupationally exposed workers. Lately, it has been applied to environmental dosimetry with considerable results (O. T. Marinkovic, V. M. Spasic Jokic, 2008).

A new equipment from 1992

LPD has got Harshaw TLD Reader Model 6600, 12000 dosimeters (card with two LiF crystals) and DOS version of Harshaw Computerized Glow Curve Deconvolution Programme (CGCD). Being 12th serial unit the Reader is controlled by REMSMENU software. Next new TLD cards were not bought until 2007.

LPD has participated in two national TLD intercomparasions before 2000 and EURADOS IC2008. The first international participation was very successful. All LPD’s reported results: Hp(10) and Hp(0.07) at EURADOS IC2008 were excellent.

Recognizing low level of personal dosimetry reputation among occupationally exposed workers prescription for elapsed time estimation in User’s Manual (HARSHAW/FILTROL, 1988) was rated as very useful tool. First calibration for elapsed time estimation according CGCD was prepared in 1995 (O. Marinkovic, 1995).

Very high Hp(10) was appearing from time to time. Elapsed time estimation for one-shot irradiation is a part of special report. Sometimes, special report prevented misused of intentional irradiation; sometimes helped to detect unknown irradiation. Undoubtedly, using CGCD helped LPD to upraise common credence.

Collecting experience based on hundreds analyzing glow curves results are systemizing to support a method for recognizing one-shot, repeated or continuously exposure of TLD.

LiF Crystal

Elapsed time estimation is based on LiF five temperature peaks below 300^{o}C. First one has so short half-life that is of no importance to speak about. Peaks 2, 3 and 4 have half-lives of the order of several hours and a few months respectively. Peak five has long half-life (~ 80 years) and is used as stable.

Read-out cycle keeps recommended time temperature profile. Crystal is heated with constant rate. Output signal is registered in 200 channels during heating. Plotting glow curve we can see different shape due to elapsed time between irradiation and read-out moments. Figure 1. shows an example for very short and very long elapsed time after irradiation.

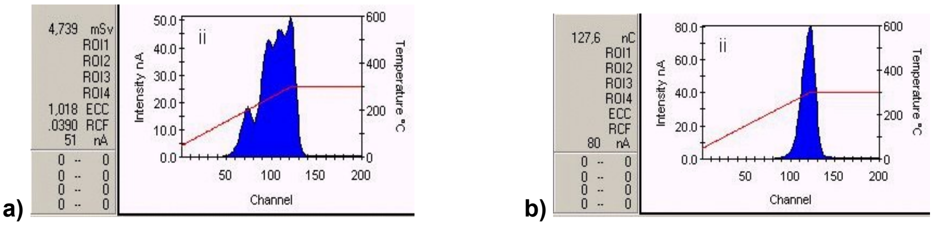

Figure 1. Glow curve shape: a) short elapsed time; b) long elapsed time after TLD irradiation.

Calibration for elapsed time estimation

Two hundreds and fifty crystals were irradiated and read-out after different elapsed time (O. Marinkovic, et al. 2001). Verification is performed from time to time with a few dosimeters in different range.

Peak area ratios *peak2/peak5* and *peak3/peak5* are functions of elapsed time *T*. Linear regression parameters are given in equations (1) and (2).

$$peak2/peak5 = 0.22 - 0.075 \times LogT_2 \quad (1)$$

$$peak3/peak5 = 0.88 - 0.26 \times LogT_3 \quad (2)$$

T_2 and T_3 theoreticaly represent the same elapsed time *T* for one-shot exposure. ETAM analyses these values for repeated and continuos exposure.

Here is an example (Figure 2.) of glow curve deconvolution for crystal read-out prolonged enough after irradiation to loose peak2 completely.

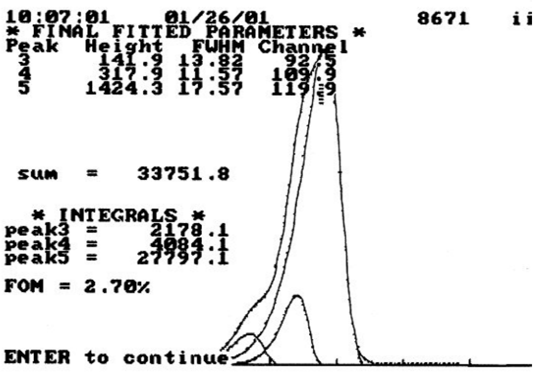

Figure 2. A glow curve deconvolution result.

Limited interval for application (1) and (2) are respectively 857 days and 2424 days. According experience from routine practice monthly read-out cycle is preferred.

ETAM parameters

REMSMENU has option for creation file selected.crv from primary files (DAT, I1, I2, I3). CGCD is applied to selected.crv and gives result visible at Figure 2:

– First line: reading time (10:07:01), reading date (01/26/01), TLD bar-code with chip's identification (8671 ii);

- Second line: Title ∗FINAL FITTED PARAMETERS∗;
- Third line: subtitle for four columns – Peak, Height, FWHM, Channel;
- Next lines: results for deconvoluted peaks respectively (values peak2 would be detected if elapsed time was not more then 500 hours)
- Sum: TLD signal after background subtraction.
  Note that ″background″ is ″system″ background (crystal+photomultiplier background); not consequence of natural radiation;
- Another title ∗INTEGRALS∗: there are written peaks area due to CGCD result;
- FOM – Figure of Merit in percents.

Final fitted parameters are acceptable or not acceptable for ETAM. If results cannot be accepted, CGCD should be repeated with corrections.

An example for not accepted first deconvolution results is given in Table 1.

Table 1. CGCD unacceptable results.

Bar-code & date (mm/yy)	FOM (%)	Sum (r)	Peaks			Sum (v)
			Height	Channel	Integral	
5652 (ii) 05/99	21.60	476.3	Peak 2			956.4
			-1.676	95.8	0.000	
			Peak 3			
			3.805	148.0	183.8	
			Peak 4			
			-8.007	125.7	0.000	
			Peak 5			
			13.33	142.3	772.6	
12657 (ii) 07/08	14.86	119.9	Peak 2			221.266
			0.360	118.3	6.066	
			Peak 3			
			-3.956	93.7	0.000	
			Peak 4			
			4.081	97.0	103.2	
			Peak 5			
			3.687	150.4	112.0	

Peak height is relevant for ETAM. Negative peak height clearly indicates faulty deconvolution.

Peaks detection **Channels** are prompt criteria for deconvolution quality. From peak2 to peak5 detection channels upraise. If two peak channels are not successive (for example from Table 1, 5652ii: peak 3 was detected at channel 148.0, but peak 4 at channel 125.7), we have indication that deconvolution is not useful.

CGCD gives TLD signal after background subtraction - "**Sum**". This value is parameter for dose calculation (depended on calibration factor). Could be used also for deconvolution appraisal for ETAM purposes meanness what are reported unites. We mark this value with "**Sum (r)**" - real. A total peaks area is marked with "**Sum (v)**" which can be named "the area of **virtual** glow curve". Difference between Sum (r) and Sum (v) is a measure for correspondence real glow curve area and virtual glow curve area.

FOM – Figure of Merit - is a measure of the accuracy of deconvolution. Composite glow curve (above mentioned as virtual) is reconstructed adding the peaks areas and compared with the original curve. Recommendation in CGCD User's Manual for one-shot elapsed time estimation is that FOM higher then 2% represent uncertain deconvolution. For ETAM criteria even FOM =17.87% is acceptable (see TLD 9006iii; Table 3) if other results are clear for analyzing. In this case irradiation was not one-shot but happened in repeated portions.

ETAM – Three types of dosimeter irradiation

Speaking about workers' exposing condition we are talking about dosimeter exposing condition in fact. Usually, exposing is devided into portions during working time.

ETAM recognizes three types of exposing: one-shot, type **"O"** ; repeated, type **"R"** and continouslly exposure, type **"C"**.

Table 2. Examples for exposure type "O".

CGCD results for these types of irradiation are given in Tables 2, 3. and 4. Data of reading-out dosimeters are recorded and is keeping with all relevant documentation. Here was not important to put full date. Only month and year is written in the same column with dosimeter identification number (barcode added with chip's position sign – crystal ID).

A LiF crystal is exposed at least to natural ionizing radiation between two read-out cycles. Additional irradiation comes in portions: extremely short (in digital radiography) or long lasting during interventional diagnostic. Accidental exposure is an example of one-shot exposure.

Results presented in Table 2. are type "O". TLD was irradiated in LPD and elapsed time is well known. Notice that FOM in these cases are from 2% to 6%.

Table 3. Examples for exposure type "R".

TLD 9006 (Table 3.) is regular personal dosimeter belonging to a cardiologist for many years. Dosimeter is worn above apron. There are a lot of similar examples related to working conditions where TLD (and worker) is exposed several times to high dose in interventional diagnostic during one month.

Important differences between "R" and "C" type of irradiation is peak 2. In the Table 4. there are results for dosimeters exposed continouslly to low dose rate between two read-out cycles. Peak 2 is detected here. Repeated exposure enlarge peak 3 more then peak 2. It is the most important difference between types "R" and "C".

Table 4. Examples for exposure type "C".

Determination of irradiation type

Calibration equations (1) and (2) enable two results for elapsed time: T_2 and T_3 for one LiF crystal. LPD operates with dosimeters (personal and environmental) which have two LiF crystals.

Elapsed time estimation usually is based upon four results: $T_{2(ii)}$, $T_{2(iii)}$,, $T_{3(ii)}$ and $T_{3(iii)}$. A few results calculated with equations (1) and (2) are given in Table 5.

Table 5. Elapsed time calculation.

crystal ID	peak2	peak3	peak5	T_2 (h)	T_3 (h)
		type "O"			
8486 (ii)	13,98	99,83	290,00	195	115
8486 (iii)	15,34	78,99	248,60	129	145

6631 (iii)	0,20	0,68	7,37	374	1066

Discussion

ETAM is based on results obtained with CGCD Programme. LPD has many data to support ETAM. Here are ones selected by criteria to clearly demonstrate method applied during fifteen years.

There are three types of dosimeters exposing: one-shot, repeated and continouslly.

Table 5. - Type « O »

$T_{2(ii)}$, $T_{2(iii)}$,, $T_{3(ii)}$ and $T_{3(iii)}$ are compatible. Elapsed time can be calculated and uncertainty can be expressed separately for peaks:

TLD 8486: $T_2 = (162 \pm 33)$ h; $T_3 = (130 \pm 15)$ h or finally $T = (150 \pm 40)$ h.
TLD 5632: $T_2 = (463 \pm 22)$ h; $T_3 = (309 \pm 80)$ h or finally $T = (390 \pm 80)$ h.

Table 5. - Type « R »

$T_{2(ii)}$, $T_{2(iii)}$,, $T_{3(ii)}$ and $T_{3(iii)}$ are incompatible.

Result for peak2 can be explained as one-shot exposure 857 hours before heating. But, result from peak3 tell us that time of exposure (if it was one-shot) happened before dosimeter have been distributed to worker. So, conclusion is that dosimeter was irradiated in separately portions during using period. Peak2 and peak3 half-lives are shorter then peak5 one. So, first two decreased with time while peak5 increased.

Table 5. - Type « C »

Taking into account that FOM is very good in the case of one-shot exposure T_2 and T_3 have to determine elapsed time with uncertainty less than 50%. Here we have distinction T_2 and T_3 of about 100%, 200% or even 300%.

Conclusions

ETAM is powerful tool for analyzing working conditions in occupational exposure as well as in environmental monitoring.

Disadvantage is time consume. Recognizing benefit in very important cases it justifies spent time for applying ETAM.

ETAM should be upgraded. Huge experience and keeping records from fifteen years can support ETAM with more analysis.

Neutron and photon response of a CMOS pixel detector for a future electronic dosimeter

Abstract
The RaMsEs group of the IPHC in Strasbourg is working on a new compact device for active neutron dosimetry. The electronic part of the detector is a CMOS active pixel sensor based on MIMOSA5 technology, originally designed for tracking in particle physics. The thin active layer of these sensors leads to a low sensitivity to γ-photon background, which is an attractive feature in neutron fields. Measurements have been carried out with various radioactive sources: α-particles from ^{241}Am for calibration in counting rate and photons from ^{241}Am (59 keV) and ^{60}Co (1.17 MeV and 1.33 MeV). When the device is exposed to the fast neutrons of a ^{241}AmBe source, we obtain good discrimination between recoil protons from fast neutrons and the electron background.

Introduction
Active neutron dosimetry has become mandatory since 1995 for people receiving more than 20 mSv per year (international norm IEC 1323). About 60 000 workers are affected by this policy in Europe, mainly those in nuclear power plants and in medical physics (Queinnec 2008).

Since the RaMsEs group is concerned by dosimetric applications, we aim at developping a new real-time dosimeter based on CMOS technology. Successful tests have already been performed to estimate the response of the sensor to fast neutrons (Trocmé et al. 2008) at the LMDN (Laboratoire de Métrologie des Neutrons), IRSN, Cadarache, France.

As neutron environments usually consist of mixed γ/n fields, new experiments have been carried out to test the response of the sensor to γ-rays and to determine a threshold for removing the photon background. The sensor was exposed to photon sources and to AmBe, a mixed n/γ source. All experimental results have been compared with Monte Carlo simulations performed with MCNPX 2.6.0f using the LA150 libraries for neutrons (Hendricks et al. 2008).

Material and methods

Neutrons can generate charged particles through various elastic or inelastic processes, and the choice of a converter material (in composition and thickness) depends on the energy of incident neutrons.

Converter

As this work involves only fast neutrons, we chose a hydrogen-rich polyethylene radiator to benefit from a high (n,p) elastic scattering cross section (> 1 barn below 10 MeV). This $(CH_2)_n$ converter has a 900 µm thickness, such as to optimize the number of recoil protons produced by the AmBe source. This optimal thickness produces proton equilibrium, as shown by Monte-Carlo simulation with MCNPX 2.5.0 (Trocmé et al. 2008).

Sensor

The CMOS chip, called MIMOSA5 (Minimum Ionizing MOS Active pixel sensor), has been described elsewhere (Turchetta et al. 2001). It is made of four independent matrices each of 512×512 pixels, with each pixel having an area of 17×17 µm². One sensitive matrix has 0.75 cm² area.

A standard sensor consists of several layers. The "front side" is a 6 µm-thick SiO_2 layer in which is contained the readout electronics. The sensitive area is the epitaxial layer of 14 µm thick pure silicon grown on a silicon substrate of 300 µm. For our dosimetry application, a thinned down sensor has been used, meaning that the substrate has been chemically removed. In this chip, the epitaxial layer has a thickness of 10-12 µm covered by a passivation layer of about 100 nm SiO_2 (Deptuch et al. 2005). In our experiments, the chip is back-illuminated: the incident particles impinge directly onto the passivation layer. This chip configuration allows to detect low-energy protons and α-particles which otherwise would partially be stopped by the 6 µm-thick SiO_2 layer that now lies downward the epitaxial layer.

When a charged particle crosses the sensor, electron-hole pairs are created along the path of the particle in the epitaxial layer, and the electrons are collected by pure thermal diffusion on the pixels (Turchetta et al. 2001). The initial charge is spread over many neighbouring pixels, defining a "cluster". To determine if the cluster is selected or not as a real event, a cut on the signal-to-noise ration ($S/N > 5$) is applied on the pixel of maximum amplitude known as the seed pixel.

Acquisition system

The sensor is bonded to a PCB (Printed Circuit Board). The chip delivers four analog outputs (one per matrix) which are received by a motherboard driven by a FPGA (Field-Programmable Gate Array) and a four-channel 10-bit ADC/pixel (Analog to Digital Converter). The acquisition PC includes a standard digital card (National Instruments PCI-6534) which sends instructions and treats the data signals from the motherboard. The acquisition program is coded in C.

A complete reading of one matrix is called a frame. A reset signal is applied on all pixels after two consecutive frames to suppress the important contribution to electronic noise from the leakage current. In order to cancel the pedestal (the pixel charge without any detection), a frame-to-frame subtraction is operated (Correlated Double Sampling)

(Turchetta 2001). The reading frequency is 5 MHz and one pixel is read every 200 ns. The readout time of one full frame is about 50 ms ($512\times512/5.10^6s^{-1}$) and the data flow reaches 10 MB/s.

Results for α-particles

To calibrate the sensor in counting rate, α-measurements were carried out with a ^{241}Am source, emitting on average 5.45 MeV α-particles with an activity of 22.3 kBq (± 10%) in the forward direction (2π). These α-particles generate large clusters with a total charge well above the electronic noise (Fig.1).

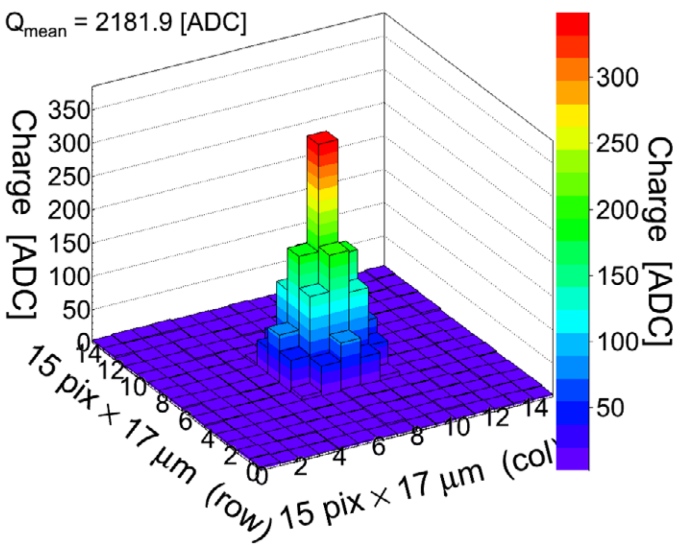

Fig.1. Mean α-cluster seen in the sensor for the ^{241}Am and at 2.3 cm from the source.

The source was placed at four distances. Our experimental results (Table 1) and simulations show excellent agreement, leading to detection efficiency for α-particles close to 100%.

Table 1. Summary of the results for ^{241}Am α-measurements confronted with simulation. Uncertainties on experimentally detected particles are statistical only.

Source-sensor distance (cm)	Detected α/min (experimental)	Detected α/min (simulation)	α detection efficiency (%)
1.8 ± 0.2	52220 ± 229	52740 ± 230	99.0 ± 0.6
2.3 ± 0.2	34872 ± 187	34980 ± 187	99.7 ± 0.8
2.8 ± 0.2	23914 ± 155	24240 ± 156	98.7 ± 0.9
3.6 ± 0.2	13646 ± 117	13800 ± 117	98.9 ± 1.2

Results for photons

As the photon background is a major concern in all neutron fields, experiments were also performed with γ-ray sources to determine the response of the sensor to photons.

Unshielded ^{241}Am source

Our point-like ^{241}Am source of (11.35 ± 0.57) µCi activity is sealed to absorb alphas and electrons. The main photon rays of this source are X-rays of 13.9 (13 %), 17 (19 %) and 21.2 keV (5 %), and γ-rays of 26.3 (2 %) and 59.5 keV (36 %) (in brackets the respective intensities) (LNHB 2007). To remove the X-rays of the ^{241}Am, a 3mm thick aluminium absorber can be inserted between the sensor and the source.

A first set of measurements was carried out without X-ray shielding. Knowing that the polyethylene converter itself generates electrons, we started without converter. As usual, the fired pixels are grouped into clusters, but the electrons generate lower charge than α-particles. In this case, the applied cuts to distinguish signal from noise lead to a significant loss of signal.

The response of the sensor can be simulated with MCNPX, and according to Table 2, a count rate of 1667 events/min are expected. The calculation assumes that a photon, once converted in the epitaxial layer, is necessarily detected. This cannot be the case as the signal generated by low energy electrons (or by electrons whose range in the sensitive layer is short) will be lost in the electronic noise.

Table 2. Response to ^{241}Am photons (without X-ray shielding): experimental and simulated events as a function of cut in deposited energy E_{dep}. Uncertainties are statistical only. Electrons produced in the aluminium absorber are included in the simulation results. The sensor was placed 3 cm from the source.

Cut on deposited energy	γ detected/min - simulation	γ detected/min – experimental
No cut	1667 ± 41	446 ± 21
E_{dep} > 10 keV	1472 ± 38	
E_{dep} > 15 keV	662 ± 26	
E_{dep} > 20 keV	100 ± 10	

Table 2 shows the effect of three different cuts on the detected energy, to find which simulated cut fits experiment. The simulation shows that retaining more than 20 keV deposited energy would underestimate the number of photons detected. Obviously, our sensor has a sensitivity which goes down to X-ray energies. According to this, we conclude that the lower detection limit of this detection chain (DAQ+analysis) is between 15 keV and 20 keV.

Shielded ^{241}Am source

To check our sensitivity to low energy photons, a 3 mm thick aluminium absorber was inserted between the source and the sensor. The thickness is a compromise between reducing the X-ray signal while retaining enough intensity for the γ-rays.

The counting rate obtained without absorber (to 3 cm from the source) is 446 γ/min whereas we find 70 γ/min when the absorber is used. It decreases significantly with shielding. Knowing that a 60 keV photon crosses our absorber with 80% probability, this is a clear demonstration that X photons are detected in our sensor and that an efficient shielding will remove them.

^{60}Co source

As mentioned earlier, the polyethylene neutron-to-proton converter is also a source of electrons. Simulations have been carried out to determine the effect of the 900 µm converter on the electron contamination in a neutron experiment.

According to simulation results shown on Fig. 2, the γ-ray contamination will be highest for incident energy between 1 and 2 MeV. To test this result, experiments with the two γ-rays 1.17 and 1.33 MeV of (0.43 ± 0.02) µCi ^{60}Co have been performed with and without converter (distance source-sensor: 1cm). The photon response is estimated by the ratio γ-rays detected/γ-rays emitted. The results are summarized on Table 3.

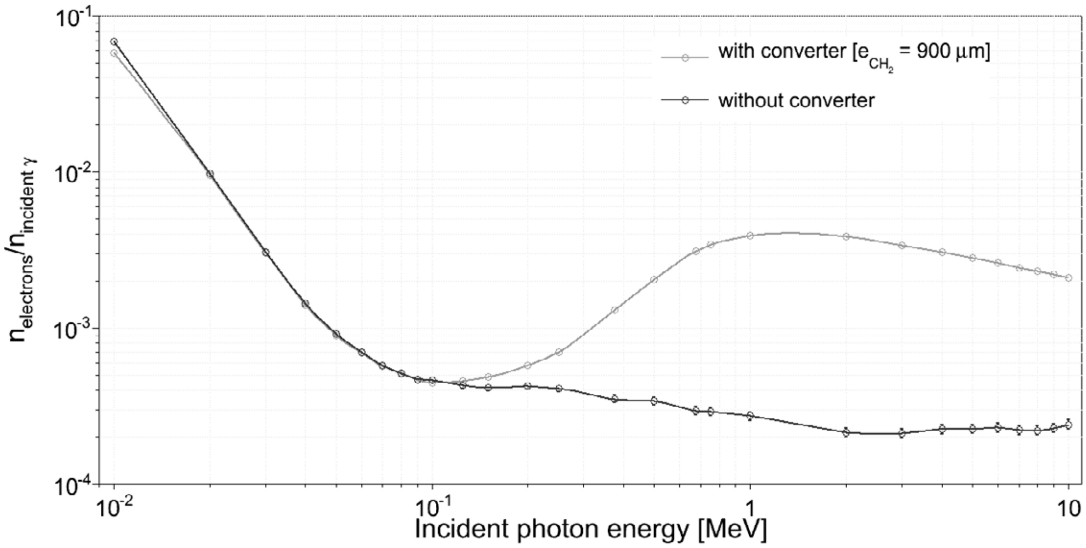

Fig. 2. Effect of the converter on the number of secondary electrons able to generate a signal charge in the epitaxial layer (simulation MCNPX).

For the ^{60}Co source without converter, the experimental response of our detector is of about 0.03 %, in good agreement with the simulation. The agreement is worse when the polyethylene converter is present, because of the secondary electrons generated by the $(CH_2)_n$ converter. However, the resulting energy deposited by electrons in the sensor is about 5 keV (Fig. 3), which is far below the detection limit of our electronics (as has been suggested by the ^{241}Am experiments). With a simple 15 keV cut on deposited energy in the simulation (Table 3), a good agreement is obtained between simulated and experimental efficiency. This is consistent with a sensitivity threshold of the sensor around 15 keV, as shown by previous ^{241}Am experiments.

We conclude that in a mixed field of neutrons and MeV photons, the additional photon effect of the converter will remain negligible.

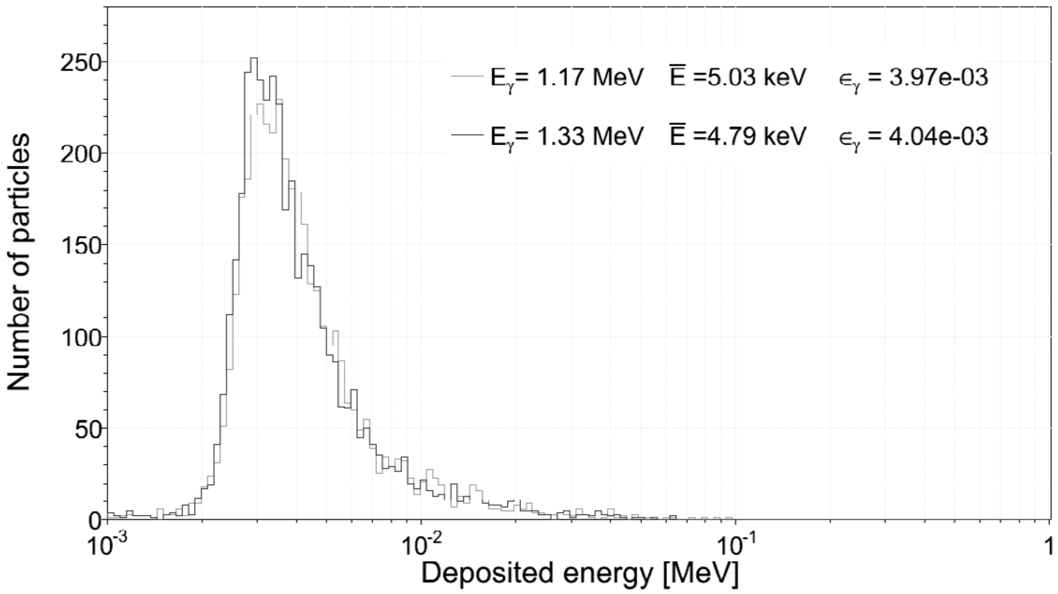

Fig. 3. Deposited energy distribution obtained by simulation for a ^{60}Co source with a 900 µm polyethylene converter (number of emitted photons : 10^6). The mean deposited energy is given by $\bar{E}$ and the detection efficiency for each γ-ray by ε_γ.

Table 3. Measured and simulated photon response for ^{60}Co. The results for ^{241}Am photons are added for comparison.

Source - configuration	Experiment	Simulation	Simulation with cut on energy (E_{dep} > 15 keV)
^{60}Co	(0.28 ± 0.02).10^{-3}	(0.71± 0.02).10^{-3}	(0.30 ± 0.02).10^{-3}
^{60}Co + $(CH_2)_n$ converter	(0.26 ± 0.01).10^{-3}	(8.03 ± 0.10).10^{-3}	(0.25 ± 0.01).10^{-3}
^{241}Am	(2.27 ± 0.05).10^{-3}	(7.76 ± 0.09).10^{-3}	(2.97 ± 0.02).10^{-3}
^{241}Am + Al screen	(0.29 ± 0.01).10^{-3}	(0.34 ± 0.06).10^{-3}	(0.25 ± 0.01).10^{-3}

Results for fast neutrons

To check that the recoil proton signal of a fast neutron source is easily distinguishable from photon signal, AmBe experiments have been performed. The neutron fluence rate of the source has been determined with Bonner Sphere Spectrometry by the University of Barcelona: (2.24 ± 0.10).10^6 s^{-1} (Domingo et al. 2009). According to MCNPX, our AmBe source generates two distinct populations in the sensor corresponding to 4.438 MeV γ-rays, which originate from the AmBe (Liu et al. 2007) and a much higher signal coming from the recoil protons from the converter (Fig. 4).

AmBe results and discussion

Fig. 5 shows the charge distribution in pixel clusters measured for a 30-min exposure at 15 cm from the source. We notice indeed two populations of particles, the first one peaked at low values of charge and the other one widely extended at much higher charge. In the measured distribution however (Fig. 5), the separation of the two populations is less than expected.

As already stated, the electron/hole transport mechanism in our silicon detector (which is not depleted) results in an incomplete charge collection (Turchetta et al. 2001). This implies a large spreading of the recorded signal, which is what we observe on Fig. 5. According to simulation (Fig. 4) a simple charge threshold should completely suppress the photon-background but the real situation (Fig. 5) is more complicated, since the photon signal overlaps slightly the proton distribution and vice-versa.

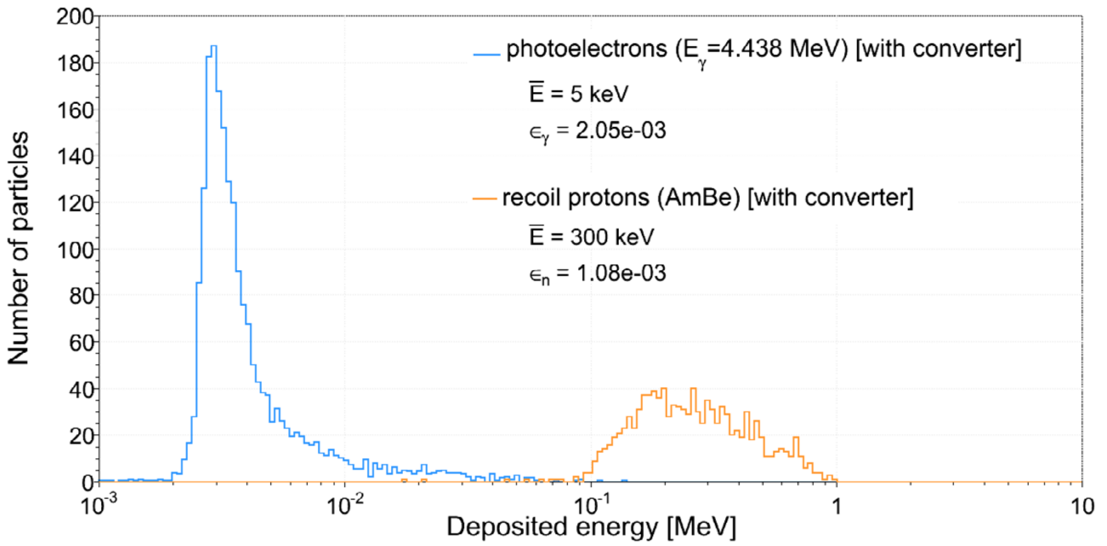

Fig. 4. Deposited energy distribution calculated with MCNPX for AmBe source. Photons are simulated as monoenergetic γ-ray of 4.438 MeV, with an intensity of 0.57 to the neutron flux (Liu et al. 2007). The mean deposited energy is given by $\bar{E}$ keV.

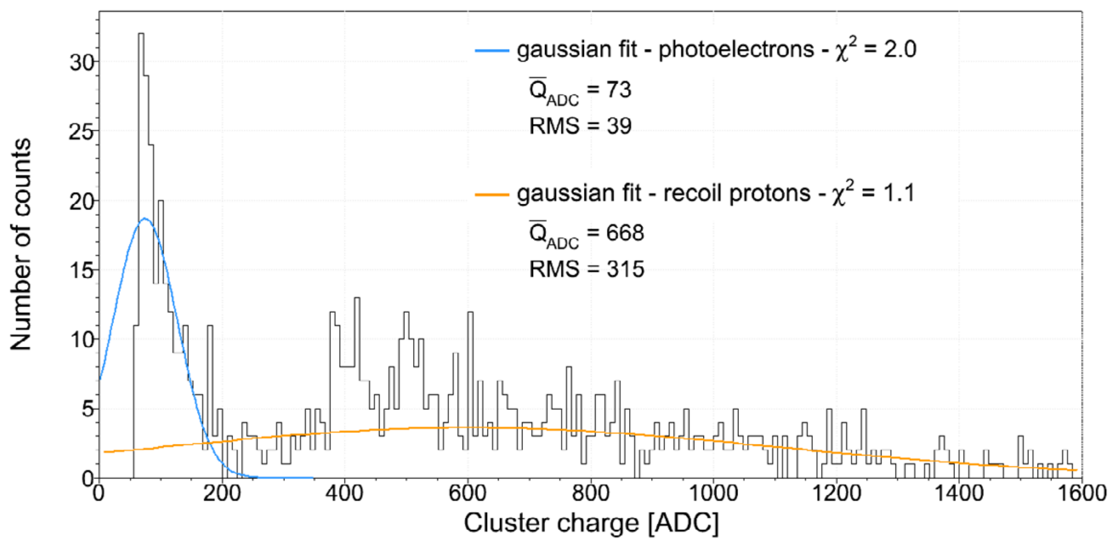

Fig. 5. Cluster charge distribution measured with a 30-min exposure at 15 cm from the ^{241}Am-Be source. Two gaussian functions were fitted on the two populations to estimate the number of recoil protons hidden in the photon peak and the number of photons that pollute the proton signal.

Proton clusters have high charge but also a high multiplicity (defined as the number of hitted pixels in a cluster) in each cluster, whereas secondary electron clusters have between 1 and 3 pixels. If we chose to cut the signal to 200 ADC, we remove the main part of the photon peak while keeping enough proton signal. To estimate the number of (low energy) protons lost in the photon peak, gaussian fits on the two populations of Fig. 5 allow an extrapolation for each population. Other parameterizations to fit the two populations have been tested. These other functions do not significantly change the conclusions.

To take into account the photon contamination in the proton peak, we define the signal purity p as $p = 1 - \frac{n_\gamma}{n_{hits}}$. For this fit, we can choose to cut the signal below 200 ADC counts leading to a high 99% purity (and a low 10 % ratio of lost protons).

We finally determine the absolute detection efficiency of our sensor as the ratio of the number of detected protons (i.e. number of counts above 200 ADC + number of protons lost in the electrons peak) and the number of incident neutrons. This leads us to a high efficiency $\varepsilon_{corrected} = (0.91 \pm 0.03).10^{-3}$ for AmBe neutrons whereas the simulated value is $\varepsilon_{MCNPX} = (1.08 \pm 0.33).10^{-3}$. Both efficiencies are in good agreement.

Conclusions

A test of a CMOS pixel sensor for AmBe neutrons (mixed with a possible photon contamination) has been successfully performed.

The sensitivity threshold of the sensor was checked with a ^{241}Am γ-source, which gave a threshold around 15 keV.

The X-ray response of the sensor is easily eliminated by an appropriate aluminium shielding.

A high γ-transparency of the sensor is demonstrated by its response to ^{60}Co photons, and the additional contribution of the polyethylene radiator itself to the electron background is negligible.

An efficient response of the sensor of nearly 10^{-3} is measured for fast neutrons from an AmBe source. This good sensitivity to neutrons is obtained with a signal almost free of photons. With an appropriate ADC cut of 200 for AmBe, we can remove the most part of electrons and obtain a low sensitivity to photon-background.

The next step will be to study the sensor response to thermal and intermediate neutrons with ^{10}B and ^{6}Li converters.

Development of approaches for realistic retrospective evaluation of doses of selected cases of internal contamination

Vrba, Tomas
CTU in Prague, Brehova 7, 11519 Prague, CZECH REPUBLIC

Abstract

The work was focused on estimation of the intake and committed effective dose from internal contamination with americium 241. The various models of americium bio-kinetic were described primarily. Mathematical background of the intake estimation was expressed together with the test of the quality of the model fit to measured data. The uncertainty of the data was estimated in order to obtain reasonable estimate of the intake. The extensive uncertainty analysis of the in vivo measurement of the head and related assessment of the total activity in the skeleton was performed. For that issue was build a voxel phantom of the human head. The most of the factors affecting the measurement of the activity retained in the skull were characterized and its magnitude was quantified. The uncertainties for bioassay quantities, urine and stool samples, were estimated also. The intakes and doses of all subjects were assessed, but the default parameters of the americium model had to be changed. The discrepancy between the model and the data was discussed.

Introduction

The paper resumes achievements and work presented in the thesis of the same name. Estimation of the committed effective dose for seven worker contaminated with ^{241}Am during late 70'a 80's in the Czech Republic was main goal of the work. The workers follow-up started in 1995 in National Radiation Protection Institute (NRPI) in Prague and thus long term data were available. The difficulty of the task grounded in a fact that data start about more than four thousand days since intake, hence no information on intake route and pattern. Secondly, data did not match with prediction from standard model for americium published in ICRP 67 (ICRP 1993).

Material and methods

Subjects

The subject group consists of six men and one woman. Follow-up starts in 1995 while regular data for all seven subjects began in 1998. Subjects processed AmO_2 in 70's and 80's and their internal contamination were find on a whole body counter equipped with

NaI(Tl) scintillation crystals. There were no special calibration for Americium in this time and thus no early data are available, but the whole body measurements were used for time of intake estimation. All subjects were retired or did not work with americium anymore when follow-up started.

Bioassay data

Daily urine samples for all workers and daily stool sample for five subjects were collected. Samples of excreta were analyzed by the means of radiochemical separation followed by alpha spectrometry in NRPI. The combined uncertainty of the measured values was known and the data no need any special treatment, because alpha spectroscopy method is quite standard. More over NRPI laboratory regularly undergo PROCORAD comparison in order to ensure procedure quality (Filgas et al. 1998).

Estimation of the skeletal activity

The skeleton activity estimates were given on the beginning of the work; however there was suspicion on data quality. Fact that preliminary estimates of intake, based on skeleton data, significantly overestimates intakes based on bioassay data was main reason. An effort were undertaken in order to improve data quality. The original data on skeleton activity of ^{241}Am had been determined by equation 1

$$A_{skel} = \frac{N}{Y \times t \times \eta \times q}, \qquad \text{Eqn. (1)}$$

where A_{skel} is skeleton activity in Bq, N is detector counts (net peak area) from the skull measurement, Y is yield for gamma ray with energy 59.6 keV (^{241}Am), t is time of the measurement in seconds (typically 1800 seconds), η is detection efficiency in counts per emitted photon (CPP) and q is skull to skeleton activity ratio used to recalculate skull activity to the whole skeleton. Some terms from equation one, like Y, t and N, were known well and thus could not caused significant error. Detection efficiency of the skull measurement and skull to skeleton ratio were studied therefore.

NRPI whole body counter, equipped with two LEGe detectors, had been calibrated by a four head phantoms in the past (Malátová et al. 2000). Skull measurement geometry used in NRPI is shown in figure 1 (left).

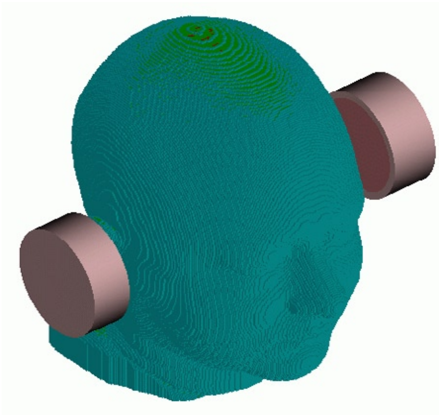

Fig. 1. Geometry of the measurement in NRPI: reality (left - property of NRPI), simulation with a voxel phantom (right)

Detector efficiency estimated from the phantoms ranged from 0.0055 to 0.122 CPP. The lowest value, belonged to the most realistic phantom BPAM-001 (Hickman et al.1988) borrowed from United States Transuranium and Uranium Registries (USTUR) was used for the skull activity calculations. There was supposition that observed spread of the detection efficiencies is caused by the different size of the phantoms. A Monte Carlo (MC) simulation with simplified measurement geometry and realistic detector models were performed in order to examine the hypothesis. Concentric spheres were used as substitute of real heads. Results of the simulations are shown in figure 2 (top), where head size (on x axis) was described by single parameter called head mean radius. The radius was calculated as arithmetic mean of three skull perimeters (Vrba 2007).

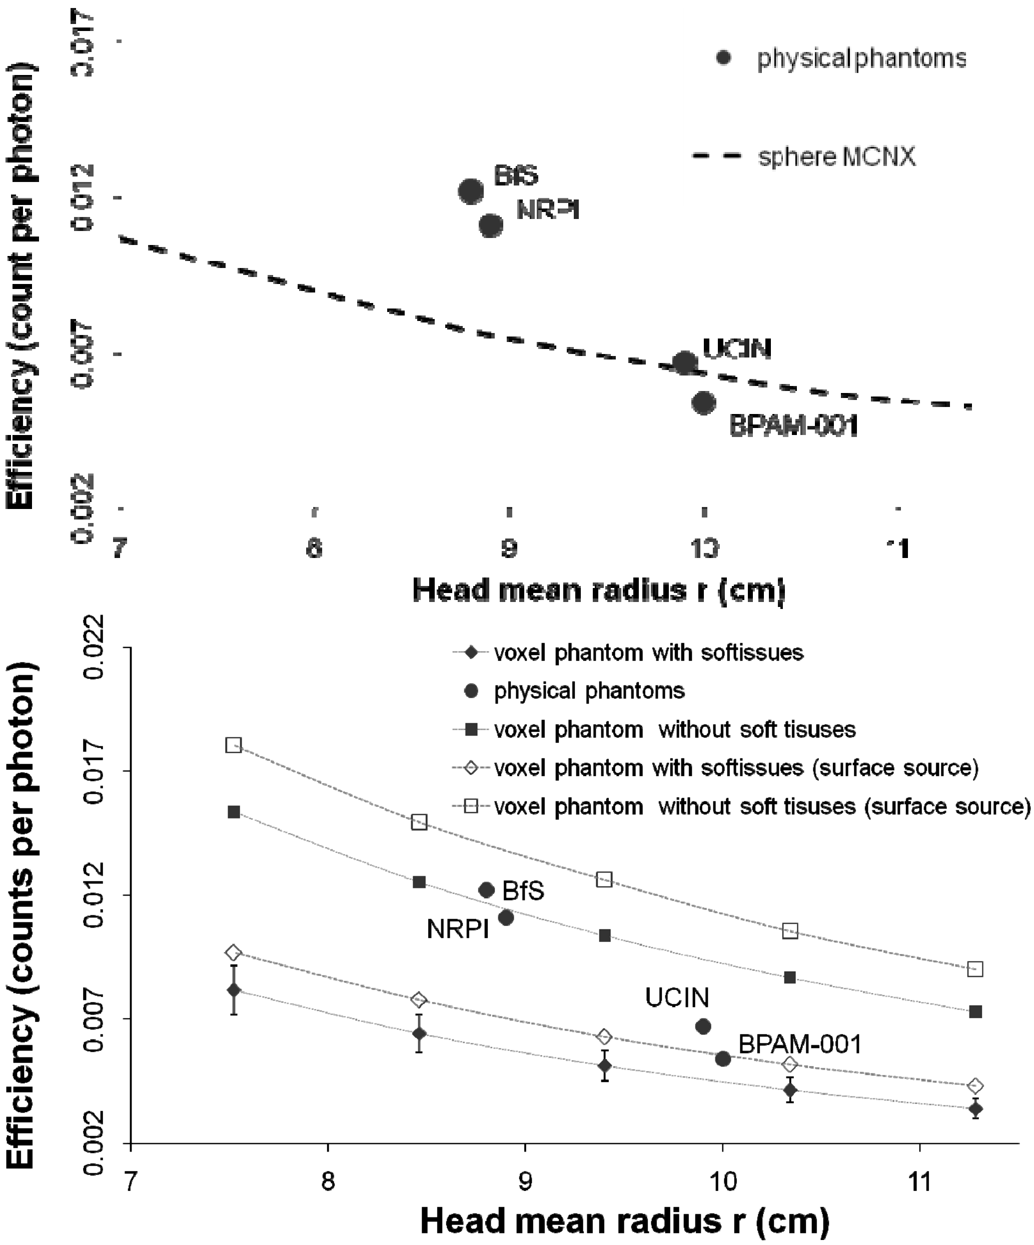

Fig. 2. Comparison of detection efficiencies of physical phantoms with Monte Carlo simulations: Sphere approximation (top), voxel phantom (bottom)

The decision to build a head voxel phantom and simulate measured geometry more accurately was made because the results were not conclusive. The detail description of the voxel phantom (sketch in figure 1 left) production and most of the results was published previously (Vrba 2007). Important study information is summarized in figure 2 (bottom) and the following list of the findings:

1) Detection efficiency depends on head size but not in extent shown by physical phantoms (visible from figure 2)
2) The main cause of detection efficiency discrepancy among physical phantoms is source distribution and insufficient inner filling of the cranial cavity.
3) Simulation with a voxel phantom can be better choice for calibration of detection system when physical calibration phantoms suffer from inaccuracy.
4) MC is capable to estimate the most important sources of uncertainty of ^{241}Am skull activity.

