Radon concentration in crawl spaces also showed very high values (maximum of *ca*. 14000 Bq.m^{-3}), especially if we take into account the mean height of these spaces, which is around 2m, and the fact that some degree of natural ventilation exists.

Given that no indications of the presence of radioactive wastes was found in dwelling #2, its radiological values were assumed as representative of background values, since they also correlate well with results from others studies carried out in similar geological settings where no mining activities were carried out (Pereira et al. 2003).

Conclusions

The results showed important differences between the several radiological parameters measured, reaching sometimes a few orders of magnitude. In dwelling #1, radioactive waste was identified in the sub-slab, with the presence of these materials contributing to an excess in dose of about 50 mSv/year, assuming as background the values measured in the second dwelling, where no radioactive waste was found. The very high indoor radon levels are the main contributors to this excess value (more than 95% of the total dose).

The methodology developed for this study proved to be a time/cost-effective procedure, and was subsequently applied to more than 75 dwellings of the region with good results.

Bioremediation of land contaminated by radioactive material

Koretskaya, Liubov
National Scientific and Applied Centre of Preventive Medicine, Radiation Protection and Radiation Hygiene, MOLDOVA

Abstract

Objectives: Radionuclide pollution arises as a result of many activities, largely industrial, such as mining and the provision of nuclear energy. These pollutants are discharged into the atmosphere and aquatic and terrestrial environments and may reach high concentrations, especially near the site of entry for point source emissions, and/or be transported between different environmental compartments. Metallic radionuclide has also entered the environment as a result of weapons-testing and accidents such as Chernobyl. The effects of radionuclide in ecosystems are not well understood, although a degree of understanding exists over their fate; it is primarily concerns over transfer along aquatic and terrestrial food chains that are of current economic and public-health significance. Microbial biotransformations of metallic radionuclides are of great importance in the biosphere and several have additional applications for bioremediation. Reactions mediated by microorganisms include solubilization from organic and inorganic complexes, compounds and minerals by the production of acids or chelating agents. The aim of our study consisted in elaboration of the new biotechnological method for environmental pollution risk reducing.

Methods: Screening the importance of soil micro-organisms on radionuclides mobility have been performed.

Results and conclusions: The influence of microorganisms on the environmental fate of radionuclides was elucidated, using some nonpathogenic strains of Penicillium sp. and Mucor sp., active producers of extra cellular pectolitic enzymes. Higher degree of radio nuclides insoluble compounds solubilizition, especially cobalt compounds, was observed under the influence of investigated strains in vitro (Invention nr. 3657 MD). Such mechanisms are important components of radionuclide biogeochemical cycles and should be considered in any monitoring analyses of environmental radionuclide contamination.

Establishment of research network for natural radiation exposure studies in Asia

Abstract

A new project entitled gConstruction of natural radiation exposure study network h has been recently adopted in the Program of Promotion of International Joint Research under the Special Coordination Funds for Promoting Science and Technology operated by the Ministry of Education, Culture, Sports, Science and Technology of Japan. Eight institutions are involved in this project and the project will continue until March, 2012. The aims of the project are to assess the dose for natural radiation exposures using state-of-the-art measurement techniques in four Asian countries (China, India, Korea and Thailand) and their outcomes will be distributed worldwide. Conventional measurement techniques will be improved and be optimized. More scientific data and results will be obtained throughout this project. In particular, the following advanced technologies for inhalation exposures will be introduced:

1. Discriminative measurements of radon (^{222}Rn) and thoron (^{220}Rn) gases,
2. Evaluation of thoron decay products concentration,
3. Simple but effective particle size distribution measurements.

The measurement of the natural radiation background in a salt mine

Stochioiu, Ana; Bercea, Sorin; Sahagia, Maria; Ivan, Constantin; Tudor, Ion; Celarel, Aura
"Horia Hulubei" National Institute of R&D for Physics and Nuclear Engineering,
Bucharest, ROMANIA

Abstract

The Unirea Salt Mine is situated at a depth of 208 meters beneath the surface of the earth that corresponds to a water-equivalent thickness of about 560 meters. It has a remarkable stability of microenvironment, characterized by a constant temperature over the years of 12.5 ±0.5 ºC and a relative humidity of 60-65 %.

In order to set up a calibration laboratory in this mine, for the measuring systems dedicated to the dosimetric measurements and environment, the natural radiation background had to be measured.

The measurements were made using two different dosimetric systems: An electronic type, consisting from two ratemeters: an Eberline FH 40 GL 10 and an AUTOMESS 6150 dose ratemeter with external scintillation probes; A TLD dosimetric system SD-TL type, which consists of the TL laboratory reader-analyze, 770 A type and thermoluminiscent detectors by LiF:Mg, Cu, P. The results obtained with the two systems are in good agreement.

Introduction

The measurement of the absorbed dose or of the integral ambient dose equivalent, and their rates, at the level of natural radiation background is a basic aspect of the dosimetry of the environment. In this case, an important problem to be solved in the calibration of the dosimetric measuring systems, is the low level of the measuring range, which has to include the values corresponding to the natural radiation background (50÷100) nSv·h-1.

In order to reach the adequate conditions to perform such calibrations, an ultralow level background laboratory is necessary. So, the "Horia Hulubei National Institute R&D for Physics and Nuclear Engineering" (IFIN-HH) decided to develop an ultralow level radiation background in the former Unirea salt mine, located in the town Slanic, at a distance of about 100 km from Bucharest.

The Unirea Salt Mine is located at a depth of 208 meters beneath the surface of the earth; taking into account the geological structure of the soil in the area of the mine, is was found that this depth corresponds to a water equivalent thickness of about 560 m, Margineanu et al. (Margineanu, 2008).

The salt mine is characterized also by a remarkable stability of the microclimate: a constant temperature, measured over several years, of 12.5± 0.50C and constant relative humidity, measured in the same conditions, of 60-65%. Of course, in order to set up a calibration laboratory in this mine, the first step was to perform accurate measurements of the absorbed dose and of the integral ambient dose equivalent and their rates, corresponding to the natural background in a hall where the new laboratory is located.

Material and methods

In order to perform accurate measurements of integral ambient dose equivalent $H^*_{(10)}$ expressed in mSv and of the rate $H^*_{(10)}$, expressed in nSv h-1, in the area were the laboratory was located, two different dosimetric system were chosen:
Two electronic dose ratemeters, with external scintillation probes;
One TLD dosimetric system, SD-TL type.

a) As for electronic dose ratemeter, we used many instruments and finally we have selected two of them:
   – an Eberline FH 40 GL 10 dose ratemeter, with the external probe FHZ 5023E. This probe has a large scintillation NaI detector of 3x3 inch. We calibrated it in terms of absorbed dose per impulse, with a value of the calibration factor of: F = (0.17±0.03) nGy·imp-1. The energy dependence of the response instrument in the ratemeter mode, is of maxim ±30% for the whole measured energy range. The conversion of units from absorbed dose, Gy, to ambient equivalent dose, Sv, was done by considering a conversion factor f = 1 Sv/Gy. It was used only for preliminary measurements.
   – a thermo Automess 6150, with the external probe 6150 AD-6/H having also a scintillation detector.

This instrument, metrologically certified by its producer, has the following characteristics, according the technical specification
   – measuring range (digital): 0.01µSv·h-1÷9.99 mSv·h-1, with a declared uncertainty of 10%;
   – energy range: 60 keV-1.3MeV; energy dependence of the response in this range: ±30%.

The reported results were obtained with this instrument.

The TLD dosimetric system, SD-TL type, consists of TL reader-analyzer, model RA-94 and the thermoluminiscent dosemeters with commercial thermoluminescent detectors type LiF:Mg,Cu,P, known as GR 200A. The dosemeter for environmental monitoring, designed and made in our laboratory, consists of a plastic cylindrical container with the external dimensions: Φ=50 mm and h = 9 mm. Each dosemeter is provided with three detectors. A detailed description of the system and of its dosimetrical characteristics is given in the paper by Stochioiu et al. (Stochioiu, 2009).

Measurement conditions

The electronic dose ratemeters measuring directly the dose equivalent rate $\dot{H}^*_{(10)}$, were used in several pre established significant locations inside the laboratory. The TLD system is calibrated in units of dose equivalent, $H^*_{(10)}$. The dose equivalent rate is calculated as the ratio of dose equivalent, mSv, and exposure time, h. In our case, two series of exposure, for periods of 39 d and 93 d were performed. In the case of the TL dosemeters, when processing the measured values, we took into account their irradiation during the transportation from Bucharest to the salt mine, and an appropriate correction was done. The reported values are the means obtained from the two exposition intervals.

For the purpose of the comparison of measurements and the establishment of consistence of results, the locations for the two types of measurements, electronic ratemeters and TLD system, were the same.

Results

Table 1 represents the measured values of the ambient equivalent dose rate [nSv·h-1], obtained with the two systems, respectively the electronic AUTOMESS 6150 and the TLD system SD-TL, in four representative locations and their comparison. These points were selected as the most representative from a large number of measurements areas of the mine.

Table 1. Mean ambient equivalent dose rate values , measured with the two systems and their comparison

Location	Mean ambient equivalent dose rate [nSv·h-1], AUTOMESS 6150 system	Mean ambient equivalent dose rate[nSv·h-1], TLD, SD-TL system	Difference, %
1	1.17±0.42	1.49±0.41	27
2	2.22±0.42	2.15±0.82	3
3	1.87±0.57	1.55±0.30	17
4	2.56±0.55	2.14±0.32	16

The reported uncertainties were calculated from the instruments' calibration factor uncertainties, respectively 10% and 7.5% and additional uncertainties: nonlinearity outside the certified interval, statistical uncertainty, etc.

Discussion

Such as it can be seen from the Table 1, two conclusions can be drawn:

1. The levels of background inside the underground laboratory are about 25 - 50 times less than the usual ground level, (50 -100) nSv h-1. The explanation is that the cosmic radiation is strongly attenuated by the rocks. The registered values are due to the residual content of radioactive elements existent in rocks, whose influence is also reduced by the existence of thick pure salt walls surrounding the laboratory. The influence of salt purity over the influence of 226Ra - 222Rn decay chain and of 40K was reported by Cristache and al. (Cristache, 2009), by using classical chemical analyses methods, Nenitescu (Nenitescu, 1982) and Neutron Activation Analysis.
2. The results obtained with two independent and different as operating principle dosimetric systems are in agreement within their measurement uncertainties.

Conclusions

– The low level of background in an underground laboratory was systematically studied, in order to characterize the environmental dose of the new laboratory.
– Two independent systems, an electronic and a TLD one were used. Their operating principles are different, but the results are in good agreement, what demonstrates the consistence of measurements.

Abstract

Everybody who flies frequently is exposed to elevated levels of cosmic radiation of galactic and solar origin and to secondary radiation produced in atmosphere. The annual average radiation dose to aircrew may become similar or even large than that of other occupationally exposed groups. The assessment of effective dose for aircrew members was performed by using programs EPCARD*. Altogether about 180 pilots were monitored during 2007 year and about 500 air crew members were monitored during 2008 years. In 2007 annual average effective dose (E) was 2.5 mSv and maximum personal dose was 4.0 mSv compared to next year annual average 2.3 mSv and maximum 3.7 mSv. Mobile Dosimeter Unit (MDU) Liulin Si spektrodosimeter and Exploranium GR 135 have been used for experimental measuring of levels of cosmic radiation on the airplane board.

Additionally to personal cosmic radiation monitoring, small human trial was conducted to monitor life style, nutrition and various clinical, biochemical, genotoxicity, immune and molecular markers from blood samples of exposed as well as control subjects and to investigate the possible effects of radiation exposure on human health.

Introduction

The recommendation of International Commission on Radiological Protection (ICRP) No. 60 from 1991 year (ICRP 60) included the exposure of the aircrew from the cosmic radiation among the occupational exposure. Council Directive 96/29/Euratom (CD96/29), the Basic Safety Standards (BSS) has been published on May 13, 1996 laying down basic safety standards for the health of workers and members of the general public against the dangers arising from ionizing radiation(BSS 1996). Article 42 of the directive on the protection of aircrews from EU member states have been transposed into the national legislation directives. The directive has been also incorporated into the Slovak regulation since 2000. Ministry of Health of Slovak

Republic funded the project “Radiation load of aircrew and biomonitoring of health risk of combined exposure to radiation and stress factor” which was conducted from 2006 to 2008. The main aims of the project were to introduce radiation monitoring (periodical monitoring system build on experimentally measurements as well as theoretically confirmed effective dose assessment) and to identify the effect of exposure on biological markers of genetic stability, DNA repair, oxidative stress and on immune markers. This contribution presents results of radiation monitoring.

Material and methods

The EPCARD* calculation program was used for evaluation of aviation personnel radiation load exposure. We created software for computing of data from large number of monitored members of aircrew. The interactive database was created for data on occupational exposure the aviation crew members for every month, as well as for annual exposure. This database enables data elaboration and analysis, the statistical evaluation, and the assessment of other radiation protection quantities.

Onboard aircraft exposure measurements were provided by Mobile Dosimeter Unit (MDU) – Liulin Si diode based spectrodosimeter and gamma spectrometer Exploranium GR 135. Measurements have been performed on an B737 aircraft Sky Europe Airlines at an altitude 12 000 m.

Results

Estimate of personnel radiation load

In 2007 we observed the radiation load of 181 pilots. The results show that the average annual effective dose is 2.5 mSv, the maximum annual effective dose is 4.0 mSv and the collective dose is 460.6 mSv.

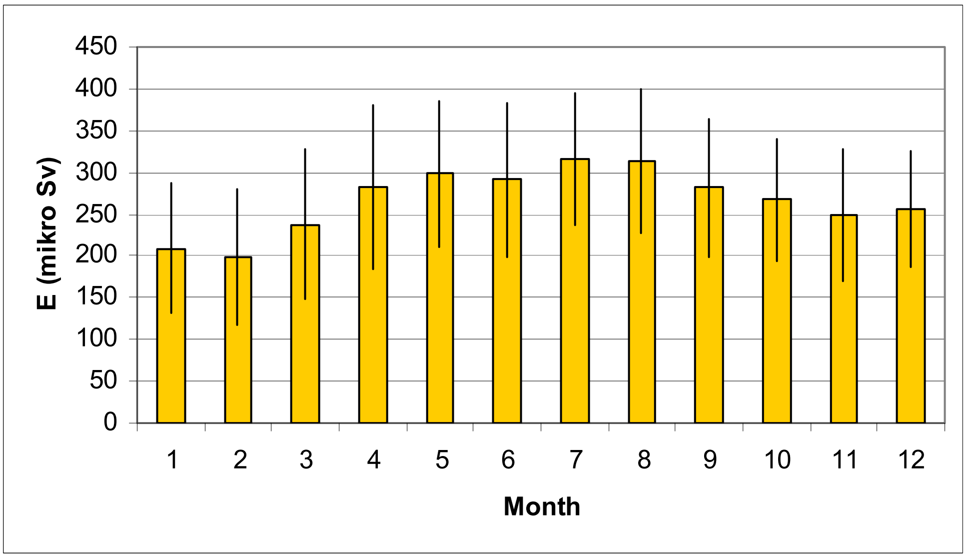

Fig. 1. Average monthly effective dose – pilots 2007.