There was introduced head size dependent calibration curve, based on MC data, which respects mentioned results. Skull to skeleton activity ratio, originally based on skull to skeleton mass ratio and assumption on ^{241}Am homogenous distribution in skeleton, was revised in order to accord with USTUR whole body cases (Lynch et al. 1998). Neck vertebrae influence number of detected counts and thus correction coefficient were established. Mentioned changes are described by equation 2.

$$A_{skel} = \frac{N}{Y \times t \times \eta(R) \times q \times v}, \qquad \text{Eqn. (2)}$$

where $\eta(R)$ is head size dependent detection efficiency, v is vertebrae correction factor and the meaning of other symbols is same as in equation 1. Innovated method of the skeleton activity determination leads to activities even higher (for the most of the subjects) than the original ones, but the data credibility was improved.

Data uncertainty

Proper uncertainty assessment is crucial for correct data interpretation and thus the uncertainty of different datasets was determined. The system of scattering factors, introduced in IDEAS guidelines (Doerfler et al. 2006), was used in order to describe the uncertainty. The total uncertainty of any measurement involved in the intake assessment process can by approximated by lognormal distribution while natural logarithm of the Scattering Factors (SF) is equal to relative standard deviation of the distribution.

The total uncertainty for bioassay samples was derived from the data directly according methodology described in paper by Marsh and coworkers (Marsh et al. 2007). The SF for urine data was 1.36 and 1.77 for feces. There were included following uncertainties in the total uncertainty estimate of skeleton activity: reproducibility of detector position, counting error, calibration errors (uncertainty of Monte Carlo modeling), spectra evaluation, activity distribution in the skull bones, neck vertebrae correction, skull to skeleton ratio and effect of head size to the measurement. Scattering factors values for particular sources are summarized in table 1.

Americium models

Biokinetic models for americium were studied and compared in a theoretical part of the thesis. The ICRP 67 (ICRP,1993) model was chosen for evaluation because committed effective dose is bind with the ICRP biokinetic model.

Table 1. Uncertainty sources assumed for skeleton activity.

Uncertainty source	SF value	method of assessment, note
density and tissue composition of the voxel phantom	1.03	MC study with changed density within ±10%
statistical - calculation MCNPX	1.005	from MCNPX output file
cross -section library MCNPX	1.05	Guess
micro distribution in head	1.01	MC study simulating inhomogeneous distribution according USTUR data
neck vertebrae correction	1.05	correction uncertainty equals to correction factor
number of counts	1.1	Poisson error 10%
spectra evaluation	1.08	blind test – trials with one real measurement spectra, software and manual methods
detector position	1.13	dislocation of the detector centre within -2 to 2 cm in plane parallel to temporal bone and -1 to 1 cm perpendicularly
skull to skeleton ratio	1.16	inefficient statistic estimate of ratios for USTUR whole body cases
head size (known/unknown)	1.14/1.28	inefficient statistic estimate and data from MC study
Total (known/unknown head size)	1.32/1.37	

Fitting method and test of the fit quality

The maximum likelihood method supported by IDEAS guidelines were chosen, replacing weighted least square method. The quality of the fits was controlled by chi-square statistic test (one-side) and by autocorrelation coefficient proposed by Puncher et al. (Puncher et al. 2007). Lognormal character of the data to fit deviations was checked with Kolmogor-Smirnov test. All test were performed with significance level $\alpha = 0.05$.

Intake assumption

The exact time of intake and the intake pattern was unknown for all subjects. It was presumed that americium aerosol with AMAD = 5 μm and lung absorption class M was inhaled in a single intake. Such assumption was made in order to have conservative estimates and reduce complexity (to avoid too many assuming parameters). It has to be mention that the choice has no significant effect on data to model relation because earliest data staring 4000 days since assumed intake and are not influenced by the way of the intake any more.

Results

The first step of the internal dose evaluation is intake evaluation. This was done be a fitting of the data by default model setting (inhalation, class M, AMAD = 5μm). Each data set (urine, feces, skeleton) was fitted solo and also all together, when scattering factors were used as the weights. Chi-square and autocorrelation statistic were calculated and tested subsequently together with Kolmogor-Smirnov lognormality test. Results are summarized in table 2.

Table 2. Intake estimates with default americium model (inhalation, class M, AMAD 5 μm)

Subject ID	Data	Intake (Bq)	Statistic for all data fit*

[*]test results for null hypothesis (that fit is right) while the intake was based on all data sets evaluated together, [a] chi-square test, [b] autocorrelation test, [c] Kolmogorov-Smirnov test, [d] not applicable or too few data points.

Intakes based on different data namely skeleton and bioassay differs about factor 2 to 9, but intakes based on urine and feces are in a reasonable agreement when data uncertainties are taken in account. Given results had not been acceptable and model modification has to be done in order to fit data in more plausible way. The modification of the material specific parameters will not bring any improvement, because such changes affect just early data. Modification of person specific parameters, such as skeleton liver uptake ratio or excretion rates was only possibility. Usage of person specific parameters results in a dose (person specific dose), which is no more consistent with the ICPR meaning of the effective dose. The analysis and justification of the following approach is given in the discussion.

The uptake ratio for skeleton and liver was a fist choice. The ratio was determined from the skeleton retention data and feces measurement (feces data partially depends on liver activity) because direct liver retention was unknown. This modification improves intakes agreement for skeleton and faces data but did not improve match with intake based on urine set. Adaptation of transfer rate from the blood directly to the urinary bladder was performed in order to match intakes based on skeleton and feces. Transfer rate from blood to small intestine has to be changed for the subject JH because skeleton retention was higher than fecal excretion and liver to skeleton ratio were not sufficient to reduce discrepancy between intakes. Newly estimated intakes from all data, with the model parameters are given in table 3.

Table 3. Intake estimates, personal dose and model parameters

Quantity	Subject ID						
	HV	SS	FK	PP	JH	PV	PS
transfer rate from blood to liver (d^{-1})	3.95	1.86	7.66	2.32	0.23	3.25[c]	3.25[c]
transfer rate from blood to skeleton (d^{-1})[a]	7.32	8.36	5.46	8.13	9.17	7.66[c]	7.66[c]
transfer rate from blood to urinary bladder (d^{-1})	1.05	0.95	0.65	1.19	0.12	0.4	0.81
transfer rate from blood to small intestine (d^{-1})					0.15		
Intake (kBq)	13.2	5.7	7.5	7.9	141.6	89.3	34.2
conversion coefficient[e] ($Sv \times kBq^{-1}$)[d]	0.0337	0.0347	0.0342	0.0336	0.0393	0.0367	0.0349
Person specific dose (Sv)[b]	0.44	0.2	0.26	0.27	5.56	3.28	1.19

[a] cortical and trabecular bone, [b] calculated as committed effective dose but with person specific parameters, [c] mean value of cases with feces data (PV and PS has no feces data), d conversion coefficient respecting modified model behavior. [e] recalculated conversion coefficient respecting changes of biokinetic.

Some statistical tests failed even for adjusted model; predominantly for urine data. An effort was undertaken in order to find out explanation.

The relative values, i.e. ratios of values from different datasets (urine, feces, skeleton) were used in order to normalize measured data. Such approach allows combining data from individual cases; however one degree of freedom is lost. A more stable dataset (activity in skeleton, excreted activity with urine), with lower scattering factor (excluding systematic part of uncertainty) was used for denominator. Figure 3 provides comparison of the measurements and the model predictions. It can be seen clearly, that feces to urine ratio is predicted properly, however both ratios with skeleton in denominator show significant difference.

Another way of comparison of the observed data with model predictions was that skeleton data of each case were fitted with a single exponential function and the exponents were compared with those predicted by the ICRP 67 americium model in the time interval from 5000 to 10000 days since the intake. Experimentally obtained exponents ranged from -7.44×10^{-5} to -2.45×10^{-6} with geometric mean -2.47×10^{-5}, which differs from the value of -4.07×10^{-5} from the ICRP model. When the same approach as for skeleton was applied for time course of excreted activity by urine and feces, the agreement of trends was poorer. The geometric mean of real data exponents is -3.14×10^{-4} for urine and -2.32×10^{-4} for feces, whereas the ones from standard ICRP 67 model are -1.02×10^{-4} and -1.08×10^{-4} respectively.

Discussion

The most questionable issue of the thesis was model modification. There are two serious questions: How can be interpreted intake estimates obtained from the improper fit? and What is credibility of the intakes or doses obtained from the person specific model? The reasoning of the author lead to conclusion that intakes with poor statistical measures has no any scientific value, and thus model has to be changed or not used.

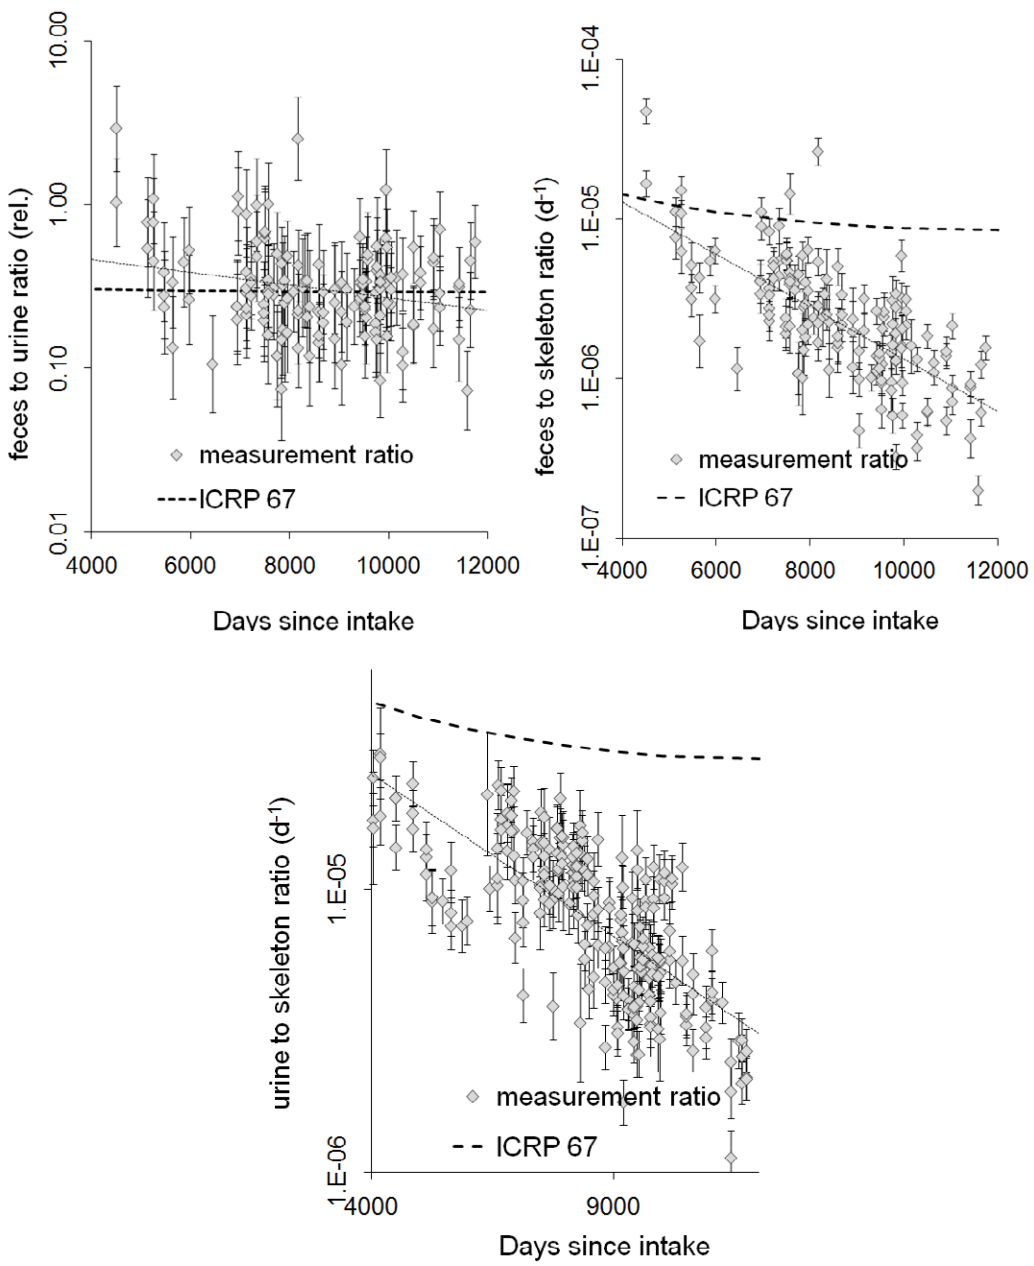

Fig. 3. Comparison of data and ICPR model prediction with basic setting.

The ICPR 67 model for americium consist of 14 compartments and together with the model of human alimentary tract represent quite complex system with many degrees of freedom, compare to three available data sets.

Ratio between skeleton and liver is quite variable base on autopsy data. Model assumes that 80% of the activity reaching blood is transfer to skeleton (30 %) and liver (50%). Increase of the skeletal portion (of these 80%) leads to reduction of activity excreted by feces and higher dose to bone surface. Thus overall dose to a subject will be higher. Adjustment of skeleton to liver ratio has no effect on bone metabolism (redistribution among bone surface, volume and marrow) which is based on studies with laboratory animals and has to be kept unchanged. Lower liver uptake can be explained by a radiation liver damage which may lead to rerelease of the liver activity to the blood. This issue was observed at high americium intakes per body mass of beagle dogs (Luciani et al. 2006).

Modification of urine excretion is more problematic. Reduction of excreted activity by urine could be adjusted by a change of soft tissue retention or directly by kidney to urinary blade or blood to urinary bladder transfer. There were no data on soft tissues and kidney thus blood to urinary bladder transfers was modified. The intervention does not change proportionality among kidney, soft tissue liver or skeleton i.e. does not affect model balance. Reduction of transfer rate from the blood to the small intestine, applied in JH case, has similar effect, i.e. does not significantly affect ratio among tissues and does not reduce overall dose too.

Author is aware that presented modification overestimate, compare to the standard model setting, dose and has an effect on early excretion of the americium in the model and thus used setting has neither general validity nor robustness. However, model adjustments improve significantly fit qualities to the level where can be accepted.

The trend of bioassay data was not imitated by the modified model. Insufficient data (no information on liver, kidney and soft tissue) does not permit more serious intervention to the model. Any trial in that way will be scientifically unjustified without data.

Conclusions

Every step of internal dose assessment was examined and relevant approach was used in the thesis. Application of MC technique for in vivo calibration and uncertainty assessment greatly improved skeletal data quality and provide valuable information on problematic issues among physical calibration phantom (namely USTUR BPAM-001 and BfS skull phantom). Estimated uncertainties of all data types enable better evaluation (proper weighting in fitting procedure) of the intakes as well as checking of the ICRP 67 americium model validity. Maximum likelihood fitting procedure together with statistical tests provided robust framework for intake estimation. Standard ICPR 67 model predictions between 5000 and 10000 days since intake were not able fit observed data of all subjects in acceptable manner. Person specific modification of the model lead to acceptable fits but not for urine data sets. Analysis of all cases together showed up that urine to feces ratio is predicted very well. Time trend of bioassay to skeleton ratios is quite constant in the model, while real data trends drop more rapidly. Detail analyses of the data trends imply that model underestimate retention in the skeleton, which was estimated from data to be about 77 years (mean half-time) over given time period. Time dependent reduction of exceed activity via bioassay is more rapid in the reality, i.e. excretion is lessen with the increasing time, than in the model. Person specific doses were determined however results are not only way to solution. All subject data and general findings were presented in 2009 on International Conference on the Health Effects of Incorporated Radionuclides and accepted for publication in Journal of the Health Physics Society (Malátová, in press).

Radiation protection dosimetry using recombination chambers at radiotherapy facilities

Gryzinski, Michal
Institute of Atomic Energy POLATOM, POLAND

Abstract

Radiation protection measurements in radiotherapy departments concern either patients or medical personnel and technical personnel. In some rare cases radiation doses to other persons (carers, comforters and visitors), should also be evaluated. Patient protection involves in-phantom measurements, which are performed first of all for treatment planning but can also be used for determination of dose equivalents in patient's organs outside the treatment field. Occupational radiation protection is based on determination of ambient dose equivalent H*(10) at workplaces and on individual monitoring of exposed persons. In the paper we will discuss only the radiation protection dosimetry.

Usually, free-air ionization chambers are used for X-ray measurements at electron accelerators and neutron rem-meters with appropriate moderators for determination of neutron dose in case of radiotherapy with protons and heavy ions. The paper presents additional possibilities offered by use of recombination chambers and measuring methods based on initial recombination of ions. The main advantage is that the recombination methods can provide information about parameters of radiation quality (radiation quality factor, neutron-to-gamma dose ratio, distribution of absorbed dose versus LET).

The paper shows four examples how the chambers can be used at different radiotherapy facilities:

1) Measurements of H*(10) and neutron dose along the patient table at 15 MV X-ray therapy (Oncology Centre, Warsaw, Poland). The measurements were performed in the cabin, in the maze, in the control room and in the corridor at the entrance to the maze with slightly opened door;
2) Measurements of H*(10) and evaluation of radiation quality factor near a phantom irradiated by 170 MeV protons in the proton therapy treatment room of the Dubna phasotron (Russia);
3) Characterisation of mixed radiation field inside and outside therapy cave for eye proton therapy (60 MeV proton cyclotron, Kraków, Poland);
4) Measurements of H*(10) behind shielding of heavy ion therapy facility (GSI, Darmstadt, Germany).

Introduction

In general there are two types of radiotherapy facilities: electron/X-ray and hadron. In the paper we will discuss only the radiation protection dosimetry at those facilities because the dosimetry for radiotherapy is a substantially different subject (values of dose rates in the irradiated organ and outside shielding differ up to a billion times). For the radiation protection of the patient, personnel and other persons e.g. comforters, it is necessary to estimate the equivalent dose in the patient's organs or in appropriate phantoms, and the ambient dose equivalent values inside and outside the treatment room. This obviously should be taken into account when selecting an appropriate detector.

Radiotherapy departments are usually equipped with dosimetric detectors for X-ray and gamma radiations. Sometimes, there are also neutron dose-equivalent-meters (rem-meters), especially at hadron therapy facilities. The additional use of a recombination chamber can be advantageous, because this chamber is sensitive to all kinds of radiation and provides information on radiation quality.

Material and methods

Recombination chambers and recombination methods

Recombination chambers are high-pressure ionization chambers, designed in such a way that, for a certain range of gas pressure and dose rates, initial recombination of ions occurs when the chamber operates at polarizing voltages below saturation, and is much greater than volume recombination. This phenomenon is used for the determination of dosimetric quantities dependent on radiation quality, using a relationship between the initial recombination efficiency and local ion density (in ionised gas).

Electrodes of the chambers are mostly made with a tissue-equivalent material. Gas in the chamber usually contains hydrocarbons; however, hydrogen-free chambers are also used as detectors with very low sensitivity to high-LET radiation.

Measurements of H*(10) were mostly performed with a large recombination chamber of the REM-2 type. This is a cylindrical, parallel-plate ionization chamber with 25 tissue-equivalent electrodes, volume of 1800 cm^3, mass of 6 kg and effective wall thickness of about 2 g/cm^2. The chamber of the same design, but with Al electrodes and filled with CO_2 (2.8 MPa), is denoted as GW2. The tissue-equivalent chamber filled with BF_3 is referred as BOR-3.

All recombination methods are based on the comparison of ion collection efficiency at a given polarizing voltage U, in the investigated radiation field, and the ion collection efficiency at the same voltage U in the reference gamma radiation field (in our measurements, this was the radiation field of a ^{137}Cs source). Therefore, either the whole saturation curve should be determined or a number of points on this curve (at least two), depending on the dosimetric quantities to be determined and on the desired accuracy.

About 30 types of recombination chambers and about 20 recombination methods have been developed until now (Zielczynski and Golnik 2000, Golnik 1996, Zielczynski et al. 2007); however, only a few of them were used at RT facilities. Among them, there are:

(1) The method based on the determination of the recombination index of radiation quality (RIQ, Q_R) (Zielczynski and Golnik 1994). In this method, two values of the polarizing voltage should be applied consecutively to the chamber electrodes in order to determine the absorbed dose and to estimate the radiation quality factor. One voltage should be high enough to ensure that the chamber operates close to saturation. At the second voltage, specific for certain chambers, initial recombination occurs and the ion collection efficiency is measured.

(2) The extrapolation recombination method (ERM) (Zielczynski 2004). Measurements of the ionization current at four to seven voltages are needed in order to determine separately the low- and high-LET components of the absorbed dose.

(3) The recombination microdosimetry method (RMM) (Golnik 1995 and Golnik 1996). Here, about 20 polarizing voltages should be applied in order to obtain a crude distribution of the absorbed dose versus restricted LET. When RMM is used for the determination of only two components of the absorbed dose, associated with low- and high-LET particles, this method becomes similar to ERM.

Difficulties associated with measurements

(1) When recombination chambers operate also at low voltages (several volts), the charge memory effect may occur, i.e. the measured ionization current depends on history of the chamber's operation (Zielczynski and Golnik 2000). The uncertainty caused by the charge memory effect can be practically eliminated by performing measurements at both polarities of voltage applied and averaging the measured values of ionization current.

(2) Cables connecting the chamber with registration units are usually long. This is, above all, inconvenient; but also, long electrometric cables can cause additional noise therefore diminishing the accuracy of the measurements.

(3) Precise monitoring of facility radiation filed is needed, especially when sequential measurements of the ionization current at different voltages are performed.

Results

The examples shown here were selected mainly with the intention to present the measurements of such parameters which could be determined with recombination chambers, while they were not measurable neither with free-air ionization chambers nor with standard neutron rem-meters.

Measurements at the treatment room at a 15 MV medical accelerator at the Maria Curie Oncology Centre in Warsaw (Poland)

Several measurement series were performed at the 15 MV Varian Clinac 2300C/D accelerator at the Oncology Centre in Warsaw. H*(10) was measured also in the treatment room and in the control room using a BOR-3 chamber placed in a 1 kg paraffin moderator. The chamber was designed so that its response (the ratio of the current at appropriate voltage to H*(10)) was nearly the same for gamma radiation and for neutrons of the energy range similar to the neutron energy spectrum at medical accelerators.

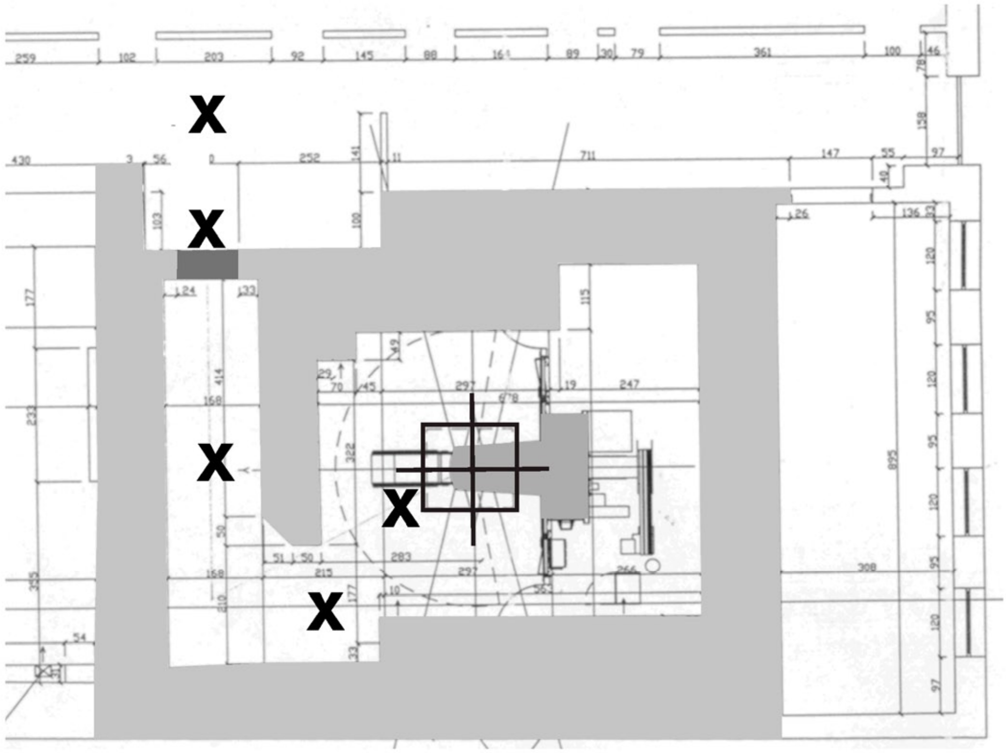

Fig. 1. The measurement points at 15 MV Varian at the Oncology Centre in Warsaw: by the patient table, in the maze, in the corridor (slightly opened door).

The following values of H*(10) have been obtained for a 4×4 cm^2 irradiation field, and a dose rate of 1 Gy/min at the isocentre: 33 mSv/h at 1 m from the isocentre (contribution of neutrons to the dose equivalent was found to be equal to 34%), 8 mSv/h at 3 m, 0.8 mSv/h in the maze and 1,3 μSv/h in the control room.

The measurements with recombination chambers have been performed also in the corridor behind the heavy shielding door (opened, partly opened and closed). This situation simulates the radiotherapy session in case of children irradiated and desired possibility of quick intervention of medical staff inside the treatment room (mentioned shielding door opens to slow).

The measurements were performed using the REM-2 chamber. During the measurements accelerator was operated continuously. The absorbed dose rate in the isocentre was 2.4 Gy/min. The total ambient dose equivalent rate at the entrance to the maze with door opened was H*(10) = 76 μSv/h, the ambient radiation quality factor Q*(10) was 2.6 Sv/Gy. The contribution of gamma radiation to H*(10) was determined by the hydrogen-free (neutron insensitive) recombination chamber GW2 was approximately 33% The value was H_γ*(10) = 24 μSv/h and neutron rem-meter Studsvik 2200 showed H_n*(10) = 51 μSv/h.

In the corridor with free access for people, the total ambient dose equivalent was 3 times smaller H*(10) = 25 μSv/h. When the shielding door was partly closed the value decreased to the value 2.7 μSv/h. Closing the door completely causes decrease of the value below 0.3 μSv/h).

Proton therapy facility of the Joint Institute for Nuclear Research in Dubna (Russia)

The measurements were performed at the Dubna phasotron using a 170 MeV proton beam with the intensity of 1.7 μA. The beam was directed onto the water phantom, and the Bragg peak was slightly broadened (2 cm at 90% of the maximum absorbed dose). The REM-2 chamber was used for the determination of H*(10) in the treatment room (Gryzinski et al. 2009).

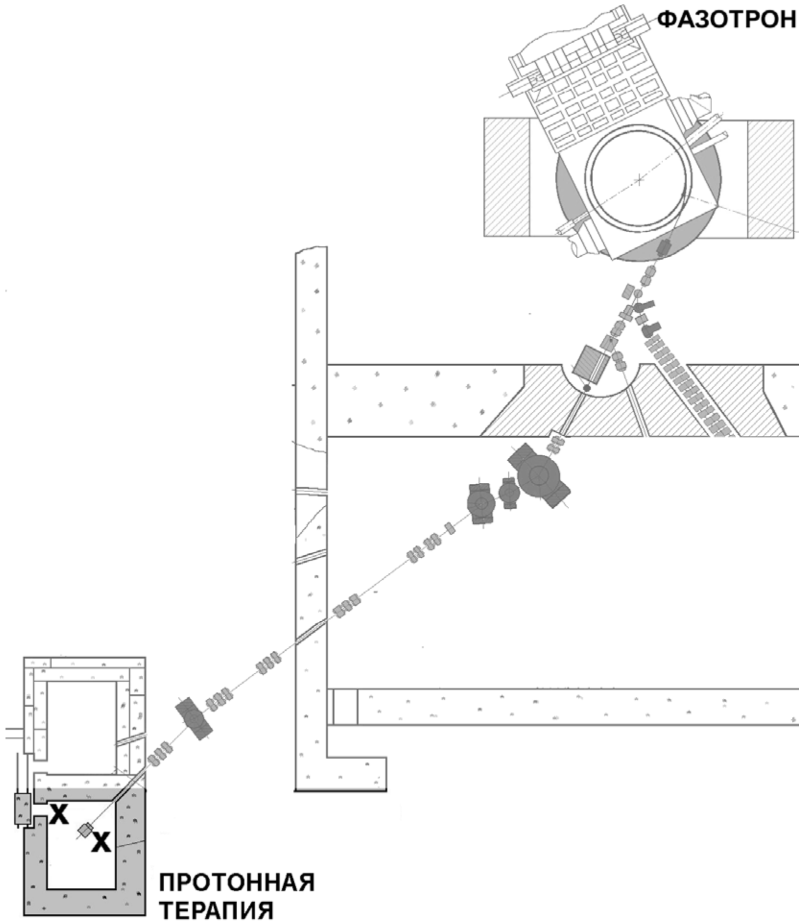

Fig. 1. The sketch of treatment room at 170 MeV proton therapy in Dubna.

A large recombination chamber of REM-2 type has been used for determination of the ambient dose equivalent, H*(10) and the ambient quality factors Q*(10) at different distances from the water phantom irradiated by 170 MeV protons – the water phantom represents the patient in the middle of the cabin. Measurement points represent places of eventually standing comforter: by the patient (at the distance 0.5 m and near the door at the distance 2.2 m from the isocentre). At the distance of 0.5 m, the ratio H*(10)/D was equal to 0.05 mSv/Gy, where D is the absorbed dose in the broadened Bragg peak. It shows that in specific cases it is possible to consider a bystander near the patient. It was shown that H*(10) was approximately inversely proportional to the distance from the phantom. The radiation quality factor Q*(10) was equal 3.5 ± 0.7 Sv/Gy at the distances from 0.5 m to 3.5 m.

The treatment room for proton therapy of the eye, Kraków (Poland)

An eye phantom was irradiated with a 40 MeV proton beam at 10% of the nominal intensity for the treatment. The total ambient dose equivalent rate (neutron + gamma), measured with an REM-2 chamber at the distance of 2.5 m from the phantom (point inside the treatment room P1), was H*(10) = 220 µSv/h, i.e. the value 10% higher than the reading of the neutron rem-meter NM2B of Nuclear Enterprises Ltd. The contribution of the gamma radiation, determined by a GW2 chamber, was about 5% of the total H*(10). The ambient quality factor Q*(10) was 7.7 Sv/Gy.

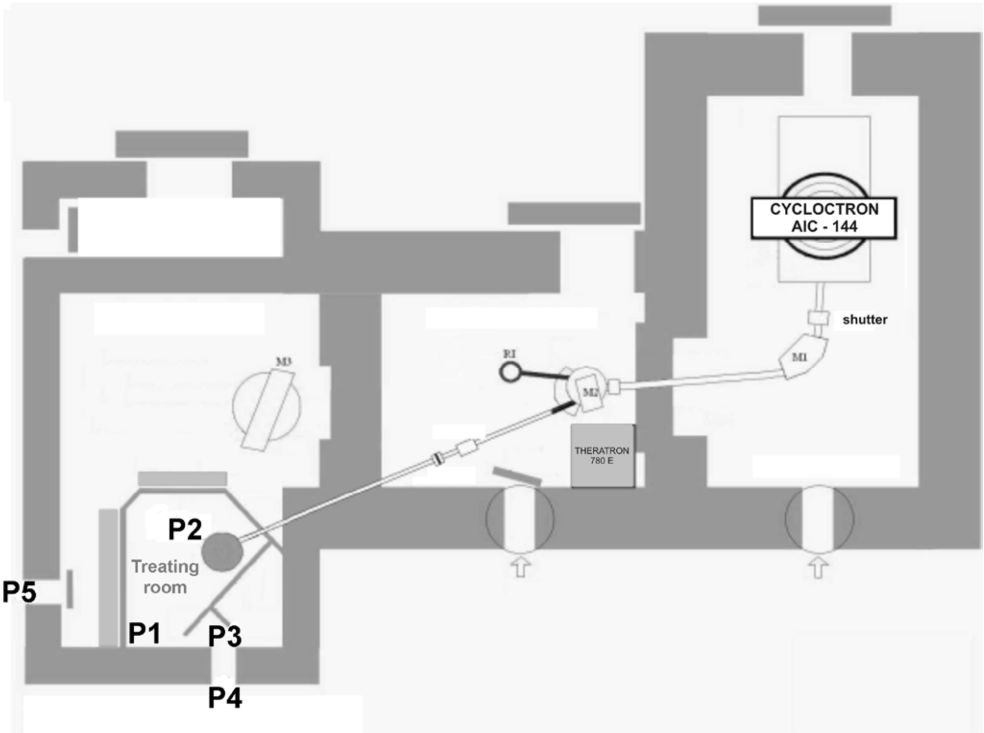

Fig. 1. The situational sketch of AIC-144 cyclotron in Kraków.

The measurements made inside the treatment room and in two points in the corridor (one near the entrance door P4 and the second on the line of accelerator beam P5) resulted in H*(10) 2 and 1.2 µSv/h, respectively. In the maze, close to the entrance door P3, the value was equal 18 µSv/h (40 MeV proton beam at 10% of the nominal intensity).

After shifting the energy to 57 MeV of protons in the facility in Kraków to its final form and intensity for eye therapy the values of H*(10) in those points are: 0.8 mSv/h at the distance 0.5 m (P2) and in the corridor 15 µSv/h (P4) and 10 µSv/h (P5). The contribution of gamma radiation was approximately 4% inside and 6% outside the treatment room.

Discussed possibility of a bystander near the patient for facility in Dubna could also be taken into account here. The ratio H*(10)/D for such person stayed during the treatment nearby patient (P2) was only 0.005 mSv/Gy, where D is the absorbed dose in the broadened Bragg peak (absorbed dose will not exceed 1 mSv for the treatment).

Outside shielding of a heavy ion therapy facility at GSI Darmstadt (Germany)

A beam of carbon ions with energy of 4.8 GeV was directed onto an Al target. Measurements of H*(10) were performed at the point denoted as OC-10, behind a concrete shield, using an REM-2 chamber, a hydrogen-free chamber GW2, and a BOR-3 chamber filled with BF_3 . The measurements gave the value of H*(10) = 26 µSv/h, which was about 1.5 times higher than the values measured with standard rem-meters. The contribution of gamma radiation to H*(10) was approximately 7%. The value of the ambient radiation quality factor Q*(10) was 4.7 Sv/Gy at the point of measurements.

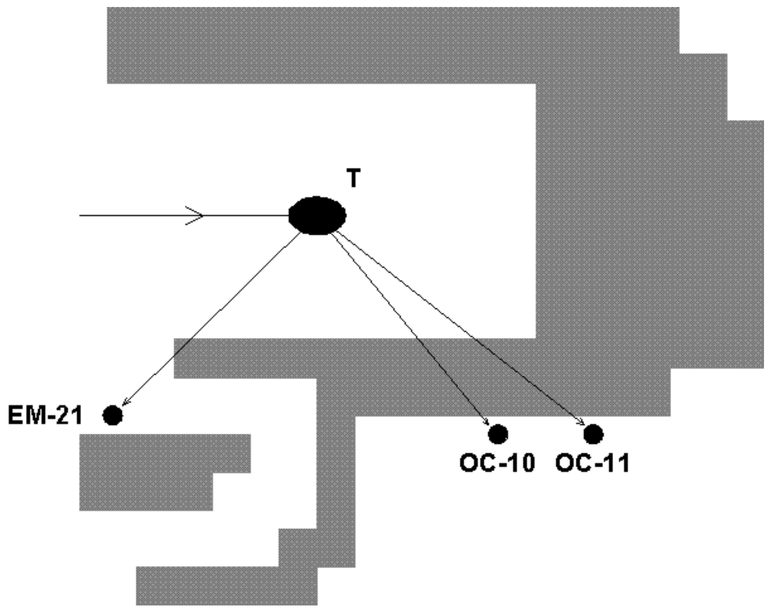

Fig. 1. The situational sketch of GSI ion therapy beam and concrete shielding. Results presented in this paper concern the point OC-10.

Conclusions

The measurements performed with recombination chambers at different radiotherapy facilities generating mixed radiation fields confirmed that the use of recombination chambers was very useful for the determination of the ambient dose equivalent and of other parameters of interest for radiation protection. The main advantage is that recombination chambers provide information on radiation quality, and it is possible to match the design of the chamber to the measure conditions.

The use of recombination chambers is especially advantageous in high-energy hadron therapy, because recombination chambers are sensitive to all kinds of radiation, including high-energy neutrons. The value of H*(10) measured with recombination chambers at high-energy facilities (outside the beam) is 10 to 50% higher than the values resulting from the measurements with standard rem-meters. There are two main reasons for such a difference: the first, that neutron rem-meters are insensitive to radiation other than neutrons, and the second, that they usually underestimate the ambient dose equivalent due to high-energy neutrons.

Abstract

In this paper Ozone production from radiolysis process (Kanda, 2001, 2005) due to radiation fields around a biomedical cyclotron has been studied. Ozone is known to be the most toxic gas produced by ionizing radiation around particle accelerators (Swanson, 1980), (Holloway et al., 1980) , (NCRP, 2005).

In order to evaluate Ozone concentration in working environment, two measurement campaign, with short term and long term, were performed, using passive diffusion dosimeters. Considering the concentration's limits issued by ACGIH (American Conference of Governmental Industrial Hygienists) as reference values, the results of measurement campaigns demonstrated that Ozone is typically present at levels of < 0.1 ppm and does not represent a significant risk factor for workers around a biomedical cyclotron.

Introduction

Intense radiation fields can produce Ozone in ambient air around particle accelerators, due to radiolysis process. This toxic gas is produced in the interaction of radiation with major air components, Oxygen and Nitrogen; this process is considered to be relatively independent from the type of radiation, so that it is expected that gamma, beta and also neutron radiation are effective Ozone generators (Swanson, 1980).

Ozone is a very reactive molecule. It can cause damages to the respiratory system if inhaled in ambient air concentration about 1 ppm; higher concentrations can cause also pulmonary edema. Moreover, it is known that there are relevant individual differences in response to Ozone inhalation (CDC, 2005). Being then Ozone presence a potential risk for operators at accelerator facilities (Holloway et al., 1980), an evaluation of its concentration in a specific work environment becomes a relevant component of health and safety assessment.

The number of cyclotron installation in the world is strongly increased, in the last 10 years, due to the success of Positron Emission Tomography (PET); in these installations, the principal risk factor for workers is clearly related to radiation fields;

nevertheless, concurring risk factors should be considered as well. Among these factors, Ozone needs particular attention; however, few data have been published as regards Ozone production in biomedical cyclotron installations.

In this work we tested the use of simple and inexpensive passive Ozone monitoring dosimeters, in order to assess their functionality in an accelerator facility and to obtain and estimate of Ozone concentration in the vault of a PET cyclotron and nearby laboratories.

Material and methods

In order to evaluate Ozone production at our installation, we perform a series of experimental measurements using a model of diffusion badge dosimeter (ChromAir, K&M environmental, AFC International Inc., La Motte IN). This is a direct reading, passive, diffusion dosimeter based on the indigo dye discoloration method (Bader, 1982).

The principle of operation of the diffusion dosimeters is shown in Fig. 1 .

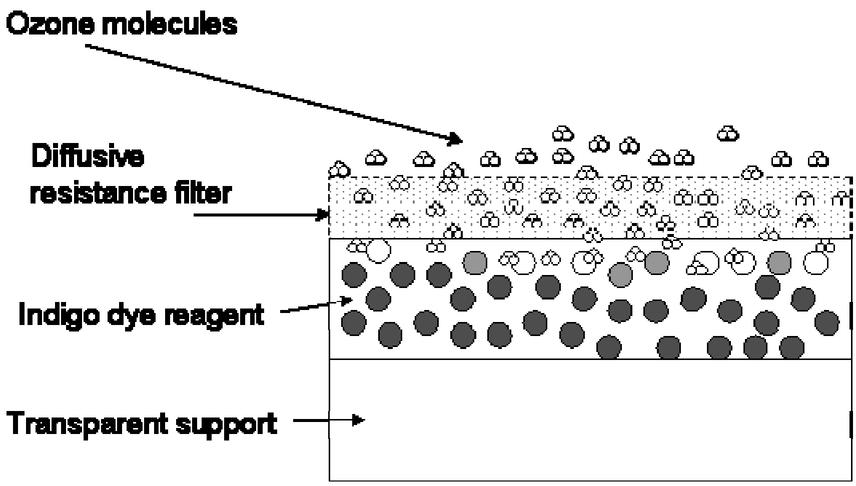

Fig. 1. Illustration of a section of the sensitive part of a dosimeter; the Ozone molecules diffuse gradually through diffusive resistances of different thickness. As they react with the dye (potassium indigo trisulfonate) this is decolored from blue to white.

Each dosimeter has six measurements cells, in contact with ambient air through diffusive resistance filters of increasing thickness; this produces a graduation of the exposure in each cell, that allows for a stepwise measurement on scale of integrated exposure (e.g. the product of concentration by exposure time) from 0.08 to 1.8 ppm·hour.

This type of device is simple to use and inexpensive, but its major advantage is that it is completely not influenced nor damaged by the intense radiation fields produced during irradiations; this makes possible to estimate the Ozone generation not only in working environments, but also inside the cyclotron bunker. The dosimeters are factory calibrated; reading is made by visual inspection and comparison with the background color in the scale reported in the back side of each badge (Fig. 2).

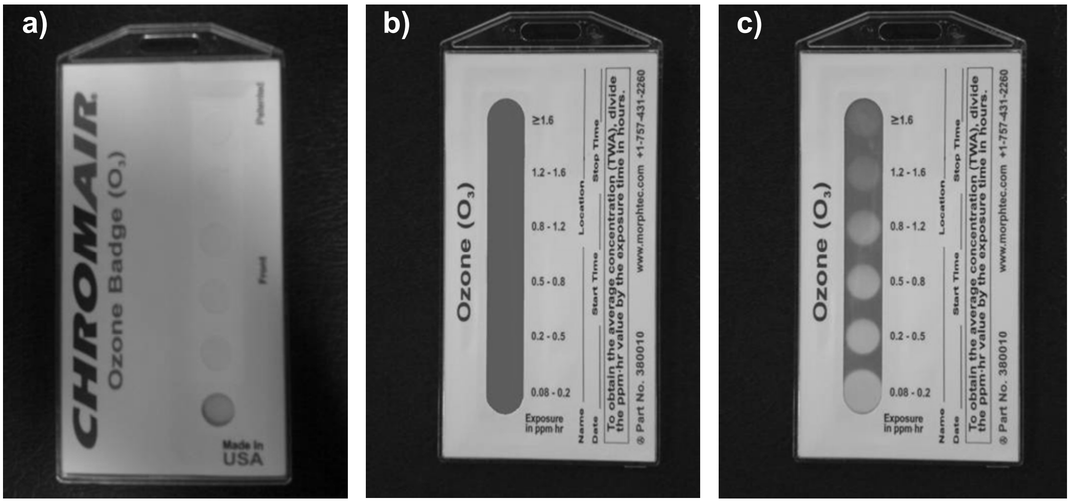

Fig. 1. a) front side of a dosimeter badge; b) Blank dosimeter backside; c) Dosimeter back side: decoloration due to Ozone absorption is evident.

As previously said, dosimeters provide measurement in ppm·hour; to set out the average concentration during the time of exposure, the reader has to pick the higher exposure cell, that is the higher in order with a color variation, and divide the corresponding value by the sampling time in hours.

On the other hand, these dosimeters are only moderately accurate; for our visual direct reading approach, measurement uncertainty has been evaluated as the half width of each measurement step between cell and cell. This means an uncertainty of the order of 40% at the lower level of concentration of 0.08 ppm·hour; in the central range of measurement, at a level of about 1 ppm·hour the uncertainty is evaluated at about 20 %; this is considered in line with the type of device and acceptable for the aim of this work.

Measurements were performed during routine irradiations with our GE PETtrace cyclotron, accelerating H- ions at 16.5 MeV on H218O liquid target for 18F- production (Marengo et al., 2008). The cyclotron in our site is "naked", e.g. not self-shielded, so that the total mass of air irradiated is relevant; the total volume of the vault is 120 m^3.

Diffusion dosimeters were placed in significant positions: inside the cyclotron bunker, in the radiopharmacy laboratory and, to assess the Ozone background, in adjacent rooms in which leakage radiation is very limited and outside the PET facility. The dosimeters positions were chosen in accordance with previous works, where radiation field at our site were characterized (Gallerani, 2008). Dosimeters were placed at an height of 1.5 m from the floor.

Two different series of measurement were preformed: a) limited time exposures, with the ventilation system off during normal and prolonged irradiation cycles and, b) long time exposures, with the ventilation system on the bunker working at the normal rate of air changes.

Limited time exposure were made either by exposing the dosimeters during typical 1 hour bombardment, with ventilation off, the removing the dosimeters, packing them in a sealed plastic bag and storing at 4°C until new exposure. A total time of 7.6 hours of bombardment were sampled in this way; furthermore, a single prolonged irradiation of 3.7 hours was performed.

One dosimeter was placed in air at a distance of 100 cm from the $H_2{}^{18}O$ target, at an angle of 45° from the beam direction. In the geometry of installation of the PETtrace cyclotron, this position represents the reference point for dose measurements. A second dosimeter was placed inside the bunker, on one of the peripheral walls at 180° form the beam direction and at a distance of 350 cm from the target.

During these measurements a "blank" dosimeter was positioned outside of the bunker, in the electronics technical room at a distance of 300 cm from the bunker shielded door. This dosimeter was left exposed to ambient air during the whole time interval of measurement (223 hours).

In long time sampling, with room ventilation on at normal air exchange rate of 10 vol/hour, two dosimeter were again placed in the bunker, one at the reference position at 100 cm form the target and the second on the peripheral wall at 180° at a distance of 350 cm from the target. Other dosimeters were placed in the electronics technical room, in the radiopharmacy laboratory (two positions), in front of the two most used synthesis hot cells, at a distance of 250 cm form the surface of the bunker wall and about 100 cm from the front of the hot cells. Furthermore, a "blank" dosimeter was placed in the exterior of the PET centre building, to sample environmental Ozone outside of the facility. Two long term sampling, each for a time of 240 hours of continuous exposure were performed. During each of these samplings, the effective bombardment time was of 20 hours, while during the remaining time the cyclotron was in standby mode.Body text, first paragraph after the heading.

Results

During all the experimental measures, no sign of damage was observed at a visual inspection on all the 30 dosimeters used. Activation was negligible, even for the dosimeters placed at the reference position at 100 cm from the target, were the secondary neutron flux is relatively intense.

In the short time measurements performed only during bombardment time, with room ventilation off, none of the dosimeters showed any discoloration, even in the first cell. Ozone exposure was lower than the minimum detectable quantity. Being the lower level of measurement of the dosimeters at 0.08 ppm·hour, the upper limit of concentration was obtained by dividing the detection limit by exposure time. Table I reports the results of these measurements; it has to be recalled that the "blank" dosimeter in this series of sampling was exposed during all the campaign (223 hours); The results of long term samplings of 220 hours, with normal room air ventilation, are shown in Table II.

In these measurements, all the detectors being exposed for a long time, thus to increased amounts of Ozone, showed discoloration up to the third / fourth cell. However, average concentrations resulted to be very low and in agreement with the minimum detectable concentration evaluated for short term measurements.

All the average concentration measured were less than 0.01 ppm and, in particular, there was no significant difference, in consideration of measurement uncertainties, between the values obtained in the working areas and in environment air outside of the facility. In long term irradiations with ventilation off ($^{18}F^-$ target loaded with $H_2{}^{18}O$, 4 hours irradiation at 40 μA), the concentration measured was less than 2.10^{-2} ppm.

Table 1. Summary results of the short term measurements with room ventilation off.

Measurement position	Average concentration (ppm)	Uncertainty (ppm)
Inside the bunker, at reference position at 100 cm from the target	< 0.01	0.008
Inside the bunker, peripheral wall	< 0.01	0.008
Electronics technical room	0.002	0.0007

Table 2. Summary results of the long term measurements with room ventilation on.

Measurement position	Average concentration (ppm)	Uncertainty (ppm)
Inside the bunker, at reference position at 100 cm from the target	0.006	0.0008
Inside the bunker, peripheral wall	0.005	0.0008
Electronics technical room	0.003	0.0006
Radiopharmacy lab position 1	0.005	0.0008
Radiopharmacy lab position 2	0.005	0.0008
Exterior of the facility	0.006	0.0008

Conclusions

The American Conference of Governmental Industrial Hygienists (ACGIH) indicates exposure limit values, TLV (Threshold Limit Value), representing the concentration levels in ambient air to which workers may be exposed without adverse effects for health (ACGIH, 2001, 2009). Concentration's limits issued by ACGIH were assumed as reference values for comparison of our results (CTIPLL-ISPESL, 2006).

The most important quantity to be considered is the TLV-TWA, set to 0.1 ppm for Ozone. TLV-TWA is the Time Weighted Average limit, that represents the value of concentration to which workers are exposed in continuous, long time working conditions.

It's important to pay attention to the fact that TLV does not represent a border line between danger and safety, but they are only indicative values for comparison in the sake of optimization .

The main result of our work is that all our experimental measures showed that Ozone concentration in a busy PET facility with a non self-shielded cyclotron, are at least one order of magnitude less than the TLV, not only in the radiopharmaceutical laboratory area, but also inside the cyclotron vault.

According to our results, if an assessment of Ozone production in a PET cyclotron facility still worth careful consideration, it is confirmed not to be a relevant risk factor, even in conditions of limited air exchange rate. This conclusion can guide choices in term of the needs for monitoring. In particular, on the basis of our results, provision for installed systems for continuous sampling or investment for dedicated active monitoring equipment should be considered not justified.

Instead, passive, easy to use and relatively inexpensive dosimeters like the ones we tested in this study, proved to be adequate and, taking into account complete insensitivity to radiation fields, they can be considered a useful tool for periodic monitoring campaigns aimed to confirm working conditions.

Reproducibility assessment for a new neutron dose evaluation system

Mayer, Sabine; Boschung, Markus; Fiechtner-Scharrer, Annette
Paul Scherrer Institut, Radiation Metrology Section, CH-5232 Villigen PSI, SWITZERLAND

Abstract
The Paul Scherrer Institut (PSI) is investigating a new neutron dose evaluation system manufactured by TASL. This system takes images of the etched tracks in CR-39 detectors by a high magnification microscope, which are then analysed by a software algorithm. Each measured track is characterised by a multitude of separate parameters, which are then used in the neutron exposure algorithm to enable optimum noise discrimination, sensitivity calibration and dose calculation. However, before the system can be used in the routine dosimetry service, it has to be tested for its intrinsic properties, such as reproducibility, linearity, stability etc. In this paper we focus on the reproducibility of the evaluation process. Three sets of detectors, i.e. non-irradiated detectors as well as detectors irradiated with 3 mSv and 6 mSv, were analyzed for reproducibility study throughout the duration of 10 weeks. Interesting behaviour was observed, which will be used as input for potential improvements in the treatment of the detectors and for possible adaptations of the evaluation algorithm by the manufacturer.

Introduction
The Paul Scherrer Institut in Switzerland has been accredited by the Swiss Accreditation Service (SAS) for measuring the personal neutron dose equivalent with chemical etched CR-39 (PADC, Poly Allyl Diglycol Carbonate) detectors since 1998. Since then the track counting has been performed with the Autoscan 60 reader, where a “light-in-the-detector’s side” technique is used, which causes the etched tracks or pits in the detector to be seen as points of light and can hence be counted (Fiechtner and Wernli 1999). However, the Autoscan 60 has the disadvantage that it is no longer manufactured and a direct consequence of this is the shortage of spare components. For this reason the PSI is investigating a new evaluation system manufactured by TASL. However, before the system can be used in the routine dosimetry service, it has to be tested for its intrinsic properties, such as reproducibility, linearity, stability etc. In this paper we focus on the reproducibility of the evaluation process.

Material and methods

CR-39 detectors

The study was carried out with CR-39 detectors from the manufacturer TASL. For measuring the neutron dose the CR-39 detector is packed into a dosemeter holder (Figure 1), made of hydrogenous material (about 10% hydrogen). The neutron dosemeter is sensitive to neutrons with energies above ~200 keV.

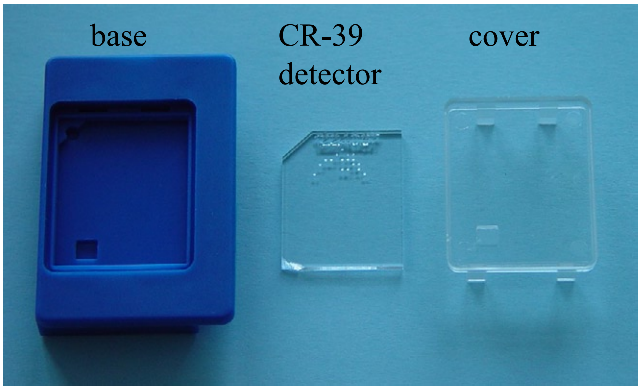

Fig. 1. CR-39 detector and dosemeter holder (base and cover).

Etching procedure and evaluation

Before the CR-39 detector can be evaluated, it has to undergo a chemical etching process. According to the recommendations by the manufacturer, the detectors are etched for 2 h 50 min with 6.25 N sodium hydroxide at 85°C. The etching process is terminated via a neutralisation for 15 min in a weak hydrochloric acid solution (0.1 N HCl) and a cleaning with hot and cold distilled water. After this process the detectors are evaluated on the evaluation system by TASL. This system acquires images of the etched tracks by a high magnification microscope, which are then analysed by a software algorithm. Each measured track is characterised by a multitude of separate parameters, such as covering size, shape, position, optical density, noise discrimination or quality of measurement. These parameters are then used in the neutron exposure algorithm to enable optimum noise discrimination, sensitivity calibration and dose calculation.

Measurements and Results

Reproducibility testing was performed with a set of 30 detectors consisting of 10 non-irradiated detectors, 10 detectors exposed to a personal neutron dose equivalent of 3 mSv and 10 detectors to a personal neutron dose equivalent of 6 mSv. The calibration was performed in an Am-Be reference field at the calibration laboratory of PSI. All detectors were analyzed with the TASL-system 16 times over the course of two months. Initially a scan was carried out every second day and afterwards with an increasing time interval but always at least once per week. The readings of each sub-set over time are shown in Figure 2-4. From the figures following observations can be made:

(a) The non-irradiated detectors have a mean background dose equivalent of 0.03 mSv. The standard deviation is 0.06 mSv. Because of the internal dose algorithm the background values can also be slightly negative. Over the period of testing the analyzed set shows a constant pattern.

(b) The set of detectors irradiated with a reference dose equivalent of 3 mSv show a mean dose equivalent of 3.6 ± 0.8 mSv over all readings during the complete time period. The measured dose increases over time from a mean value of 3 ± 0.2 mSv at scan 1 (averaged over detector 1 to 10) to a mean value of 3.8 ± 0.8 mSv at scan 16. From time to time outliers (scan 5, 8, 15) are observed, which were not identified by the software as a problem.

(c) For the set of the detectors irradiated with a reference dose equivalent of 6 mSv the average dose equivalent of 6.1 ± 1.0 mSv was obtained over all readings during the complete time period. The measured dose increases over time from a mean value of 6 ± 0.6 mSv at scan 1 (averaged over detector 1 to 10) to a mean value to 6.6 ± 0.6 mSv at scan 16. Detector 9 shows a strange behaviour in the middle of the testing period, but this effect was indicated as “rejected” by the evaluation software. The variance of the readings is smaller for the higher reference dose of 6 mSv than for 3 mSv.

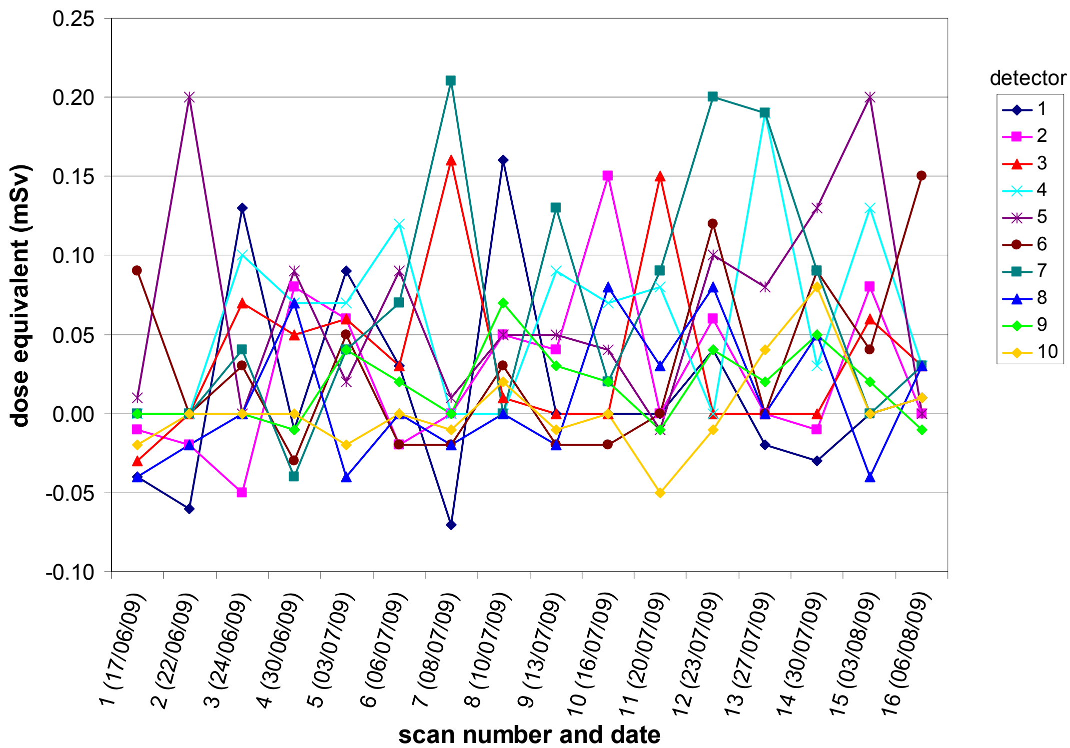

Fig. 2. Readings of 10 non-irradiated detectors versus scan date.

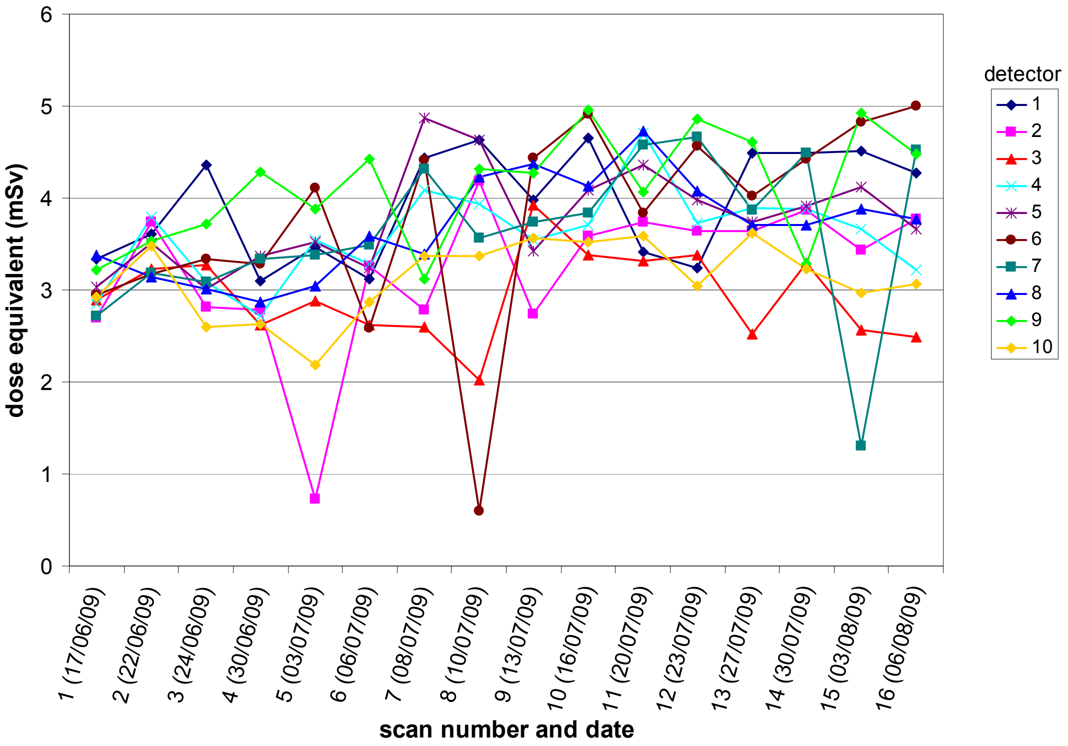

Fig. 3. Readings of 10 detectors irradiated with 3 mSv versus scan date.

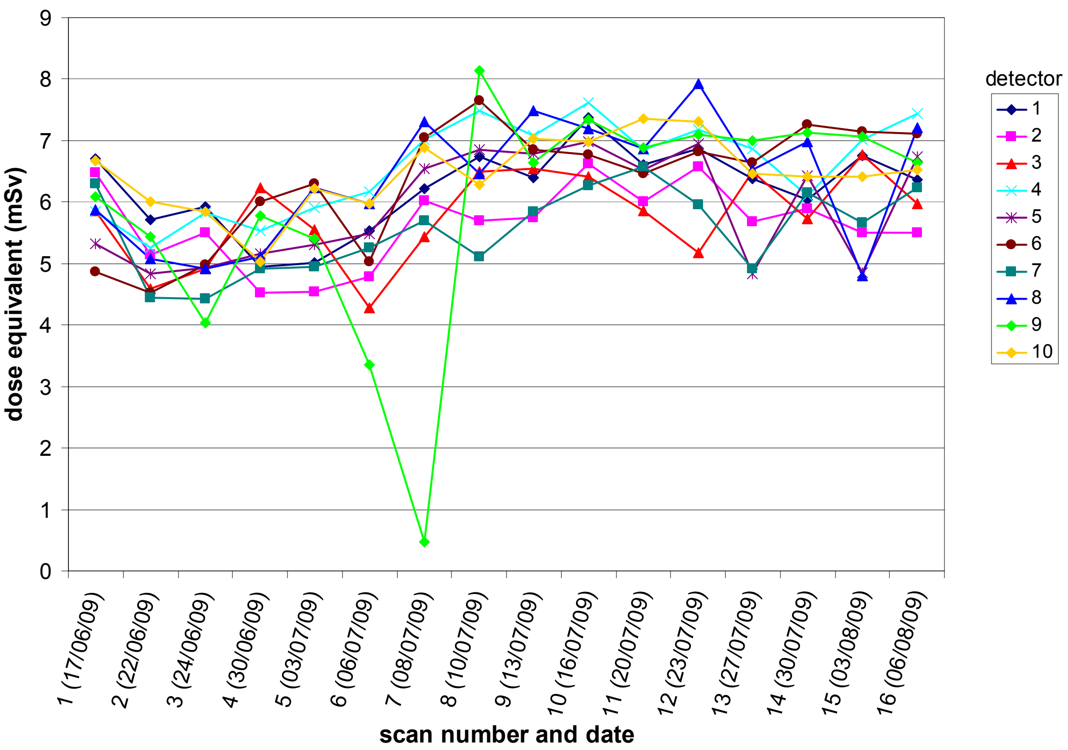

Fig. 4. Readings of 10 detectors irradiated with 6 mSv versus scan date.

Discussion and conclusions

The analysis of the non-irradiated detectors shows a stable behaviour over the testing period. In case of the irradiated detectors, a time effect could be observed. Especially the detectors irradiated with 6 mSv appear to have lower doses during the first few scans before settling down to a higher dose value. In addition, the study shows that some detector's scans have unexpectedly low values. Only in case of the higher reference dose, this effect was indicated as a problem by the evaluation software and rescanning was advised. The other outliers were not identified by the software algorithm.

The study indicates that there is a strong need for a subsequent reproducibility study to collect more data for a better interpretation of the behaviour of irradiated detectors. Moreover, linearity tests and an intensive collaboration with the software developers are foreseen for eventual adaptations of the neutron dose algorithm.

Simulations of radiation fields of a photon and a fast neutron calibration facility

Becker, Frank; Harrendorf, Marco A.
Karlsruhe Institute of Technology (KIT) – Institute for Radiation Research (ISF), GERMANY

Abstract
At the Karlsruhe Institute of Technology (KIT) (formerly: Forschungszentrum Karlsruhe (FZK)) exists a calibration laboratory for dosimetry and radiation protection purposes. The laboratory provides different radiation fields such as photons stemming from Cs-137 sources and X-ray devices as well as fast neutrons from a Cf-252 source.

The reference fields, which are mainly used for calibrations of active and passive radiation protection monitoring instruments, are characterized according to ISO calibration procedures. In order to verify that radiation field qualities are according to international standards not only measurements but also simulations were performed. In this way suitable conditions for research and calibration purposes are guaranteed. Additionally the variability of the fields (including backscattering) which is difficult to impossible to measure can be determined by simulations.

The simulations were carried out with the Monte Carlo Codes MCNP5 and PENELOPE2008.

Introduction
In the field of radiation protection dosimeters and dose rate meters are used in many areas such as individual monitoring or environmental monitoring. The corresponding measuring instruments are calibrated in reference radiation fields defined by a national or international standard. The proof that the fields comply with the regulations of ISO standards can be provided by measurements and/or radiation transport simulations. But measurements are often too complex and laborious so that simulations are used which can be verified by few relevant measurements.

The calibration laboratory at KIT provides different photon and neutron radiation fields for dosimetry and calibration purposes. Among other things the calibration laboratory possess a Cs-137 radiation facility consisting of four Cs-137 sources with different source strengths and an X-ray irradiation facility consisting of a low and a high energy X-ray tube. The photon irradiation devices are installed in a concrete bunker, while a Cf-252 neutron radiation facility is located in a wooden hall.

For research and quality management purposes simulation models of the different calibration facilities were created and first simulations to investigate the properties of the radiation fields of these facilities were performed.

Examples of investigations are:

- The determination of the influence of backscattering on the dose conversion for the Cs-137 irradiation facility
- The determination of X-ray spectra for the X-ray irradiation facility and the comparison with reference spectra
- A dose estimation at and around the Cf-252 neutron irradiation facility

The determination of the influence of backscattering on the dose conversion for the Cs-137 irradiation facility

Dosimeters for individual and environment monitoring indicate the dose (or dose rate) in personal dose equivalent or ambient dose equivalent. However, air kerma is the radiation quantity often used for calibrated ionization chambers (secondary standards) to determine the reference photon dose at a calibration point. Therefore conversion coefficients from e.g. air kerma to ambient dose equivalent are needed.

For a proper characterization of the Cs-137 irradiation field it is essential to know the uncertainty of the dose conversion. The uncertainty is mainly caused by backscattered photons who lead to a difference between the real Cs-137 energy spectrum at the point of calibration and the theoretical ideal energy spectrum defined in the international standard ISO 4037-1 (ISO 4037-1 1996). This difference could lead to non-negligible uncertainties when applying a dose conversion calculation.

The ISO 4037-1 requires an uncertainty of 2 % for the dose conversion, when no better estimation is known. An irradiation place specific estimation for the dose conversion uncertainty was obtained from simulations with the radiation transport program MCNP5 (X-5 Monte Carlo Team 2003).

The determination of X-ray spectra for the X-ray radiation facility and the comparison with reference fields

The energy distribution of X-ray radiation fields is dependent on the construction of the X-ray tube and the surrounding area. Variations of the energy distribution can lead to fundamental dose variations and therefore wrong calibrations. For that reason one has to prove that the energy distribution of the calibration fields conforms to the reference energy distribution given by ISO 4037-1.

Simulations with the radiation transport program PENELOPE2008 (Salvat et al. 2008) were performed to determine the theoretical energy spectra produced by the two X-ray tubes of the calibration facility. The simulation model is based on the technical drawings of the X-ray tubes. The simulated energy spectra were compared to energy spectra which were measured at the reference radiation fields of the Physikalisch-Technische Bundesanstalt (PTB). Mean energies as well as the full-width-at-half-maxima (FWHM) of the spectra were determined.

The dose estimation for fundamental measuring points of the Cf-252 neutron radiation facility

The calibration laboratory possesses a Cf-252 neutron irradiation facility. The neutron source is now 7 years old and according to the half-life of 2.7 years the source activity becomes quite low. Therefore it is aimed to buy a new Cf-252 source with a higher activity. Due to the short life-time it is advantageous to order the highest possible source activity with respect to the given dose limits at and around the facility.

Simulations with the radiation transport program MCNP5 were performed to estimate the neutron dose at different measuring points inside and outside of the calibration laboratory. By comparison of the calculated doses with measured ones the used simulation model could be verified and the highest tolerable activity for a new source could be estimated.

Material and methods

Simulation models for the radiation facilities were created and simulations were performed either by using the radiation transport program PENELOPE2008 or MCNP5. MCNP5 was used for the Cs-137 photon source and the Cf-252 neutron source. PENELOPE2008 was used for the X-ray irradiation facility, because it is optimized for simulating electrons and photons in the low energy range of X-rays. While MCNP5 uses class I algorithms, PENELOPE2008 allows to apply a class II algorithm.

Cs-137 source

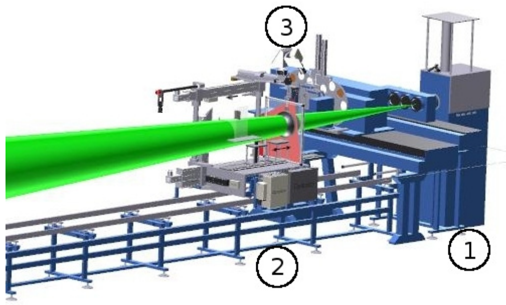

Figure 1. Drawing of the photon irradiation facility inside the concrete bunker (Liedtke 2008): Shown are the shielded storage place for the Cs-137 sources (1), the slide system to place dosimeters/devices at different distances on the central axis of the photon beam (2), in green an example for a collimated Cs-137 beam, and the two X-ray tubes which can be moved to the central beam axis instead of the Cs-137 sources (3).

A simplified model of the photon irradiation facility was created. Figure 1 shows the drawing on the facility inside the concrete bunker. Four Cs-137 sources with different source strengths are located in a shielded storage place and can be moved out in a system which provides a collimated beam. A slide system provides the possibility to place dosimeters/devices at different distances on the central axis of the Cs-137 beam. For the simulations the surrounding concrete walls and floors were also considered.

X-ray device

Models of the two different tubes were realized according to their construction specifications (see fig. 1 for the location of the devices). The simulation of the X-Ray fields originates in the process of electrons impinging on the anode of the X-ray tube. The simulations include the influence of self-absorption and the effect of the exit window as well as the individual absorbers required for N-Series standards after ISO-4037-1. In figure 2 a "model"-tube is displayed.

To determine the spectra of the fields, a „virtual“ detector was placed on the central beam axis at one meter distance from the anode. This geometry complies with the measured reference spectra from PTB (Böttcher Büermann 2009).

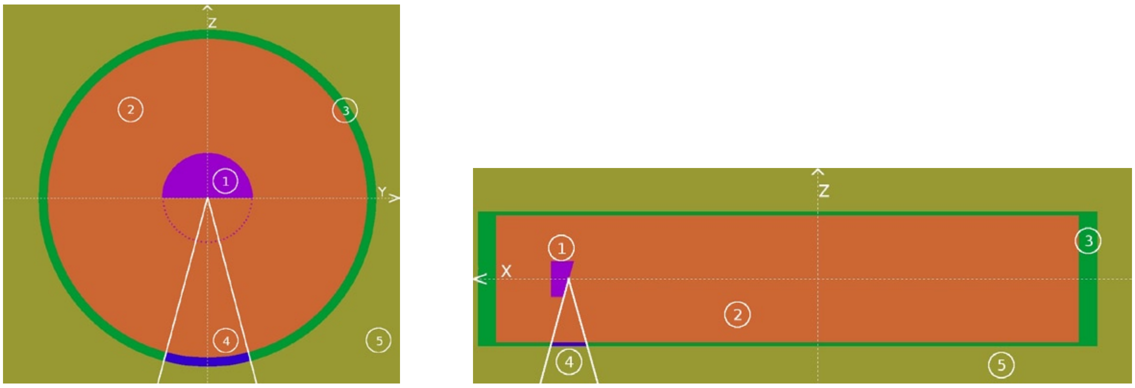

Figure 2. Simulation model of the low energy X-ray tube in top (left) and side view (right) (Harendorf II 2009): Shown is the tilted anode (1), the vacuum (2) in the steel cylinder (3), the exit window (4) and the surrounding air space (5).

Cf-252 source

The Cf-252 source is stored in a shielded place in the ground and can be moved out in a flexible tube to the irradiation place. Driven out in irradiation position, the source is placed in a thin aluminium cylinder. This cylinder together with the source inside has a PTB-reference calibration for the neutron flux. To realize almost free-in-air conditions the device is installed in a wooden irradiation hall and usually mounted 3-4 m above the ground.

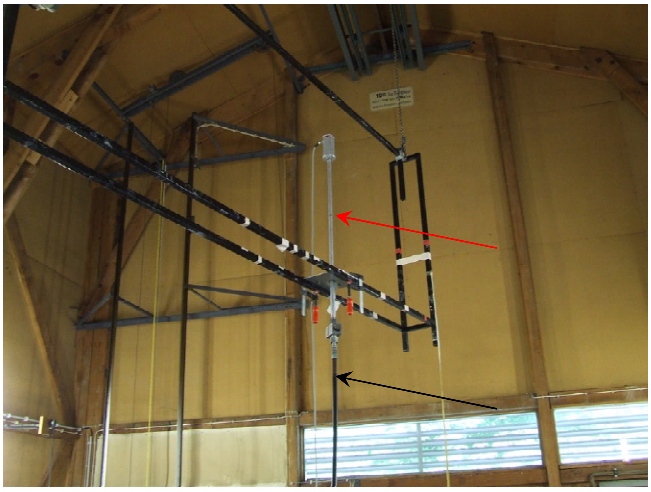

Figure 3. The irradiation device in the wooden irradiation hall: The red arrow indicates the position of the moved out Cf-252 source in a thin aluminium cylinder. The source can be moved to this place in a flexible tube from a shielded storage place (black arrow). The black frame of a provisional hoist system and parts of the wooden hall are visible too.

Results

Cs-137 source

Simulations were performed to investigate the uncertainties of the conversion from the photon fluence into air kerma and into ambient dose equivalent, respectively. Scattered photons in the irradiation facility yield the main contribution to the uncertainty of this conversion procedure. From both conversions finally an uncertainty of the conversion from air kerma into the ambient dose equivalent was deduced. The result for this uncertainty amounts to 1.34 % (Harrendorf I 09).

However this value for the uncertainty is mainly limited by the statistics of the simulations. To obtain the result 7.5 x 10^8 source photons were simulated with MCNP5. With the used complex geometry of the irradiation device including walls and floors the simulation took almost a week to finish.

X-ray source

In figure 4 a comparison of simulated and measured X-ray spectra is exemplary shown for a tube potential of 40 kV (Harrendorf II 2009). Plotted is the "PENELOPE" named spectrum of the simulation and the two spectra measured at PTB (PTB 150 kV, PTB 300 kV). The simulated and measured spectra agree quite well.

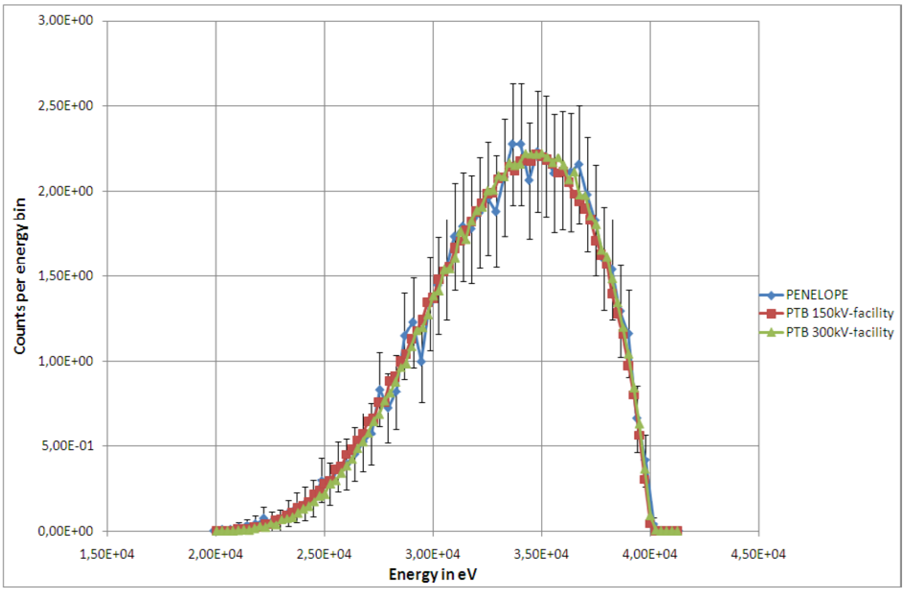

Figure 4. X-ray spectra for an X-ray tube potential of 40 kV (Harrendorf II 2009, Böttcher Büermann 2009). The error bars belong to the simulation.

Table 1 shows the mean energy E_{SIM} of the simulated spectra and the mean energy E_{ISO} for the specific tube potential according to ISO 4037-1. ΔE represents their percent difference.

According to ISO 4037-1 a calibration laboratory has to prove that the deviation is less than 3 % for tube potential ≥ 30 kV and 5% for tube potential < 30 kV. For all tube potentials shown in table 1 the difference is less than 3 % and therefore the requirements of the ISO 4037-1 are fulfilled.

Furthermore the resolution RSIM (FWHM) of the simulated spectra is shown in table 1. For comparison the specified resolution RISO of ISO 4037-1 is listed together with the difference of both resolutions ΔR. The ISO 4037-1 requires that the resolution of the spectra differs less than 15 % for a tube potential below 30 kV and 10 % for a potential ≥ 30 kV. This is fulfilled for all tube potentials shown in table 1.

Table 1. Results for the mean energy and resolution of the X-ray spectra (Harrendorf II 2009): Shown is the mean energy for the simulated spectra E_{sim}, the mean energy given by ISO 4037-1 E_{ISO} as well as their percent difference ΔE. Furthermore the resolution (FWHM) of the simulated spectra R_{SIM}, the required resolution R_{ISO} after ISO 4037-1 and the their difference ΔR is given.

Radiation quality	Tube potential	E_{SIM}	E_{ISO}	ΔE	R_{SIM}	R_{ISO}	ΔR
N-15	15 kV	12355 eV	12000 eV	2,96 %	29,01 %	33,00 %	12,10 %

N-250	250 kV	205993 eV	208000 eV	0,97 %	27,34 %	28,00 %	2,34 %
N-300	300 kV	249713 eV	250000 eV	0,11 %	26,70 %	27,00 %	1,13 %

Cf-252 source

Measurements and simulations were performed in and outside the wooden calibration hall. The position of the measurements and simulations of a dose distribution are displayed in figure 5. The simulated dose distribution inside the hall is indicated by different colours from red (high dose) to dark blue (low dose). The simulations and measurements were performed for positions below the source. Therefore the simulations show a reduced dose close to the source position due to shielding effects of the holding structure and flexible tube.

Figure 6 shows the comparison of the dose rate for both the measurements and simulations for the positions shown in fig. 5. There is a good agreement between the measured and simulated results. The differences of ≤ 20% are covered by the uncertainty of the LB 6411 neutron dose rate detector (Berthold Technologies 1995).

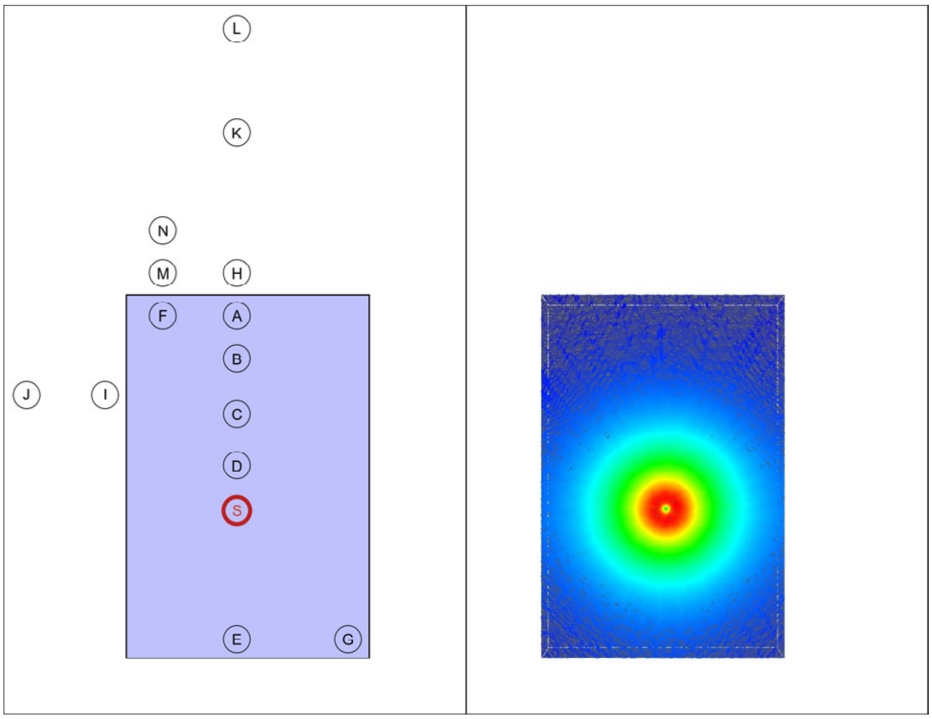

Figure 5. Left: Location of the measuring points for the determination of the neutron dose rate: the outline of the wooden hall is shown in blue, the source (S) in red and the different measuring positions are labelled with (A-N). Right: simulated dose distribution inside the hall.

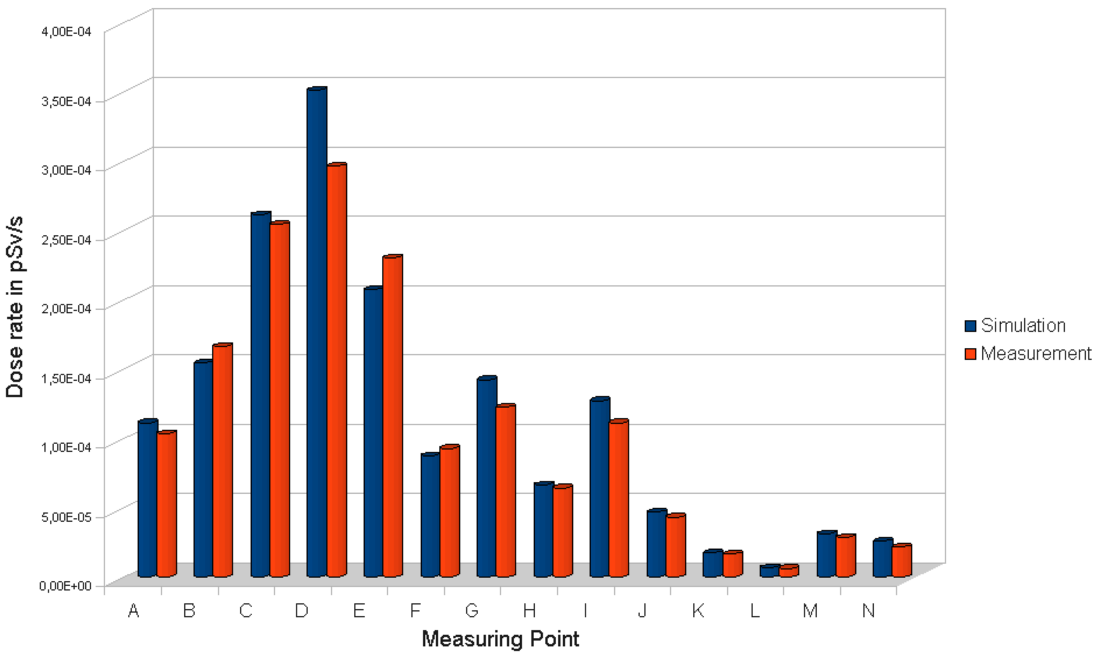

Figure 6. Comparison of the neutron dose rate of the simulations and measurements (Harrendorf 2008): shown is the ambient neutron dose rate in pSv/s normalized to one neutron emitted by the simulated source. The position of the different points are indicated in figure 5.

Discussion

The first simulations for radiation fields of the three different devices in the KIT calibration laboratory show good results. All simulation data contribute to the goal to describe the radiation fields in a suitable way. Usually simulations have to verified by measurements to be reliable.

For the Cs-137 irradiation facility a smaller uncertainty than given by ISO 4037-1 could be estimated. The uncertainty is mainly influenced by the amount of backscattered photons in the radiation field. For the simulations also the uncertainty of the statistics plays an important role. May be our simulation results could be improved with an increased number of source photons.

For the X-ray radiation facility the investigated spectra (Narrow-spectrum series) fulfil the following requirements of ISO 4037-1:

- Within an uncertainty of 5% the simulated X-ray spectra agree with those of the PTB reference fields
- The deviation of the mean energy of the simulated spectra are within the ISO limits
- The resolution of the spectra is conform to the ISO specifications

The Cf-252 irradiation facility can be well described by simulations. Hence detailed dose estimations e.g. for radiation protection purposes can be obtained in this way.

Conclusions

A future goal is to employ simulations for quality management purposes. To determine or verify the properties of a radiation field with measurements alone is often too time-consuming and complicated. The measurement of the X-ray spectra and to measure the amount of backscattered photons in a radiation field are examples. Once a verified simulation model for a specific irradiation device exists, simulations should be able to describe the radiation fields properly. Therefore reliable simulations could limit measurements to a few key-measurements verifying the simulations and at the same time the device properties. For example the half-value layer for an X-ray irradiation device could be measured only for one or two radiation qualities indicating the correct working of the device. Moreover, the simulations could indicate the most sensitive measurements for this purpose.

For quality assurance regular repeated controls of the radiation fields are mandatory. The employment of simulations as quoted above would help to reduce the effort for this procedure.

TL and OSL techniques for calibration of $^{90}Sr+^{90}Y$ clinical applicators

Antonio, Patrícia L.[1]; **Pinto, Teresa N. O.**[1,2]; **Caldas, Linda V. E.**[1]

Abstract
The $^{90}Sr+^{90}Y$ clinical applicators are beta sources used in brachytherapy in the treatment of superficial injuries of eyes and skin. According to international recommendations, these applicators must be calibrated periodically. Thermoluminescent dosimetry (TLD) may be used for the calibration of these sources. However, the optically stimulated luminescence (OSL) technique has been already demonstrated as useful for beta dosimetry. In this work, thermoluminescent pellets of $CaSO_4$:Dy and Al_2O_3:C nanodot OSL detectors were utilized for the calibration of some clinical applicators. Both kinds of dosimeters were exposed to different dermatological applicators for the calibration procedure. The results obtained from both luminescent techniques were compared, and agreement was achieved.

Introduction
The thermoluminescent phenomenon is a luminescent dosimetric technique that has been used for many applications for several decades. Due to its advantages (Olko 2010), it presents applications in a large field of research, including individual, environmental and spatial dosimetry. Furthermore, the use of thermoluminescent dosimeters (TLDs) has been applied with success in the calibration and dosimetry of $^{90}Sr+^{90}Y$ sources used in brachytherapy, called clinical applicators (Oliveira and Caldas 2007; Holmes et al. 2009; Soares et al. 2009).

According to Holmes et al. (2009) and to international recommendations (IAEA 2002; ICRU 2004), clinical applicators should be calibrated to assure: that a quality control program has been applied, that the sources are used correctly and that the treatments of the patients are consistent. Furthermore, it is necessary that each source has a calibration certificate traceable to a primary standard whenever possible (Holmes et al. 2009).

TLDs are recommended for the calibration of beta radiation sources (Oliveira and Caldas 2007; Soares et al. 2009) due to their small dimensions and easy handling. $CaSO_4$:Dy + Teflon pellets were studied and presented efficiency in the detection of beta radiation of $^{90}Sr+^{90}Y$ sources (Campos and Lima 1987; Oliveira and Caldas 2007).

The optically stimulated luminescence (OSL) technique has been actively utilized as a dosimetry method for archaeological and geological dating. In the present days, the OSL technique has shown usefulness for personal dosimetry too (Botter-Jensen et al. 2003).

The OSL phenomenon is based on the luminescence emitted from an irradiated insulator or semiconductor as a result of light stimulation.

Since the development of this technique, its use is restricted because of the lack of a good luminescent material presenting high sensitivity to radiation and optical stimulation efficiency, a low atomic effective number and adequate fading characteristics (Akselrod and McKeever 1999). The Al_2O_3:C detector is a very good luminescent material for OSL dosimetry, because it presents excellent dosimetric characteristics. It was the first material introduced commercially for personal monitoring based on an OSL reader system from Landauer (McKeever et al. 2004).

The OSL technique has several advantages over the thermoluminescence (TL) technique: the readout method is optical, requiring no heating of the samples; the measurement is less destructive and potentially more sensitive than TL; and the response may be evaluated several times on the same sample (Akselrod and McKeever 1999; McKeever 2001; Akselrod 2000).