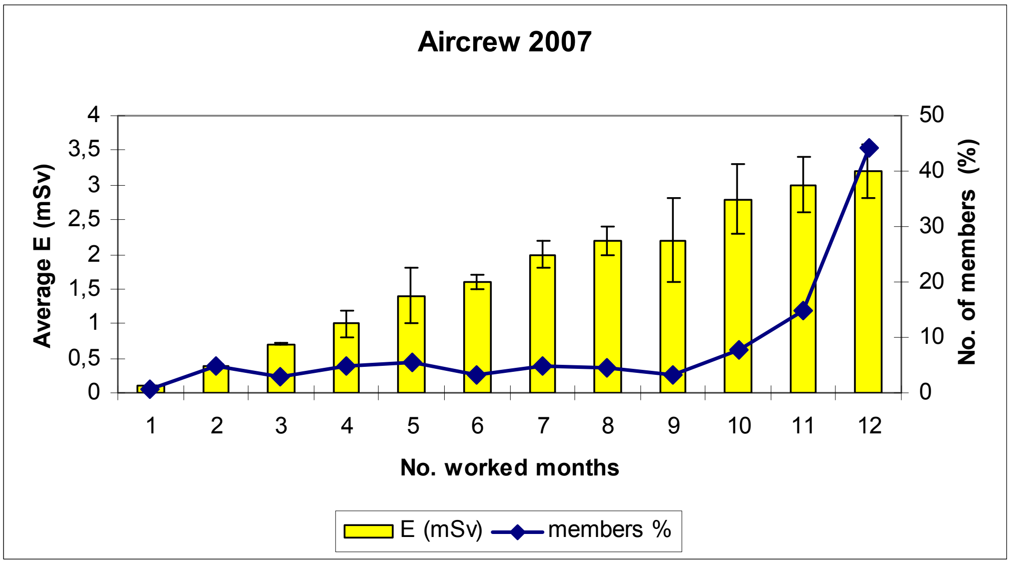

Fig. 2. The average effective dose by the number of months worked during the year 2007.

In 2008, we monitored the radiation load of 183 pilots. The results show that the average annual effective dose is 2.5 mSv, the maximum annual effective dose is 3.7 mSv and the collective dose is 463.6 mSv.

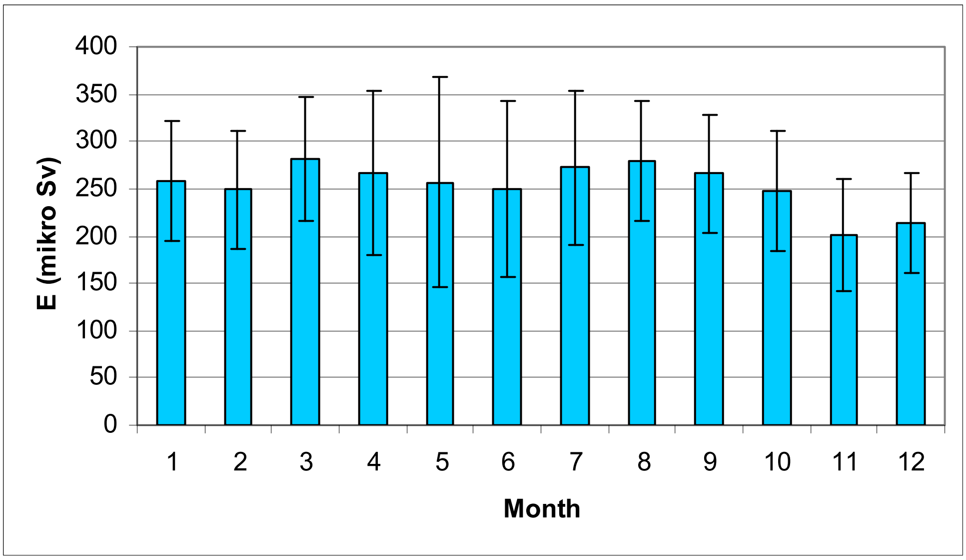

Fig. 3. Average monthly effective dose – pilots 2008.

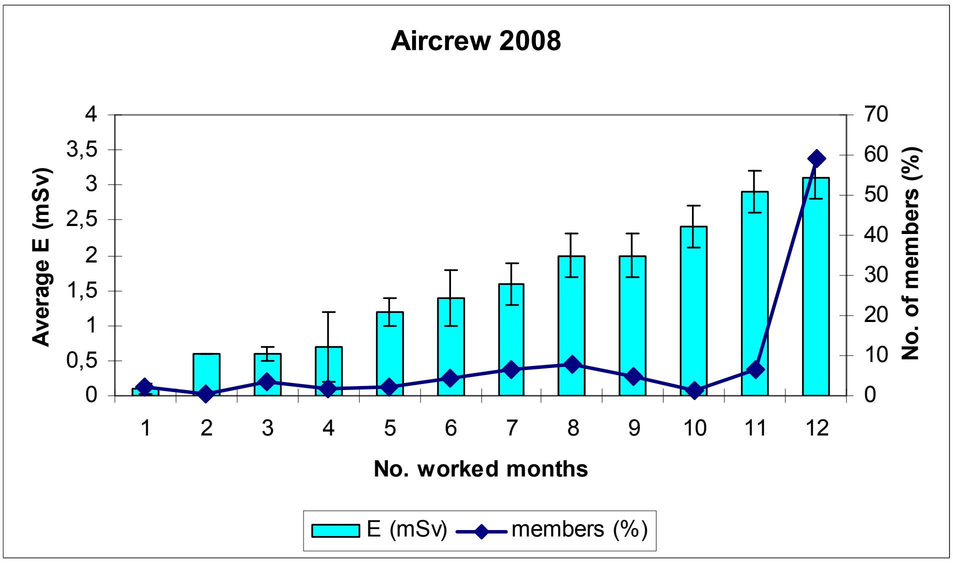

Fig. 4. The average effective dose by the number of months worked during the year 2007.

In 2008 we watched the radiation load 316 stewards too. The results show that the average annual effective dose is 2.2 mSv, the maximum annual effective dose 3.7 mSv and the collective dose is 693.1 mSv.

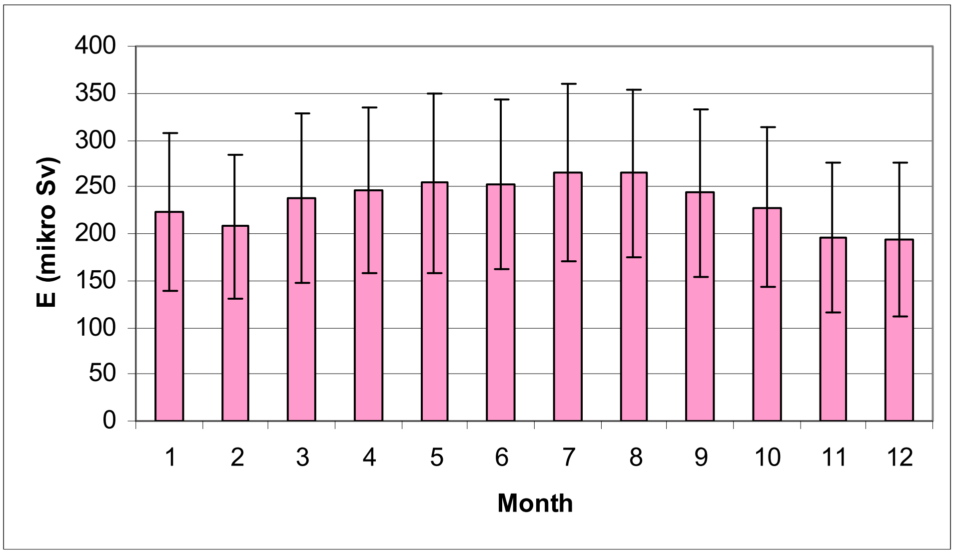

Fig. 5. Average monthly effective dose – stewards 2008.

Discussion

Annual effective dose to aircrew members who had been working more than 3 months during the year always exceeds 1 mSv. In accordance with Article 42 Directive 96/29 Euratom - Each Member State shall make arrangements for undertakings operating aircraft to take account of exposure to cosmic radiation of air crew who are liable to be subject to exposure to more than 1 mSv per year. Experimental measurements and estimates of personal radiation load from exposure to cosmic radiation were carried out during the period of minimum solar activity. We assume that during the period of increased solar activity may be higher annual effective dose. The graphic outputs from used devices show that the measured ambient dose equivalent and the intensity of cosmic radiation are dependent not only on traffic levels but also on the geographical location. Cosmic ray intensity increases towards the magnetic poles of the Earth and decreases toward the equator in the same altitudes. This is due to the different intensity geomagnetic field at the Earth's equator and poles. Magnetic field of Earth protects us from the increased intensity of cosmic radiation. We use this fact to a large extent possible to optimize the radiation load of personnel planning for deployment of staff to the route. Reducing of radiation load of aircrew members cannot be achieved by shielding in aircraft construction or using of protective shielding devices. There is the only way optimization - to take into account the assessed exposure when organizing working schedules with a view to reducing the doses of highly exposed aircrew. During the flight planning it should be take into account that a dose rate of cosmic radiation grows with the increase of latitude and flight level.

Conclusions

The project allowed for the first time in Slovakia to carry out monitoring of personnel radiation load from cosmic radiation. The results obtained confirm the eligibility of the start up of radiation monitoring Slovak air carriers and justify the need for its continuation. The obtained results show that annual effective dose to members of air crews is highly significantly higher in comparison with radiation dose of workers exposed in other workplaces.

Progress with the revision of the Euratom Basic Safety Standards and consolidation with other Community legislation

Janssens, Augustin
European Commission, Directorate-General for Energy and Transport, L-2920 LUXEMBOURG

Abstract

The revision of the Euratom Basic Safety Standards (Directive 96/29/Euratom) was undertaken to allow for the new ICRP Recommendations (Publication 103) as well as to consolidate all radiation protection legislation in a single BSS Directive. In line with ICRP the new Directive will allow for the three exposure situations: planned, existing and emergency. This required significant restructuring, together with the consolidation or recast. The new Directive will fully integrate all natural radiation sources, introducing more binding requirements for NORM industries, building materials, radon in dwellings and workplaces. The protection of the environment is now within the scope of the Directive. The Directive develops the concept of a graded approach to regulatory control, so that it is commensurate to the risk and to the effectiveness of such controls. In this context also the concepts of exemption and clearance have been worked out in more detail and new consideration is being given to the harmonisation of exemption and clearance levels. Further issues that emerged from the revision process are the definition and use of constraints and reference levels, as introduced by ICRP, and the principle of justification, in particular with regard to the deliberate exposure of people for reasons other than medical (e.g., for security screening). The revision and recast process was completed in February 2010. Harmonisation with the International Standards (IAEA and co-sponsors) is vigorously pursued in view of co-sponsorship by Euratom.

1. Consolidation of the Community legislation

The Community *acquis* in radiation protection, derived from Title II, Chapter 3 of the Euratom Treaty, constitutes a comprehensive and evolutionary legislative framework, with the Basic Safety Standards Directive (EU, 1996) as principal piece of legislation, and supplemented by eight binding instruments (Directives, Regulations, Decisions in addition to non-binding Recommendations and Communications).

The Commission undertakes the simplification of its "*acquis*" of Community legislation by the codification of related acts (without modification, e.g., amendments or complementary legislation) or recasting these if necessary (e.g., allowing for different definitions). Such recast will be undertaken for the five main Directives (all except shipment of radioactive waste (EU, 2006)). The very recent Council Directive

2009/71/Euratom on nuclear safety of nuclear installations was not considered for a recast at the present stage. In addition to the Basic Safety Standards, this recast thus concerns the following Directives:

- Medical applications of ionising radiation: Directive 97/43/Euratom (EU, 1997)
- Information in case of radiological emergency: Directive 89/618/Euratom (EU, 1989)
- Protection of "outside workers": Directive 90/641/Euratom (EU, 1990)
- Control of high-activity sealed radioactive sources and orphan sources ("HASS Directive"): Directive 2003/122/Euratom (EU, 2003).

The Basic Safety Standards Directive had introduced in 1996 some new features. A specific Title VII was introduced for the regulatory control of "work activities" involving natural radiation sources. With the exception of aircrew exposure, the Directive left the responsibility for the identification of work activities (NORM industries and workplaces with high radon concentrations) with national authorities. This flexibility was needed in order to achieve consensus on the inclusion of these new features at a time when there was little experience with such matters. The experience gathered since 1996, with transposition in national legislation (due by May 2000) and with operational implementation, demonstrated a need for enhanced harmonisation. Thus a revision of the Basic Safety Standards was undertaken amongst others to strengthen and broaden the requirements on natural radiation sources.

2. Revision of the Basic Safety Standards

The Community's Group of Experts established under Article 31 of the Euratom Treaty had established a four year work programme for the revision of the Basic Safety Standards. Initially it followed a topical approach. Working Parties took on board the redrafting of requirements on natural radiation sources, on exemption and clearance, and on a graded approach to regulatory control. Specific attention was given to the requirements on Education and training as well as to the definition of the responsibilities and qualifications of the Radiation Protection Expert, the Medical Physics Experts, and Radiation Protection Officer.

2.1. Exposure Situations

The revision of the Euratom Basic Safety Standards took account of the ICRP recommendations in Publication 103 (ICRP, 2008). While these do not necessarily require major changes in regulatory requirements, the Commission undertook to structure the requirements along the concepts of planned, existing and emergency exposure situations.

The distinction between the three exposure situations proved very helpful in structuring the Standards. However, very precise definitions are needed in a regulatory context, rather than the somewhat loose descriptive formulations in ICRP Publication 103.

For instance, ICRP defines a planned exposure situation merely as one involving the planned operation of sources. Existing exposure situations relate to "sources that already exists when a decision on control has to be taken". We strongly believe that when an activity significantly affects or alters an exposure situation caused by existing sources, such as NORM (Naturally Occurring Radioactive Material) or cosmic radiation, this is a planned exposure situation. Hence NORM industries and the exposure of aircrew are planned situations and the activities can be labelled as practices.

On the other hand, NORM materials with levels of activity concentration that are common in the earth's crust should be exempted from the requirements for practices. The boundary is established through identification of those types of NORM industries that should *a priori* be managed as a practice. The concept of a threshold in activity concentration, for the application of requirements for practices, matches the concept of exemption from such requirements. The new Directive has introduced the values of 1 Bq/g for U-238/Th-232 and 10 Bq/g for K-40 taken from IAEA RS-G-1.7 (IAEA, 2004), together with a graded approach to regulatory control using dose thresholds of 1 mSv and 6 mSv per year.

Truly existing exposure situations are those for which the exposure results from where you are, rather than what you do. Radon ingress in a dwelling, from soil, is not related to any activity, so it yields in general an existing exposure situation. Any exposure at work, not necessarily resulting from the work, is however the responsibility of the employer. High levels of radon in the workplace thus should be subject to a reference level, to a threshold for the management as a planned exposure situation (which may be the same as the reference level) and to the dose limit for workers.

There are other boundaries where pragmatic choices need to be made. The production or import of commodities clearly is an activity. However, if the radioactive substances arise from an existing exposure situation, then it is more convenient to manage such commodities in the same context. Hence, building materials and contaminated food are managed under the heading, “existing exposure situations”.

An emergency exposure situation eventually leads to the existing situation of living in a contaminated area. The delineation in this case requires a management decision.