The objective of this work was to compare the absorbed dose rates obtained as result of the calibration of $^{90}Sr+^{90}Y$ dermatological applicators using two luminescence techniques: thermoluminescence and optically stimulated luminescence.

Materials and methods

Initially, the TL and OSL detectors were studied in relation to the response reproducibility, and the lower detection limits were determined. For the reproducibility study of the $CaSO_4$:Dy dosimeters, the pellets were exposed to a $^{90}Sr+^{90}Y$ standard source (1850 MBq, 1981), Buchler GmbH & Co., model BSS1, Germany, at 11 cm (dose of 1 Gy). For the reproducibility study of the OSL dosimeters, the samples were irradiated with a $^{90}Sr+^{90}Y$ standard source (460 MBq, 2004), Isotrak, model BSS2, Germany, at 30 cm (dose of 6 mGy).

In this work, a $^{90}Sr+^{90}Y$ clinical applicator (called NIST applicator), calibrated at the primary standard laboratory of the National Institute of Standards and Technology, USA, was utilized as reference system in the calibration of three $^{90}Sr+^{90}Y$ plane dermatological applicators. Two of them (A1 and A3) have calibration certificates from Amersham, and A2 applicator does not have any calibration certificate. The main characteristics of these applicators can be observed in Table 1.

For this work, $CaSO_4$:Dy thin pellets, with dimensions of 0.2 mm of thickness and 6.0 mm of diameter, were utilized. These pellets were mixed with Teflon, and they were produced at the Dosimetric Materials Laboratory of IPEN.

The TLDs were exposed to the clinical applicators at null distance between source and dosimeter. The TL measurements were taken immediately after each irradiation, using a Harshaw TLD Reader, model 3500, with a linear heating rate of 10ºC.s^{-1} and a constant flux of N_2 of 5.0 l.min^{-1}. The light emission was integrated in the temperature interval between 180ºC and 350ºC. After the irradiations, the pellets were thermally treated at 300ºC during 3 hours, for reutilization.

Table 1. Characteristics of the $^{90}Sr+^{90}Y$ NIST, A1, A2 and A3 dermatological applicators.

$^{90}Sr+^{90}Y$ applicator	Manufacturer and model	Nominal absorbed dose rate (Gy/s)	Calibrated by	Calibration date
NIST	Atlantic Research Corporation / B-1 S/N 233	0.40 ± 0.02	NIST	28.01.2003
A1	Amersham / SIQ 18	0.056 ± 0.011	Amersham	08.11.1968
A2	No information	——	——	——
A3	Amersham / SIQ 21	0.053*	Amersham	17.09.1986

*No uncertainty provided in its calibration certificate

Fig. 1. $^{90}Sr+^{90}Y$ NIST applicator (plane/dermatological source) used in this work as reference in the calibration of the other applicators.

The Landauer Al_2O_3:C nanodot dosimeter is a layer of Al_2O_3:C sandwiched between two layers of polyester for a total of 0.3 mm of thickness and 7.0 mm of diameter. These detectors were exposed to the three applicators under the same conditions that the TLDs. The OSL dosimeters were optically treated at 26x10^3 lux during one hour prior each utilization. A Delta OHM radiometer, model D09721, LUX LP 9021PHOT sensor, was utilized to determine the light level. The Landauer microStar reader and software were utilized to evaluate the OSL detector response. The measurements were taken immediately after irradiation.

Results

Initially, the TL and OSL samples were studied in relation to their response reproducibility and lower detection limit. Dose-response curves were obtained for both materials using the NIST applicator and, finally, the absorbed dose rates were obtained for the A1, A2 and A3 applicators.

Reproducibility study of the dosimeters

The reproducibility of the TL response of $CaSO_4$:Dy samples was obtained after five series of irradiations (1 Gy), measurements and thermal treatments. The maximum perceptual deviation obtained was equal to 7.1 %, and the associated uncertainty was 8.7 %.

The reproducibility of the OSL response, using ten Al_2O_3:C detectors, ten times irradiated (6 mGy), measured and optically treated, was already determined as 4.9 % (Pinto and Caldas 2009), and the associated uncertainty was 2.8 %.

Lower detection limit

The lower detection limit was obtained by the variability of the TL response of non-irradiated $CaSO_4$:Dy samples. The limit obtained for the TLDs pellets was 56 µGy, presenting the same order of magnitude of the results obtained for this material ($CaSO_4$:Dy) by Campos and Lima (1987).

In the case of OSL detectors, the lower detection limit was determined graphically. The Al_2O_3:C were irradiated with the source of $^{90}Sr+^{90}Y$ of the BSS2 beta secondary standard system in a dose interval from 0.05 to 10 mGy. A dose-response curve was obtained and presented linear behaviour between 0.2 and 10 Gy.

The lower detection limit was obtained extrapolating the dose-response curve of 0.05 to $1x10^{-2}$ mGy (Figure 2), to compare it with the detection limit presented by the manufacturer (Landauer), of 0.2 mGy to beta radiation. In this work, the value obtained was 0.13 mGy.

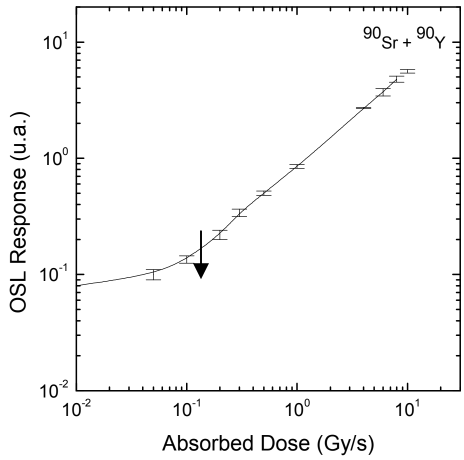

Fig. 2. Dose-response curve of the Al_2O_3:C detectors to $^{90}Sr+^{90}Y$ (BSS2), using the OSL technique, and utilized in the determination of the lower detection limit of the OSL response of Al_2O_3:C nanodot samples.

Dose-response curves of NIST applicator

The TL response of the $CaSO_4$:Dy samples was obtained in relation to absorbed dose in the air, irradiating the pellets with the NIST applicator in a dose interval from 5 to 20 Gy, at the null distance between dosimeter and source. The dose-response curve obtained can be observed in Figure 3. The TL pellets presented the expected response in the tested dose interval, with linear behaviour up to 10 Gy.

A dose-response curve was obtained for the OSL detectors (Figure 4) using the NIST applicator, under the same conditions of TLDs, but in a dose interval from 3 to 10 Gy. A linear behaviour can be observed.

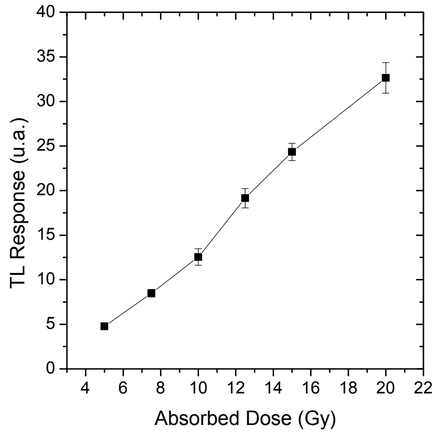

Fig. 3. Dose-response curve of the $CaSO_4$:Dy thin pellets, irradiated with the reference NIST applicator ($^{90}Sr+^{90}Y$).

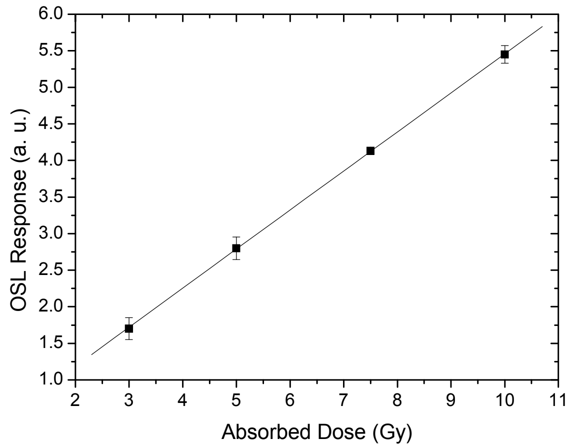

Fig. 4. Dose-response curve obtained of the Al_2O_3:C detectors, irradiated with the reference NIST applicator ($^{90}Sr+^{90}Y$).

Calibration of the $^{90}Sr+^{90}Y$ dermatological applicators

Using the dose-response curves of TL and OSL detectors, it was possible to calibrate the A1, A2 and A3 clinical applicators.

The $CaSO_4$:Dy thin dosimeters and the Al_2O_3:C detectors were exposed to each one of the clinical applicators during the irradiation time interval of 330, 330 and 300s, respectively for the A1, A2 and A3 applicators. These time intervals were chosen according to the activity of each source. The null distance between pellets and clinical applicators was always used during these irradiations.

The absorbed dose rates were determined and the results can be observed in Table 2.

Table 2. Absorbed dose rates obtained in this work, using the TL and OSL techniques, of the clinical applicators, in comparison with those provided in their calibration certificates.

$^{90}Sr+^{90}Y$ applicator	Absorbed dose rate (Gy/s)		
	Certificate	TL technique	OSL technique
A1	0.0213 ± 0.0043	0.0254 ± 0.0051	0.0275 ± 0.0055
A2	No certificate	0.0294 ± 0.0060	0.0336 ± 0.0067
A3	0.0299 ± 0.0060	0.0342 ± 0.0068	0.0386 ± 0.0077

The maximum relative uncertainty for the TL measurements was equal to 9.6 % for the A1 applicator. In the case of the OSL measurements, the maximum relative uncertainty was equal to 1.7 % for the A2 applicator.

Discussion

The same procedure was adopted for the calibration of $^{90}Sr+^{90}Y$ clinical applicators using two techniques: TL and OSL. The usefulness of the TL detectors in the calibration of these applicators was verified in a previous work (Antonio and Caldas 2009), but the TL measurements in this work were taken in another TL reader (Harshaw Nuclear System, model 2000 A/B). These results, using different models of TL readers, are very similar (maximum difference of 16 % for the A3 applicator) demonstrating the efficiency of this kind of calibration method.

Conclusions

The reproducibility study of both TL and OSL detectors showed satisfactory results.

The absorbed dose rates obtained using TL dosimeters of $CaSO_4$:Dy and OSL detectors of Al_2O_3:C, in the calibration of the $^{90}Sr+^{90}Y$ clinical applicators, in comparison with the values provided in their calibration certificates, presented a maximum difference of 22 % (for the OSL technique and A1 and A3 applicators) between techniques and respective certificates, and of -12 % (A2 applicator) also between the two techniques.

It can be concluded that the OSL technique is as effective as the TL technique for the calibration of dermatological clinical applicators used in brachytherapy procedures.

Abstract

This paper describes the Institute of Nuclear Energy Research (INER, Taiwan) established the reference air kerma rate (RAKR) calibration standard for measurement of the HDR ^{192}Ir brachytherapy source strength. An bilateral comparison has been made in the RAKR standards for HDR ^{192}Ir brachytherapy sources at the INER and PTB (Germany) and the measurement difference was within the overall standard uncertainty and showed a good agreement of the two calibration standard systems established at the INER and the PTB. The accuracy in RAKR determination has increased the use of robust well-type chambers designed for brachytherapy. Besides, INER also designed a set of portable measuring device and worked with 20 domestic hospitals to organize an on-site measurement comparison program exploring the status of HDR ^{192}Ir brachytherapy source strength determination in Taiwan. A comparison result was present the ratios of RAKR with vendor values, as determined by INER and hospitals from the program. The ratios fall in all cases within the ±3% guaranteed by the vendors for a coverage factor of k=2 or at 95% confidence level.

Introduction

The isotope ^{192}Ir is frequently used in high dose rate (HDR) brachytherapy sources. The source strength is to be determined in terms of the reference air kerma rate (RAKR) (ICRU 1997, IAEA 2002) before such a source can be used in clinical practice. The RAKR is the air kerma rate to air, in air, at a reference distance of $d_{ref} = 1$ m, corrected for attenuation and scattering and refers to the quantity as determined along the perpendicular bisector of the source (commonly shaped as a cylinder). Compared to techniques for free-in-air RAKR measurement using small ionization chambers, the use of well-type chambers at hospitals is highly recommended. The objective of this research is to fabricate spherical ionization chambers as the INER's calibration standard for RAKR measurement of the HDR ^{192}Ir brachytherapy source strength to provide dosimetry traceability and well-type chambers calibration services in Taiwan. To verify the accuracy of the HDR ^{192}Ir RAKR standard, a HDR ^{192}Ir brachytherapy source calibration comparison has been made at the National Radiation Standard Laboratory of INER and PTB (Germany) in 2009.

In addition, ^{192}Ir sources have a half-life of approximately 74 days and hospitals renew their HDR sources with intervals of around 3 months. Each source comes with a certificate on which the vendor states its strength. An independent check of this value performed by the hospital is widely recommended as an important part of a quality assurance program (Baltas et al. 1999). To investigate the status of HDR ^{192}Ir brachytherapy source strength determination in the afterloading units in Taiwan, measurements at the hospitals are carried out by the authors using calibrated equipment from the National Radiation Standard Laboratory of INER. The source strengths are compared to values specified by vendors and those measured by the physicists at the hospitals using their routines and the same source.

Material and methods

The INER uses a Nucletron microSelectron HDR Classic brachytherapy unit fitted with the 'Classic' source, part number 096.001, manufactured by Mallinckrodt Medical B V (The Netherlands). The average photon energy for HDR ^{192}Ir brachytherapy source is close to 0.4 MeV (Douysset et al. 2008). Fig. 1 shows a schematic diagram of the HDR ^{192}Ir brachytherapy source simulated in this work. The enclosure of the radioactive material consists of a cylindrical stainless steel AISI 316L capsule (length: 5.0 mm, radial thickness: 250 μm) which is sealed by laser welding. The ^{192}Ir is contained in the capsule as a metallic ^{192}Ir cylinder (length: 3.5 mm, diameter: 0.6 mm). The stainless steel capsule is welded to a metal plug and a 1500 mm long flexible stainless steel AISI 316 cable. The other end of the capsule is welded to a steel pin (tail). The identification of the source is engraved on the long side of the tail. The nominal initial activity of the source is between 370 GBq and 550 GBq. The photon intensity and spectrum for the source at the RAKR determination point was calculated using MCNP code of version 5 (X-5 Monte Carlo team 2003). In the calculation the geometry model of the HDR ^{192}Ir source was constructed and simulated in detail. The energy cut-off settings for the photon and electron transport were both 0.001 MeV. Photons were sampled uniformly in the core and were scored at the side of the HDR ^{192}Ir source

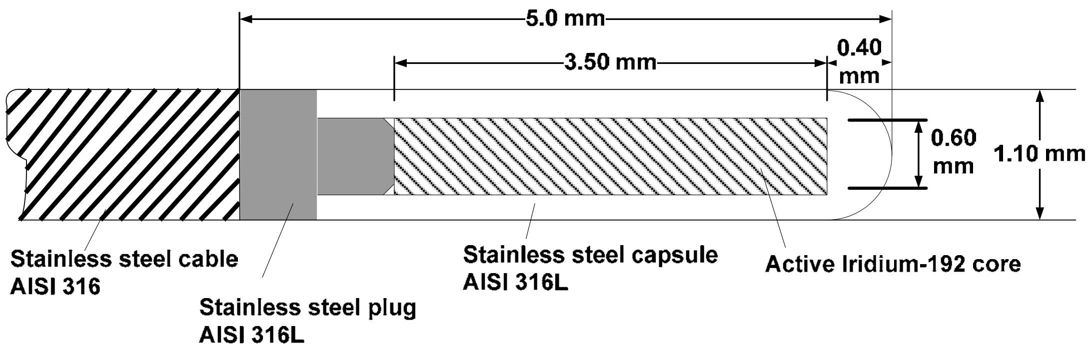

Fig. 1. Geometric model of the Nucletron mircoSelectron HDR ^{192}Ir Classic source.

INER designed and fabricated two spherical polarity ionization chambers which were numbered respectively A5SP4 SN: 001 and SN: 002 as the calibration standard for HDR ^{192}Ir brachytherapy source RAKR measurement. The contributions to the air kerma calibration factor for the different photon energies of the ^{192}Ir spectrum have to be weighted over the energy response of the ionization chambers. The method used at INER is to determine the calibration factors for the ionization chamber at ten different photon energies (ISO narrow-spectrum series, ^{137}Cs and ^{60}Co) ranging from 48 to 1250 keV. The energy response curve is plotted as a function of the photon energy. The correction factors associated with the standard chamber were determined by measurements and calculations. The RAKR can be calculated generally using the following expression:

$$\dot{K} = Q \times k_i \times k_{T,P} \times k_s \times k_a \times k_e \qquad (1)$$

where

$\dot{K}$ is the RAKR at the chosen reference time,

Q is the displayed ionization current (nA) on the electrometer corrected for leakage,

k_i denotes the average interpolated calibration factor of the chambers for the ^{192}Ir spectrum

$k_{T,P}$ is the temperature and pressure correction

$k_a\, k_s$ is the combined air attenuation and scatter correction which corrects the measured current for air attenuation and scatter between the source and the point of measurement

k_e is the calibration factor for the electrometer, thermometer and pressure meter

Besides, we decided to compare the calibration for HDR ^{192}Ir brachytherapy sources using the recommended well-type chamber calibration procedure. INER designed a set of portable measuring device and worked with 20 domestic hospitals using 20 afterloading units to organize an on-site measurement comparison program on source strength determination for HDR ^{192}Ir brachytherapy. Measurements at the hospitals are carried out by the INER using calibrated equipment. The calibrated well-type chamber, PTW 33004 was available. The electrometer, thermometer and pressure meter were calibrated against reference equipment at INER. The source strengths are compared to values specified by venders and those measured by the physicists at the hospitals using their routines and the same source. All participants employ their own well-type chambers traceable to INER and fulfill recommendations for use in brachytherapy.

Results and discussion

The photon spectrum at the RAKR measurement point was estimated by assuming the photon-emission probabilities for ^{192}Ir decay and calculating the attenuated spectrum reaching the measurement point. The calculation took into account the attenuation along all photon paths through the various materials by integrating over all source points in the cylindrical core. Fig. 2 shows the ^{192}Ir source photon spectrum calculated in this research, with which the spectrum for the similar field from the independent Monte Carlo calculations of Borg and Rogers (1999) shows a good agreement.

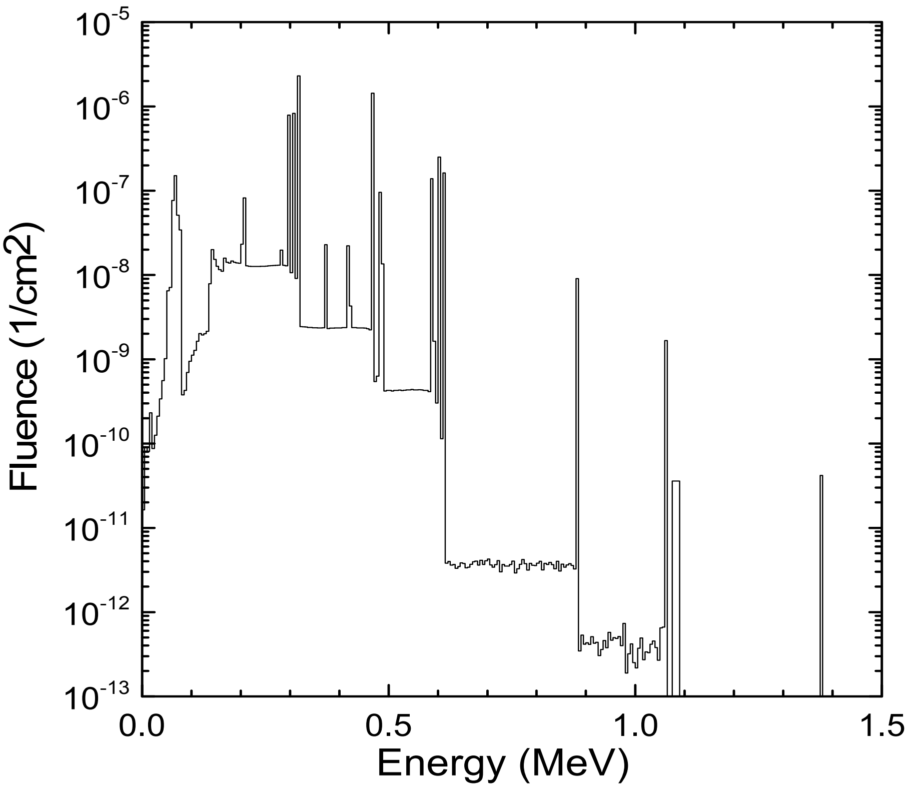

Fig. 2. Fluence spectrum for the Nucletron mircoSelectron HDR ^{192}Ir Classic source at the RAKR measurement point.

With ISO narrow spectrum series x-rays, ^{137}Cs and ^{60}Co beam qualities, we calibrated the INER-made spherical chambers (A5SP4 SN:001 and SN:002) and got the calibration curves of the chambers against the photon energy as Fig. 3. According to Fig. 3, the chamber calibration factors for various energies of the ^{192}Ir spectrum were found. By weighing the calibration factors with the relative intensity of each spectrum line, the calibration factors of the two spherical chambers against ^{192}Ir were obtained as 9.99×10^5 and 9.95×10^5 Gy C^{-1}, respectively.

From Eq. (1), it is seen that there were three correction factors needed for the RAKR calibration of the HDR ^{192}Ir brachytherapy source including the temperature/pressure correction factor ($k_{T,P}$), the room scattering correction factor (k_s) and the air attenuation correction factor (k_a) at 1 m distance from the source. They are described as the following:

- When the environmental conditions are different from reference conditions (22 □ and 101.325 kPa) during calibrations of chambers or sources, it is necessary to have temperature and pressure corrections.
- The shadow-shield technique (Bueermann et al. 1994) was used to evaluate the impact of scatter toward chamber measurement signal. It was performed that the

positions of source, shadow shield and the chamber were kept at least 1 m above the floor as well as 1 m away from the wall. The lead shields of 7 cm in diameter and 10 cm thick were placed between the chambers and the source to stop the primary radiation from the source getting to the chambers. By this shadow-shield technique, the average value of the dose fraction caused by scatter radiation of the two chambers was 6.19%. Therefore the scatter correction factor, k_s=1-0.0619 = 0.9381.

- Through the mass attenuation coefficients of various photon energies in the ^{192}Ir spectrum weighed with the relative intensity of each spectrum line and air density, the air attenuation at 1 m was expressed as $e^{-\mu x}$=0.987, so the correction factor, k_a = 1.0136.

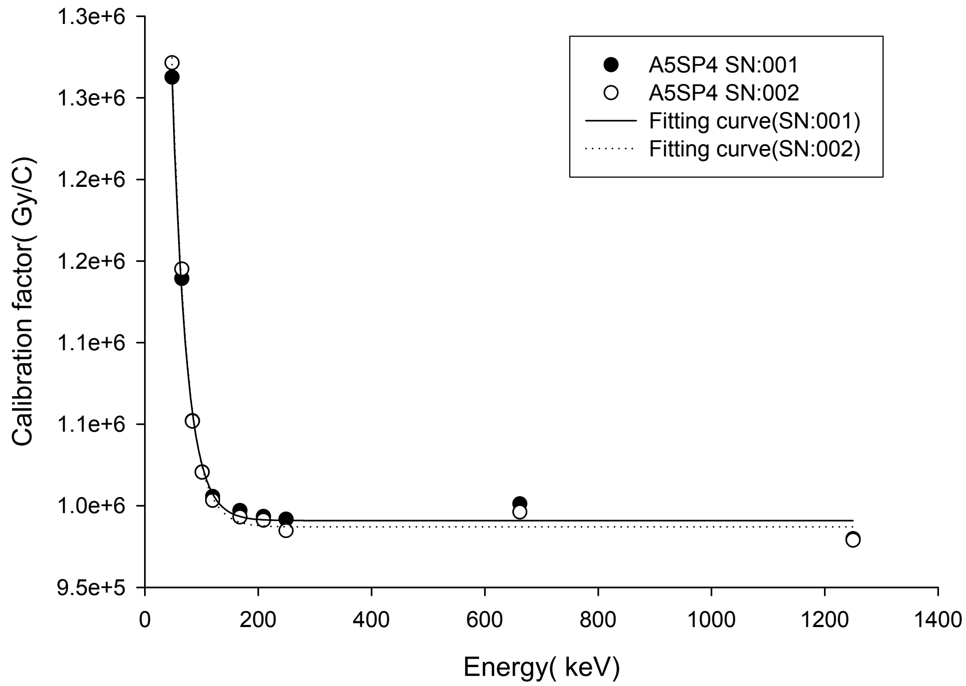

Fig. 3. The calibration factors of INER-made spherical chambers as a function of the mean energy of the radiation qualities.

INER adopted the method recommended by the ISO/IEC Guide 98-3 (2008) to calculate the RAKR measurement uncertainty and the result was 2.28% (k=2). INER used the ^{192}Ir source which had been calibrated by PTB (expanded uncertainty 2.5%, k=2) to make comparisons on RAKR measurements and learned that the difference of both sides was about 1.26% which was less than RAKR measurement combined uncertainty. It was verified that the measurement results of the ^{192}Ir RAKR standard system established by INER agreed with that of PTB.

The uncertainty of the source strength as stated by the vendors is ±3% at 95% or k=2. Fig. 4 presents ratios of RAKR with vendor values, as determined by INER and hospitals. The type of each source is specified in Table 1. The ratios fall in all cases within the ±3% guaranteed by the vendors at k=2, irrespective of the source type for each hospital included here. With the analyses of the measurement comparison program results, we could evaluate the variations in this ratio can therefore serve as an early indicator on problems in some part of system; either with the equipment or the measurement technique at the hospital or the vendor laboratory.

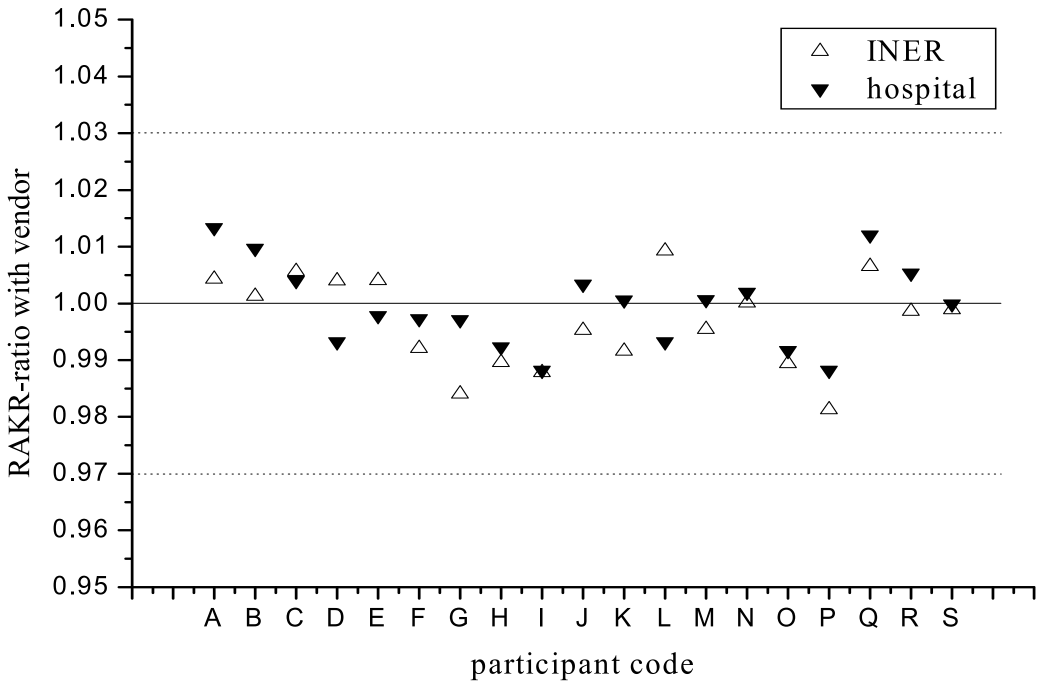

Fig. 4. Ratios of INER- and hospital-determined RAKR values, respectively, to the correcponding values on vendor certificates.

Conclusions

The technique for the dosimetry calibration laboratories to determine RAKR of HDR ^{192}Ir brachytherapy sources used in this study is simple and effective. The comparison of RAKR standards for HDR ^{192}Ir source between INER and PTB showed that the two national metrology institutes (NMIs) were in good agreement. The results indicated that the INER could provide accurate brachytherapy dosimetry traceability and well-type chambers calibration services Besides, a draft guide for quality assurance to institutions performing the HDR ^{192}Ir sources calibration was suggested based on the sources strength on-site measurement program results. If an institution determines ratios of RAKR with vendor values and differed more than 3%, that institution should review the data for calculations and measurements. With the analyses of the on-site measurement data, we could evaluate the feasibility to establish verification and audit technologies under the support of the competent authority to recognize the accuracy of brachytherapy source strength in hospitals and secure the treatment quality of patients.

Instadose – Web based system for reading and monitoring dose through Internet access

Perle, Sander[1]; Kahilainen, Jukka[2]; Bennett, Kip[3]

[1] Mirion Technologies, Dosimetry Services Division, President, UNITED STATES

[2] Mirion Technologies, Chief Technology Officer, UNITED STATES

[3] Mirion Technologies, Dosimetry Services Division, Vice President, Technical Operations, UNITED STATES

Abstract

Instadose™ is a small, rugged dosimeter based on patented direct ion storage technology and is NVLAP accredited. This breakthrough technology provides radiation workers with a more precise measurement of radiation dose and includes accurate long-term exposure tracking. A built-in memory chip stores each user's identity via an embedded unique serial code that is assigned to the user. Instadose allows users to have the flexibility to view their radiation dose at any time from any computer with internet access. Readings via a PC are enabled by a USB compatible detector. When a user wishes to obtain a reading they simply log-in to their account, plug-in instadose to a USB port and on the homepage click-on the computer image with the message "Plug in your instadose device now and click here to get an instant reading". The accumulated dose stored on instadose is processed through a proprietary algorithm. This fully automated transfer of data minimizes the chance of human error and misidentification. Once complete a graphical representation of the current dose will load on the screen. Users can also view their cumulative dose level by clicking "View Cumulative Dose." A variety of reports are available for download through AMP (Account Management Program)." The reports include:

– Radiation Exposure Summary Report
– History Detail Report
– Who Has Not Read Their Device.

Radiation qualities for patient dosimetry in x-ray imaging: from calibrations to clinical use

Toroi, Paula; Kosunen, Antti; Tapiovaara, Markku
STUK – Radiation and Nuclear Safety Authority, Radiation Metrology Laboratory, FINLAND

Abstract

The response of an ideal dosemeter does not have energy dependence and same calibration coefficient can be used for different x-ray spectra. In calibration practice, the energy dependence should be studied by using different radiation qualities. Standard RQR and RQR-M radiation qualities (IEC 61267: 2005), intended to represent the x-ray beam incident on the patient in radiographic, fluoroscopic, dental and mammography examinations, are generally used for calibration in laboratories. They differ from the ones used in patient imaging and they do not cover the total HVL range of clinical use. The calibration coefficients need to be converted to the actual clinical radiation qualities by interpolation using appropriate specifiers of the energy spectrum. For reference class ionization chambers the response depends rather smoothly on the radiation energy, and the half-value layer (HVL) is often sufficient for specifying the radiation quality. However, this may not be the case for dosemeters with a strong energy dependence. In this study, calibration coefficients of different dosemeter types were determined using the standard radiation qualities and several other radiation qualities that are typically used in medical x-ray imaging. The HVL was used as the specifier for the energy distribution of the x-ray beam. The accuracy of air kerma measurements at different radiation qualities was investigated, especially with respect to the interpolations between the radiation qualities used in calibration procedures in order to derive the calibration coefficients for the radiation qualities in clinical practice. KAP meters and semiconductor detectors are examples of dosemeters, which have a strong energy dependence. For accurate measurements, it is not sufficient to make the interpolation based on HVL alone. With KAP meters the difference between calibration coefficients for standard and clinical radiation qualities with same HVL may exceed 15%.

Ambient dose equivalent measurements at IMRT medical accelerator

Tulik, Piotr[1]; Golnik, Natalia[2]; Zebrowska, Edyta[2]; Bulski, Wojciech[3]
[1] Institute of Atomic Energy POLATOM, POLAND
[2] Warsaw University of Technology, Institute of Metrology and Biomedical Engineering, POLAND
[3] Maria Curie Oncology Centre, POLAND

Abstract

A dose equivalent meter based on a recombination principle has been used for measurements of ambient dose equivalent in mixed (gamma + neutrons) radiation fields outside the irradiation fields of linear medical accelerator. The main detector was a recombination chamber, i.e. tissue-equivalent, high-pressure ionization chamber operating under conditions of local recombination of ions. The second ionization chamber served as a monitor of the beam intensity. The use of recombination chambers makes it possible to determine the total absorbed dose, which is proportional to the saturation current, and recombination index of radiation quality, Q_4, which can be used as an approximation of the radiation quality factor. Ambient dose equivalent H*(10) can be well approximated by the product of the ambient absorbed dose D*(10) and Q_4. The automatically controlled measuring cycle includes determination of the ionization current at four different polarizing voltages, which are sequentially applied to the recombination chamber electrodes. Then, the readings are normalized to the monitor chamber readings and Q_4 values and ambient dose equivalent are calculated taking into account the relationship between the initial recombination of ions and radiation quality factor. Tests were performed at the 15 MV Varian Clinac 2300C/D accelerator and at the accelerator configured for IMRT treatment. The measurements confirmed that the ambient dose equivalent of mixed radiation in clinical conditions could be determined with accuracy of about 20%.

Quality mammography essential in detecting breast cancer

Mossang, Daniela[1]; Dadulescu, Elena[1]; Sorop, Ioana[1]; Iacob, Radu[2]; Pera, Corina[3]
[1] Laboratory for the Hygiene of Radiations, Public Health Authority of Dolj County, ROMANIA
[2] University Alexandru Ioan Cuza, Iasi, ROMANIA
[3] County Emergency Hospital Resita, ROMANIA

Abstract
Between 1991 and 2007 breast cancer incidence increased 3.4 times with the Romanian women, the trend continuing to grow. Knowing that mammography can detect early breast cancer and that this is the key to successful long-term control of diseases and good prognoses, the present study aims at evaluating the influence of quality control in order to detect small changes in breast tissue.

There have been assessed five mammography labs (A, B, C, D, E), of which only A had partially implemented the system of quality control. The measurements performed include the evaluation of X-ray units, image receptors, image processors, patient dose and image quality. Mean glandular doses were calculated the way the American College of Radiology does (1999).

The assessment pointed out the following differences between labs B, C, D, E, vs. A: (1) the kVp reproducibility was good but the accuracy differs by more than ±5% from the nominal kVp setting (81.2% in E vs. 1.2% in A); (2) the developer temperature was up to 10^0C under the value specified by the film manufacturer; (3) the automatic exposure control was not used; (4) the number of visible test objects on the phantom image was unacceptably small in the B, C D, E; (5) the radiation beams and the mean glandular doses are higher or lower than guidance levels recommended for a high quality mammogram ($p<0.001$).

Quality control does not remove the problems but it can detect them before the clinical results are seriously affected. Mammography is the most exacting radiological examination and that’s why it is paramount to apply the quality control in all the labs.

Introduction
In the breast imaging, mammography is the safest method for detecting and managing breast cancer being associated with a false negative rate of 10-20%, according to the patient’s age, and the only method that facilitates detection of micro-calcifications.

The main objectives of a quality control programme are to improve diagnostic accuracy without unnecessary radiation, and to minimise the costs (Faulkner 2004). Such a programme may identify the problems before patients’ health is affected. The smallest modification in equipment functioning or film processing can seriously affect the image quality and the breast dose.

Starting with 2002, although the Romanian legislation has included performance criteria to be fulfilled by mammography labs (Order no. 285 2002), there still is no programme of quality ensuring and quality control. However, there are 10 pilot centres that took part in a programme of disseminating quality control activities organized in 2005 with the help of the American International Health Alliance and coordinated by Romanian Society of Breast Imaging. Such educational programmes were carried out in other countries (Vassileva et al. 2005), too, and they had three main objectives: quality control promotion, operator training with simple instruments and procedures, and operator training in quality control data analysis. Each centre received a special kit at the end of the programme so that they could carry out the film processing tests, compression and image quality tests.

As breast cancer incidence grew 3.4 times in Romania between 1991 and 2007, the present study aims at evaluating the influence of quality control in order to detect small changes in breast tissue and also attempts at evaluating some mammography labs in order to see whether they are efficient or deficient, and whether they correspond to the standards of quality control.

Material and methods

Five mammography labs, in five county hospitals have been checked. Only one has partially implemented the system of quality control.

The infrastructure:

- Hospital A - Senograph DMR – quality control partially implemented;
- Hospital B - Senograph DMR – without quality control;
- Hospital C - Senograph DMR – without quality control;
- Hospital D - Senograph DMR – without quality control;
- Hospital E - Mammomat 3000 – without quality control.

The following system components have been checked: the tube voltage (the kVp accuracy and reproducibility, the beam quality assessment), the film processing, and the system properties (the image quality and the average glandular dose).

In order to measure the high voltage accuracy and reproducibility of the radiation beam, the multi-functional device for testing radiological systems of the RMI – 242 type was used, that has a flat ionization chamber, calibrated for mammography.

There have been checked the highest, lowest and most commonly used clinical kVp. The kVp delivered by the X-ray generator was compared with the measured values.

The kVp accuracy was determined by comparing the average measured values with the values of the preset nominal kVp.

The kVp reproducibility was determined by calculating the coefficient of variation for each kVp setting.

The image quality was checked using the standard phantom accredited for mammography, of the Nuclear Associates 18-220 type, which simulates a compressed breast of 4.2 cm thick consisting of 50 % glandular tissue and 50 % adipose tissue. The phantom has an acrylic support and a wax insertion which contains appropriate details (6 fibres, 5 groups of specks and 5 masses) ranging from visible to invisible on the mammography image. The American College of Radiology (ACR) minimum score is 4 visible fibers, 3 speck groups and 3 masses (Hendrick et al. 1999).

This procedure is the most important in mammography quality checking as it verifies the functioning of all the imagistic chain components except for those regarding breast positioning and patient movement.

The phantom was exposed to the parameters used for the standard breast and the film was processed. The evaluation was made by counting the number of visible test objects on the mammography image.

In order to check the density difference (DD), the phantom was attached an acrylic disc (1 cm in diameter and 4 mm thick) which was placed a little under the first two largest fibres so that it shouldn't hide details.

After exposing the phantom to the parameters used for the standard breast and after processing the film, the background optical density (OD) in the geometric centre of the phantom was measured and the density difference between the inner values of the acrylic disc and outer values, right or left, perpendicular on the anode – cathode axis was computed.

The beam quality assessment was performed by measuring the half–value layer (HVL). For this reason 0.1 mm aluminium alloy sheets of 99.9 % purity (alloy type 1145) were used.

The entrance surface dose in the phantom has also been measured with the RMI – 242 device, by positioning the detector in the X-ray field besides the phantom, centred 4 cm in from the chest wall edge of the image receptor and with the centre of the chamber level at the same level with the phantom surface (Hendrick et al. 1999).

The average glandular dose for the standard breast was estimated out of the phantom entrance surface measured dose to which the conversion factors used by Faulkner K in RC-4 entitled Mammography Screening, at the 11^{th} Radioprotection Congress, Spain, 2004 were applied:

$$AGD = K_{air} \cdot p \cdot g \cdot s$$

where: p converts incident air kerma for perspex phantom to that of the standard breast (*table 1*);

g converts incident air kerma for standard breast to mean glandular dose;

s spectral conversion factor (*table 2*)

Table 1. The conversion factors p and g (Faulkner 2004).

HVL (mmAl)	p	g (mGy/mGy)
0.25	1.12	0.155
0.30	1.10	0.183
0.35	1.10	0.208
0.40	1.09	0.232
0.45	1.09	0.258
0.50	1.09	0.285
0.55	1.07	0.311
0.60	1.06	0.339

Spectre	s
Mo/Mo	1.000
Mo/Rh	1.017
Rh/Rh	1.061
Rh/Al	1.044
W/Rh	1.042

Results

The kVp accuracy and reproducibility were within the action limits except for Hospital E, where accuracy was above 5 % (*table 3*).

The measured value for kVp in hospital E is almost double compared to the recommended value (the mammography device hasn't been checked for three years).

Table 3. The kVp accuracy and reproducibility.

Hospital	mAs	kVp		Accuracy (%)	Reproducibility (CV) (%)
		Nominal setting (kVp)	Average measured (kVp)		
A	117	26	27.07	4.1	0.49

* Mammography Quality Control, Radiologist's Manual, Radiologic Technologist's Manual, Medical Physicist's Manual (Hendrick et al. 1999)

Due to these high values of tension, the AEC cannot be used in Hospital E. The technician chooses the exposure parameters according to the breast size and to what he feels while touching it, and sets very small vlues for the mAs product no matter what the breast size is (*table 3*).

The measured HVL was higher than the superior recommended limit [kVp/100 + 0.03 < HVL < kVp/100 + 0.12 for Mo/Mo or 0.19 for Mo/Rh in units of mm aluminum, with the compression paddle (Hendrick et al. 1999)], in all hospitals except for Hospital A (*table 4*).

Table 4. The half-value layer (HVL).

Hospital	Parameters				HVL (mmAl)	Recommended limits* (mmAl)	
	kVp	Target	Filter	mAs		HVL_{min}	HVL_{max}

* Mammography Quality Control, Radiologist's Manual, Radiologic Technologist's Manual, Medical Physicist's Manual (Hendrick et al. 1999)

In all five hospitals we measured the optical density of the glandular tissue area on the mammograms carried out that day. Except for Hospital A, where the optical density was 1.6 OD, in all the other hospitals the optical density was either lower than 1 OD (in B, C, E) or higher than 2 OD in Hospital D.

The first noticed thing on the film imaging the phantom was the poor quality of the image(especially the Mediphot type).

Figure 1 presents an ideal image of the test objects of the standard phantom and also one of the images we obtained in one of the hospitals.

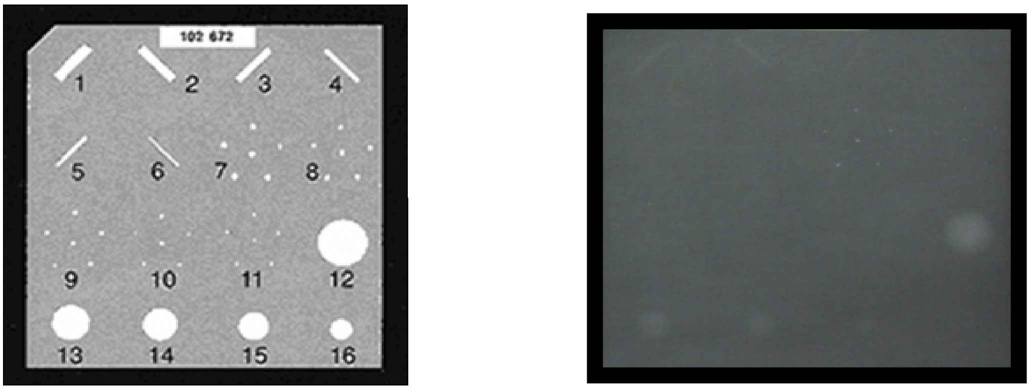

Fig. 1. The ideal image of ACR accreditation phantom (Maalej 2005) and the image we obtained at one of the hospitals.

All the labs were penalized because the films presented artefacts under the shape of fibres and specks so, C and D got the score of zero for the speck groups after artefact deduction.

The number of visible test objects on the phantom image was unacceptable in C, D, and E (*see table 5*).

Table 5. The image quality evaluation.

Hospital	Film	Density Diference (OD)	Background Optical Density (OD)	Number of visible objects *		
				Fibres	Speck groups	Masses
A	Kodak	0.42±0.02	1.66±0.09	5	4	5
B	Foma	0.35±0.05	1.4±0.1	4	3	3.5
C	Mediphot	0.30±0.04	1.23±0.05	4	0	3
D	Mediphot	0.51±0.03	2.3±0.1	4	0	3.5
E	Foma	0.29±0.02	1.06±0.08	4	2	1
Action limit *:		**0.4±0.05**	**<1.4±0.2 >2±0.2**	**4**	**3**	**3**

* Mammography Quality Control, Radiologist's Manual, Radiologic Technologist's Manual, Medical Physicist's Manual (Hendrick et al. 1999)

We can also notice in *table 5* that the background optical density was lower than the recommended values in C and E, and higher in D affecting thus the image quality.