In earlier drafts of the new Directive the provisions for emergency and existing exposure situations had been laid down in specific titles. Later if was found preferable to have, for example, all aspects of occupational exposure, including emergency workers and the follow-up to accidental exposure of workers, in a single title. Hence there is a title on “justification and regulatory control of planned exposure situations”, but the chapters on the protection of workers, patients and members of the public are no longer part of an overall title on “planned exposure situations” (as is the case with the current draft of the international standards.) It was proposed to have a clear 3 x 3 matrix structure with the categories of exposure (occupational, public and medical) on the one hand, and the three exposure situations on the other hand. (see Table 1).

Table 1. New matrix structure of the Euratom BSS.

OCCUPATIONAL EXPOSURE	PUBLIC EXPOSURE	MEDICAL EXPOSURE
Planned exposure situations	Planned exposure situations	Planned exposure situations
Emergency exposure situations	Emergency exposure situations	Emergency exposure situations
Existing exposure situations	Existing exposure situations	

2.2. Emergency exposure situations

The new management scheme for emergency exposure situations builds on recent guidance of ICRP (ICRP, 2009). The old approach of an emergency plan with different *intervention levels* is replaced by a more comprehensive system:

– threat analysis;
– overall emergency management system;
– emergency response plans for identified threats;
– pre-planned strategies for the management of each postulated event.

The key difference is that each strategy should aim at keeping doses below the *reference level*, optimising the available preventive and protective actions rather than justifying each action. New Annexes list the elements to be included in the management system and in the emergency response plan.

2.3. Natural radiation sources

The Working Party of the Article 31 Group of Experts on natural radiation sources undertook in the first place the harmonisation of the identification and regulatory control of NORM-industries. The Working Party agreed on a “positive list” of types of industries that will be subject to controls in all Member States. It will be the task of the national authorities to inform the concerned industries and to make sure that they understand the radiation protection issue and take, if necessary, appropriate measures to reduce exposures within the overall Health and Safety policy of the undertaking.

The industries (those listed and such other industries as identified at national level) will be requested to investigate activity concentration levels at any point of their process. On the basis of an assessment of occupational exposures in identified industries a graded approach to regulatory control will be applied. Where doses are all below 1 mSv per year, the practice is exempted. Where doses are in the range of 1 to 6 mSv per year the only requirement is to review whether optimisation calls for further reduction of exposures, and whether the exposures remain broadly the same over many years. Since there is in general no risk of accidental exposure, there is no need for individual dosimetry or medical surveillance. In the exceptional case that doses exceed 6 mSv per year the full set of requirements for classified workers will apply.

In the same way as for practices involving artificial radionuclides, the concepts of exemption and clearance should merge (even more so, since the output of one NORM industry often is the input to another). The values proposed for this purpose in earlier Community guidance (Radiation Protection 122 part II (EC, 2000)) were 0.5 Bq/g for (U238/Th 232 and 5 Bq/g for K-40, on the basis of an exemption criterion of 300 µSv per year for natural radiation sources. The values endorsed for the sake of international harmonisation (RS-G-1.7), twice as high as in (EC, 2000), are not always suitable for clearance of residues from NORM industries. The Euratom Directive therefore establishes unambiguously that the values in RS-G-1.7 for naturally occurring radionuclides apply neither to the recycling of residues into building materials nor to situations where there is a specific risk such as groundwater contamination.

While NORM industries and the exposure of aircrew are managed as planned exposure situations, a management system for existing exposure situations applies to:

– building materials;
– radon in dwellings and public buildings (workplaces are considered either as an existing or as a planned exposure situation).

An indicative list of types of building materials considered for control in view of the emitted gamma radiation has been included in an Annex. On the basis of earlier guidance (EC, 1999), requirements for the placing on the market and use of building materials have been incorporated in the Basic Safety Standards. The activity concentration index I :

$$I = C_{Ra226}/300\ \mathrm{Bq/kg} + C_{Th232}/200\ \mathrm{Bq/kg} + C_{K40}/3000\ \mathrm{Bq/kg}$$

may be translated into two classes of building materials depending on the use of the material and on whether a common reference level of 1 mSv per year (above background) would be exceeded. This is the only reference level that will be imposed through the Directive. Indeed, leaving a free choice to Member States would lead to very complex requirements to allow for free trade within the EU.

Currently, radon in dwellings is excluded from the scope of Directive 96/29/Euratom and is covered by a Commission Recommendation (EC, 1990). Recent epidemiological findings from residential studies demonstrate a lung cancer risk from indoor radon exposure at levels of the order of 100 Bq m^{-3}. ICRP is currently re-considering its earlier guidance on the dose conversion factors relating to concentrations of radon gas and its progeny in the decay chain. The ICRP Main Commission has issued a statement in November 2009 now proposing a maximum value for the reference level in dwellings of 300 Bq m^{-3}, in line also with the WHO handbook on indoor radon (WHO, 2009). The new Directive has incorporated this value for existing dwellings. The lower value for the reference level proposed by WHO, 100 Bq m^{-3}, is suitable as a long-term goal but a maximum value of 200 Bq m^{-3} for new dwellings has been maintained in the Directive.

A maximum value for the reference level for radon in workplaces has been set at 1000 Bq m^{-3}, in line with the ICRP Statement and with the current draft of the international standards. With the possible doubling of the dose conversion factor, a radon concentration of 1000 Bq m^{-3} would correspond to around 10 mSv per year, which is a high threshold for managing radon at work as planned occupational exposure and well above 6 mSv per year, used in the definition of Category A workers. It is expected that most Member States will set or maintain a reference level much lower than 1000 Bq m^{-3}.

Member States will be required to establish a national action plan which will cover radon in dwellings and in workplaces. The action plan will offer transparent information on the scope and objectives pursued at national or regional level, define the rationale for the conduct of surveys and for the delineation of radon-prone areas or other means of identification of affected buildings, and establish reference levels and building codes. An Annexe to the Directive gives an indicative list of items to be covered in the national action plans for radon.

2.4. Graded approach

The current system of regulatory control is a two-tier system: reporting of practices above exemption levels, and prior authorisation for certain categories of practices. IAEA (IAEA, 1996) had introduced a three-tier system: notification, registration and licensing. The Directive identifies which type of practices will be subject to each pillar, which general conditions need to be fulfilled and what is the content of requirements laid down upon registration or as part of a specific operating licence.

The current system for exemption of apparatus and of consumer goods relies very much on the concept of “type approval”. This concept was not worked out further and there is a lack of harmonisation of conditions for type approval and corresponding decisions in the EU. A system of mutual recognition (or at least allowance for) type approvals granted in other Member States has now been introduced.

Directive 96/29 had introduced exemption values in terms of activity (Bq) and activity concentration (Bq/g). In addition, the reuse or recycling of materials with negligible levels of contamination, especially arising from dismantling, could be authorised so that the materials would be released from regulatory requirements, subject to compliance with clearance levels. The clearance levels should be established in such a way that individual doses would be below about 10 μSv (and collective doses below 1 man Sv), taking Community guidance into account. Such guidance has been adopted by the Group of Experts for specific materials such as metals (scenarios for steel, copper and aluminium), buildings and building rubble, and default values for any type of material (EC, 2000).

Meanwhile the IAEA adopted similar guidance in RS-G-1.7 (IAEA, 2004), on the basis of scenarios to a large extent inspired by those underlying RP 122 part I. The IAEA levels were not specifically developed for the purpose of clearance, but it was suggested to use them for this purpose. For the sake of international harmonisation it was decided to introduce in the Directive the RS-G-1.7 values rather than those in RP-122. A study (EC, 2009) has investigated whether the differences between the two approaches and series of values has any significance in practical terms. In general the RS-G-1.7 values are equal to or higher than those in RP 122, but the differences can rather well be explained through the scenarios and assumptions. Nevertheless, several Experts consider that the Community guidance has a better scientific basis, and they are concerned with the increase of some of the values for artificial radionuclides.

The same concentration values now apply by default both to the concepts of exemption and clearance. It has been investigated whether lowering the exemption values will affect any consumer goods placed on the market. While the EC study (EC, 2009) concluded that there would be indeed no adverse practical consequences, it also highlighted some Member States’ reluctance to abandon the old numbers already incorporated in national law. In addition IAEA's transport standards committee (TRANSC) advocated keeping the existing values.

As part of the graded approach exemption from any requirements is built in at all levels of control. Specific exemption and specific exemption or clearance levels are a powerful tool in addition to the criteria for general exemption of practices from the scope of the requirements. Whenever the exempt activity concentration values laid down in Directive 96/29/Euratom, on the basis of Radiation Protection 65, would be preserved in national legislation, these values should be used only for moderate amounts of material, as defined in legislation or as specified by the competent authority.

2.5. System of protection

The overall "system of protection" mirrors the wording used in ICRP Publication 103. The main elements of the system of protection: justification of practices, optimisation of protection and limitation of individual doses are not essentially different from those in the current BSS. More weight is given to the principle of optimisation, subject to constraints and reference levels. The bands of constraints/reference levels proposed by ICRP (0-1 mSv, 1-20 mSv, 20-100 mSv) have been introduced explicitly, including the societal criteria that ICRP listed for each band (Table 5 of Publication 103).

The concepts of justification and authorisation in planned exposure situations were brought together in one title in view of the fact that they are the two main pillars of regulatory control. Also, the more elaborate requirements for the type approval of apparatus or consumer goods relate both to justification and to authorisation.

The concept of justification is described very much in the same terms as before. The so-called "medico-legal" exposures introduced in the Medical Directive (EU, 1997) have now been clearly identified as "non-medical imaging exposures" (deliberate exposure of individuals for other than medical purposes), and have been put under appropriate regulatory control. The need for justification of such practices, in three stages as for medical exposures, and for establishing associated conditions, has been worked out, including differentiation between procedures implemented by medical staff using medical equipment and procedures implemented by non-medical staff using non-medical equipments (e.g. security screening). While, in general, the annual dose limit and corresponding constraints for public exposure should apply, exceptions should be allowed for some specific non-medical exposure procedures carried out in a medical environment (e.g. drug search within the body).

The current dose limits for practices are kept, but the annual dose limit for occupational exposure will be simply 20 mSv per year. There should be no need for averaging over 5 years, except in special circumstances specified in national legislation.

On grounds of the precautionary principle, the Directive applies the optimisation principle also, where appropriate, to keep organ doses as low as reasonably achievable. The Scientific Seminar in 2008 (EC, 2008) on emerging evidence for radiation induced circulatory diseases indicated that epidemiological evidence is accumulating on an increased risk in circulatory diseases for cumulative doses higher than 0.5 Gy low-LET radiation.

In view of the conclusion of the Scientific Seminar in 2006 (EC, 2006) on the issue of radiation induced cataract and the further review of scientific literature performed by the Group of Experts, the dose limits to the lens of the eye should be reduced. ICRP will soon issue guidance on this matter and the Commission will take this guidance into account. Furthermore, the Directive requires the set-up of adequate systems for individual monitoring of (significant) doses to the lens of the eye.

3. Categories of exposure

3.1. Occupational exposure

A specific title covers all types of occupational exposure: of workers, apprentices and students, emergency workers, workers in identified NORM industries, aircrew and space-crew.

The graded approach to arrangements for occupational exposure is made more explicit, with a threshold of 1 mSv per year. The categories A and B workers are preserved. For workers in NORM industries, as part of the graded approach and if doses are in the range 1 to 6 mSv, it is sufficient to keep the exposures under review.

Emergency workers are subject to a dose limit of 50 mSv or, for specific cases identified in national emergency plans, an appropriate reference level. In the current Directive provision was made also for “specially authorised exposures”. This provision will now be applied to the exposure of space-crew.

3.2. Medical exposure

Medical exposure applies to the protection of patients, carers and comforters and volunteers in bio-medical research ("other individuals submitted to medical exposure"). There are very few changes to Directive 97/43, except the removal of “medico-legal” exposures and emphasis being given to the information to patients, to interventional procedures, diagnostic reference levels and dose indicating devices. A new feature is the introduction of accidental or “unintended” exposures.

3.3. Public exposure

There are little changes to the protection of members of the public. More precise requirements on the establishment of discharge authorisations have been introduced, as well as on the monitoring of discharges, with reference to a Commission Recommendation (EC, 2004).

3.4. Protection of the environment

The general objective of the Directive is the health protection of workers, members of the public and patients. The recast introduces complementary objectives on the control of sealed sources and on providing information to the public in the event of a radiological emergency. The health protection of the population and workers against the dangers of ionising radiation includes the protection of the human environment as a pathway from environmental sources to the exposure of man. In line with ICRP Publication 103 it is now felt that this should be complemented with specific consideration of the exposure of biota in the environment as a whole.

This extension of the scope of the Basic Safety Standards Directive will enable a better integration of the Euratom legislation with overall environmental legislation adopted under EC Treaty provisions, as well as the observance of international agreements, such as the OSPAR Convention on the protection of North-Atlantic waters, and meet the concerns of stakeholders.

While Chapter 3, “Health & Safety” of the Euratom Treaty only relates to the health protection of workers and members of the public, the policies for the protection of man and the environment should be coherent. For instance, environmental criteria as well as dose constraints should be considered for the authorisation of discharges of radioactive effluent.

Publication 108 of ICRP (ICRP, 2008) offers guidance on the definition of reference animals and plants, and the assessment of the impact of radiation on non-human species. The application of the principles of radiation protection on non-human species and ecosystems needs to be further developed however. The protection of the environment does not seem to warrant a high level of regulatory control, and the means for the demonstration of compliance should be proportionate to the expected relevance of the issue, in line with the graded approach. Also in view of the limited experience so far, the Commission envisages to leave enough time for transposition of these requirements in national law, pending the results of further research and international guidance of ICRP.

4. Prospects

The Group of Experts under Article 31 of the Euratom Treaty finalised the text of the new Directive in February 2010. The text of the Experts and their Opinion are the basis of a Commission proposal scheduled for the end of 2010. Adoption of the Commission's proposal by the Council may take another few years and, taking into account the time granted for transposition into national legislation, it may not be before 2014 that the requirements become truly effective.

Meanwhile the Commission is closely following the revision of the international Basic Safety Standards. As a result of the decision making rules in the European Union, the EC has so far never formally co-sponsored the international Standards. It is now envisaged to do so, in the same way as for the Safety Fundamentals. The aim is to harmonise as much as possible the definitions and requirements, both reflecting the ICRP Recommendations.

It should be emphasised, however, that the Euratom Standards and the international Standards will still look very different, on the one hand because the structures are not the same as well as the amount of detail in existing legislation; on the other hand because of the legally binding nature of the Euratom Standards, applicable to the 27 Member States of the European Union.

As a result of the rules of the recast procedure the current draft of the new Basic Safety Standards has in principle not introduced any requirements that had not been part, possibly in a different way, of the earlier Directives (except for the much broader requirements on natural radiation sources). In particular, no major changes have been made to the most recent Directive on High Activity Sealed Sources and orphan sources, except for the application of some of the requirements to any sealed sources, where this is considered to be good practice. The HASS Directive had introduced new safety, security and enforcement aspects, some of which have now been applied to all radiation sources. On the other hand there are still problems with orphan sources, and there have been important cases of contaminated metal being imported from third countries. Some requirements on orphan sources have therefore been strengthened, and a requirement on the notification of incidents with orphan sources or the contamination of metal has been introduced. Further international efforts are needed in this area to meet the conclusions of the Conference held in Tarragona in February 2009, striving for world-wide consensus on further legislative initiatives, in particular with regard to the restriction of trade in metal and scrap metal.