The values obtained for the difference of density were considered unacceptable in C, D, and E, being either too low or too high in comparison to the recommended values.

The conversion factors recommended by ACR could not be used in order to estimate the mean glandular dose for the standard breast because, for the Mo/Mo target-filter combination, at such HVL values, they simply do not exist (Hendrick et al. 1999).

The entrance surface air kerma (ESAK) varied on a broad range, and differed from hospital to hospital and even for the same type of device. The AGD estimated for the standard breast were comparable to the reference levels only in the lab which had implemented the system of quality control (*figure 2*).

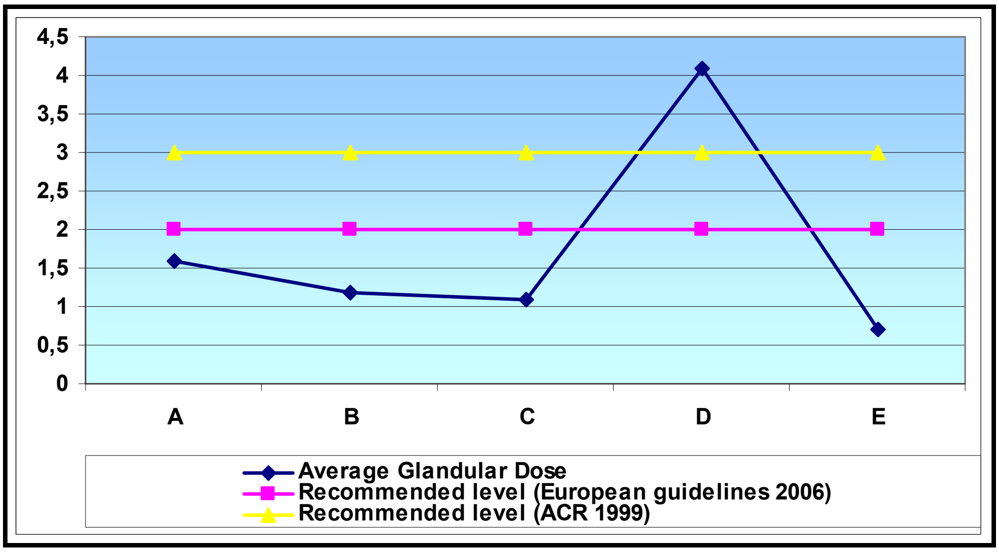

Fig. 2. The average glandular dose for the satndard breast at the five hospitals compared to the recommended levels.

Table 6 shows that the average glandular dose for the standard breast is obviously under the reference levels in Hospitals B, C and E, and over in D (p-value<0.001).

Table 5. The average glandular dose for standard breast.

Hospital	HVL (mmAl)	ESAK (mGy)	Conversion Factors			AGD (mGy)
			p	g	s	
A	0.31±0.02	7.9 ± 0.84	1.10	0.183	1	1.59±0.17

Discussion

Except for hospital A, the technologists were not familiar with the quality control procedures, with the recommended frequency for performing any of the routine quality control procedures and the recommended maximum dose for a mammogram. The activity in these labs is reduced to performing the mammography and its interpretation by the radiologist.

It is well known that a mammogram with an acceptable contrast can be obtained only using an adequate X-ray beam, a firm compression, the grid when necessary, and a correct processing. From this point of view, the results of our research emphasised the presence of some major problems in B, C, D, and E laboratories.

In three out of five hospitals (B, C, and E) they don't use the Automatic Optimization Parameters (AOP), the exposure parameters being set out approximately according to the breast size or to what has been noticed while palpating. Radiologists consider that the image obtained using AOP is worse than their own eyes and experience, a possible fact as long as they have no control over the equipments which are not set by specialists when the film producer changes and they increase the contrast as the developing solutions grow older.

In all five hospitals they use one single type of high contrast film, irrespective of the breast size or its density. The films used are produced by some firms while the developing solutions by other firms due to the deficient acquisition system and public auction, which lead to acquiring the cheapest product.

The measured background optical density was lower or higher than the recommended values which also influences the image quality, as the films used in film-screen mammography lose their contrast at too low or too high optical densities. The glandular tissue, where the cancer starts from, generates the lowest optical density on the film. If the optical density is too low or too high, tracing the low contrast injuries in the glandular tissue is compromised. In order to guarantee the exposure of glandular tissues to sufficiently high optical densities, adjusting the automatic exposure control should have obtained optical densities for the phantom between 1.4 and 2.0 OD, which happened only in hospital A.

The contrast was also affected by the very low temperatures of the developing substances compared to those recommended by the producers. The developer temperature was smaller in B, C, and E, between 1.5 and 10 ^{0}C when the recommended action limits by the ACR are ±0.3 ^{0}C of the value specified by the film manufacturer. In fact, no hospital presented a technical checking report for the developing devices. What's more, hospital E processes the films together with the other diagnose films.

All these shortcomings that led to a decrease of the contrast are probably balanced, partially, by the very high compression (almost double in the three mentioned hospitals).

All the hospitals use only grids though it is known that using them increases the in-taken dose, and it is recommended not to use them for small breasts (the operators don't know how to remove the grid or if this is possible).

Except for hospital E, all the other hospitals use very rarely or not at all rhodium filters, recommended for very dense breasts.

Radiologists and mammography technologists should be familiar with the numerous artefacts that may create pseudo lesions or mask true abnormalities (Hogge et al. 1999).

The presence of artefacts was attributed to the poor film quality, to the dust, and/or to the processing way (roller, developer was mixed with the fixer, concentration of the developer, chemistry replenishment).

Quality image assessment underlined a clear difference between lab A and the other labs under scrutiny. The number of visible test objects on the phantom image was unacceptably small in the other hospitals, a fact that makes us consider that the benefit of the patient exposed to radiations in these labs was minimum, while the risk of not detecting the illness maximum.

Though the measured HVL were higher than the recommended superior limits, this fact does not infringe any standard, but a high HVL leads to a contrast decrease (Order no. 285 2002, Hendrick et al. 1999).

The estimated glandular average doses for the standard breast were either too low or too high, and it's a known fact that both high and low doses lead to missing minute details, diminish the early diagnose possibilities of cancer and increase the risk of inducing breast cancer through repeated irradiation (Law et al. 2002).

The maintenance firms that should ensure the service also raise problems, as they neither have specialists nor do they wish to sign contracts with hospitals, because these have only one mammography device which renders displacement unprofitable (in A and B hospitals more auctions were necessary until a contract could be concluded).

The technical checking is the only one at this particular moment which can bring information about the way the equipment works.

Conclusions

To sum up, the results indicated that the level of equipment performance is correlated with the image quality, which image quality estimated by radiologists is correlated with the phantom score. At the same time, the coincidence in clinical mammography reports is not correlated with equipment performance but seems to depend on the radiologists' experience.

$CaSO_4$:Dy TL response for photons energies between 33 keV to 15 MeV

Campos, Letícia Lucente; Rocha, Felícia Del Gallo; Campos, Vicente de Paulo
Instituto de Pesquisas Energéticas e Nucleares/CNEN-SP, Gerência de Metrologia das Radiações, BRAZIL

Abstract

In the last decade radiotherapy has been the object of a technological revolution because of the new techniques developed such as Three Dimensional-Conformal Radiation Therapy and Intensity Modulated Radiation Therapy (IMRT). The clinical use of these techniques requires a complete knowledge of the imaging of the volumes to be treated and also the dosimetry of the clinical electron and photons beams that are used in those cases. Thermoluminescence (TL) or thermally stimulated luminescence has been actively developed in the past years due to its reliability, sensitivity and commercial availability and is currently in use with LiF: Mg, Ti (TLD-100) commercial dosimeters in the dosimetric quality assurance of the output of therapy machines which must be verified routinely. This work proposes the use of $CaSO_4$:Dy sintered discs as an alternative to LiF commercial dosimeters in the radiation therapy dosimetry of photons beams, studying the photon energy dependence response with energies ranging from 33 keV to 15 MeV using different phantoms such as water filled phantom, a PMMA and a solid water phantom. $CaSO_4$:Dy was chosen because is one of the most useful and sensitive thermoluminescent dosimetric material for radiation dosimetry, and in the form of sintered discs are very suitable for applications requiring a large number of measurements. The thermoluminescence dosimetry reader 3500 (Harshaw Model) was employed for the readout of the irradiated dosimeters. Results on reproducibility, radiation dose response and energy dependence show the possibility of their use as an alternative dosemeter of clinical photon beams.

Development and validation of a low dose simulation algorithm for computed tomography

Joemai, Raoul; Geleijns, Jacob; Veldkamp, Wouter
University Medical Center Leiden, NETHERLANDS

Abstract

Purpose: The purpose of this study was to develop and validate software for facilitating observer studies on the effect of radiation exposure on the diagnostic value of computed tomography (CT).

Methods: A low dose simulator was developed which adds Gaussian noise to the CT raw data with an automatically derived standard deviation according to the desired dose level. A validation was performed with two phantoms: a cylindrical test object and an anthropomorphic phantom. Images of both were acquired at different dose levels by changing the tube current of the acquisition (500 mA to 20 mA in five steps). Additionally, low dose simulations were performed from 500 mA downwards to 20 mA in the same steps. Noise was measured within the cylindrical test object and in the anthropomorphic phantom. This was performed in actual and simulated images. Finally, noise power spectra (NPS) of actual and simulated images were measured in water.

Results: The low dose simulator yielded similar image quality compared with actual low dose acquisitions. Mean difference in noise over all comparisons between actual and simulated images was 5.7 ± 4.6% for the cylindrical test object and 3.3 ± 2.6% for the anthropomorphic phantom. NPS measurements showed comparable shape and intensity.

Conclusion: The developed low dose simulator creates images that accurately represent the image quality of acquisitions at lower dose levels and is suitable for application in clinical studies. The major practical benefit of the algorithm is that it can be retrospectively applied to CT to optimize acquisition protocols in order to reduce the radiation dose.

Basic data for radiotherapy: Stopping of protons in liquid water

[6] Technical University Darmstadt, GERMANY

Abstract

Protons have been used for years in external beam radiotherapy to treat patients with malignant tumours. Obviously, for successful treatments, the knowledge of the absorbed dose to the tumour and to the surrounding tissues is of paramount importance.

In proton radiotherapy, the dosimetry is usually carried out relative to the ^{60}Co beam, in terms of absorbed dose to water. As this dose is determined with the aid of an air-filled ionisation chamber, the ratio of air and water stopping powers for protons needs to be known with a high accuracy. However, the experimental data are scarce (or non-existent, depending on energy); these stopping powers are usually calculated with the refined Bethe-Bloch formula. Recent investigations in the low-energy region (below a few MeV) by other authors have shed doubts on the accuracy of the widely-used stopping power data for water. In addition to the proton therapy, an accurate knowledge of proton stopping is a prerequisite for a reliable neutron dosimetry. Dosimetry of proton and heavy ion exposure is also of importance in space missions and other branches of radiation dosimetry.

In this contribution we describe the measurement programme for determining the proton, and heavy ion, stopping in liquid water at energies below 30 MeV per nucleon; this is the region where the stopping power models typically have the largest uncertainties. Our method is based on a time-of-flight transmission technique using microchannel plate and semiconductor detectors. The major challenge with thin liquid targets in vacuum is to maintain the target as uniform as required by the desired experimental accuracy. Therefore, a special emphasis is placed on the construction and the characterisation of the liquid target. The methods for target thickness determination using mechanical and optical means are presented, together with preliminary results from the actual stopping power experiment.

Fast neutron detection by ALNOR type dosemeters with MCP-N thermoluminescence pellets

Szewczak, Kamil
Central Laboratory for Radiological Protection, Konwaliowa St. 7, 03-194 Warsaw, POLAND

Abstract
MCP-N thermoluminescence pellets with ALNOR type individual dosemeters were used to measure the fast neutrons component ot the ^{241}Am-Be source. The differences betwen TL signal of the pellets covered by the Al filter and without filter during irradiation were observed. The point of work was to find out the rison of observed differences in TL signal. Two possibilities, as activation of the Al filter and anisotrophy of the pellets were taked into consideration. The calculations that have been carried out show that the activities of radionuclides deponed in the Al filter after 600 s irradiation were to less to had influence to incerase the TL signal of the covered pellets. Olny the obtained dependence of TL signal from the pellets mass and high anisotrophy in consistance could explain the observed differences.

Introduction
Correct individual monitoring of the workers exposed to the neutrons is still one of unsolved problem in radiological protection. According to ICRP Report 103 (ICRP 1991) the neutrons at energy from 100 keV to 2 MeV have the highiest value of radiation weighting factor w_R, equal to 20 and equal to 10 for the neutrons at energy from 2 MeV to 20 MeV. In general the neutrons are regard as the most dangerouse type of radiation in the light of radiation protection purpose. The neutrons sources are mainly used in the calibration facielities and reaserch units. Today the most ofen exploit isotropic sources are Am-Be, Cf and Pu-Be. The neutrons emited by mentioned sources were mainly in the range of energy from 0,5 MeV to 10 MeV. The ideal dosemeter should to fulfil two main requirements, it should be able to detect the neutrons in wide range of energy from thermal to fast ones and it should have reasonably low neutron flux density detection threshold. In addition the dosemeter should to be unsesitive for gamma or should give opportunity to discrimination the gamma component. Courently for neutron individual monitoring a combinaton of properly designed albedo TLDs (Nikodemova et al. 1992) or bubble detectors (Apfel, Lo 1989) were mainly involved. In this paper some initial results for new individual neutron dosemeter concept were presented. The point of idea is to applicate in dosemeter two process. First relide on activation of the Al filter of the dosemeter and the secound relide on measurement of gamma component of the activation products using thermoluminescence material. Some

investigations to use the activation of Al for neutrons measurements by TLD were made before (Sants et al. 2006).

The following sections will present initial results which suggest possibility of realization of the new neutron dosemeter concept. In addition some consiterations about barriers and appear problems will be present.

Material

Filter and TL material

For all measurements presented in this work a MCP-N thermoluminescent material was used. MCP-N is a thermoluminescence material based on LiF with the enrichment 7,5% ^{6}Li and 92,5% ^{7}Li, doped with Mg, Cu and P, the material was in form of pellets of 1mm thickness and 4,5mm in diameter. Read out of the pellets was carried out with a RADOS RE-1 reader. It will be show that the pellets are characterised by high anisotropy of mass and consistence. During irradiation pellets were placed in ALNOR type dosemeters which had three 1mm thickness and 5mm in diameter Al filters and one possition without any cover. Each dosemeters were equipped in two pellets, one covered by filter and one in bared position.

Irradiation facielity

Irradiation was carried out in Central Laboratory for Radiological Protection (CLOR) using ^{241}Am/Be calibration source at activity 185 GBq. According to source certificate the neutron emmision of the source amount to 1,1 x 10^{7} n/s. Irradiations were made in four different distances from the source 0,8m; 1m; 1,2m and 1,4m.

Method

Basically the work was divided for two steps: calculation and measurement. Calculations cover a counts of the neutrons flux densities at dependence of distance from the source and counts of the activities of the activation products according to equiation (1), whereas activity of two isotopes ^{27}Mg and ^{24}Na as a results of the nuclear reaction respectively (n,p) and (n,α) were taked into consideration.

$$A = \int_{E=2}^{E=11} S(E)\sigma(E)\phi N(1-e^{-\lambda t})dE \qquad (1)$$

where *S(E)* is a percentage part in the spectrum of the neutrons at energy *E*, *σ(E)* is a cross section of the neutron at energy *E*, *φ* is a neutrons flux density, *N* is a nuber of Al nucleus in the filter, *λ* is a decay contant and *t* is a time of irradiation.

For calculations a Mathematica softawre was involved, wherease a input datas as cross sections, delay decais and energy spectrum of the Am-Be source were taked respectively from IAEA Evaluated Nuclear Data File (http://www-nds.iaea.org/exfor/endf.htm), LBNL Isotopes Project – LUNDS Universitet (http://ie.lbl.gov/toi.htm) and IAEA Technical Reports Series No. 252 (IAEA 1985).

Experimental part covers a measurements of TL signals of the pellets covered and bared during irradiations by neutrons beam. Time of irradiation was set to 600s. For irradiations four dosemeters were prepared, each of them includes two pellets which the TL signal registered just after annealin was in range (*c-σ, c+σ*) where *c* is an average TL signal from 40 pellets and *σ* is a standard deviation.

In addition to provide the dependence of the intensity of TL signal from mass of the pellets theirs mass measurements and TL signal registration after 1mSv irradiation using ^{137}Cs source were carried out.

Results and discussion

Read out of the pellets irradiated by neutrons shows systematic increase of TL signal from pellets covers by Al filter during irradiation, results for four distances are presented in Figure 1. To veryfi supposed influence of gamma radiation emmited by ^{27}Mg and ^{24}Na deponed in the dosemeter filter the adecvate calculations were carried out, results of them and values of neutrons flux densities at four distances are shown in Table 1. It was shown that the activities of activation products can not have influence on the differences in TL signals. Mass measurement of 19 pellets gives results from 33,72 mg to 37,34 mg. There is no clear dependence betwen TL signal and tha pellets mass, Figure 2. Results of mass measurements testify to quite high composition anisotrophy of the pellets. For example the TL signal for a group of pellets which mass is around 35,7 mg (marked in Figure 2) oscillate from 0,93 to 0,97.

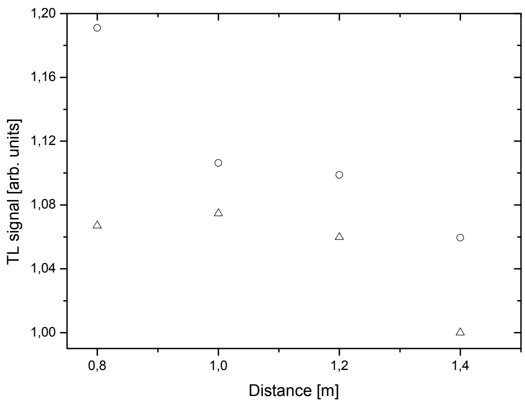

Fig. 1. Differences in TL signal from pellets covered (o) and bared (Δ) during irradiation at four distances.

The ratio of TL signal at the distances 0,8; 1; 1,2; 1,4m are respectively 1,12; 1,03; 1,04; 1,06.

Table 1. Neutron flux density and activities of the activation product. Time of activation 600s.

Distance [cm]	Neutron flux density [n/cm^{2}s]	Activity of ^{27}Mg [Bq]	Activity of ^{24}Na [Bq]
80	142	0,083	0,037
100	91	0,053	0,024
120	63	0,037	0,016
140	46	0,027	0,012

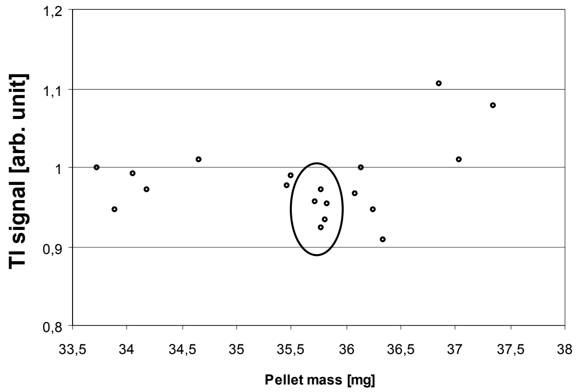

Fig. 2. Dependence of TL signal from the mass of pellet.

Conclusions

The concept to measure fast neutrons component indirectly by thermoluminescence materials which register the gamma ray of the activation products seems to be possible to realization. The main requirements that need to be fulfil are enought mass of the activated material and the very carefully prepared calibration of the TL material. One dosemeter should consist two or more TL materials which sensitivities are in very good agreement.

Abstract

Fricke gel dosimeter is one of the gel dosimeters that have been widely studied for application to clinical dosimetry. This work aims to evaluate the performance of the Fricke gel dosimeter developed at IPEN, prepared with 270 Bloom gelatine from porcine skin made in Brazil, for clinical electron beams from a VARIAN® electron linear accelerator in the energy range from 6 to 16 MeV to reference depth, using a water phantom and spectrophotometry technique. The following parameters were studied: color change, intra and inter batches reproducibility, dose response, dose rate and angular dependent response and response stability in function of storage time under two different conditions: 1) refrigeration and light protected and 2) room temperature and environment light. The excellent results obtained in this study indicate that the studied FXG solution can be a useful option for quality control of treatments of superficial tumours, using clinical electron beams.

Introduction

Different techniques and dosimetric materials have been widely studied because of the increasing demand for efficiency and safety in radiotherapy and radiosurgery treatments. The gel dosimetry has been highlighted because dosimeters can be shaped in three dimensions (3D) and different sizes and shapes so that they become very useful for complex dosimetry techniques such as intensity-modulated radiation therapy (IMRT) (Ibbott 2006).

Among the currently studied gel dosimeters is the Fricke gel dosimeter which is based on the oxidation of ferrous (Fe^{2+}) to ferric (Fe^{3+}) ions by action of ionizing radiation. Its response can be measured by optical absorption (OA) spectrophotometry and magnetic resonance imaging (MRI) evaluation techniques (Gore et al. 1984).

In this work the performance of the Fricke xylenol gel (FXG) dosimeter developed at IPEN, prepared with 270 Bloom gelatine from porcine skin made in Brazil, for clinical electron beams from a VARIAN® electron linear accelerator in energy range from 6 to 16 MeV to reference depth, using a water phantom and OA spectrophotometry technique was evaluated. Different parameters were studied namely: color change; intra and inter-batches reproducibility; dose response, dose rate and angular dependent response and response stability in function of storage time under two different conditions: 1) refrigeration and light protected and 2) room temperature and environment light.

Materials and methods

FXG solutions preparation

Different batches of Fricke gel solution using 5% by weight of 270 Bloom gelatine from porcine skin (GELITA®), ultra-pure water (ELGA® model PURELAB Option Q DV 25 water purifier), 50 mM of sulphuric acid (H_2SO_4), 1 mM of sodium chloride (NaCl), 1 mM of ferrous ammonium sulphate hexahydrate or Mohr's salt [$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$] and 0.1 mM of xylenol orange ($C_{31}H_{28}N_2Na_4O_{13}S$) were prepared (Olsson et al. 1989). The chemical reagents (MERCK®) are of analytical grade.

The Fricke gel samples were conditioned in polymethyl methacrylate (PMMA) cuvettes (SARSTEDT®), with two parallel optical faces, dimensions of 10 x 10 x 45 mm^3 and optical path length of 10 mm and were individually sealed with polyvinyl chloride (PVC) film. The samples were stored under refrigeration ((4 ± 1) °C) and light protected during about 12 h (Olsson et al. 1989) after preparation and maintained 30 min at room temperature and light protected before irradiation.

FXG samples irradiation

The Fricke gel solution samples were irradiated in the reading cuvettes using a water phantom. Each three samples set of Fricke gel solution was packed with PVC film (Fig. 1) in order to avoid contact of the FXG solution with water. A 40 x 40 x 40 cm^3 MEDINTEC® water phantom filled with tri-distilled water was used to samples irradiation (Fig. 2).

Fig. 1. Three samples set of FXG solution packed with PVC film.

The samples were irradiated with clinical electron beams using a VARIAN® clinical electrons linear accelerator model CLINAC 2100C (Fig. 2) of the Radiotherapy Unit of the Cancer Centre of the Hospital Israelita Albert Einstein (HIAE), with electron energies between 6 and 16 MeV, absorbed doses from 0.05 to 21 Gy, dose rates from 80 to 400 cGy/min, irradiation angles between 0º and 180º, using a radiation field size of 10 x 10 cm^2 and different reference depth (0.6 to 2.0 cm/water) to ensure the maximum dose in the centre of each FXG sample. The temperature, humidity and atmospheric pressure of the irradiation room were maintained at 21° C, 55% and 697 mmHg, respectively, during the irradiations.

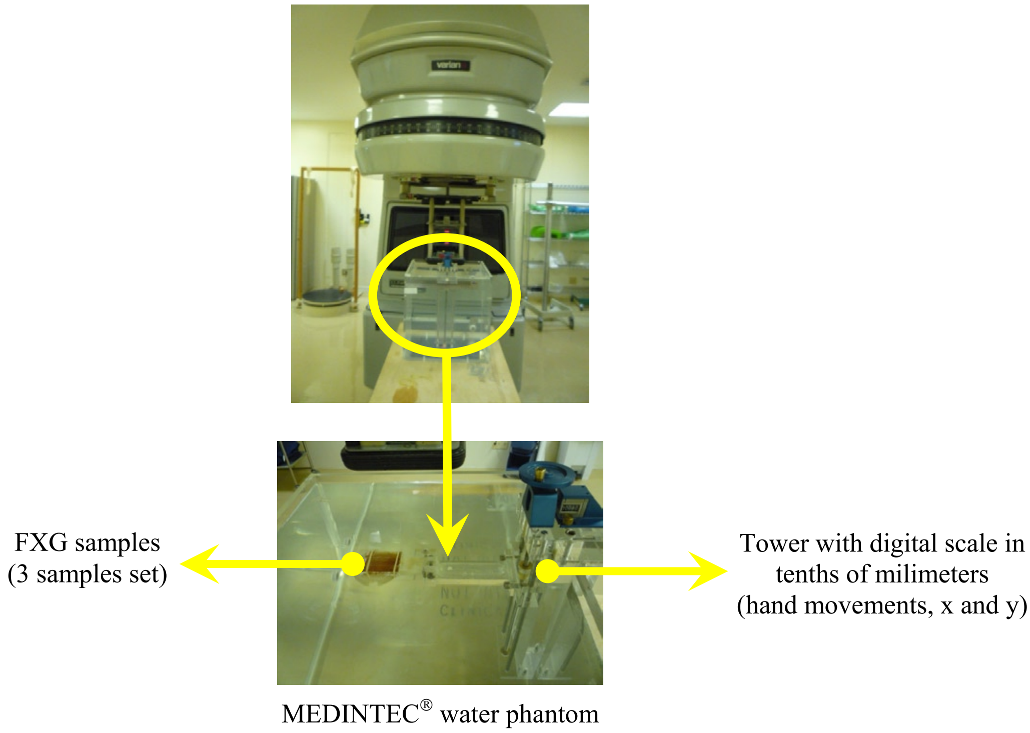

Fig. 2. Experimental set up for FXG samples irradiation in VARIAN® linear accelerator (CLINAC 2100C) using a water phantom.

OA evaluation

The OA spectrophotometry evaluation technique was used in this study. The measurements were performed using SHIMADZU® spectrophotometer model UV-2101PC (High Doses Laboratory of IPEN) immediately after dosimetric solution preparation and about 30 min after irradiation. The dosimetric wavelength was determined for each irradiated sample analyzed. This wavelength was used to obtain the absorbance values of the irradiated samples.

The following parameters were studied: color change (using an E.M.B.® lightbox model PRENDOGRAV of IPEN); intra and inter-batches reproducibility; dose response, dose rate and angular dependent response and response stability in function of storage time under two different conditions: 1) refrigeration and light protected and 2) room temperature and environment light.

The presented spectrophotometric responses correspond to the average of absorbance values of three samples and the error bars the standard deviations of the mean (type B uncertainties were not considered). The background value (non-irradiated samples) was subtracted from all absorbance values.

Results and discussion

Colour change

The colour change of the Fricke gel solution (in PMMA cuvettes) non-irradiated and irradiated with clinical electron beams with doses from 0.05 to 21 Gy, 12 MeV and 400 cGy/min is presented in Fig. 3. The samples present colour range from yellow-gold (non-irradiated solution) to violet (21 Gy) and the same colours are presented by FXG solutions irradiated with the others electron energies and dose rates studied.

Fig. 3. Colour range presented by Fricke gel solution non-irradiated and irradiated with doses between 0.05 and 21 Gy.

Intra and inter-batches reproducibility

To evaluate the intra-batch reproducibility of the FXG solution irradiated with clinical electron beams (1 Gy and 16 MeV) measurements of 5 sample sets subjected to the same experimental conditions were performed (Cavinato et al. 2010).

Five batches of 100 mL of FXG solution were prepared in the same day and under same experimental conditions in order to evaluate the inter-batches reproducibility of the dosimetric solution studied. These solutions were also irradiated with clinical electron beams (1 Gy and 16 MeV) and the optical measurements of samples were performed.

The intra and inter-batches reproducibility obtained is better than ± 3% (Cavinato et al. 2010) and ± 2%, respectively.

Dose response

The optical absorption spectra and spectrophotometric dose-response curve obtained of the FXG solution irradiated with clinical electron beams (12 MeV and dose range from 0.05 to 21 Gy) is presented in Fig. 4.

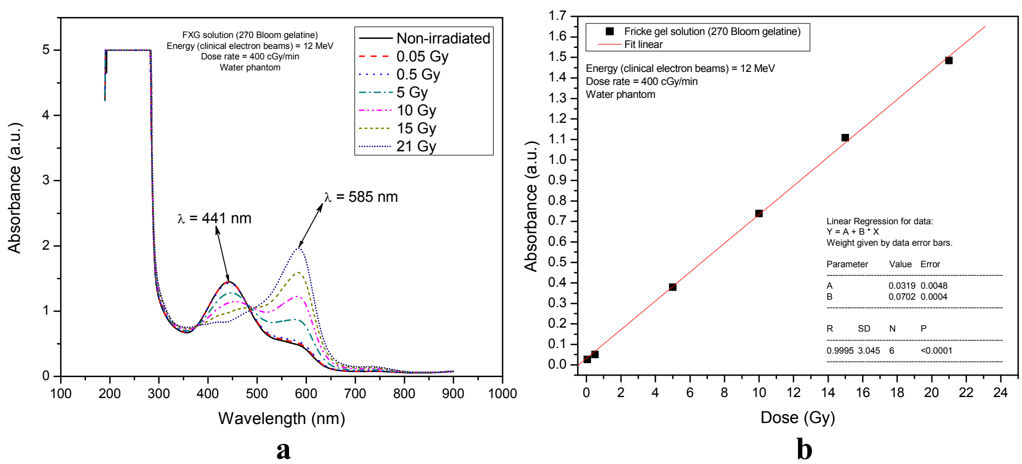

Fig. 4. Optical absorption spectra of FXG samples non-irradiated and irradiated with clinical electron beam (a) and dose-response curve of the FXG solution (b).

The solution prepared with 270 Bloom gelatine presents two absorption bands, as expected: one at 441 nm (Fe^{2+}) and other at 585 nm (Fe^{3+}) generated by induced oxidation of Fe^{2+} ions by ionizing radiation. It is observed intensification of absorbance values of the band at 585 nm (Bero et al. 2001) with increasing radiation dose while the absorption band at 441 nm tends to disappear (Fig. 4a) depending on the dose.

The Fricke gel solution presents a linear response over the dose range studied (Fig. 4b).

Dose rate

The dose rate dependent response (relative to higher absorbance value) of the FXG solution irradiated with 12 MeV, 10 Gy and dose rates from 80 to 400 cGy/min is presented in Fig. 5. The dose rate dependent response obtained is better than ± 3%.

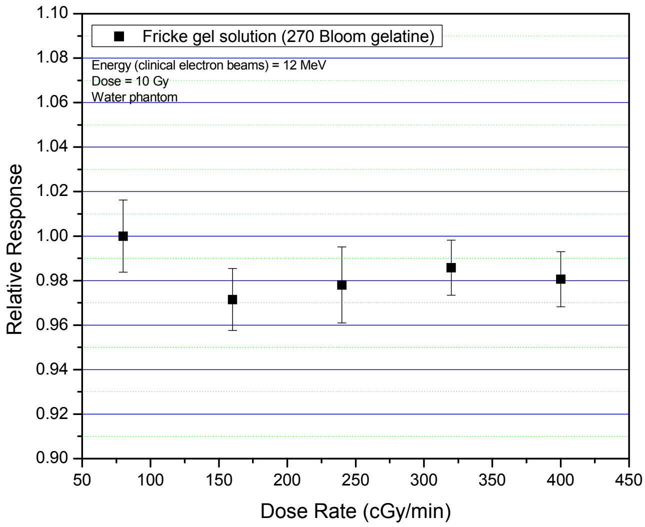

Fig. 5. Dose rate dependent response of the FXG solution irradiated with clinical electron beams.

Angular response

The angular dependent response (relative to higher absorbance value) of the Fricke gel solution irradiated with 6 and 12 MeV, 10 Gy and irradiation angles from 0º to 180º is presented in Fig. 6. The angular dependent response obtained for electron energies of 6 and 12 MeV is less than 1%.

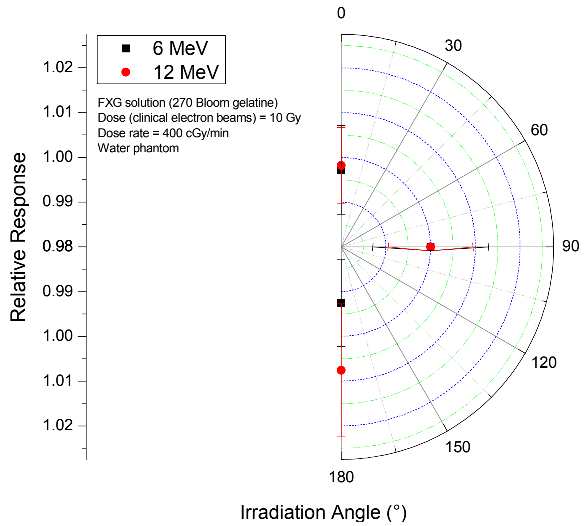

Fig. 6. Angular dependent response of the Fricke gel solution irradiated with clinical electron beams.

Response stability

The response stability of the FXG solution non-irradiated and irradiated (16 MeV and 1 Gy) in function of storage time under the conditions 1 and 2 studied (refrigeration and light protected, room temperature and environment light, respectively) is presented in Fig. 7.

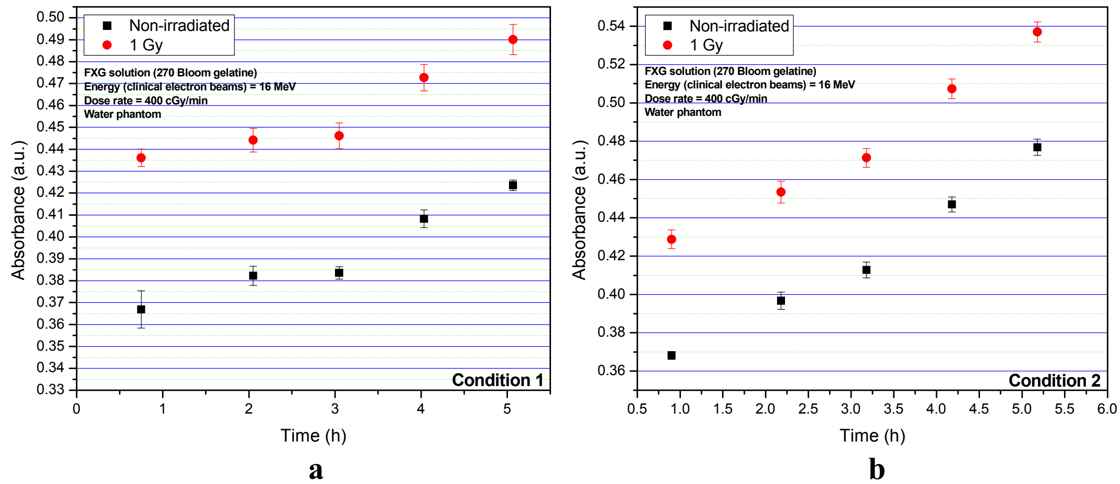

Fig. 7. Response stability of the Fricke gel solution non-irradiated and irradiated (clinical electron beams) in function of storage time under conditions 1 (a) and 2 (b).

It can be observed that in both storage conditions occurs intensification of absorbance values over time. However, for the non-irradiated and irradiated solution, there is a variation of the spectrophotometric response of less than 5% for conditions 1 (up to 4 hours after irradiation) and 2 (up to 3 hours after irradiation). Thus, the dosimetric samples should always be kept under refrigeration and light protected.

The energy dependent response previously studied (Cavinato et al. 2010) is better than ± 10% for the nominal energy of 9 MeV in the energy range studied. For energies greater than ≅ 12 MeV no energy dependent spectrophotometric response is observed.

Conclusions

The Fricke gel dosimeter developed at IPEN prepared with 270 Bloom gelatine produced in Brazil provides excellent results when irradiated with different energies, absorbed doses and dose rates of clinical electron beams. The results obtained in this study complement previous work using clinical electron beams (Cavinato et al. 2010) and indicate that the studied FXG solution can be a useful option for quality control of treatments of superficial tumours, using clinical electron beams. The obtained results also indicative the viability of employ this dosimeter in electron 3D dosimetry.

Dosimetric properties of agate stones

Teixeira, Maria Inês[1,2]; Caldas, Linda V. E.[1]
[1] Instituto de Pesquisas Energéticas e Nucleares (IPEN-CNEN/SP), BRAZIL
[2] Associação Educacional Nove de Julho (UNINOVE/SP), BRAZIL

Abstract
Brazilian stones have been studied for use in gamma high-dose dosimetry. Agate samples were studied in relation to their TL dosimetric properties, in this work. The TL curves obtained due to absorbed doses of 50 Gy up to 10 kGy exhibit two peaks around 150^{0}C and 210^{0}C. The minimum detection limits, dose-response curves and reproducibility of the TL response were obtained. The results indicate the possibility of use of these agate samples as radiation detectors for gamma high-doses, using the TL technique.

Introduction
Quality control programs in radiation dosimetry play an important role. Radiation processing presents several advantages such as food preservation, sterilisation of pharmaceutical and medical products and treatment of various materials. McLaughlin et al described several kinds of high-dose dosimeters, discussing their advantages and disadvantages. At the Radiation Metrology Laboratory of IPEN, Brazil, different stones have been studied for application in high-dose dosimetry. Amethyst [Rocha et al, 2003], quartz (Santos et al, 2001 and Navaro et al, 2002), topaz [Sousa et al, 2002] and jasper [Teixeira and Caldas, 2007] have already shown their usefulness for gamma dosimetry, using the thermoluminescent technique (TL).

Agate is a variety of chalcedony, a form of quartz, in which the color appears in bands or concentric zones. The bands may be of different colors or also of a uniform tone. The samples for this study were prepared from four different types of agate stones: yellow, moss green, gray and purple. The objective of the work was to characterize agate stone samples as detectors for gamma high dose radiation.

Materials and methods
Brazilian agate samples were studied in the work. All samples were initially cleaned, pulverized, and grain diameters between 0.075 and 0.180 mm were obtained. To facilitate easy handling, sintered agate pellets were prepared at the Laboratory for Production of Dosimetric Materials, IPEN, using Teflon as binder, and the parts were mixed in the ratio 2 (Teflon):1 (powdered sample). For the sintering process, the samples were thermally treated at 300^{o}C for 30 min followed by 400^{o}C for 1.5h.

The thermal treatment for reutilization of the material was established as 300°C for 1h. The irradiations of the samples were performed using a Gamma Cell-220 System of ^{60}Co (dose rate of 2.18 kGy/h), for doses from 50 Gy up to 10 kGy. The irradiations were made at ambient temperature; to guarantee the occurrence of electronic equilibrium during the irradiations, the samples were fixed between 3.5 mm thick polymethyl meth-acrylate plates (Lucite). The TL measurements were taken using a Harshaw Chemical Co. reader, model 2000 A/B, and the data acquisition was realized using a virtual instrument (ADC-212), Pico Technology Ltd., and a personal computer.

Results and discussion

Dosimetric properties such as lower detection limits, reproducibility and dose-response curves were obtained in this work. Figure 1 shows the thermoluminescent glow curves of the agate samples: gray, purple, moss green and yellow, taken 1h after their irradiation with 10 kGy. All samples present two main TL peaks, one around 150^0C and the second about 210^0C (dosimetric peak).

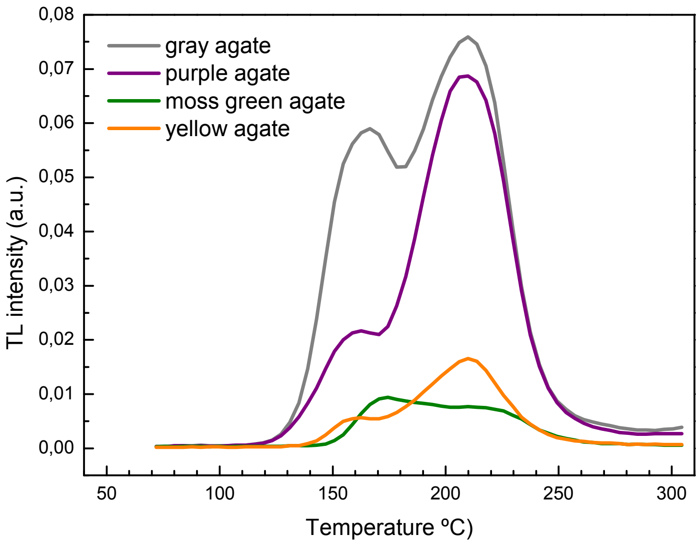

Fig. 1. TL glow curve of an agate-Teflon pellet irradiated with 10 kGy (^{60}Co)

To remove the first TL peak (150^0C) of the agate sample glow curves, thermal treatments at 130^0C during different time intervals: 5 min, 10 min, 15 min, 30 min and 60 min were tested. All thermal treatments presented the same results: peak 1 was removed and the thermal treatment of 130^0C/5min was chosen as adequate (Figure 2). All agate samples (gray, purple, moss green and yellow) presented the same results.

The TL response of the agate sintered pellets as a function of the absorbed dose was measured from 50 Gy up to 10 kGy (Figure 3). The standard deviation values were less than 3.2%. The lowest detectable value was determined studying the variation of the signal obtained by the reading of non-irradiated samples. The lowest detectable value was 4 mGy, 1.5 Gy, 1.0 Gy and 0.2 Gy for gray, purple, moss green and yellow agate samples, respectively. Figure 3 shows that the dose response is linear up to 5 kGy in case of gray agate samples and supralinear for the other samples.

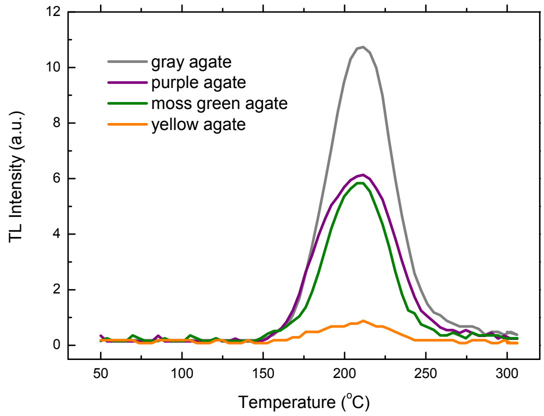

Fig. 2. TL glow curves of agate samples irradiated with 5 kGy (^{60}Co),after thermal treatments of 130^{0}C/5min.

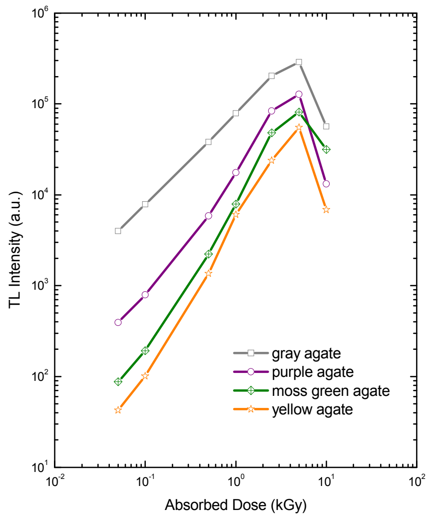

Fig. 3. Dose-response curves of agate samples for ^{60}Co radiation. Measurements were taken after the irradiation and the thermal treatment at 130^{0}C/5min.

Conclusions

The results obtained on the main dosimetric characteristics (reproducibility, dose response up to 5 kGy and lower detection limits) show that agate samples can be applied in high-dose dosimetry. The advantages of this kind of material are: found in Brazilian natural mines, easy to handle and very low cost. Agate samples may be applied for dosimetry in the main radiation process of pasteurization, processes of water purification, sterilization and disinfestations of products, among others.

Characterization of polycarbonate dosimeter for gamma-radiation dosimetry

Galante, A. M. S.; Campos, L. L.
Institute of Energetic and Nuclear Research, IPEN – CNEN/SP, BRAZIL

Abstract

A simple and inexpensive polymeric material whose special properties can be determinate, quantified and related to absorbed dose was studied in this work. Commercial polycarbonate (PC) is a new type of film detector that suffers yellowing upon radiation exposure and the color change was used as dosimetric property to measure the absorbed doses. The dosimeter consists of a piece of polycarbonate film of dimensions 3 x 1 cm^2 and 3 mm thick and the spectrophotometry was the investigation technique used. PC films were irradiated with gamma doses between 1 and 150 kGy from a ^{60}Co Gammacell source. The absorbance was measure on a spectrophotometer Shimadzu UV-2101PC. The main dosimetric characteristics studied were: pre- and post-irradiation stability, dose – response, environmental conditions influence and response dependence with dose rate. PC films are easy to prepare and to analyze. The influence of environmental conditions was observed and must be corrected. Polycarbonate dosimeters presents good stability and reproducibility and linear behavior in the dose range studied indicating that the dosimetric characteristics are suitable to determine high gamma doses.

Introduction

Some polymeric materials present changes in their properties due to the interaction of ionizing radiation that can be related with the absorbed dose [2]. Radiation induced chemical reactions results in rearrangements and/or formation of new bonds and the main effects are scission of main chain (degradation) or cross-linking, which are simultaneous and competing processes. To be applied in radiation dosimetry polymer films must present preferentially linear response in the dose range to be measured. It is necessary to determine its dosimetric properties such as lower and upper limits of useful dose range; dose rate dependent response; stability before and after irradiation and environmental conditions effects [1,4,5]. Polycarbonates are usually applied in neutron and alpha particles detection using nuclear tracks detection technique nowadays they have been studied as a dosimeter to measure gamma-rays doses [6]. The radiation induced main chain scission of PC and produces phenoxy radical responsible for the yellowing [4,5]. PC films are easy to prepare and to analyze and inexpensive. The influence of environmental conditions was observed and must be corrected in the studied material. Polycarbonate dosimeters presents linear behavior in the dose range studied and indicates that the dosimetric characteristics of are suitable to determine high gamma doses. In this work samples of commercial polycarbonate were investigated to be applied as dosimetric material evaluating the radiation dose response to ^{60}Co gamma radiation.

Material and methods

Samples of commercially available polycarbonate with and without protection against UV radiation manufactured by "Policarbonatos do Brasil" (3 x 1 x 0.3 cm^3) were irradiated free in air, under electronic equilibrium conditions and at room temperature with doses between 1 and 150 kGy and dose rate of 2.60 kGy/h using a ^{60}Co gamma radiation source.

The radiation induced color change was the basis of measuring absorbed doses. Optical absorption measurements of non irradiated and irradiated samples were taken in a Shimadzu spectrophotometer UV-2101PC at wavelength ranging between 190 and 900 nm.

The lower dose detection limit was obtained by the absorbance values of the maximum wavelength of at least 60 non irradiated detectors and the upper limit was determinate by external limitations.

All presented results are the average of 3 measures and the error bars the standard deviation of the mean. The observed standard deviation of the mean for all applied doses was better than 96 %.

Results

The typical non irradiated PC spectrum was obtained and presents differences between PC with and without protection against UV radiation damage as showed in Fig. 1.

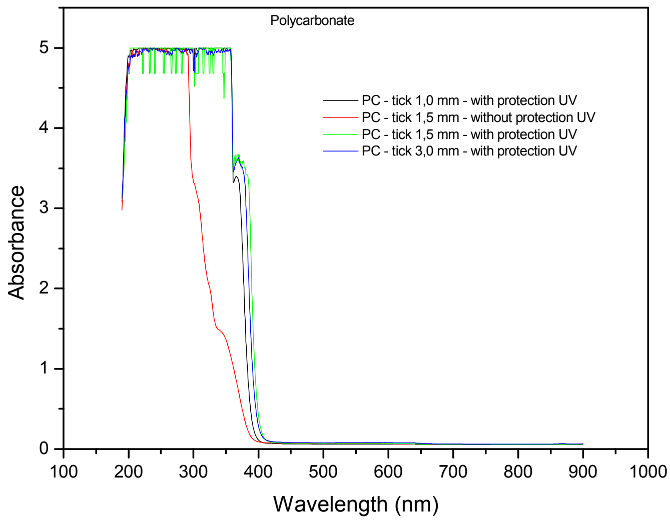

Fig. 1. Non irradiated polycarbonate samples absorption spectra.

The optical response stability before irradiation is better than 95% when PC samples are exposed to normal ambient conditions (20°C and 60% humidity), however, after irradiation the samples must be maintained at low temperature to avoid losses of response, approximately 30% after 48 hours at room temperature and 8% if maintained at 5°C and light protected.

The lower detection limit was obtained taking three times the value of the standard deviation of measurements of at least 60 non-irradiated PC samples, expressed in units of absorbed dose. The dose value of 1 kGy was obtained [7].

After irradiation PC spectra presents an absorption band centred in 412 nm, Fig. 2, that was used to evaluate the optical response.

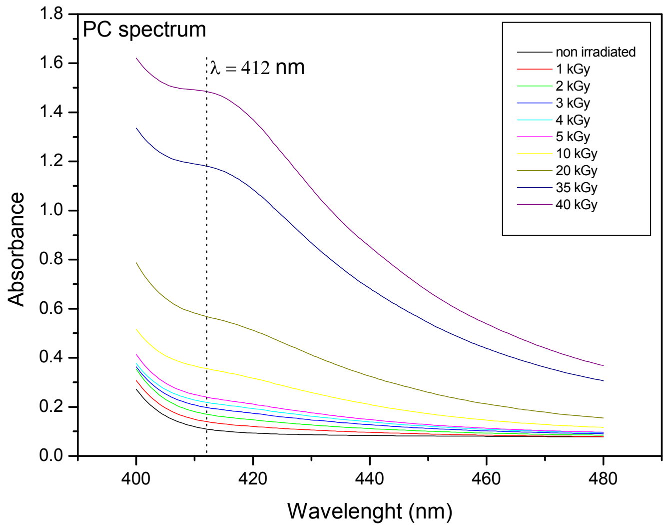

Fig. 2. Non irradiated and irradiated PC absorption spectra.

The change color of PC samples originally transparent to yellow dark when are irradiated with different gamma radiation doses can be seen in the Fig. 3

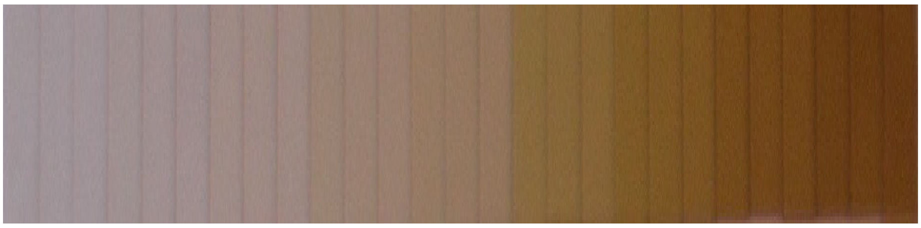

Fig. 3. Color change of PC samples irradiated with gamma doses between 1 and 150 kGy.

Experimental results show that the response reproducibility is better than 96%.

The dose rate dependence was significant for low doses and reading corrections must be made because this dependence can introduce large errors in the dose measures [3].

The absorption intensity of the 412 nm peak increase linearly as a function of absorbed dose as showed in the Fig. 4 to gamma radiation in the dose range between 1 and 150 kGy.

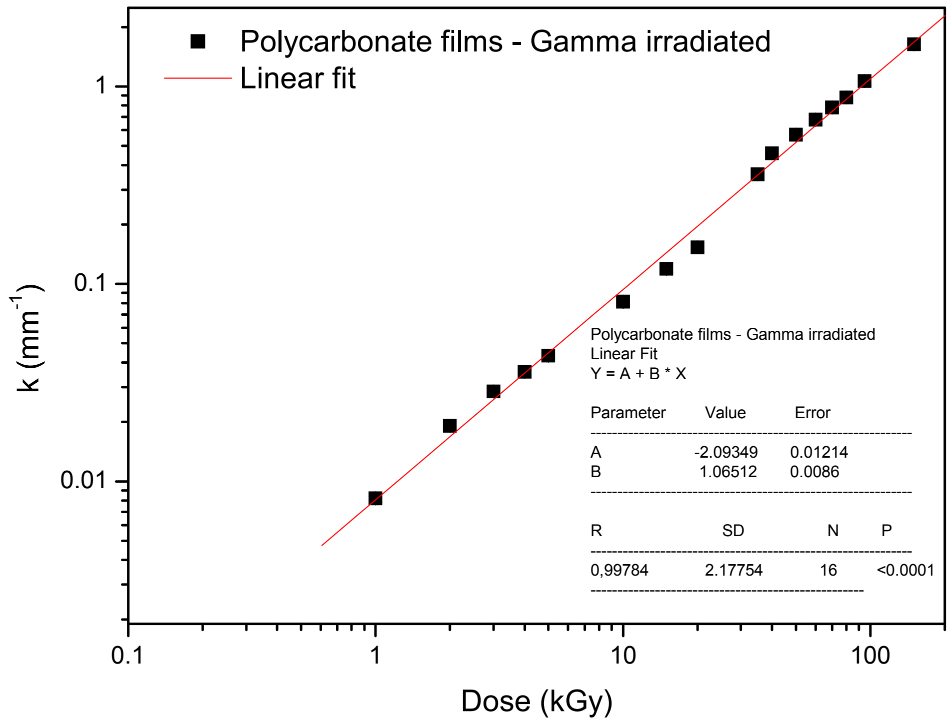

Fig. 4. Dose response curve of polycarbonate films irradiated with ^{60}Co gamma radiation, λ = 412 nm.

Conclusions

The results obtained indicate that PC can be used as an alternative dosimetric material. The advantages of the use of PC detectors in high-dose dosimetry are the reduced size, very low cost, easy handling and the fact that the absorbance analysis is very simple. The storage conditions doesn't affect the non-irradiated detector response, however, after irradiation the detector must be kept under refrigeration to preserve its optical response and reading must be done up to 24 hours after irradiation.
The dose response curves obtained show that this dosimeter can be used in an useful dose range between 1 and 150 kGy.

Pellets of oyster shell for high dose dosimetry: Preliminary study

Vila, Gustavo B.; Caldas, Linda V. E.
Instituto de Pesquisas Energéticas e Nucleares, Comissão Nacional de Energia Nuclear, IPEN-CNEN/SP, São Paulo, BRAZIL

Abstract
Several kinds of silicates have demonstrated their usefulness as radiation detectors for high dose dosimetry. In this work, oyster shell powdered samples were tested for high doses using the thermoluminescence (TL) and thermally stimulated exoelectron emission (TSEE) techniques. Pellets were obtained from the oyster shell powder mixed with Teflon followed by a sinterization process of thermal treatments of 300°C/30min and 400°C/1.5h. The TL glow curves showed two peaks at 110 and 220°C, and in the TSEE case, two peaks at 120 and 180°C. The main dosimetric properties were studied: reproducibility, dose-response curves and lower detection limits. The preliminary results showed the potential use of the studied material as radiation detectors.

Introduction
The mean objective of the study of new materials is to identify and to overcome the limits imposed, naturally, for their physics and chemical properties (McLaughin *et al*, 1989). The research of new materials applied in dosimetry and other activities that involve ionizing radiations began as early as 1663 when Robert Boyler reported his observations to the Royal Society in London (Becker, 1973). Thereafter several researchers have published results about new materials. In the radiation metrology research group at IPEN some works have been carried out with silicates. Caldas (1989), Caldas and Souza (1991), Teixeira (2004) studied the dosimetric properties of Brazilian and imported glasses applied to gamma and electron radiations. The dosimetric properties of jade and inossilicates were carried out by Melo et al (2004; 2008). They studied the dose-response in the range of 10Gy to 20kGy through the thermoluminescent (TL) technique, verifying the linear behaviour between 10Gy and 1kGy, and the sublinear behaviour between 100Gy and 20kGy, using the thermally stimulated exoelectron emission technique.

Other materials as the calcium-based phosphors have been studied and showed good dosimetric properties. Since the 60's these materials have been studied by several researchers. Among them are Medlin (1968) and Nambi and Mitra (1979), that used the TL technique, to study these materials; they verified that calcites are strong emitters of TL; the dose response is linear up to 2 kGy. Bapat and Nambi (1975) showed that the calcite response becomes sublinear at higher doses before reaching a maximum intensity at a dose of about 20kGy, and the TL emission spectra consist of a broad band with maximum at 630µm.

The components that form the oyster shell are $CaCO_3$, CaO, SiO_2, MgO, Al_2O_3, SrO, P_2O_5, Na_2O and SO_3 (Yoon *et al*, 2003, Freire *et al*, 2009). In addition to all these compounds, there are trace amounts of Mn^{2+}, Pb^{2+}, Ce^{3-}, $(UO_2)^{2+}$, Dy^{3+}, Sm^{3+}, Tb^{3+}, Nd^{+3}, Eu^{3+} that are responsible for the luminescence of calcite and for a radiation-induced center of violet emission (Marfunin, 1979). Although the oyster shell is formed by many compounds, the $CaCO_3$ (calcium carbonate) corresponds to approximately 96% of material that forms it. Calcium carbonate is found in two polymorphic forms, calcite (rhombohedral) and aragonite (orthorhombic) (Ikeya, 1993). The aragonite is only meta-stable under ambient conditions, transforming to calcite on heating. A reconstructive aragonite to calcite transformation takes place in the 300 – 400°C range in biogenic samples (Balmain e*t al*, 1999). Due thermal treatment the luminescence in $CaCO_3$, that is due to band-to-band recombination, will blueshift or enhance the higher energy part of the spectra (Medeiros *et al*, 2006).

TL signal is present in two polymorphic forms and caused by presence of Mn^{2+}. This presence of Mn^{++} results in glow peaks at 180° and 250°C in aragonite (Medlin, 1963), strong glow peaks at 80° - 100°C and weaker ones at 150°-175°, 215°-230°C and 320° - 330°C in calcite (Sunta,1985).

The objective of the present work was to study of the dosimetric properties of gamma induced centers in marine oyster shell using the TL and TSEE techniques.

Materials and methods

The materials studied in this work, known as oyster shells (Figure 1), usually used for decoration, were obtained in a market of Recife city originating from the northwest coast of Brazil. The pellets were prepared mixing powered oyster shell, with diameter between 177µm and 74µm, with powered Teflon in a 1:2 proportion.

Fig. 1. a) Bracelet made of natural oyster shell; b) pellets of oyster shell powder with Teflon and c) powder of oyster shell on an aluminium foil.

The oyster shells were powered and sieved retaining the 177µm – 74µm size fraction. The samples were thermally treated at 300ºC/1h and kept in dark until the irradiation and the TL and TSEE measurements were performed. After the treatments the pellets were irradiated at room temperature using a ^{60}Co panoramic source of the Centre for Radiation Technology (IPEN), and a ^{60}Co radiotherapy source of the Centre for Radiation Metrology. The pellets were irradiated with doses in the range from 5Gy to 10kGy. All measurements were taken at room temperature, and the pellets were sandwiched in Lucite plates with 3.5mm thickness to guarantee the electronic equilibrium during the irradiations. The TL measurements were taken using a Harshaw TL reader model 2000 A/B in the range from 50° to 300°C and the TSEE measurements were taken using a home-made system developed at the Centre for Radiation Metrology in the range from 30° to 300°C. All TL and TSEE measurements were obtained with linear heating rates of 10ºC/s in nitrogen flux and P10 flux, respectively.

Results

The TSEE measurements show peaks appearing at approximately 120°C and 180°C (Figure 1a). The TL emission curve, presented in Figure 1b, shows two characteristic peaks at 110°C and 220°C.

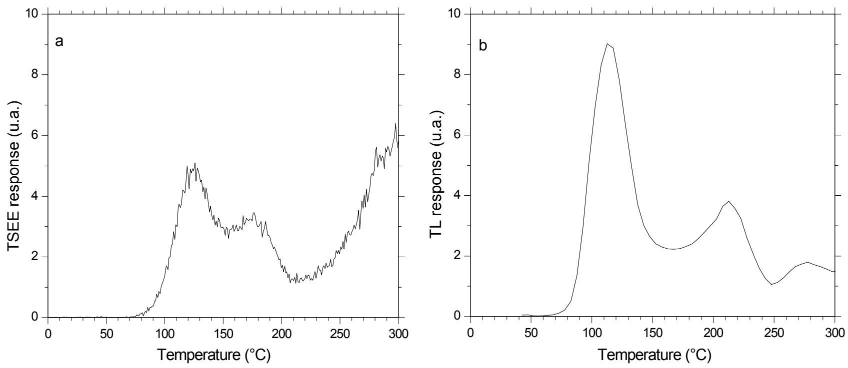

Fig. 1. TSEE(a) and TL(b) curves of the oyster shell in pellets, irradiated to 400Gy at room temperature, using a ^{60}Co source.

Figure 2 shows the dose-response curves of oyster shell pellets irradiated (^{60}Co) at room temperature over a range of 5Gy to 10kGy. The curve shows the increasing behaviour in function of the absorbed dose. The maximum standard deviation for the dose response curves was 3.5% for TSEE measurements (Figure 2a) and 4.5% of the TL measurements (Figure 2b).

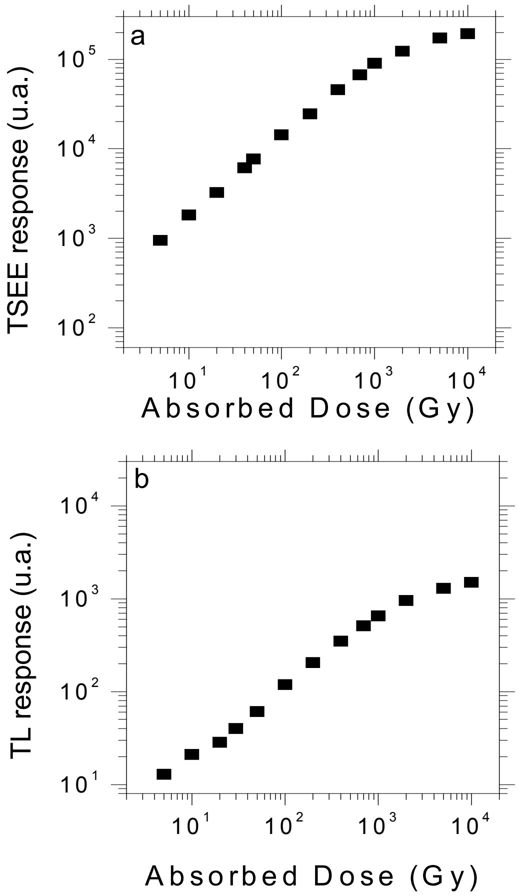

Fig. 2. TSEE (a) and TL (b) dose-response curves of the oyster shell in pellets, irradiated at room temperature, using a ^{60}Co source.

Reproducibility tests were carried out in samples irradiated to 5Gy (^{60}Co) at room temperature. The thermal treatment used before each irradiation of the samples was 300°C/1h. The maximum standard deviation, for irradiated samples, was 4.2% for TL measurements and 2.4% for TSEE measurements.

The lower detection limits were determined by variability studies of the TL and TSEE responses of samples treated at 300°C/1h and not irradiated. The value obtained using the detection of triple standard deviation of the samples was 500mGy.

Discussion

The results obtained show that oyster shells present possibility of use in high dose dosimetry. Oyster shells are biogenic materials in which the main minerals constituent is calcium carbonate. Observations carried out by Carmichael *et al* (1994) on the morphology of the oyster shells conclude that there is a great variation in the extent and type of mineralization. However, in studies carried out by Parker and Balmain *et al* (1999), they showed that a reconstructive aragonite to calcite transformation takes place in the 300 – 400°C. In the present work the pellets were made of powered oyster shell mixed with polytetrafluoroethylene and treated 400°C/1.5h, a procedure that probably transforms the aragonite in calcite.

The TL curves of calcium-based phosphors show two characteristic peaks at 175°C and 240°C (Anderle *et al*, 1998; Medlin, 1963; Nambi and Mitra, 1978) using a heating rate of 4.75°C/s. In the present work, the heating rate was 10°C/s that may have caused the dislocations of the TL peaks to 110°C and 220°C. The TSEE emission curve showed two peaks at 120°C and 180°C

The response of TL measurements shows a behaviour that agrees with that published by Bapat and Nambi (1975).

Conclusions

The good preliminary results of the studies with oyster shell samples in this work show the possibility of their use for high-dose dosimetry.

Design and assembly of a simple monitor ionization chamber

Yoshizumi, Maíra T.; Caldas, Linda V. E.
Instituto de Pesquisas Energéticas e Nucleares IPEN-CNEN/SP, BRAZIL

Abstract

At the Instituto de Pesquisas Energéticas e Nucleares, Brazil, a new monitor ionization chamber was designed, developed and characterized. This monitor is a parallel-plate type ionization chamber, and it has two sensitive volumes formed by three conductive foils. The chamber body is made of PMMA disks that are positioned outside the primary radiation beams. The pre-operational tests and the response stability tests were performed. The pre-operational tests, as saturation curve, ion collection efficiency, polarity effect and response linearity showed very good results. The response stability tests (repeatability and long-term stability) also showed satisfactory results, within international recommendations. Besides the good results, this ionization chamber is very simple to manufacture, and all materials used in this project are of low-cost and commercially available.

Introduction

Ionization chambers are the most used dosimeters. They are simple and they can be used for many purposes, depending on their material, volume and design.

A special kind of ionization chamber is the transmission chamber that is used as a monitor chamber for X-radiation beams. This kind of ionization chamber has some particular characteristics, such as a large sensitive volume which may cover the entire radiation beam section and is made of materials which are transparent to the X-rays (IAEA 2007).

In a Calibration Laboratory, the transmission ionization chamber can be used as a reference instrument since its response shows good stability and the calibration factor is transferred from a standard device (IAEA 2007). In this case, the transmission chamber may be calibrated periodically.

In the Calibration Laboratory of IPEN, two monitor chambers have recently been constructed (Yoshizumi and Caldas 2010a, 2010b). These ionization chambers have a ring-shaped design, and they measure only the radiation penumbra. They showed usefulness according to international recommendations.

Materials and methods

A simple transmission ionization chamber was designed and assembled at the Calibration Laboratory of IPEN. This ionization chamber has two sensitive volumes formed by two aluminized polyester foils and a graphite coated polyester foil. The chamber body is made of PMMA and the electrodes are connected to co-axial cables.

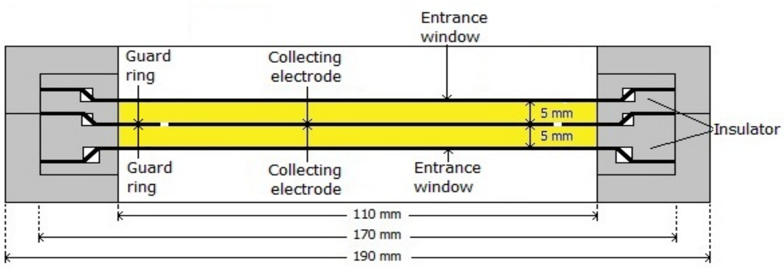
An electrometer, *Physikalisch-Technische Werkstätten* (PTW), model UNIDOS was used as a measuring assembly.

The characterization tests were performed using an X-ray unit, Pantak/Seifert, model ISOVOLT 160HS. Diagnostic radiology beam qualities, defined by IEC 1267 (1994), established in this equipment, were utilized in this work. The air kerma rates were measured using a secondary standard ionization chamber, PTW, model 77334. This standard ionization chamber calibration factors are traceable to the German primary standard laboratory *Physikalisch-Technische Bundesanstalt*, PTB.

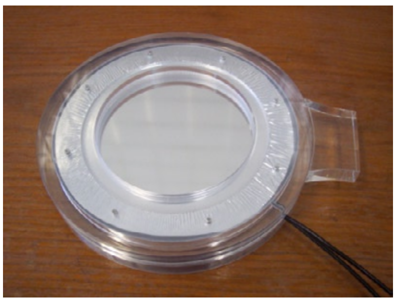
The response stability tests were performed using a $Sr^{90}+Y^{90}$ check source, PTW, model 8921.

Results

The transmission chamber developed at IPEN has two entrance windows of aluminized polyester foils of superficial density of 1.87 mg.cm^{-2}. The collecting electrodes and the guard rings are made of a graphite coated polyester foil. The graphite coating was made using a commercial lubricant spray Aerodag G, Acheson. A ring-shaped mask was made to separate the collecting electrode and the guard ring when spraying. A diagram and photography of the transmission chamber can be seen in Figure 1. The total sensitive volume of the chamber is about 63.5 cm^{3}.



(a)



(b)

Fig. 1. (a) Diagram and (b) photograph of the transmission ionization chamber.

Saturation curve, ion collection efficiency and polarity effect

The saturation curve was determined using the radiation beam quality RQA5 at a distance of 30 cm from the tube focal spot. The voltage applied to the sensitive volume of the chamber was increased in steps of ±50 V, covering a range from -400 V to +400 V. The results can be seen in Figure 2. The chosen operating voltage was -300V.

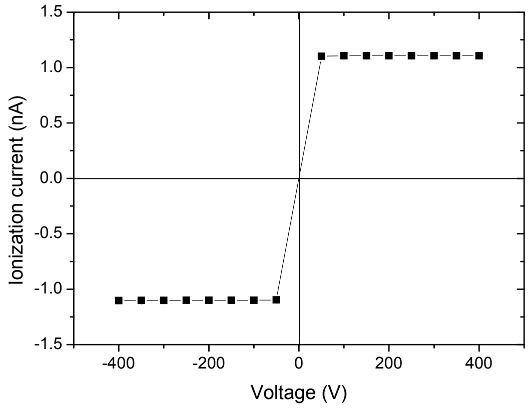


Fig. 2. Saturation curve of the transmission ionization chamber. The uncertainties associated to the measurements are negligible and they do not appear in the graph.

From the results obtained in the saturation curve test, the ion collection efficiency and the polarity effect of the chamber could be determined.

The ion collection efficiency was calculated using the two-voltage method (IAEA 2000):

$$k_s = \frac{\left(\frac{V_1}{V_2}\right)^2 - 1}{\left(\frac{V_1}{V_2}\right)^2 - \left(\frac{M_1}{M_2}\right)},$$

where $V_1 = \pm 300$ V and $V_2 = \pm 150$ V and M_i is the chamber response obtained when V_i is applied. For both voltages, the ion collection efficiency was higher than 99%, i.e., no ion recombination occurs in the sensitive volume.

The polarity effect measures the variation between the responses obtained for the same voltage but of opposite signals. For all tested voltages, the maximum variation was 0.66%, which is within the recommended limit of 1% (IEC 1997).

Response linearity

The chamber response linearity test was evaluated using the X-ray unit Pantak/Seifert and the diagnostic radiology quality RQA3. In this test, the ionization current applied to the tube was varied from 0.5 mA to 40.0 mA, covering a range of air kerma rate from 1 mGy.min^{-1} to 88 mGy.min^{-1}. As can be seen in Figure 3, the transmission chamber presents a linear response for the air kerma rate range studied. A linear regression was obtained that resulted in a correlation factor R of 0.99997.

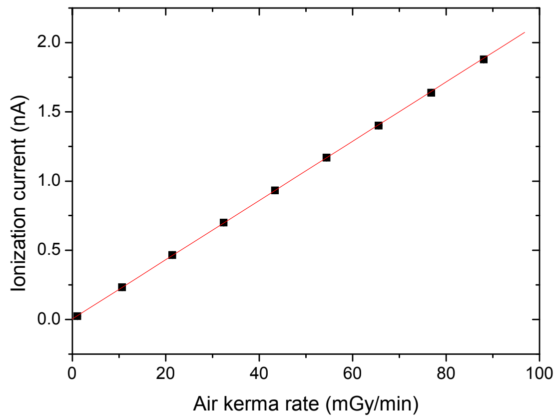

Fig. 3. Response linearity of the transmission ionization chamber. The uncertainties associated to the measurements are negligible and they do not appear in the graph.

Response stability tests

To evaluate the stability of the chamber response, four tests were performed: stabilization time, leakage current, repeatability and long-term stability. A PMMA holder was used to position the check source in front of the entrance window of the chamber.

For the stabilization time test, the check source was positioned in front of the transmission chamber, and then the chamber was connected to the electrometer, in the operating voltage of -300 V. The ionization current was measured ten times, 15 min, 30 min, 45 min and 1 h after the chamber connecting. The mean values obtained for each measurement time are shown in Table 1.

Table 1. Mean values of the ionization current obtained at different times from the application of the operating voltage to the transmission chamber.

Time (minutes)	Mean value of the ionization current (pA)
15	-100.9 ± 0.8
30	-101.2 ± 1.6
45	-101.1 ± 2.8
60	-101.2 ± 0.8

The ionization current obtained 15 minutes after switching on the chamber is 99.7% of the 1 h stabilization current. This result is within the recommended limits of ±2% of response variation (IEC 1997).

The leakage current was measured before and after irradiation. The charge was collected during 20 minutes with no radiation source present. The maximum leakage current was lower than 1.0% of the ionization current obtained with the minimum air kerma rate studied (using the beta check source), therefore within the recommended limit of 5.0% (IEC 1997).

For the repeatability test, ten consecutive measurements of the collected charge accumulated during 15 s were performed. The standard deviation of these measurements shall not be greater than 3% of the mean value according to the IEC 61674 publication (IEC 1997). This test was performed seven times in different days and the maximum variation obtained was 0.2%, therefore within the recommended limit.

From the mean values determined in the repeatability test, the long-term stability of the transmission chamber can be evaluated. Figure 4 shows the result of the seven tests performed.

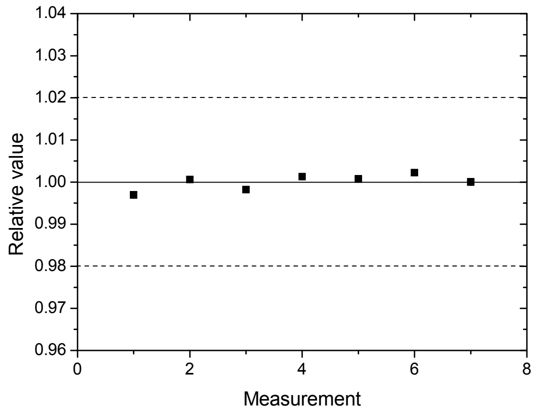

Fig. 4. Long-term stability of the transmission ionization chamber. The dashed lines represent the recommended limits. The uncertainties associated to the measurements are negligible and they do not appear in the graph.

From the results shown in Figure 4, the maximum variation of the chamber response in a period of 10 days was 0.3%. The IEC publication recommends a maximum variation of ±2% for the long-term stability test (IEC 1997), so the chamber response is stable according to this recommendation.

Conclusions

A simple transmission ionization chamber, using commercially available materials, was assembled. The characteristics and the response stability of the home-made transmission ionization chamber were evaluated. All performed tests resulted in good agreement to international recommendations. This chamber represents a good alternative since it is simple, easy to construct, and uses low-cost materials.

Ackowledgements

The authors are grateful to Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) and Ministério de Ciência e Tecnologia (INCT for Radiation Metrology in Medicine), Brazil, for the partial financial support.

The use of TL dosemeters in HZE radiation fields

Pugliese, Mariagabriella[1,2]; Roca, Vincenzo[1,2]; Durante, Marco[3]

[3] GSI Biophysik, Darmstadt, GERMANY

Abstract
Astronauts in space are exposed to a radiation environment that can have deleterious consequences. To carry out an accurate dosimetry for the radiation protection of astronauts and cosmonauts engaged in long-term space flights, we measured efficiencies of Thermoluminescence detectors (TLDs) exposed to high-energy heavy ions accelerated at the NASA Space Radiation Laboratory (NSRL) at the Brookhaven National Laboratory (Upton, NY). The achieved knowledge will be applied to the experimentally measured dose onboard the International Space Station (ISS).

LiF:Mg, Ti (TLD-100), ^{6}LiF:Mg, Ti (TLD-600) and ^{7}LiF:Mg, Ti (TLD-700) were exposed at the NSRL to iron, protons and oxygen high energy beams. The preliminary results indicate that efficiency of TLDs is reduced for iron more that for protons and oxygen.

Introduction
The radiation hazard for the astronauts consists of protons and electrons trapped in the Earth magnetic field, proton emitted in the course of solar particles events (SPE), and protons and the energetic nuclei of other elements (HZE particles) that constitute galactic cosmic rays (GCR). It is necessary to accumulate new data on dosimetric and microdosimetric characteristics of onboard spacecraft radiation fields and passive dosimeter systems could help to fulfil this task [Reitz, 1994]. In particular, Thermoluminescence detectors (TLDs) are widely used in space dosimetry because of their small size, resistance to environmental conditions and the possibility of accumulating data for long periods of time without external power. The main purpose of these ground-based measurements was to acquire TL-efficiency to apply this knowledge to the determination of dose equivalent from space radiation. Since the energy range of space radiation ranges up to a few GeV/n and its spectral composition extends from protons to Fe nuclei, evaluation of TL-efficiency is crucial to the performance of TLDs.

The relative TL-efficiency, $\eta(E)$, describes quantitatively the efficiency of conversion of radiation energy absorbed in the detector into TL light, as compared with efficiency of such conversion after with standard radiation (γ radiation):

$$\eta(E) = \frac{TL(E)/D(E)}{TL(\gamma)/D(\gamma)}$$

Our interest is to determine TL efficiencies, because it depends not only upon the LET but also on the ion charged.

The scientific reason for the change in the TL-efficiency with increasing ionization density of the particle relates to the dose deposition profiles from high charged particles. A slowing down high charged particle deposits its energy to an overhelming extent by secondary electrons (δ electrons) created in the slowing down process. Depending on the charge and the velocity of the ion, the energies and ranges of these secondary electrons vary greatly [Berger et al, 2008].

Material and methods

We used TL phosphor, LiF:Mg, Ti: TLD-100, TLD 600 and TLD 700 (size 3.2 x 3.2 x 0.89 mm, see figure 1). Table 1 summarizes the laboratory procedures, such as heating cycles, reference radiation, TL reader etc., for all types of TLDs.

Table 1. Parameters of laboratory procedures.

Reference radiation	Photons 6MeV
TL reader	Harshaw 3500
Heating rate	5°C/s
Maximum temperature	400°C
Annealing cycle	400°C (1h), 100°C (2h)
Cooling rate	Slow
Calibration	Single chip

The reference radiation for the evaluation of TL-efficiency was a 6 MeV photon beam obtained at LINAC of “Istituto per la Cura dei Tumori di Napoli, Fondazione Pascale”.

Although GCR consist of 85% protons, 14% helium, and 1% heavier particles (iron 0,02% only), HZE nuclei are very important in space radiation dosimetry because highly charged and very densely ionizing. As a consequence, even though the number of HZE particles is relatively small, they have a significant biological impact that is comparable to that of protons. For this reason, TLDs were exposed to 1 GeV/nucleon iron beam, 1 GeV proton beam and 400 MeV/nucleon oxygen beam accelerated at the NASA Space Radiation Laboratory (NSRL) at the Brookhaven National Laboratory (Upton, NY). The size of the beam was about 15x15 cm and the disuniformity in this area below 5%. The dose was measured by a Far West thimble chamber. Details of dosimetry at NSRL are described in the reference [Lowenstein et al, 2007]. Until now, the maximum beam energy of charged particles for whom TLDs were exposed to evaluate TL-efficiency was 500 MeV/nucleon, at the Heavy Ion Medical Accelerator (HIMAC) of the National Institute of Radiological Sciences (NIRS) in Chiba, Japan [Yasuda et al, 2006].

Results

Post-exposition reading of TLDs was performed by an Harshaw model 3500 manual TL reader. In table 2 the preliminary results of TL-efficiencies for all types of TLDs exposed to different beams are reported.

Table 2. TL-efficiencies for different charged particle beams and different TLDs.

TLD type	Charged particle beam	Tl-efficiency
TLD 100	Protons 1 GeV/nucleon	0,58±0,05
TLD 100	Iron-ion beam 1 GeV/nucleon	0,30±0,03
TLD 100	Oxigen-ion beam 400 MeV/nucleon	0,51±0,05
TLD 600	Protons 1 GeV/nucleon	0,76±0,07
TLD 600	Iron-ion beam 1 GeV/nucleon	0,40±0,04
TLD 600	Oxigen-ion beam 400 MeV/nucleon	0,68±0,06
TLD 700	Protons 1 GeV/nucleon	0,73±0,07
TLD 700	Iron-ion beam 1 GeV/nucleon	0,35±0,04
TLD 700	Oxigen-ion beam 400 MeV/nucleon	0,71±0,07

These TL-efficiencies values suggest that the dose equivalent from space radiation for astronauts, calculated with calibration factor obtained exposing TLDs at 6 MeV photon beam was underestimated [Pugliese et al, 2008]. Consequentely, more accurate determinations of this parameter have to be performed, also taking into account the real spectrum of the radiation field in the space.

Conclusions

These preliminary results indicate that it is necessary to investigate more about TL-efficiency exposed to high energy charged particle beams to obtain the correct dose equivalent for astronauts in particular in view of planning future missions to the Moon and Mars. As expected, TL-efficiency of detectors exposed to iron beam is lower respect TL-efficiency obtained for protons beam at the same energy.

Intercomparison of various dosimetry systems for routine individual monitoring

Koguchi, Yasuhiro[1]; Yamamoto, Takayoshi[1]; Ranogajec-Komor, Maria[2]
[1] Chiyoda Technol Corporation, Oarai Research Center, JAPAN
[2] Ruđer Bošković Institute, CROATIA

Abstract

According to the studies of EURADOS (www.eurados.org) in addition to film dosimeters thermoluminescent (TLD) and recently radiophotoluminescent (RPL) dosimeter systems are the most widely used for individual monitoring. The situation in personnel dosimetry is permanently changing. For example in the last years because of introducing RPL dosimetry in Europe, the number of film controlled workers was reduced about 50%. In order to reach a high international standard in the application of these dosimeters for routine individual monitoring, there is a need for intercomparisons. Therefore an intercomparison was organised with the participation of six dosimetry services from six countries.

The objectives of the study were to compare and to improve laboratory calibrations, to compare the results of different dosimetry systems at the same irradiation conditions. The task of the participating laboratories was to irradiate their own dosimetry system used for routine individual dosimetry together with RPL dosimeters received from Chiyoda Technol Corporation with a dose $H_p(10) = 0.1$ mSv by narrow spectra X-ray beams of radiation quality N-60. The RPL (GD-450) dosimeters after irradiation were evaluated by Chiyoda Technol Corporation.

The results of this intercomparison indicated that the RPL and the other passive solid state detectors are very suitable for individual monitoring. The establishment of this international intercomparison allowed a broad exchange of experience. As a consequence, the calibration and measuring procedures used in particular laboratories, as well as the quality of the dosimeter systems employed could be improved step by step. We expect that the results of this investigation may encourage the participating services to improve the dosimetry methods and procedures.

Uncertainty of in vivo assessment of actinides activity in human skeleton

Vrba, Tomas
CTU in Prague, Brehova 7, 11519 Prague, CZECH REPUBLIC

Abstract

In vivo assessment of the actinides activity in the skeleton is valuable source of information on internal contamination of the human subjects. Two different methods, for uncertainty determination, were applied on in-vivo based assessment of skeleton actinides activity performed in National Radiation Protection Institute in Prague. Both methods provide quite comparable results why overall uncertainty depends on measures activity and ranges from 1.23 to 1.65 when expressed in scattering factors.

Introduction

In vivo assessment of the actinides activity in the skeleton is valuable source of information on internal contamination of the human subjects. The proper estimation of the overall uncertainty is highly important, however not simple task because there are various sources of uncertainties. Many of them are connected with a measurement but some of them, like skeletal or bone activity distribution need to introduce assumptions about them. Combining of the uncertainties can by difficult when uncertainty from one source is influenced by other one and thus common rule of uncertainty propagation for independent sources is not applicable.

The presented work tries to estimate overall uncertainty of the method used in National Radiation Protection Institute in Prague for assessing of ^{241}Am activity in the skeleton. Primal step of the process is measurement with two LEGe detectors placed 3 cm of the temporal bones of the skull (Malátová et al. 2000). The recalculation of the skull activity to whole skeleton is done after measurement spectra analysis and skull activity assessment by a ratio.

Material and methods

Estimation of the uncertainty from the long term measurement of subjects with old internal contamination (distanced from the time of intake) can provide some information on stochastic part of the process, like detector placement. Such approach is useful, but it does not carry out any information on systematic errors which could by of mayor terms of overall uncertainty. The most important sources of systematic uncertainty are differences of the real head and calibration phantom in term of activity distribution, size and attenuation, skull to skeleton activity ratio (used for recalculation of measured activity to total skeletal content) and spectra evaluation. Other uncertainty sources, like neck vertebrae, can affect measured counts and thus has to be considered too.

Two methods for uncertainty estimation were used in the paper. First one, IDEAS methodology, recognizes two type of the uncertainty: counting error which follows Poisson distribution (A type uncertainly) and other uncertainties which can by described by log-normal distribution and its standard deviation (called scattering factor –SF). Combining of these two types is possible as shown by Eqn. 1 when type A error is less that third of total uncertainty or relative Poisson uncertainty is less than 30% (Doerfler et al. 2006).

$$SF_i = \exp\sqrt{[\ln(SF_A)]^2 + [\ln(SF_B)]^2} \qquad \text{Eqn. 1}$$

Second method use Mote Carlo approach. All influencing parameters, like activity of the skull, number of the emitted photons during measurement period, detector position etc., are sampled from considered ranges and distributions. Total or marginal uncertainty is obtained from statistical evaluation of aggregated representations with given condition. In the other word: the MC method simulates the estimation process many times and from the sum of results builds distribution (histogram) and estimates its mean and deviation.

Uncertainty

The estimation of the different uncertainty for IDEAS method was done previously in a thesis (Vrba 2007a) and considered values and related assumption are summarized in table 1 side by side with values from Malátová (Malátová et al. 2000).

Table 1. Scattering factors assumed for IDEAS methodology estimate of total uncertainty.

Uncertainty source	Current study		Malátová[a] SF
	method of assessment – note	SF	
voxel phantom composition	MC study density variation ±10%	1.03	Not Applicable

a - equivalent value, b - single calibration constant based on physical phantom, c - calibration function with known head size, d - single calibration constant based on voxel phantom. (Vrba 2007b)

The algorithm of the MC uncertainty evaluation is described in figure 1 where sampling of the random variable is expressed by square brackets. The assumptions on variables from unknown distributions were same as for IDEAS approach, if applicable, or chosen in a conservative way.

Displacement of detectors, expressed by a centre of their windows, were sampled uniformly in region from -2 to 2 cm in plane parallel to the temporal bone and from -1 to 1 cm perpendicularly. Uniform distribution of the activity in the skull ranged from 3 to 100 Bq was chosen in order to cover activity interval from minimal detectable activity (MDA) to the region where the uncertainty from the counting is marginal.

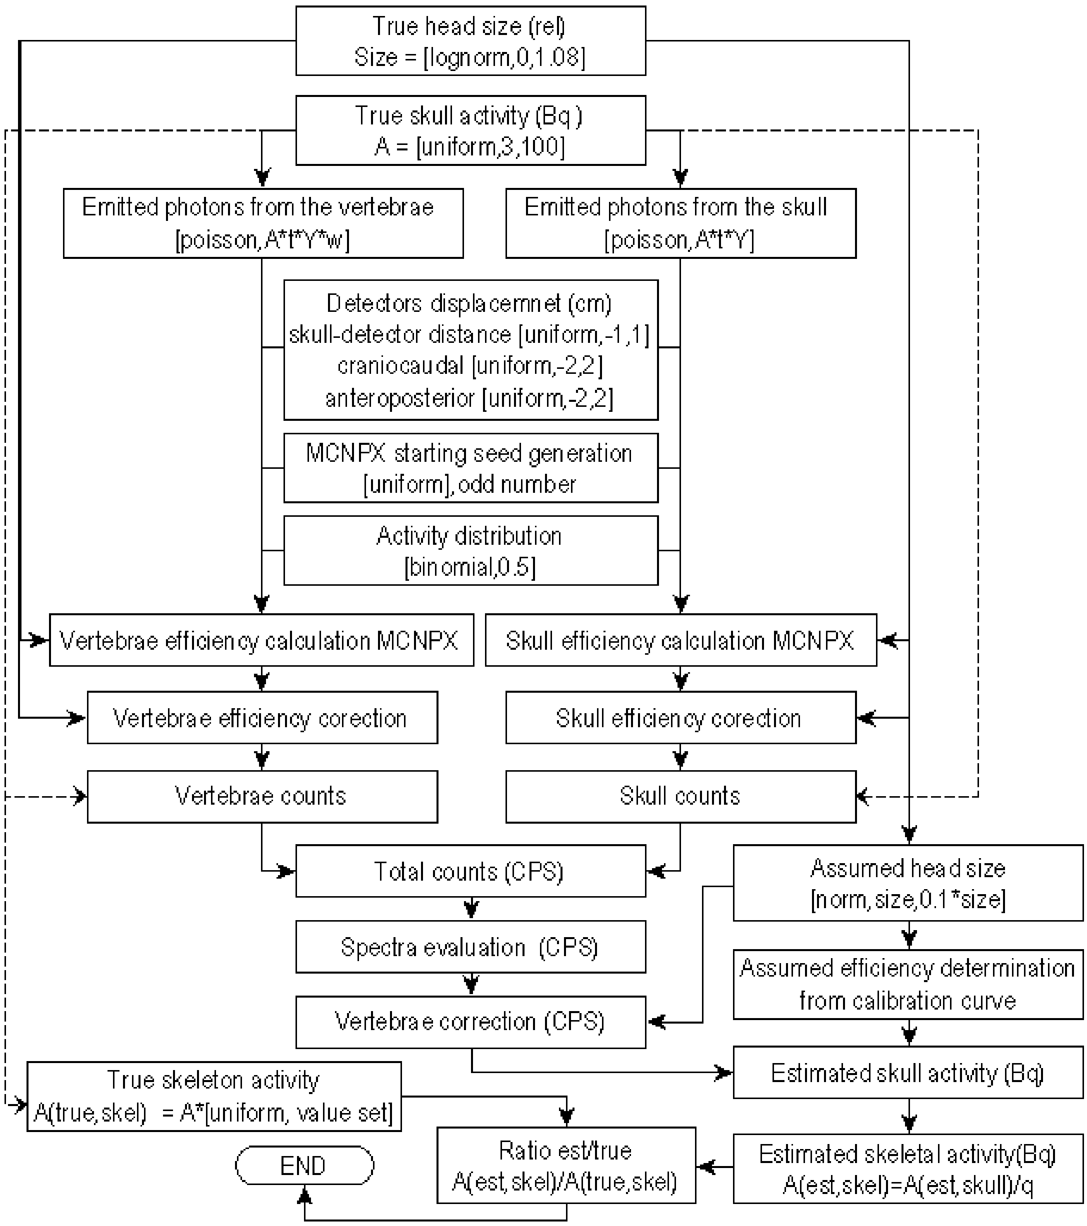

Fig. 1. Monte Carlo algorithm used to estimate uncertainty of americium skeleton activity assessment.