Comparison of current clearance standards and their brief history

Koskelainen, Markku[1, 2]

[2] The University of Manchester, UK

Abstract

Over the last 30 years, governments and the nuclear and non-nuclear industry have funded efforts to assess the potential for tightening of materials cycles and minimisation of waste containing measurable levels of radionuclides. A number of studies have demonstrated the technical efficacy of converting various forms of radioactively contaminated materials into safe form and demonstrated that this can be achieved cost effectively and safely. However, until now clearance of materials considered safe has only occurred in small volumes, or within the nuclear industry for specific internal uses.

In the near future large amounts of radioactively contaminated and activated materials will be generated by the decommissioning of first generation nuclear power plants and the historic case by case approach will not be sufficient to handle the associated volumes. To minimise the waste arisings and encourage clearance of radioactively contaminated materials number of governments and international organisations have redrafted their regulations and guidance, allowing for a more fluent release of materials, from regulatory control.

The current approach taken by the international organisations and national authorities is risk based. It intends to provide protection to workers, public and environment alike. Although the International Atomic Energy Agency (IAEA), European Commission (EC) and United States Nuclear Regulatory Commission (USNRC) recommendations are in general agreement on the principles of how clearance should be applied there is still some way to go before clearance values are harmonised.

This study looks a the historic development of clearance standards over the last 30 years and compares the current risk based models and specific activity limits given by the IAEA, EC and the USNRC.

Introduction

Together the governments and nuclear and non-nuclear industry have tried to identify options for waste minimisation and tightening of materials cycles. Hence numbers of regulations and standards have been developed since the 1970s dealing with the de-minimis values. These approaches to exemption, exclusion and clearance are documented in reports published by International Atomic Energy Agency (IAEA), European Commission (EC), United States Nuclear Regulatory Commission (USNRC) and many other national regulatory bodies.

Exemption, exclusion and clearance are often discussed as coincident concepts. To a degree this is true as they are concepts to exempt radioactive materials from regulation, so that the effects of radiation on the human body are not subject to any further consideration.

Of these, the concept of exclusion is fundamentally applied to the radiation from anthropogenic origin so called “natural radiation”. There are various sources of “natural radiation” in the nature, uranium in soil, radon in air and radioactive potassium in bananas. Another source of “natural radiation” are cosmic rays, which bombard us relentlessly. The global average dose received from “natural radiation” is estimated to be 2.4 mSv/a. This radioactive dose is not subject to regulation and is hence excluded from regulation. The radioactive materials that are subject to exclusion are specified in IAEA International Basic Safety Standards (BSS) for Protection against Ionizing Radiation and for the Safety of Radiation Sources" (IAEA, 1996) and EC Basic Safety Standards (EC, 1996), as materials that are not suitable to be controlled or cannot be controlled.

There is an exception to the “natural radiation” rule: although not from anthropogenic origin radioactive fallouts on the earth surface due to nuclear tests are usually treated as exclusion, as they cannot be controlled.

The concepts of clearance and exemption, on the other hand, mean that the materials are exempt from regulation in terms of radiation protection. These concepts are possible to be applied for two kinds of materials; one not subject to regulation at the onset and the other subject to regulation at the onset but exempt afterward. Today, the former concept is termed exemption and the latter clearance.

IAEA had previously used the term of de-minimis to combine both of these concepts. In early 1980s, the term of exemption began to be used, but at this time it still included both concepts. The two concepts were first differentiated by IAEA around 1995, when both terms clearance and exemption were given in IAEA BSS, which was published in co-operation with international organizations of FAO (International Food and Agriculture Organization), ILO (International Labour Organization), WHO (World Health Organization), EC etc.

Materials requiring clearance

So what is material requiring clearance? In general it is material which is regulated, but due to low levels of radioactive materials could be exempted from regulation. From this arises another question what materials are regulated? In most developed regulatory systems regulated materials arise from utilisation of nuclear energy and radiation. The material composition and the type of contamination present will vary depending on its origin. Virtually all facilities which have been sites of nuclear activity will, at some point, become sources for radioactive materials which can be cleared. Nuclear power plants are by no means the only source of radioactive materials. For instance each step in the uranium ore processing results in uranium contaminated equipment and contaminated slag. The utilization of uranium for the production of power or weapons results in equipment contaminated not only with uranium, but also with fission and activation products. Fuel handling, storage, and reprocessing also result in more contaminated materials. Radioactive source manufacture facilities and laboratories undertaking nuclear research are another source, and yet more radioactive materials can be expected from accelerator facilities.

Albeit that there are a number of sources for radioactive materials the commercial nuclear power plants have by far the largest arisings. Previous research and regulatory databases can be utilised to assess the material composition, type of contamination present and volumes of contaminated materials. Generally the radionuclides found in nuclear power plants differ according to reactor type. According to research radionuclides resulting from activation of iron, ^{54}Mn, ^{59}Fe, cobalt, ^{60}Co, and zinc, ^{65}Zn (ICRP, 1983) were shown to be present at similar levels in pressurized water reactors (PWR) and boiling water reactors (BWR), unlike the activation nuclides for nickel and tin. The nuclides resulting from the activation of nickel, ^{58}Co and ^{63}Ni, were found to be present at a higher level in PWR's, whereas the tin activation nuclide, ^{125}Sb, was present at higher levels in BWR's. Contamination of materials by caesium isotopes, ^{134}Cs and ^{137}Cs is higher in PWRs, while strontium isotopes ^{89}Sr and ^{90}Sr are usually present at the same level (Dyer and Bechtold, 1994). A survey of reactor parts showed that the radionuclides which accounted for 1% or more of the total activity were ^{54}Mn, ^{55}Fe, ^{60}Co, ^{65}Zn, ^{125}Sb, ^{134}Cs, and ^{137}Cs (Schlienger et al., 1996). These are the key radionuclides for all materials arising from nuclear power plants.

History of clearance standards

Since the early 1980's IAEA have demonstrated an interest in the clearance of materials, when they established the basic principles, which underlie the current approach in their safety series document 89 (IAEA, 1988a). In 1996 IAEA further defined the issue of clearance when they published their first interim report on the recommended clearance limits (IAEA, 1996). In 2004 IAEA revised these clearance limits, which now include 1650 radionuclides (IAEA, 2004).

From 1996 EC has developed the idea of clearance further from the early 1980s attempts, when they were assessing the possibilities of recycling radioactive material and published a number of reports dealing with the issue. These reports address the issue for specific cases concerning a number of fields where radioactive material is generated. There is also a specific EC radiation protection report, RP-89, dealing with the radioactive scrap metal (EC, 1998).

The most recent EC report in 2002 EC RP-122 gives the specific clearance limits for 197 radionuclides, which could be present in any type of contaminated material (EC, 2002). These clearance limits added, modified and eliminated radionuclides compared with the previous EC clearance limits published in 1996 (EC, 1996).

The decision to apply the clearance criteria in the EC countries remains the responsibility of the competent authorities in the Member States, and they can have their own clearance values where appropriate. The guidance on clearance in RP-89, different from other EC guidance, has a caveat for a less stringent clearance limits allowing for slightly radioactive metal scrap, components and equipment from nuclear fuel cycle installations to be authorised for clearance to the public domain whenever recycling within the nuclear industry is not appropriate subject to meeting the clearance criteria (EC, 1998).

US Atomic Energy Commission (AEC), the predecessor of the USNRC, has since 1940's considered slightly contaminated materials, but the original 1957 rule for the protection against radiation did not include specific values for clearance of slightly contaminated materials. An amendment was later added which allowed the regulator to grant a licensee a permission to release materials on a case by case basis. During the 1970's USNRC began the process to set uniform standards for clearance of materials from regulatory control. These efforts have continued through the 1980's and 1990's (USNRC, 1999). The latest effort came in 2003 where the technical document declared that materials with low concentrations of radioactivity can be cleared and de-regulated (USNRC, 2003).