Skull size comes from lognormal distribution with SF 1.08 when maximal and minimal head size were limited according known head size (equivalent to hat-size 44 and 67 cm respectively). Finally skull to skeleton activity ratio was taken from uniform discrete distribution containing four known values based on USTUR whole body cases (Lynch et al. 1988). The distribution of the activity in the bones changed in time, due to bone remodeling and activity redistribution, and is quite unknown. The binomial distribution with equal probability of volume and surface activity placement was anticipated in order to eliminate underestimation of the effect.

There were not taken in account uncertainty from limited description of particle transport in MCNPX and applied cross-section libraries since there are no date on it and the expected uncertainty is small. The limitation of the phantom model was not covered either because modeling is rather difficult. The calculation of the registered photons with energy of 59.6 keV in the detectors was performed via MCNPX ver. 2.5 or 2.6, when counts from the skull and vertebrae were determined in separate simulations. The correction of the count in the bin representing total absorption had to be done because scaling of the phantom voxel side changes outer layers thickness covering the skull. Total number of MCNPX simulations pair (skull, vertebrae) was 10000 in order to have reasonable statistic even in a case when subset whit specific parameters are assumed.

Relative error of spectra evaluation is a function of the counts intercepted in the detectors. Dependency of the error was estimated by a power function which fits graph data points where gross peak area was on X axis and relative errors of the measurements on the Y axis. The sampling of spectra uncertainty takes corrected number of counts, determines relative error from the function and uses it as a parameter of the random number generator (lognormal distribution).

Results

Overall uncertainty estimated with IDEAS methodology, expressed by the scattering factor, is 1.32 if head size is known or 1.37 when head size is unknown. MC method estimates overall uncertainly almost of the same magnitude SF=1.35, when calculation cover all parameters in their full ranges and detection efficiency is corrected on head size. There is slight difference in total uncertainty when only surface (SF = 1.31) or volume (SF = 1.35) distribution in the bones tissue is concerned. When constant detection efficiency is assumed (like in the past) overall uncertainty increase to SF=1.42. Uncertainty (SF) as the function of the skull activity and source distribution is given in table 2.

Table 2. Uncertainty of skeleton activity expressed in SF.

Activity (Bq)		Considered source		
rage	mean	Surface	volume	both*
3-20	11.8	1.54	1.65	1.61
50-100	74.4	1.23	1.24	1.27
3-100	51.6	1.31	1.35	1.35

* Surface and volume sources represented with same probability

The MC approach evaluates uncertainty due neck vertebrae in more accurate way than simple assumption given in table 1. Neck vertebrae add a signal in detectors and shifts activity estimate to higher one if there is no correction. The estimated uncertainty due to vertebrae correction is about SF = 1.025 when an effect of activity distribution in bones can by neglected.

The approximation of the overall uncertainty distribution by lognormal one, proposed in IDES methodology, looks very reasonable because all MC histograms exhibit such character as is demonstrated in figure 2.

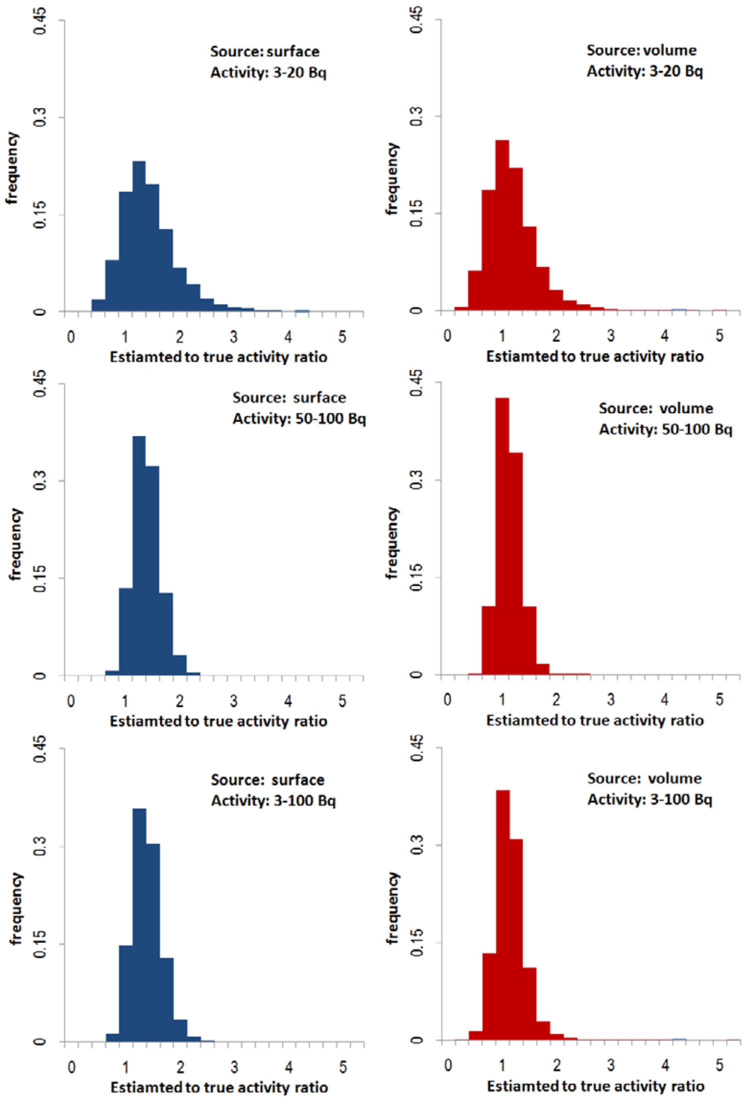

Fig. 2. Histogram of estimated to true activity ratio for different source distributions and skull activities.

Discussion and conclusion

Results of MC and IDEAS method are in reasonable agreement in a term of SF value, with regards to different approach. Distributions of the assessed activity to true one from MC approach exhibit lognormal character which is in coherence with IDEAS method. The MC estimate of total uncertainty does not cover some aspect, like difference of the tissue in the real head and phantom, however their influence is small compare to other sources. The main limitations of presented results are assumption used in order to estimate unknown parameter distributions. Usage of uniform distribution for detector positions and true skull activity is maybe too conservative; however it is not reasonable to introduce more complex assumption on them without some reliable information.

Uncertainty estimates carried out from the current study are lower than ones given in the paper by Malátová (Malátová et al. 2000). The main difference, between these two study is: more realistic estimates of same uncertainty sources (e.g. inhomogeneous americium distribution in the skull), including of some new uncertainties sources (detector position), introduction of calibration function, based on simulation with voxel phantom. Usage of the efficiency curve from the simulations reduced possible error because some physical voxel phantoms used in Malátová et al. are imperfect and thus introduces larger uncertainty.

Abstract

Human Body Monitoring Laboratory (WBML) from IFIN-HH, Bucharest, Romania, performs internal contamination IN VIVO assessments, respecting its own Quality Assurance System, agreed from the year 2000 and updated in accordance with the requirements of the standard SR EN ISO/CEI 17025:2005 and other specific national and international standards, regulations and guidelines[1-6].

The method implemented for I-131 monitoring in thyroid was applied in a case of an internal contamination through ingestion. There were performed several thyroid assessments using a Thyroid Counter equipped with a lead shielded NaI(Tl) detector for the thyroid, with an efficiency of 0.9×10^{-2} counts/Bq*s and MDA of 34 Bq for I-131.

The results obtained after the selection of the measurement data showed a good compliance of them with the model considered for the retention of the iodine in the thyroid, specified in ICRP78.

Introduction

The WBML is notified to execute: (1) the monitoring of internal contamination for workers involved in nuclear activities from hospitals, industry, research, national security, with potential risk of internal exposure to ionizing radiation, and in case of nuclear accident, for persons belonging to the public; (2) the estimation of gamma emitting radionuclide intakes; (3) the estimation of committed effective doses

The radionuclides identified during the assessment of the workers were Na-22, Co-60, Tc99m, Zn-65, I-125, I-131, Cs-137 and Ir-192, specific to different types of nuclear activities, as production of radiopharmaceuticals, production of sealed sources, nuclear medicine, cyclotron maintenance and research activities.

During a routine monitoring of workers, one case of internal exposure revealed to be special due to the fact that it was not an occupational intake, but the result of the ingestion of a capsule of I-131 used in the diagnosis of a thyroid disease. The value of intake was known by the physician that prescribed the diagnosis procedure, but unknown to the Whole Body Monitoring Laboratory. Because it was possible, there were performed eight thyroid assessments, at different intervals after intake, to see the compliance with the expected decay for the I-131 in the thyroid.

Material and methods

The system used in WBML for the internal contamination assessment with I-131 was a Thyroid Counter, a gamma spectrometer, equipped with lead shielded NaI(Tl) scintillation detector of 40mm diameter, and 50mm thickness.

The efficiency calibration was performed with a plexiglass thyroid phantom, simulating the adult thyroid anatomical shape and volume, filled with certified radioactive solution of known activity of I-131. The values determined for the efficiency and for the Minimum Detectable Amount were of 0.9×10^{-2} counts/Bq*s and of 34 Bq for I-131 (364keV), respectively.

The associated electronics of detectors consists on state-of-art analog and digital ORTEC equipments and for spectra acquisition is used the software Gamma Vision 32 supplied, also, by ORTEC.

The estimation of the intake and of the effective dose was made following the steps suggested in the new document, FZKA 7243, General Guidelines for the Estimation of the Committed Effective Dose from Incorporation Monitoring Data, for acute ingestion. All these steps are parts of different stages of intake and effective dose evaluation implemented in a flowing chart that establishes, clearly, any action to be done for an optimum estimation of the intake and of the committed effective dose.

The stages followed were:

Stage1. Check for need of evaluation

Stage2. Check on significance of a new measurement and consistency with previous evaluation

Stage3-4. Identification of pathway of intake for special evaluation

Stage6. Special procedure for ingestion

The evaluation procedure of the intake and effective dose is not very simple because the monitoring values indicate an important internal exposure and there are necessary many steps of evaluation, just to be sure that it is applied the quality assurance of data for reliable results.

Results

The thyroid retention predicted values (Bq per Bq intake) following an acute ingestion of I-131 were considered those from the ICRP 78.

Stage1. It was identified the first monitoring value and determined M_C = 3.8Bq, the critical monitoring quantity.

Stage2. (i) It was determined the order of magnitude of the intake and of E(50) from the first measurement data.

Intake = 3397143 Bq

E(50) = 73.75 mSv

(ii) There were considered realistic estimates of the overall uncertainty on each data point expressed as a total scattering factor, SF, taking into account the total uncertainties of type A and type B.

Stage3-4. It was decided that it was necessary to perform a special monitoring for a case of pure ingestion.

Stage6. There were analyzed the monitoring data to see the compliance with the iodine model for ingestion declared in ICRP78 and to look for outliers.

The monitoring data and the trend of data considering the thyroid retention predicted values (Bq per Bq intake) following an acute ingestion of I-131 from the ICRP 78 were represented in Fig.1.

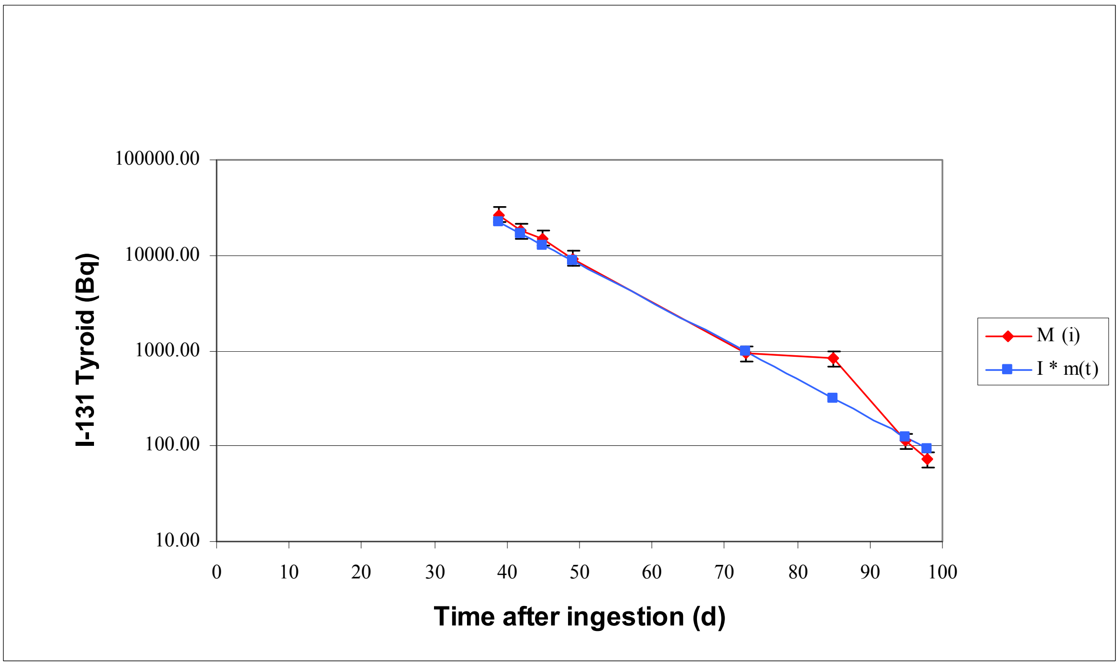

Fig. 1. I-131 Thyroid measurements.

One measurement data was found to be outlier and it was eliminated from the subsequent evaluation.

Considering the remained 7 monitoring data, they were processed for intake and effective dose estimation in 2 steps:

– the first 3 data, considering that they were obtained all in an interval of 7 days
– all the 7 monitoring data , considering that the high effective doses require more data for the evaluation. The results obtained are presented in Table 1.

Table 1. Estimated Intake and committed effective doses, E950) for 2 selection of monitoring data.

Nr.of processed data	Estimated Intake(Bq)	Real Intake (Bq)	E(50) mSv	Error (%) (absolute value)
First 3	3234628	2960000	71.16	9.3
7 (without outlier)	2859570	2960000	62.9	3.4

To qualify the fit of the measurement data, it was performed the evaluation of the observed chi-square. The values of 1.16 for $\chi_0^2(I)$ and of 0.88 for P-value certified us to consider that, there is a good fit of data.

Conclusions

The results obtained showed a good compliance of the measurements data with the model for iodine from ICRP78, fact that emphasizes the good quality of processed monitoring data. Moreover, a greater number of good monitoring data reduces the error of intake estimation. This gives us the certitude that the implemented method for the intake and dose estimation is reliable and valid.

Internal dose formation in rural society after the Chernobyl accident

Vlasova, Natalie; Rozhko, Alexander; Visenberg, Yuliya; Mactkevich, Svetlana
The Republican Research Center for Radiation Medicine and Human Ecology,
Gomel, BELARUS

Abstract

Dose is formed in person due to the personal psychological, physical and social characteristics and economic status during his practical activities interacting with polluted environment. These actively promotes consumption rate of the contaminated food stuffs, thus the dose is the property of the person.

Every person is a member of a family. A family is the same society, but concerning settlement it is a small one. Moreover, family is a social complex system, including certain individuals being in direct contact for a long time, united by connections and by the nature mutual relations. Every family as a social system determines actions of its individuals and in certain situations acts in relation to environment as a single whole.

The WBC-measurement Data Base for the period of 1989 – 2008 contains above 2 million records, which allow studying the internal dose peculiarities.

The provided analysis of internal dose distribution for inhabitants of rural settlements for 10-year period confirmed the hypothesis that every individual and also every family have their own certain place on a dose distribution curve and it is constant in time. In other words the same percentile value of dose distribution corresponds to certain person and certain family. These inhabitants have not only different doses but also different personal, social and economic characteristics.

Finally, the results of the research will allow predicting doses with enough high degree of accuracy in certain persons for any year using their own relative doses for one or several years or by known relative doses in members of their families.

This law can be used as a basis for methodological approach to reconstruction of individual doses for the subjects for practically any time period of the accident, and that is important for determining of individualized doses for people included into the Belarus State Registry of the Chernobyl affected persons and estimation of individual doses in epidemiological studies.

Introduction

The internal dose of the person is formed due to consumption of foodstuff contaminated by radionuclides and the consumption rate is defined by its personal characteristics (psychological, physical) and the social and economic status (professional occupation and a social status). The person during his practical activities interacting with contaminated environment actively promotes dose formation which is his property (Skryabin Vlasova 1995). Based on this fact, the distribution of inhabitants in a settlement by doses is not random. It reflects the attitude of certain individuals to radiation danger factor. This attitude also forms "food" behavior of people. Food habits of certain persons are formed depending on their perception of radiation danger factor. Therefore the attitude of certain persons to radiation danger is connected with their personal characteristics, such as gender, an educational level, psycho-emotional status (Skryabin 1997).

Under the same external conditions one refuse consumption of the 'contaminated' foodstuff, others act on the contrary. Internal dose distribution in the settlement is defined by personal characteristics of each of the inhabitants. Therefore obviously each person takes certain place, constant in time on a dose distribution curve (Vlasova 2007).

Besides each individual is a member of a family. Family is a social system which is compound organized, the ordered whole, including individuals united by connections and mutual relations, specifically social by the nature. Each family as the social system to some extent determines actions of individuals included into it and in the certain situations acts towards an environment as a single whole (Vlasova Stavrov 2005).

Within the framework of a family the direct consumption of foodstuffs is provided. This is preceded with formation of corresponding psycho-emotional perception of radiation danger factor. And apparently the direct factor of internal dose formation as a consumption rate of the contaminated food stuffs such as, for example, milk, forest mushrooms, game, is defined by a number of the indirect factors connected with social- demography-economic characteristics of a family. In this way, every family should be characterized by the dose. As the family forms a dose so the dose in it is a property of a concrete family (Vlasova Stavrov 2005). Thus, dose distribution in a settlement is defined also by characteristics or features of each family in a settlement. Therefore, obviously, each family, similarly to each individual, on dose distribution curve takes the certain place which is constant in time.

Really, analyzing internal dose distributions of rural settlements in dynamics for the 10-year period it was noticed that at certain persons and members of the families having numerous measurements during one and some years, relative doses are identical, in other words, the same value of a certain percentile of dose distribution in a settlement corresponds to the individual.

Material and methods

For conducting the study there was selected the settlement Kirov in the most contaminated Narovlya district of Gomel region located closely to a forest. As our studies showed the "forest" factor plays an important role in formation of internal dose caused by consumption of forest berries, mushrooms and game (Skryabin et al. 1995).

There were used data on internal doses calculated by WB-measurements on cesium content in the body of inhabitants of a settlement Kirov for 10-year period of 1990-1999, contained in the database of WB-measurements of the State Dosimetry Registry.

The methods of applied statistics as analyses of variance, multiple-factor statistical analysis were used. Statistical processing of materials was performed with the help of a package of statistical programs "STATISTICA 6.0".

Results

There were analyzed the data representative samples estimated by results of WB-measurements, internal doses for 10 years on the selected settlement Kirov. There were revealed the inhabitants having relative doses identical in time; the dose of each of them corresponds to the certain value of percentile dose distribution per every year. The descriptions of some of them are shown in the table 1.

It is necessary to note that at people distributed by this way through dose distribution` percentiles have not only doses which differ, but also different individual personal, social and economic characteristics.

Table 1. Stability of Relative Ingestion Dose at Individuals (the percentiles of Ingestion Dose Distribution), Kirov.

By method of the one-way analysis of variance there were allocated 2 seasons: spring - summer: March, April, May, June, July; autumn - winter: August, September, October, November, December, January, February (rural inhabitants use dry mushrooms in the winter prepared in the autumn) for which average internal doses significantly differ by average value (Vlasova 2007). Results are shown in table 2 and in figures 1-2.

* SGD – standard geometrical deviation of the distribution: ratio of 84%- percentile to 50%-percentile or median.

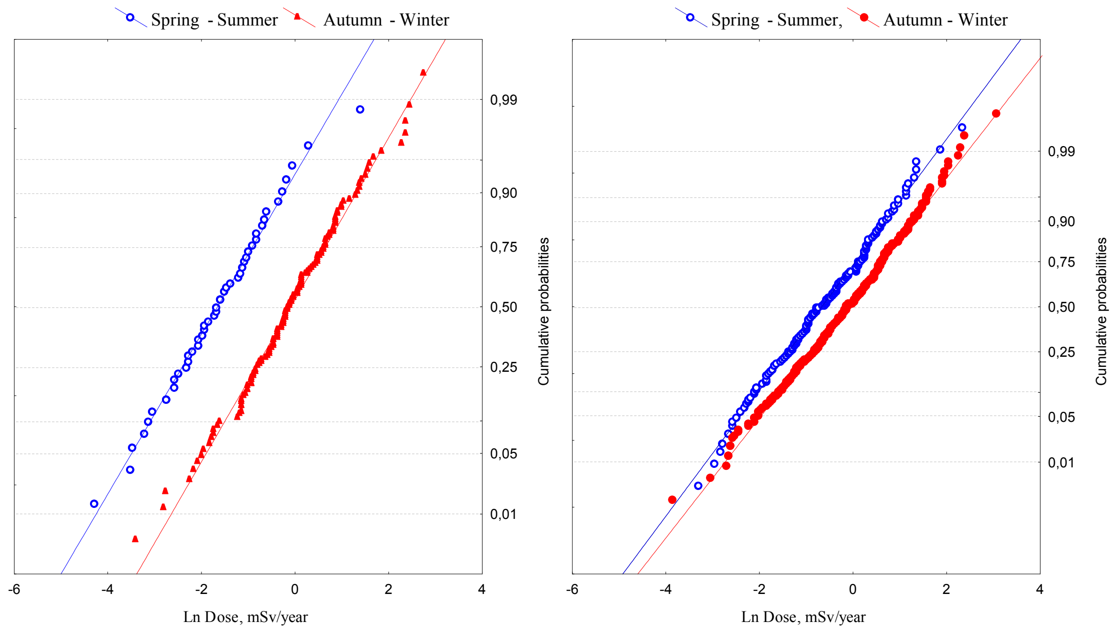

Fig. 1. Integral Internal Dose Distribution of Inhabitants of a Settlement Kirov, 1992, 1996 2 seasons of a year

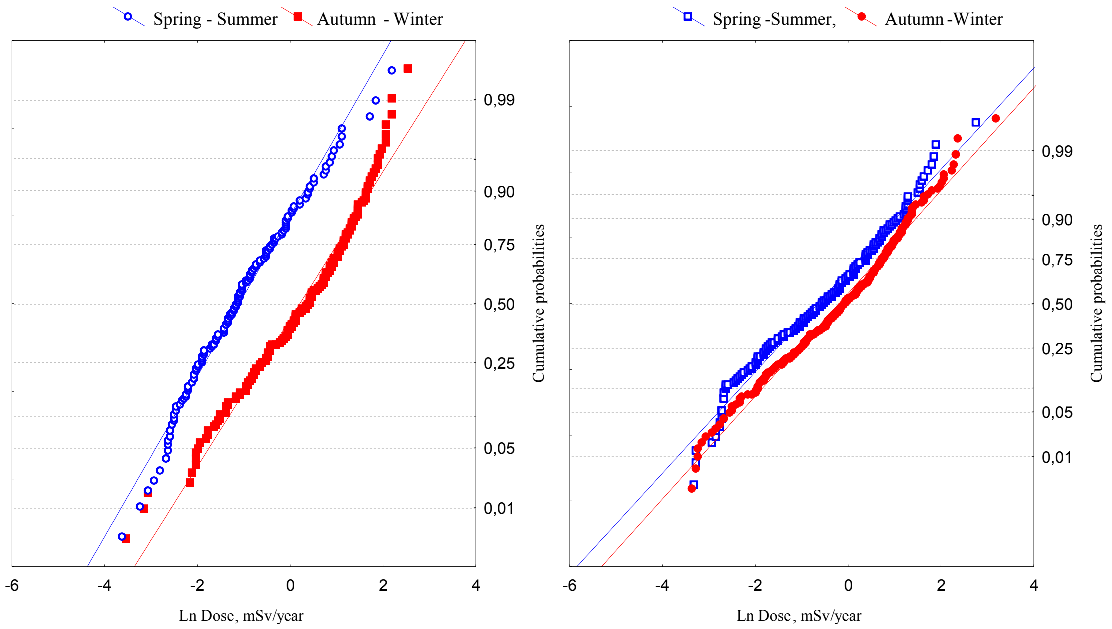

Fig. 2. Integral Internal Dose Distribution of Inhabitants of a Settlement Kirov, 1997, 1998 2 seasons.

Thus, in view of internal dose distributions on two samples of inhabitants of a settlement Kirov, corresponding to two seasons, by each year, for people and families (and members of families), having corresponding dose distributions percentiles (relative internal doses) on settlement per year as a whole (see tables 1, 2), there were identified the values of dose distribution percentiles of corresponding seasons of each of the years. The description is shown at table 3.

Table 3. Stability of Relative Ingestion Dose in Individuals (the percentiles of Ingestion Dose Distribution) Kirov, Autumn-Winter & Spring-Summer

Fam-ily	Gen der	BY	Occup.	Years Autumn-Winter & *Spring-Summer*									
				1990	1991	1992	1993	1994	1995	1996	1997	1998	1999
Yu.T.	F	1976	pupil		16%		21%		*31%*			*46%*	
D. L.	F	1957	medicin				*39%*	21%	*27%*	*14%*		*41%*	48%

P. I.	M	1909	pension	93%			*87%*				99%		

Studying the individual characteristics and parameters of internal dose distribution in classes of the same behavior of inhabitants in Kirov settlement it was revealed that in each class there are the persons forming families (Skryabin Vlasova 1999). There was found to be a considerable share of such families in each class (see table 4).

Table 4. Family structure in classes of homogeneity.

Class №	Share of Inhabitants forming families, %	Average value				Head of a family		
		Internal Dose	Number of family members	Relative index of OAG*of a family	Family educational relative level	Share of workers, %	Share of female, %	Average educational relative level
1	72	0.34	2.52	1.36	1.07	30	30	1.10
2	62	0.74	2.60	1.37	1.00	42	24	0.95
3	57	1.15	2.65	1.39	0.88	47	27	0.87
4	51	1.75	2.70	1.46	0.93	59	7	0.96
5	69	5.48	2.78	1.51	0.80	70	4	0.80

* Using the analysis of varience there were distinguished two occupational-age groups (OAG) for which the average internal doses significantly differ. Structure of OAG1 included employees, housewives, female pensioners, handicapped persons and children; structure of in OAG2 included machine-operators, drivers, workers, foresters and male pensioners (Skryabin 1995).
Relative index of OAG of a family is the average value of the corresponding values of factor.

As evident from the data of Table 4, the average number of family and relative indicator of family OAG increases with growth of the dose from class to class; the average relative educational level of family decreases, the share of working heads of the family significantly increases, a share of women among them decreases, the relative educational level tends to decrease.

The family analysis of internal doses – classification of families of Kirov settlement, had been conducted. The methodology of family analysis of internal dose formation is similar to the corresponding one of the individual analysis (Vlasova Stavrov 2005): the multiple-factor statistical analysis, i.e. classification of objects by set of informative signs.

As a result of multidimensional classification of families in Kirov it was received 10 non-crossed classes giving full enough conception about a variety of types of families. In Table 5, the signs and statistical parameters of distributions of average-family and pseudo-collective doses for the whole sample and on the obtained classes are presented.

Average values and medians of dose distributions as avarage-family ones, as well as the pseudo-collective ones, essentially differ in classes. SGD values of dose distributions in each class are low enough in comparison with the whole sample that is obvious from data of Table 5 and Figure 3. It testifies to homogeniety of classes by dose and so to adequacy of the classification.

Table 5. Description and Statistical Parameters of Pseudo-Collective Family Doses and Average Family Doses Distributions by Family Classes in a Settlement Kirov.

Family number in class	Family' Index						Family Leader				Average Family Dose			Pseudo-Collective Family Dose			
	Number of members	Avg age	Education	OAG	Number of children	Contact with the forest	Age	Education	Occupation	Share of men, %	Average	Median	SGD	Average	Median	SGD	Relat. Range %
											mSv/year			mSv/year* man

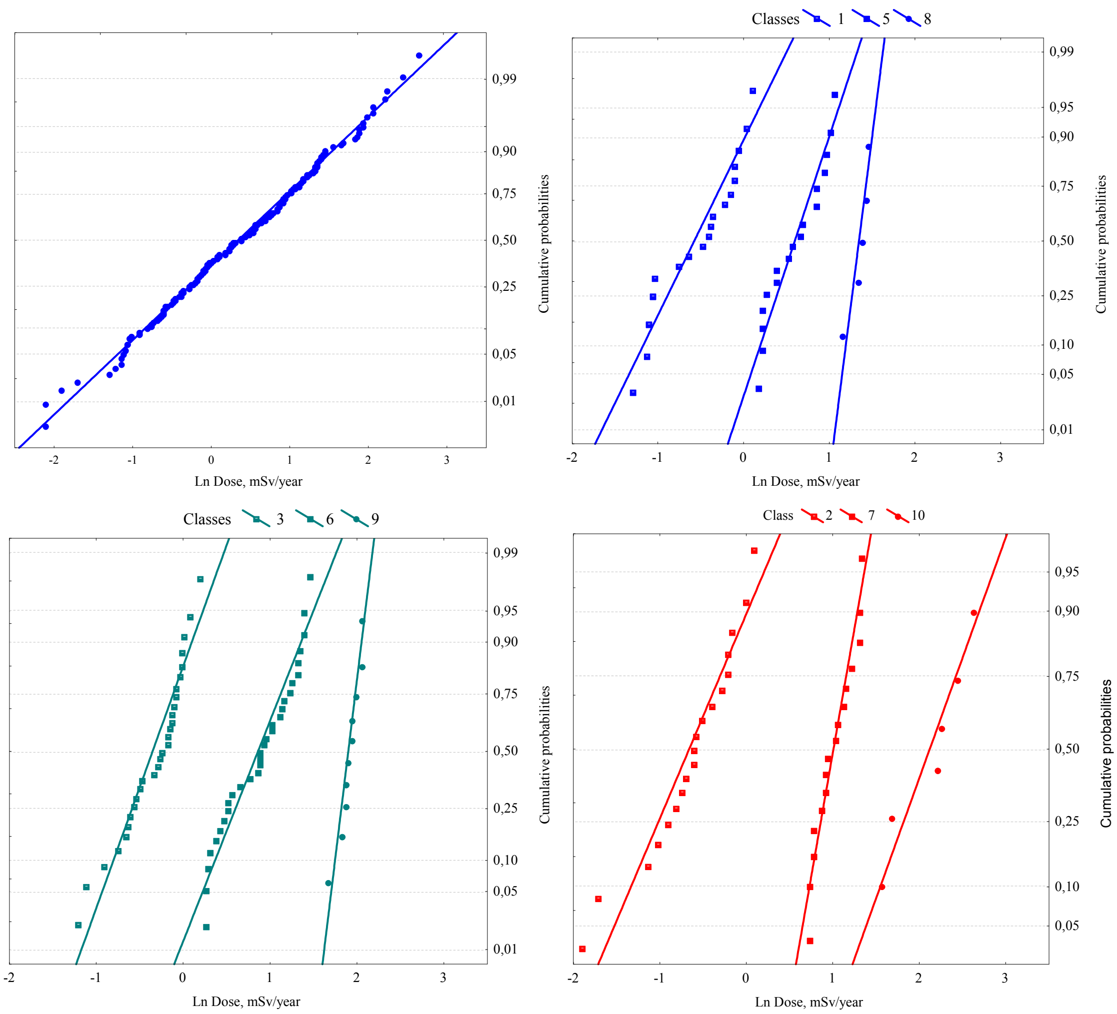

Fig. 3. Integral distribution of average-family dose of population of Kirov settlement in whole and by family classes.

The average relative scope of doses in the classes of families of Kirov settlement makes up 22 % on the average as in classes of small as well as of big number of families. That testifies to uniformity of food behaviour not only within the limits of a family, but also a class of families, that once again confirms the thesis about the defining role of a family as social system in dose formation.

Obviously, family’ classes are more significant not only by professional and forest signs, as it was for individual’ classification, but also by number of the family members, age, education, i.e. and by its social and demographic characteristics. The family’ analysis gives more clear conception of the mechanism of internal dose formating among inhabitants of rural society, at the same time it supplements the individual one. Based on the results of the family’ analysis one can adequately estimate or predict dose distribution not only in separate groups but also in settlement as a whole. The family analysis together with the individual one can form a reliable basis for revealing of the most exposed so-called “critical” groups of rural society.

ICRP recommends the following concerning critical group: “It is often convenient to class together individuals who form a homogeneous group with respect to their exposures to a single source. When such a group is typical of those most highly exposed by that source it is known as a critical group” (ICRP 1990). Following definition by ICRP, group’s criterion is homogeneity by dose.

It was noticed that dose distribution in a settlement is a mixture of logarithmetic normal distributions, each of which corresponds to a group of persons conducting the same way of life. If critical group is homogeneous by dose than a dose range is small enough, i.e. SGD of dose distribution in is low.

The analysis of dose distributions in settlements has shown that in the majority of them the homogeneous group “distant” from basic empirical distribution singled out in the “tai” of the distribution as it is shown in Figure 4. It is a critical group. Splitting of distribution into two groups, basic and critical, was performed by the corresponding value of percentile of the distribution (90 percentile in Figure 4). SGD of dose distribution in the critical group in comparison to the basic group is low (see Figure 4), which testifies to high degree of homogeneity.

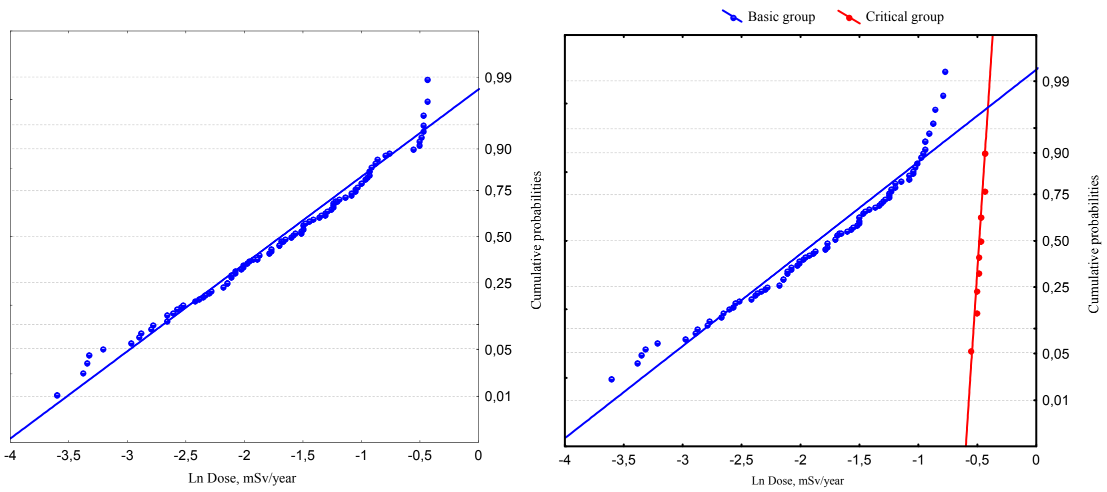

Fig. 4. Internal dose distribution of population of Neglubka settlement of Vetka district. On the left: whole settlement sampling, on the right: basic group and critical group 10% in size.

Probably, the critical group is the group of families with the same "food" habits causing the highest internal doses.

There were revealed families which members have identical in time relative doses i.e. the dose of each of them corresponds to the certain value of dose distribution percentile per every year, also and by the seasons of a year. The descriptions of some of them are shown in the Tables 6 and 7.

	F	1983	pupil			*26%*	*5%*	2%	*1%*			

Obviously, it is not casual coincidence and it is a law, and thus, the last can have practical significance.

Discussion

The results of the present research will allow predicting doses with enough high degree of accuracy at persons for any calendar year (the time period) on their relative doses for one or any several years, or by known relative doses at members of their families.

It can be used for reconstruction of individual doses at a lack of dosimetric information.

It is necessary to have the information on parameters of dose distribution in a settlement for predicting or dose reconstruction at separate subjects: for example, average arithmetic or median.

Conclusions

There was confirmed the hypothesis about the stability of a relative internal dose of individuals and the members of families of rural society.

This approach can be a methodological basis for reconstruction of individual internal doses of concrete people of any time period of the accident including initial one what extremely is important at present: namely, for filling the Belarus State Registry of the Chernobyl affected people by individualized doses, and a retrospective estimation of individual doses for radiation-epidemiological studies.

Also this approach can be used for taking into account a contribution of cesium ingestion dose to individual thyroid ingestion dose.

Determination of the main pathway of the ^{131}I intake to the urban residents of Belarus following the Chernobyl accident

Shinkarev, Sergey; Gavrilin, Yury
Burnasyan Federal Medical Biophysical Centre, Moscow, RUSSIA

Abstract

Relationship between ingestion intake with milk and inhalation intake of ^{131}I for the residents of large cities after the Chernobyl accident depended on the ^{131}I contamination level of fresh milk distributed in the city trade network. This milk was delivered from different regions with various level of ^{131}I fallout. The leading contributor to the human intake might be ingestion intake (if milk was delivered from areas with higher or similar level of the ^{131}I fallout compared to that in the city) or inhalation intake (if milk was delivered from areas with less level of the ^{131}I fallout compared to that in the city). Selection of a wrong leading route of iodine intake might result in systematic error in individual thyroid dose calculation, which can be as high as a factor of four to five.

A method has been developed allowing for objectively determination of the main pathway of the radioiodine intake (inhalation or ingestion with milk) for the residents from one settlement. The idea of the method is as follows. The dependence of the variation with measurement date of the average estimate of the ^{131}I thyroidal content for adults and for children from the same settlement in case of inhalation radioiodine intake is significantly different from that in case of ingestion intake. Comparison of such dependency derived from actual results of the thyroidal iodine measurements with two theoretical curves allows for making a decision which pathway of two possible radioiodine intakes was the main contributor to the thyroidal exposure for the residents from a given settlement.

This method was applied to the results of in vivo thyroid measurements of the residents of two large cities in Belarus (Minsk and Gomel) following the Chernobyl accident. The analysis of those results allowed for derivation of an important conclusion that the intake of ^{131}I with milk was the main contributor to the thyroidal exposure for the residents of the cities of Minsk and Gomel.

Introduction

The accident at the Chernobyl nuclear power plant on April 26, 1986 resulted in internal exposure to thyroid from radioiodines for many people over the world. The highest exposure to radioiodines was delivered to the populations of Belarus, Ukraine, and Russia. Intensive efforts on assessment of exposure to thyroid from ^{131}I, the main contributor to the thyroid dose, for populations in these countries were done. An important part of those efforts was large-scale measurements of gamma radiation using detectors placed against the neck. Within a few weeks after the accident those measurements (called "in-vivo measurements" or "direct thyroid measurements") were performed for more than 300 thousand people in Belarus (Gavrilin et al. 1999), Ukraine (Likhtarev et al. 1996), and Russia (Zvonova and Balonov 1993, Stepanenko et al. 1996).

To assess individual dose to thyroid from ^{131}I for those people it is necessary to determine the time-dependent intake function of ^{131}I. This intake function depends upon the routes of radioiodine intake. Three pathways of intake of ^{131}I are usually considered for the population after the Chernobyl accident: (1) fresh milk, (2) contaminated air, and (3) leafy vegetables. According to the interviewing conducted in the most contaminated areas in Gomel and Mogilev Oblasts in 1988 the majority of the Belarusian residents began to consume leafy vegetables in middle and late May 1986 (Gavrilin et al. 1999). Thus, in general, the consumption of leafy vegetables did not provide any substantial delivery of ^{131}I to those residents. So, the leading route of the ^{131}I intake should be identified from the two possible pathways due to (1) inhalation of contaminated air and (2) ingestion of contaminated milk.

It is worth noting that there is a general agreement that for rural populations permanently living in contaminated settlements the main route of the radioiodine intake was consumption of cows' milk locally produced rather than inhalation of contaminated air. For urban populations consuming milk from shops the situation with determination of the main route of the radioiodine intake is more complex and depends upon local conditions, for example, areas from which milk was delivered to the city trade network, when and at what size countermeasures aimed at decreasing or cancellation of radioiodine intake with foodstuffs were introduced, etc. The relative importance of two pathways for the urban residents might be either in favor of milk intake (if milk was delivered from rural areas with similar or higher level of contamination of ^{131}I compared to that in the city) or inhalation intake (if milk was delivered from rural areas which were substantially less contaminated with ^{131}I compared to that in the city). Selection of wrong pathway considered to have been the leading one might have resulted to a systematic bias in the assessment of individual thyroid dose up to a factor of four to five. So, it is an important task in the problem of retrospective dosimetry to identify correctly what pathway of ^{131}I intake was the leading one.

The purpose of this paper is (1) to describe the method of analysis of direct thyroid measurements of the residents from one settlement to objectively determine which pathway (inhalation or ingestion) intake of ^{131}I is dominant and (2) to apply this method to available direct thyroid measurements for urban residents of two large cities in Belarus (Minsk and Gomel) following the Chernobyl accident.

Material and methods

Minsk city

An extensive monitoring of ^{131}I activity in human thyroids was conducted in Minsk city starting from May 1 through June 1986. People were invited to two urban policlinics #5 and #28 where the special measuring points were organized. The SRP-68-01 instruments were used at these measuring points to measure the level of gamma-radiation near the thyroid gland for the purpose of determination of the thyroid content, mainly ^{131}I, *in vivo*. The SRP-68-01 instrument has NaI (Tl) scintillation detector and analog output in terms of exposure rate (μR h^{-1}) and count rate (counts per minute).

With respect to conditions of radioiodine intake (and exposure to thyroid from ^{131}I) the population of Minsk city is not homogeneous because part of the residents temporarily lived outside the city for at least several days during the time period from April 26 to May 31, 1986 in the areas where conditions of thyroid exposure were different from that in Minsk. It is worth noting that the above-mentioned time period is the critical one, during which more than 99% of possible ^{131}I intakes had been realized for the overwhelming majority of the Belarusian inhabitants, accounting for a short half-life of ^{131}I (8.04 days) and the main pathways of ^{131}I intakes due to consuming fresh milk and breathing contaminated air. Thus, the measured Minsk residents were divided into two groups depending upon whether the residents left the city for substantial time during April 26-May 31, 1986 or not. Two criteria were applied in order to differ those people: (1) there is archival information that a given resident was outside the city in April-May 1986 and (2) no information is available regarding the place where the resident considered was in April-May 1986, but this person has enormously high result of measurement of the exposure rate near the thyroid, that was likely to be due to spending some time in contaminated areas.

To select the residents according to the second criterion the following inequality was used:

$$P(i,t_m) > 10 \times P_{gm}(i,t_m) \tag{1}$$

where $P(i,t_m)$ is the exposure rate near the thyroid of a person of age (i) having subtracted the background level of the person considered on the day of measurement t_m, μR h^{-1}; and

$P_{gm}(i,t_m)$ is the geometric mean of the exposure rate near the thyroid having subtracted the background level for all persons of age (i) measured in the urban policlinics on the day of measurement t_m, for whom no information related to their living outside the city in April-May 1986 is available, μR h^{-1}.

Eventually, the group of the measured Minsk residents (17,842 people) who thought to have been lived in the city during a few weeks following the accident was selected. Just this group has been analyzed below in order to determine what the main route of the radioiodine intake to the urban residents was.

Gomel city

Measurements of the ^{131}I content in thyroids of Gomel residents were primarily performed with the SRP-68-01 and the DP-5 instruments. The DP-5 instrument has a Geiger-Muller counter as a detector and analogue output in terms of exposure rate (mR h^{-1}). Similar to the Minsk residents two groups of the measured Gomel residents were formed. The group considered to be a representative one of those Gomel residents whose ^{131}I intake was mainly due to their staying in Gomel city consists of two subgroups. The first one includes 1,723 residents measured in Policlinics #1 of Gomel city. The second subgroup includes 2,499 Gomel residents measured at Policlinics #28 of Minsk city.

With respect to people related to the second subgroup it is important to stress that according to available information those Gomel residents left their city for Minsk city because of their concern on the radiation exposure due to the Chernobyl accident. Those people visited the measuring point at Minsk Policlinics #28, as a rule, on the day of arrival or within one-two days upon their arrival in Minsk city. Taking into account that Minsk city was much less contaminated compared to Gomel city (deposition density of ^{131}I in Minsk city was about two orders of magnitude less than that in Gomel city), it is reasonable to assume that their measured ^{131}I thyroidal content reflected intakes of radioiodine during their residing in Gomel city.

Method to identify the main route of the radioiodine intake to the residents with direct thyroid measurements

Unfortunately, no spectrometric measurements of ^{131}I concentration in milk distributed in the trade network of Minsk and Gomel cities are available. The results of spectrometric measurements of ^{131}I in milk for rural settlements show that milk was highly contaminated (up to 400 kBq L^{-1} on May 5, 1986 in a village of Khoiniki raion Gomel Oblast). In addition, it is known that during the very first days following the accident there was no official restriction on delivery of fresh cows' milk produced in the contaminated areas of Belarus to the other areas, including trade network of cities Minsk, Gomel and other settlements. Only on May 6, 1986 a special order of the Ministry of Health of the former USSR was issued to provide a radiation monitoring of milk and milk products and to prohibit the distribution in the trade network of fresh milk with contamination level exceeding 3.7 kBq L^{-1} of ^{131}I (Anonymous 1993). Thus, contaminated milk was definitely consumed by the residents living in contaminated areas where it was produced, and might have been delivered to the residents of other areas, including Minsk and Gomel cities.

It is impossible on the basis of a single result of direct thyroid measurement to determine what pathway of ^{131}I intake to the resident considered was dominant (inhalation or ingestion). However, considering rather large set of direct thyroid measurements of the residents of various ages (children plus adults) from one settlement it is possible to objectively answer to the question what pathway of ^{131}I intake to the residents considered was dominant. The idea of this method is to analyze the time variation of the ratios of the ^{131}I thyroidal content for adults to that for children of age (i) in one settlement. This time variation of the ratios is different in case of dominant inhalation or ingestion intake.

It is well known that the total inhalation intake of radioiodine by a person is primarily provided by inhalation occurred during the passage of a radioactive cloud through a settlement. The resuspension of radioiodine plays a minor role in an overall inhalation intake and can be neglected compared to that during the passage of a radioactive cloud. Taking into account that deposition of ^{131}I was prolonged in time (Makhon'ko et al. 1996), a prolonged inhalation intake was assumed for the rural and urban residents. It is also reasonable to assume for those residents a prolonged ingestion intake of radioiodine due to consumption of contaminated milk in rural areas where it was produced and in the cities where it was delivered from the contaminated areas of Belarus.

In order to reveal a relative importance of inhalation and ingestion intake for the residents it is necessary to analyze the time dependency of average ^{131}I thyroidal content for various age-groups of residents, which is different in case of only inhalation and only ingestion intakes.

Let's consider an inhalation intake. A general equation to estimate the ^{131}I thyroidal content for a person of age (i) at time t, G(i,t), due to prolonged inhalation intake has the following view:

$$G(i,t) = \int_0^t C_{air}(\tau) \times \nu_i \times f_l \times f_{th} \times e^{-\lambda_{th,i}(t-\tau)} d\tau \qquad (2)$$

where G(i,t) is the ^{131}I thyroidal content for a person of age (i) at time t, Bq;
$C_{air}(\tau)$ is the concentration of ^{131}I in the ground-level air in the settlement at time τ, Bq m^{-3};
ν_i is an average breathing rate of a person of age (i), m^3 d^{-1}; and
f_l is fraction of radioiodine entered into blood from lung, dimensionless;
f_{th} is fraction of ingested radioiodine absorbed by the thyroid, dimensionless;
$\lambda_{th,i}$ is an effective rate of elimination of ^{131}I from thyroid for a person of age (i), d^{-1}.

Assuming the deposition velocity of ^{131}I on ground to be constant, eqn (2) can be rewritten as follows:

$$G(i,t) = (\sigma_0/V_g) \times \nu_i \times f_l \times f_{th} \times \sum_{k=1}^{t} p_k \times e^{-\lambda_{th,i}(t-k)} \qquad (3)$$

where σ_0 is the total ground deposition density of ^{131}I, Bq m^{-2};
V_g is the deposition velocity of ^{131}I on ground in the settlement, m d^{-1}; and
p_k is the percentage of the total deposition of ^{131}I on ground occurred on day (k), dimensionless.

It is reasonable to assume that the parameters of the variation of the ^{131}I concentration $C_{air}(\tau)$ in the ground-level air in the settlement were the same for each age-group of the residents. The values of parameters f_l and f_{th} are assumed to be age-independent. Then, in case of inhalation intake of ^{131}I the average ratio of the ^{131}I thyroidal content for an adult (ad) and a child of age (i) at time t, $R_{inh}(ad,i,t)$, is estimated to be:

$$R_{inh}(ad,i,t) = (\nu_{ad}/\nu_i) \times \frac{\sum_{k=1}^{t} p_k \times e^{-\lambda_{th,ad}(t-k)}}{\sum_{k=1}^{t} p_k \times e^{-\lambda_{th,i}(t-k)}} \qquad (4)$$

Thus, if the inhalation intake for the residents was the main pathway, then the variation with time of the ratio between the average ^{131}I thyroidal content for adults and that for children of age (i) derived from direct thyroid measurements should be consistent with the time dependent function $R_{inh}(ad,i,t)$ calculated according to eqn. (4).

Let's consider now ingestion intake with contaminated milk. A general equation to estimate the ^{131}I thyroidal content for a person of age (i) at time t, G(i,t), due to prolonged ingestion intake has the following view:

$$G(i,t) = \int_0^t C_{milk}(\tau) \times V_i \times f_{th} \times e^{-\lambda_{th,i}(t-\tau)} \times d\tau \qquad (5)$$

where $C_{milk}(\tau)$ is the concentration of ^{131}I in milk at time τ, Bq L^{-1}; and

V_i is an average milk consumption rate of a person of age (i), L d^{-1}.

If the considered person of age (i) ceased milk consumption at time t_1, then the ^{131}I thyroidal content, G(i,t), at time $t \geq t_1$ can be assessed according to the same eqn (5) with a replacement of the upper bound of integration (t is replaced with t_1).

It is reasonable to assume that the parameters of the variation of the ^{131}I concentration in milk $C_{milk}(\tau)$ were the same for each age-group of the residents. Then, in case of ingestion intake of ^{131}I the average ratio of the ^{131}I thyroidal content for an adult (ad) and a child of age (i) at time t, $R_{ing}(ad,i,t)$, is estimated to be:

$$R_{ing}(ad,i,t) = (V_{ad}/V_i) \times \int_0^{t_1} C_{milk}(\tau) \times e^{-\lambda_{th,ad}(t-\tau)} \times d\tau \; / \; \int_0^{t_2} C_{milk}(\tau) \times e^{-\lambda_{th,i}(t-\tau)} \times d\tau \qquad (6)$$

where t_1 is the time when an adult ceased milk consumption $t_1 \leq t$, d and

t_2 is the time when a child of age (i) ceased milk consumption $t_2 \leq t$, d.

An analytical solution of eqn (6) can be found for any particular time-dependent function $C_{milk}(\tau)$. For example, if $C_{milk}(\tau)$ was close to the function describing concentration of ^{131}I in milk for cows put on contaminated pasture, then eqn (6) can be written as follows:

$$\begin{aligned} R_{ing}(ad,i,t) = {} & V_{ad}/V_i \times \exp((\lambda_{th,i}-\lambda_{th,ad}) \times t) \times \{[1-\exp(-(\lambda_g-\lambda_{th,ad}) \times t_1)]/(\lambda_g-\lambda_{th,ad}) \\ & -[1-\exp(-(\lambda_c-\lambda_{th,ad}) \times t_1)]/(\lambda_c-\lambda_{th,ad})\} \; / \; \{[1-\exp(-(\lambda_g-\lambda_{th,i}) \times t_2)]/(\lambda_g-\lambda_{th,i}) \\ & - [1-\exp(-(\lambda_c-\lambda_{th,i}) \times t_2)]/(\lambda_c-\lambda_{th,i})\} \end{aligned} \qquad (7)$$

where λ_g is effective clearance rate of ^{131}I from pasture grass, d^{-1} and

λ_c is effective clearance rate of ^{131}I from cow to milk, d^{-1}.

Thus, if the ingestion intake for the residents was the main pathway, then the variation with time of the ratio between the average ^{131}I thyroidal content for adults and that for children of age (i) derived from direct thyroid measurements should be consistent with the time dependent function $R_{ing}(ad,i,t)$ calculated according to eqn (6). For a particular considered case this ratio is calculated according to eqn (7). For the urban residents an exact view of function $C_{milk}(\tau)$ in unknown, but its general dependency should not differ significantly from the particular considered case. Thus, if the ingestion intake with milk for the residents was the main pathway, then the variation with time of the ratio between the average ^{131}I thyroidal content for adults and that for children of age (i) derived from direct thyroid measurements should be consistent with the time dependent function $R_{ing}(ad,i,t)$ calculated according to eqn (7).

The values of age-dependent parameters used in eqns (4), (6) and (7) for children with an increment of 1 y and for adults are given in Table 1. The values of breathing rate, ν_i, for newborn, children of 1, 5, 10 15 years old and for adults were taken from ICRP Publication 66 (ICRP 1993). The values of ν_i between those ages were obtained by a linear interpolation. The values of effective rate of elimination of ^{131}I from thyroid were derived from the data in ICRP Publication 56 (ICRP 1989). The values of the effective clearance rate of ^{131}I from pasture grass and from cow to milk were assumed to be 0.15 d^{-1} and 0.627 d^{-1}, respectively, according to Arefieva et al. (1988).

Results and discussion

The method described above was applied to the results of the direct thyroid measurements conducted for the Belarusian urban populations of the cities of Minsk and Gomel. The data for two groups of people were considered and compared: (1) adults (years of birth <1968) and (2) children from 1 to 6 y (years of birth 1979-1984). In principle, the less age of children the higher difference in the time variation of the ratios of the ^{131}I thyroidal content for adults to that for children, R(ad,ch,t), in case of dominant inhalation or ingestion intake of ^{131}I. However, infants and small children up to 1 y (years of birth 1985-1986) were excluded from consideration because they might have been breast milk consumers and this could have been an interfering factor in interpretation of the results of application of the method proposed. For assessing the "measured" ratios of R(ad,ch,t) the geometric mean values of the ^{131}I thyroidal content for adults (not less than 10 persons) and children (1-6)y (not less than 10 persons) measured on the same day for the residents of the same settlement were used.

Table 1. Values of age-dependent parameters used in equations (4), (6) and (7).

Age, i, y	Breathing rate, v, m^3 d^{-1}	Effective rate of elimination of ^{131}I from the thyroid, λ_{th}, d^{-1}	Milk consumption rate, V, L d^{-1}
0-1	2.9	0.132	0.30
1-2	5.6	0.119	0.22
2-3	6.5	0.117	0.20
3-4	7.4	0.114	0.20
4-5	8.3	0.111	0.20
5-6	9.3	0.108	0.20
6-7	10.4	0.105	0.20
7-8	11.5	0.103	0.25
8-9	12.6	0.100	0.25
9-10	13.7	0.097	0.25
10-11	14.8	0.096	0.25
11-12	16.0	0.096	0.25
12-13	17.2	0.096	0.25
13-14	18.3	0.095	0.25
14-15	19.5	0.095	0.25
15-16	20.3	0.095	0.25
16-17	20.7	0.095	0.25
17-18	21.2	0.094	0.25
>18 (adult)	22	0.094	0.20

Time variation of the ratios of R(ad,ch,t) derived from the direct thyroid measurements and calculated according to eqn (4) assuming only inhalation intake of ^{131}I and according to eqn (6) and (7) assuming only intake of ^{131}I with milk is given in Figures 1 and 2.

Analysis of the time variation of the measured ratios for the urban residents of Gomel and Minsk cities allows for revealing an obvious tendency that the "measured" ratios are scattered along the curve reflecting the intake of ^{131}I with milk as a dominant radioiodine pathway for the urban residents. Scattering points between the curves relating inhalation and milk intake in Figures 1 and 2 can be explained by at least two reasons: (1) insufficient statistics and (2) objective factor that part of people did not consume milk and inhalation intake was the only pathway of ^{131}I for them. So the geometric mean value of ^{131}I thyroidal content for such set of data should be definitely between the upper and lower curves. At the same time for the residents who consumed milk (the percentage of milk-consumers among urban residents is estimated to be about 80%) the measured "ratios" are far below "inhalation" curve locating close to "milk" curve.

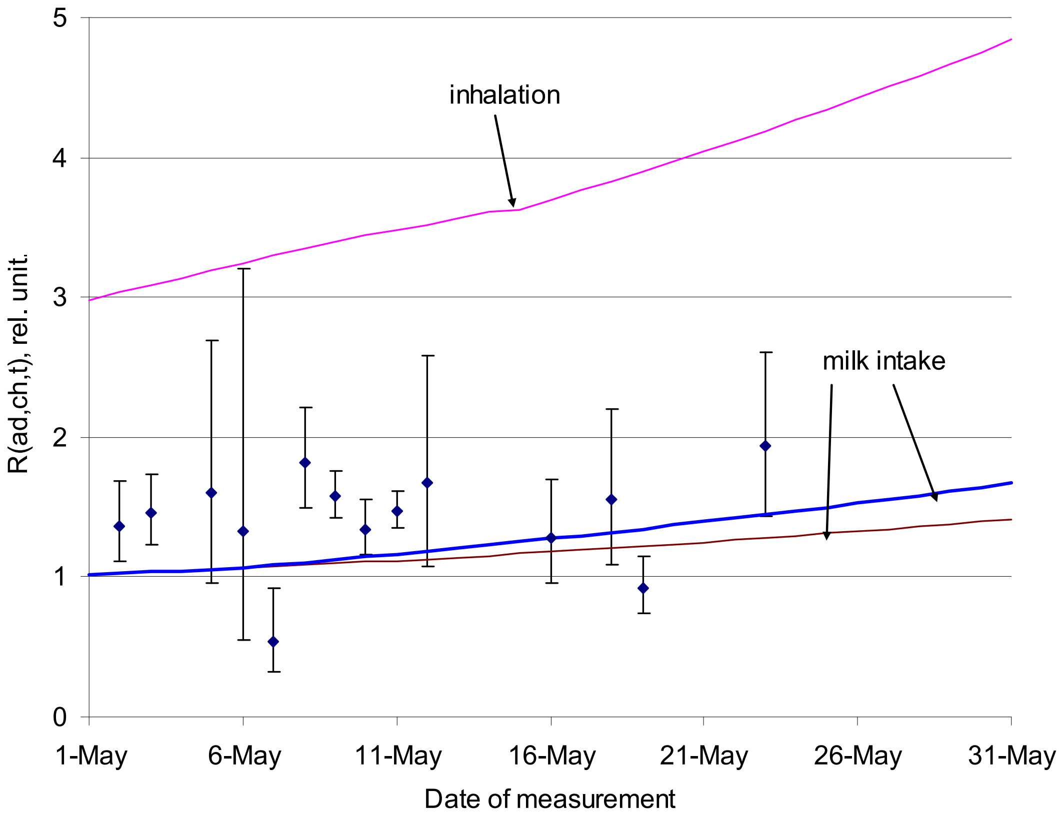

Fig. 1. Time variation of the ratios between the average ^{131}I thyroidal content for adults and that for children, R(ad,ch,t), derived from (1) direct thyroid measurements and calculated assuming (2) only inhalation intake of ^{131}I and (3) only intake of ^{131}I with milk for the adult residents and children (1-6) y of Minsk city. Diamonds denote measured ratios. Uncertainties related to 95% confidence intervals are indicated for the measured ratios.

Thus, a definite conclusion can be derived from the dependencies in Figures 1 and 2 that for the Belarusian urban residents in Minsk and Gomel cities the consumption of fresh milk was the dominant route of ^{131}I intake. It is worth noting that the dependency of R(ad,ch,t) versus time for the two variants of milk intake: (1) milk consumption was ceased on May 6, 1986 (upper curve) and (2) milk was consumed without any interruption (lower curve) shows insignificant difference, which does not play any important role in the analysis.

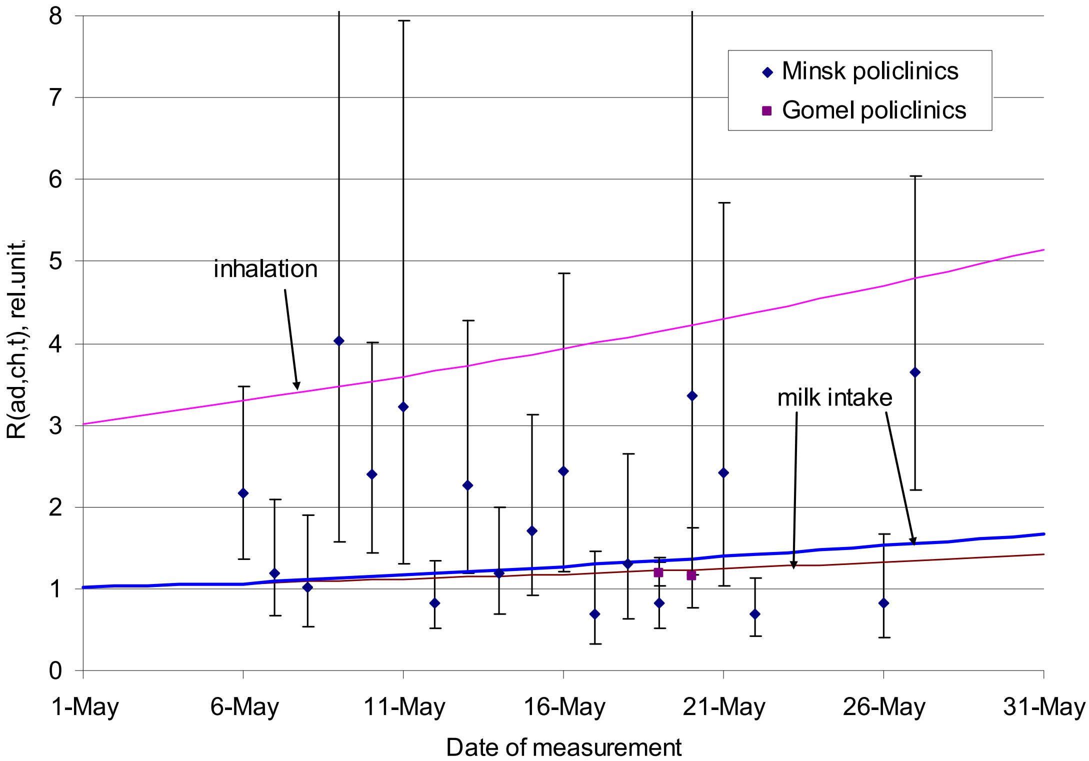

Fig. 2. Time variation of the ratios between the average ^{131}I thyroidal content for adults and that for children, R(ad,ch,t), derived from (1) direct thyroid measurements and calculated assuming (2) only inhalation intake of ^{131}I and (3) only intake of ^{131}I with milk for the adult residents and children (1-6) y of Gomel city. Diamonds denote measured ratios. Uncertainties related to 95% confidence intervals are indicated for the measured ratios.

Conclusions

A method has been developed to objectively determine the dominant pathway (inhalation or ingestion with milk) of the radioiodine intake for the populations with in-vivo measurements of ^{131}I in thyroids.

Application of the method described in the paper to the direct thyroid measurements of the Belarusian urban populations of the cities of Minsk and Gomel following the Chernobyl accident allowed for making a conclusion that the consumption of fresh milk was the dominant route of ^{131}I intake for those people.

Abstract

Accident dosimetry aims to determine the absorbed dose of exposed individuals involved in a nuclear accident. In order to achieve this, materials are needed that possess a certain radiation sensitivity and are worn close to the body. Chip cards are the perfect example and have the great advantage that nowadays everyone possesses at least one, in the form of bankcards, SIM-cards, identity cards, etc. Therefore the possibilities of chip cards as an accident dosemeter are further investigated aiming at establishing a uniform Belgian accident dosimetry system..

Using blue LED optical stimulation, several properties of chip cards that could be traced back to a single manufacturer were investigated. The shape of the OSL-curve and the fading properties were considered. Also the uncertainty on the results and the lowest detectable dose as a function of the integration area were taken into account. The results of this part of the research were used to determine the most promising part of the OSL-curve for dose determination.

Using these results, further research on the dose-response and possible sensitivity changes was made in order to propose a suitable protocol for the estimation of the absorbed dose.

Introduction

Accident dosimetry aims to determine the absorbed dose in case of a nuclear or radiological accident. The dosimetric results are useful to ensure the proper medical treatment of exposed individuals, to provide correct information to the public and are useful in epidemiological studies [4].

For the purpose of accident dosimetry objects can be used that are found within the accident area or that are worn close to the body of exposed individuals and posses a certain radiation sensitivity. Objects that meet such requirements, are e.g. ceramic materials and semiconductor devices. Previous studies have shown sensitivity for optical stimulation (OSL) and thermal stimulation (TL) of quartz in bricks [5]. Also personal objects, such as cell phone components and USB flash drive components, were investigated recently using TL and OSL [2, 9]. These devices can be regarded as personal dosemeters, since they are worn close to the body.

This study will be focusing on the pertinent OSL properties of various chip cards, in order to expand the list of personal objects useful in accident dosimetry. The great advantage of chip cards is that nowadays everyone possesses at least one, in the form of bankcards, SIM cards, etc. The exact properties of chip cards as an accident dosemeter are investigated using OSL as a sequel to earlier research [1, 7, 8, 10] in order to determine whether the results of that research can be adopted for 'Belgian' cards.

After a rough selection of various kinds of chip cards, based on the overall radiation sensitivity, a detailed investigation of the relevant OSL properties was done on one specific card type, i.e. the SIM card. The first part of the project was intended to determine the most promising part of the OSL curve for dose determination (integration window). The shape of the OSL curve was considered, in function of the sample number, the dose and inherent OSL fading. The lowest detectable dose in function of the integration window and the uncertainty on the result as a function of the integration window were taken into account as well.

In the second part of the project, properties such as fading, dose response and sensitivity changes were investigated using the proposed integration window. Finally, the dose recovery potential using a single aliquot regenerative dose method (SAR protocol) was investigated, with promising results.

Materials and methods

Several kinds of chip cards, SIM cards, SIS cards and bank cards - were investigated enabling identification of a specific wide spread type with good OSL properties. Sample preparation was done by extracting the chips from the cards using an industrial punch prior to irradiation. No chemical treatments were used. To avoid loss of information, the samples were irradiated in the absence of daylight.

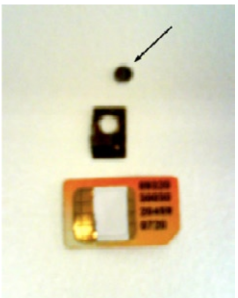

Fig. 1. Sample preparation was done by extracting the chip module from the card. Samples were taken using an industrial punch.

Fig. 2. The chip is surrounded by an epoxy encapsulant, responsible for the OSL signal [8].

OSL measurements of chip cards were executed with the Risø TL/OSL Luminescence Reader (model TL/OSL-DA-20). Continuous wave optical stimulation was performed using a cluster of blue LED's, emitting light with a wavelength of 470 nm. The LED's are equipped with a green long pass filter (GG-420) to prevent blue light from reaching the PMT [5]. A power of 45 mW/cm^2 was delivered to the samples. The stimulation time was 120 s and no thermal preheating was used. The luminescence emission was recorded using a Hoya U-340 filter in front of the photomultiplier tube (bialkali PMT, type EMI 9235Q), enabling detection in the UV-range [5]. The OSL curve was plotted using 400 datapoints. Stimulation with blue light was used, since the epoxy encapsulant, surrounding the chip (figure 2) and responsible for the OSL signal, contains SiO_2 which should respond well to blue LED optical stimulation.

The samples were irradiated using a ^{90}Sr/^{90}Y beta-source with an activity of 1,48 GBq, mounted in the Risø TL/OSL Luminescence Reader, at a dose rate of about 136 mGy/s. The gamma-equivalent dose rate was determined from Co-60 irradiated chip cards measured immediately after administration of the gamma dose. Gamma irradiations were performed with a Co-60 source delivering a dose rate of about 2 Gy/h (air kerma).

The obtained OSL curves were analyzed using the Risø Analyst software and Origin 8.0.

Results

Integration window

From the investigated chip cards, SIM cards, which are found in cell phones, turned out to be the most wide spread card with excellent radiation sensitivity. An analysis of the obtained OSL curves, following irradiation with the built in ^{90}Sr/^{90}Y-betasource (1360 mGy), revealed that three OSL components are responsible for the emitted luminescence after irradiation and optical stimulation. Normalised OSL curves were fitted with a 3rd order exponential decay:

$$y = y_0 + A_1 e^{\frac{-x}{\tau_1}} + A_2 e^{\frac{-x}{\tau_2}} + A_3 e^{\frac{-x}{\tau_3}} \qquad \text{(Eq. 1)}$$

The results in figure 3 indicate that every OSL curve can be decomposed into three OSL components with distinct fitting parameters A and τ, as can be seen from the three clusters. The clusters confirm the identical shape of all obtained OSL curves. This could mean a single protocol can be used to make an estimation of the absorbed dose, if other properties, such as fading properties and dose response properties, are identical as well for all samples. These properties are discussed in detail later in this paper.

Figure 3 shows that every OSL curve contains a so-called ‘fast’, ‘medium’ and ‘slow’ component. About 60% of the OSL signal is delivered by the fast component.

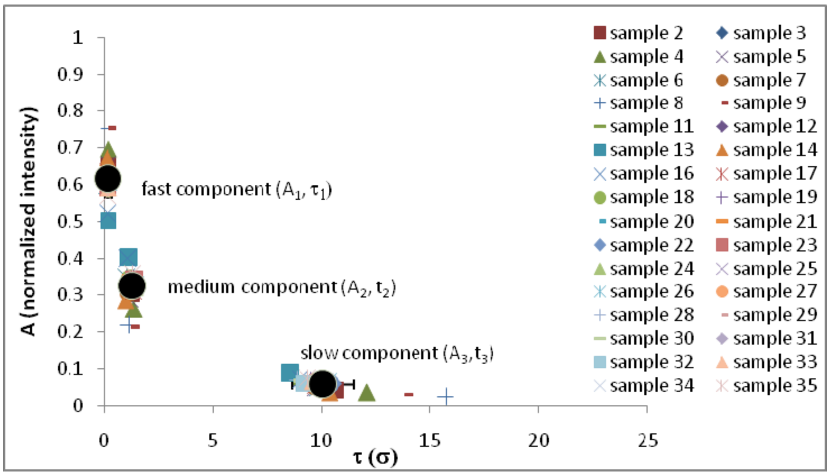

Fig. 3. OSL curves from several SIM cards were fitted using a 3rd order exponential decay. The parameter pairs (A_1, τ_1), (A_2, τ_2) and (A_3, τ_3) are consistent for all investigated cards, allowing to identify three components in the OSL signal.

The properties of the slow component, with a mean value of (10,08 ± 1,46)s for τ_3 indicate that a stimulation time of 120s would be sufficient to obtain the whole OSL signal. Exposure to different doses did not change the properties of the OSL curves. A stimulation time of 120s can thus be used in every situation, independent of the absorbed dose.

To obtain information on the stability of the components, 10 samples were subjected to a fading test. The optical stimulation was performed after varying delay times following irradiation (0, 10, 30, 100, 300, 1000, 3000, 10000 and 30000 minutes). Analyses of the obtained OSL curves showed that all components fade simultaneously, as pointed out in figure 4. This might suggest that all observed OSL components equally suffer from thermal and athermal instability (anomalous fading).

In order to make a proper choice for the integration window, the relative uncertainty as well as the lowest detectable dose (LDD) as a function of the integration window was determined for a set of 6 samples. A good integration window means that both the uncertainty and the LDD should be as low as possible.

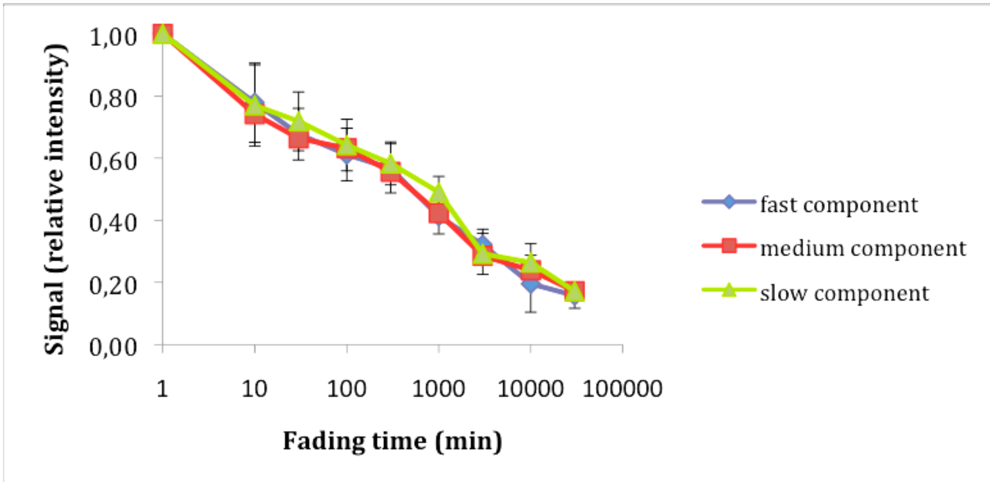

Fig. 4. Averaged fading results for the fast, medium and slow component. It can be seen that the three components have similar fading rates.

The uncertainty on the results is determined using the following formula [3]:

$$\hat{\sigma}_S = \sqrt{Y_0 - B + \left(1 + \frac{1}{k}\right)\hat{\sigma}_B^2} \qquad \text{(Eq. 2)}$$

$\hat{\sigma}_S$ being the absolute uncertainty on the calculated signal S, Y_0 the value of the entire signal including background signal and B the value of the background signal. k is equal to the ratio of the amount of channels used to determine the background signal and the amount of channels used to determine Y_0. $\hat{\sigma}_B$ is equal to the standard deviation of the background signal.

The lowest detectable dose (LDD) was estimated using the dose response curve of several samples. As can be seen in figure 5, the dose response appears to be linear over the investigated dose range from approximately 400 mGy to approximatley 10 Gy. The LDD was determined as the intersection point between the extrapolated dose response curve and the average background signal increased with three times the standard deviation of this background signal. The average background signal and the standard deviation on this background signal were determined by 10 zero dose measurements performed on every sample.

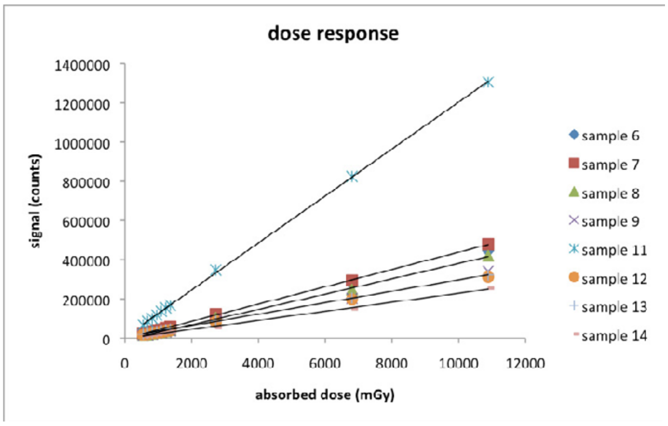

Fig. 5. the dose response of several samples appears to be linear in the range 0,4 - 10 Gy.

The multiplication of the LDD and the relative uncertainty as a function of the integration window was used as a proxy to determine the optimal integration window. The results show that multiplication minima are located within the first 2,10 s of the OSL curve. This means the fast component, responsible for about 60% of the OSL signal, is the most interesting part of the OSL curve.

The integration windows are therefore set at 0s to 2,1s to estimate the value of Y_0, and 105s to 120s to estimate the value of B. The LDD calculated with these integration windows is approximately equal to 2 mGy, depending on the sample.

Protocol for the estimation of the absorbed dose

Using the integration window as determined in the previous section, the fading rate, the dose response and sensitivity changes caused by repeated irradiation-OSL readout cycles were investigated.

Fading occurs simultaneously in all investigated samples as illustrated by figure 4. This offers the opportunity of using a universal fading factor. The latter was determined by fitting the composite fading curve of figure 6 using a 3rd order exponential decay.

$$f = 0{,}198 + 0{,}27e^{\frac{-t}{11{,}7}} + 0{,}319e^{\frac{-t}{0{,}110}} + 0{,}206e^{\frac{t}{104}} \qquad \text{(Eq. 3)}$$

with f being the percentage of the signal still available at time t (hours) following irradiation.

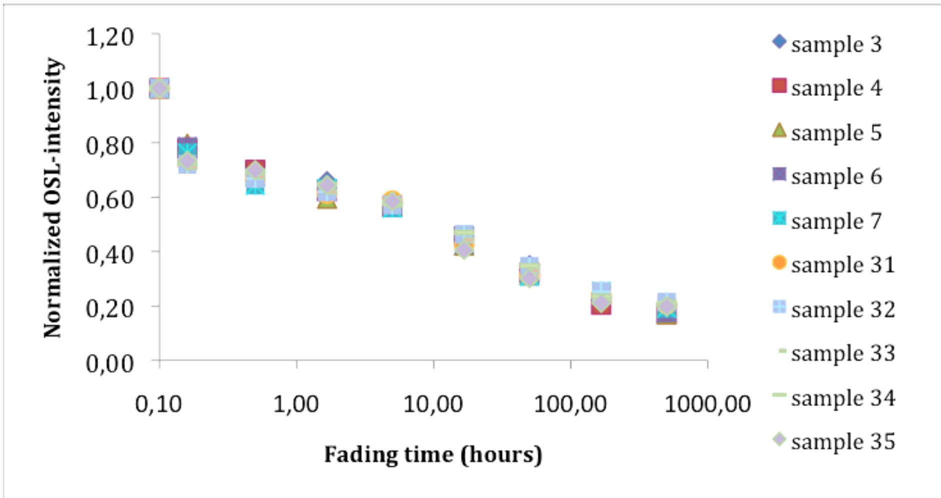

Fig. 6. Fading occurs simultaneously in every sample.

In principle, sensitivity changes can be detected using the SAR protocol (single aliquot regeneration protocol), by comparing the initial OSL output to the OSL output obtained after successive irradiations. The first OSL output gives a value for L_n, thus a value for the unknown dose D. Next, a known test dose is given, which delivers a value for T_n after optical stimulation. A known dose D_r is then delivered to the sample, giving a value for L_r after irradiation. Again the known test dose is delivered to the sample, so a value for T_r is obtained. The unknown dose can now be calculated taking sensitivity changes into account:

$$D = \frac{L_n}{L_r}\frac{T_r}{T_n} D_r \qquad \text{(Eq. 4)}$$

If no sensitivity changes occur, the values of T_n and T_r are equal, and the ratio is equal to 1, making correction for sensitivity changes unnecessary.

Ten samples were irradiated with the betasource during 10s and a SAR protocol was applied. The test dose response was investigated to check for sensitivity changes. The dose recovery test revealed that the given betadose of 10s could be recovered within ~10% uncertainty. The results of this test are shown in figure 5, with the horizontal line being 10s betadose delivered to the samples. Moreover no sensitivity changes were found as illustrated in figure 8, which means no sensitivity changes occur and no correction should be made. This, together with the linearity of the dose response and the uniform fading behaviour, opens the possibility to perform fast dose measurements using only one calibration point.

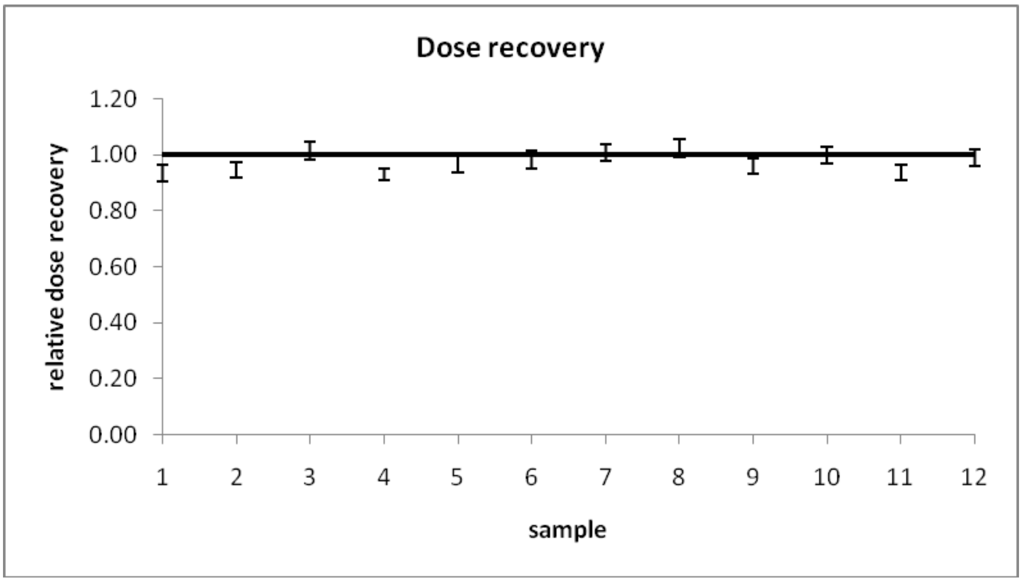

Fig. 7. Dose recovery potential of the SAR protocol using the chip module from SIM cards. The given beta dose can be recovered within ~ 10% uncertainty.

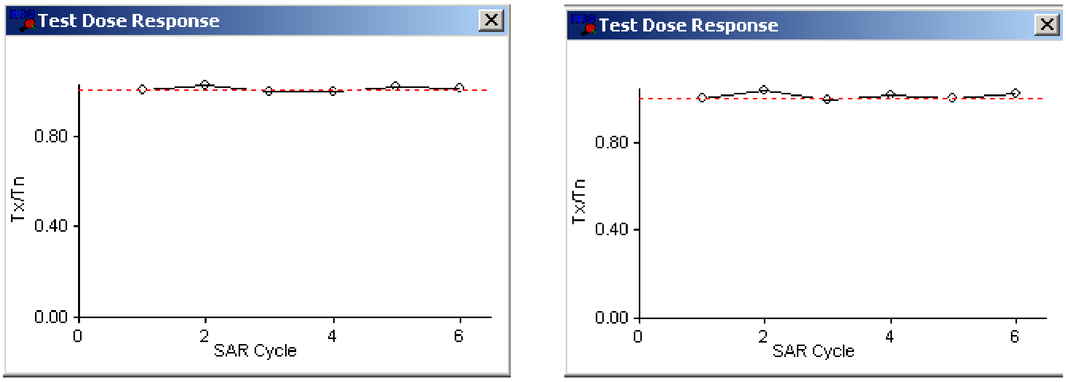

Fig. 8. Normalized test dose response of sample 13 and 16 monitored during several SAR cycles.

If the estimation of the dose is made several hours or days after the irradiation event, which is mostly the case in accident dosimetry, a correction for fading should be made. The results obtained after running the SAR protocol and processing with Risø Analyst software need modification in the following way:

– The result is given in the form $y = a + bx$, with $y = \frac{L_n}{T_n}$ and x the irradiation time in s. L_n is equal to $Y_{0,x} - B_x = S_x$, the signal caused by the accident dose. T_n is equal to $Y_{0n} - B_n = S_n$, the signal caused by the first test dose applied according to the SAR protocol. The meaning of the symbols are explained with equation 2.

– L_n should be corrected for fading, using the formula in Eq. 3 in order to obtain L_{n_corr}. L_{n_corr} is equal to $\frac{L_n}{f}$.

– By filling in this value in the equation $y = a + bx$ an irradiation time in s is obtained. By multiplying this value with the dose rate of the built in beta source the accident dose is obtained.

– The uncertainty on this value should be obtained by taking the uncertainty on $\frac{L_n}{T_n}$ into account based on the considerations in [6] and [3] as well as the uncertainty on *f*, *a*, *b* and the dose rate. The overall uncertainty is approximately equal to 8 %.

Discussion

Although the amplitude of the signal obtained from chip cards after irradiation and optical stimulation is different for every chip cards, a mathematical analyses of the obtained OSL-curves revealed that all of the investigated SIM-cards show a similar response to radiation and optical stimulation. The relative amplitudes and decay characteristics of the fast, medium and slow components show only a minor spread. This would imply that a general dose determination method can be used on this type of cards.

An important parameter to take into account is fading. Fading is clearly present in the signal obtained from the investigated chip cards. The main advantage is that background dose is essentially zero. A drawback is that large uncertainties are introduced when the original signal has to be recalculated in order to estimate the absorbed dose. Due to the fading properties, the time interval between irradiation and optical stimulation is limited, which means, in case of a severe nuclear accident, measurements must be performed within the first weeks after the accident.

The dose response is one of the most important parameters to investigate. Knowledge of the dose response relationship, allows correct estimations of the absorbed dose. For all investigated chip cards, the dose response is perfectly linear within a dose range from 400 mGy up to 10 Gy. Nevertheless a dose recovery test is performed using the SAR-protocol to check for possible sensitivity changes.

The results of the dose recovery test using the SAR-protocol are very promising, and it is also proven in this test that no sensitivity changes occur. Together with the linear dose response relationship, this means dose recovery should be possible using only one calibration point. This would offer a very fast method for determination of the absorbed dose in case of a large scale nuclear emergency situation.

Of course a protocol using only one calibration point needs testing in order to check the accuracy and the uncertainty of the obtained results.

Conclusions

The results of this study seem to confirm the potential of chip cards in accident dosimetry. Especially SIM cards seem to be the most promising given their good sensitivity to irradiation and optical stimulation using blue LED's. The lowest detectable dose is extremely low in comparison to other techniques used in accident dosimetry, but is dependent on the chip card.

Individual chip cards show differences in radiation sensitivity necessitating individual calibration for dose assessment. Fading is ubiquitous but the rate seems to be similar for all investigated samples, enabling the use of a universal fading correction factor. In order to make an estimation of the absorbed dose, the SAR protocol seems to be a very useful tool. Corrections for fading can easily be performed on the obtained results.

Abstract

The procedure for assessing doses on the basis of routine monitoring results includes use of standard model parameter values for the dose calculation and at least simple estimation of the associated uncertainty due to uncertainty of the worker exposure conditions, the uncertainty in the time of intake and the uncertainty of the measured bioassay quantity method. If the upper value on assessed dose exceeds the reference limit a special monitoring procedure is required that consist in performing additional bioassay measurements to increase the reliability of the dose assessment by obtaining better information on the model parameter values and by using statistical methods for the calculation of the associated uncertainty. An example of a numerical method application for the interpretation of in vivo and in vitro bioassay measurements of Co-60 performed during special monitoring of four nuclear power-plant workers is presented to illustrate a possibility of improving the dose assessment. It was shown that from the two compounds used in the ICRP model for cobalt the type S was the best option and the range of AMAD values could be reduced from (0,1 до 20) to (3 – 8) microns. This resulted in the reduction the uncertainty of the dose assessment from (144-155) % to (17-28) %. It was also shown that absorption type S compound was not slow enough to describe the retention of the radionuclide Co-60 in lungs in the case under study and a slower type like super S was needed.

Introduction