The final 2003 technical document NUREG 1640 includes specific activity limits for 115 radionuclides and a detailed discussion of the methodology used to estimate the resulting annual doses USNRC, 2003), which are given as a justification for the clearance limits. However, currently these clearance limits are only used for case by case clearance decisions.

According to these international and national policies clearance is seen as a logical and well-based scientific concept with the potential for avoiding unnecessary regulation. While number of studies have made it clear that clearance is justified and that its adoption is important for development of nuclear power and utilisation of radiation, the various clearance standards and conflicting research have alienated people from the decision making process making it more difficult to find acceptance for clearance.

The current developments in clearance standards seem to indicate, that harmonisation of clearance values is finally moving forward as two of the major safety standards collections have indicated that they are trying to harmonise their clearance values. The current indication is that IAEA will be implementing the clearance values given in R.SG-1.7 in their new BSS with EC following suite in their new BSS (Janssens 2009).

Comparison of current clearance standards

Current clearance standards do not agree well when it comes to the specific activity limits set for specific radionuclides. When comparing the IAEA, EC and USNRC documents there are significant differences for majority of the radionuclides listed; 1650, 197 and 115 respectively.

Comparison of the key radionuclides is presented in tabulated format in table 1, and in a graphical form in figure 1.

Table 1. Comparison of clearance values for key radionuclides.

Radionuclide	USNRC (Bq/g)	IAEA (Bq/g)	EU (Bq/g)
H-3	526	100	100
C-14	313	1	10
K-40	2,94	-	1
Mn-53	11400	100	1000
Mn-54	0,63	0,1	0,1
Fe-55	21700	1000	100
Co-60	0,19	0,1	0,1
Ni-63	21300	100	100
Sr-90	17,50	1	1
Mo-93	270	10	10
Tc-99	6,25	1	1
I-129	0,05	0,01	0,1
Cs-137	0,63	0,1	1
Ir-192	0,91	1	0,1

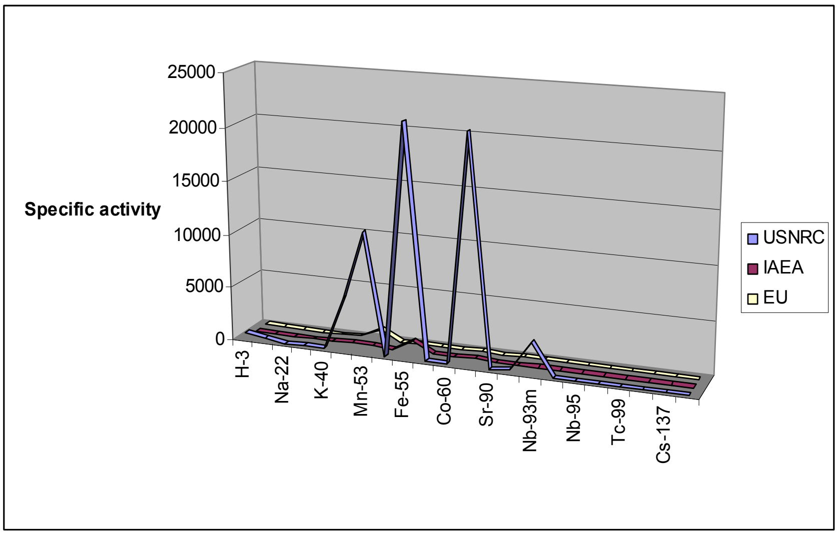

Fig. 1. Graphical comparison of clearance limits for key radionuclides.

Although the specific activity limits in the IAEA, EC and USNRC documents are not in agreement, they do agree on the principles of how clearance should be applied. The comparison of the content of these documents is given in table 2.

Table 2. Comparison of content of clearance standards.

	NUREG 1640	RS-G-1.7	EC RP 122
Waste material	All materials	All materials	Many kinds of materials
Nuclides	115	1650	197
Amount of material	Large	Large	Large
Disposition scenarios	Typical exposure scenarios for all materials	Typical exposure scenarios for all materials	Enveloping scenarios
Application constraints	No constraint on the origin and the type of materials	No constraint on the origin and the type of materials	No constraint on the origin and the type of materials
Standard dose	10 μSv/a	10 μSv/a	10 μSv/a

In all the documents the specific activity limits are based on the idea of negligible risk to the individual. All three standards have based their approach on the ICRP recommendation, that a dose of 10 μSv/a, which is 1% of the recommended public annual dose of 1 mSv, is negligible. By comparison, this means that the annual dose of 10 μSv is less than 0,5% of the natural radiation dose even in areas of very low background (~2 mSv/a) (UN, 2000), and less than 0,2% of the annual radiation dose in Finland (Muikku et al., 2007).

In the spirit of the concept of exclusion, clearance levels should be set at such levels that the resulting doses are small enough to be compared with doses from "natural radiation" so that the risk to the public health is so small it can be neglected.

Development of scenarios and dose evaluation

The clearance values in the current IAEA document RS-G-1.7 are derived numerically using 10 μSv/a for credible scenarios, 1 mSv/y for scenarios with low probabilities, and 1 manSv for the collective dose as the standard doses. The details of those derivations are shown in IAEA Safety Report Series No. 44 (IAEA 2004b).

In order to derive clearance levels, dose evaluations were performed by setting up required parameters for every pathway to be evaluated for the scenarios. Table 3 show evaluation pathways assumed for RS-G-1.7 clearance values.

Table 3. Evaluation pathways assumed by the IAEA.

Scenario	Group	Exposure path	Specific nuclides
Worker of repositories and other end-point facilities	Worker	External, inhalation and ingestion	^{239}PU and ^{241}Am (ingestion)
Worker of melting facilities	Worker	External, inhalation and ingestion	
Other workers (driver etc.)	Worker	External	
Peripheral residents of repositories or other facilities	Child	Inhalation and ingestion	^{3}H, ^{36}Cl, ^{41}Ca, ^{59}Ni, ^{63}Ni, ^{90}Sr, ^{99}Tc (ingestion)
Peripheral residents of repositories or other end-point facilities	Adult	Inhalation and ingestion	^{3}H, ^{36}Cl, ^{41}Ca, ^{59}Ni, ^{63}Ni, ^{90}Sr, ^{99}Tc (ingestion)
Peripheral residents of melting facilities	Child	Inhalation	
Residents of the house built with the contaminated materials	Adult	External	^{54}Mn, ^{60}Co, ^{65}Zn, ^{94}Nb, ^{134}Cs, ^{137}Cs, ^{152}Eu,^{154}Eu (external)
Peripheral residents of public facilities built with the contaminated materials	Child	External, inhalation and ingestion	
Residents consuming contaminated river fish and well water	Child	Ingestion	^{14}C, ^{129}I (ingestion)
Residents consuming contaminated river fish and well water	Adult	Ingestion	^{14}C, ^{129}I (ingestion)

The differences in the chemical and physical behaviour of radionuclides to be evaluated results in different doses for each nuclide at a given concentration, and hence each parameter is conservatively set up to include various postulated events. According to the dose-evaluation results for all evaluation pathways the clearance value is the minimum radionuclide concentration which is equal to the standard dose under any of the postulated events.

Table 3 also gives the major radionuclides which are critical for each of the pathways. Namely, it demonstrates that critical pathways are external exposure for gamma emitters (i.e.^{60}Co and ^{137}Cs), oral ingestion of beta emitters such as ^{90}Sr, and inhalation ingestion of alpha emitters such as ^{241}Am.

Concept of Limited Clearance

In accordance to the concept of clearance; materials, which are cleared are not subject to further regulation, but, as described in the development of EC clearance standards a concept of less stringent "limited" clearance exists, which provides more lax limits, and provides further conditions on the method of clearance or destination of cleared materials. This concept of "limited" clearance is also termed as "specific" clearance or "conditional" clearance.

As described earlier, the clearance level is usually set as the lowest concentration delivering the standard dose for the assumed exposure pathways. Therefore, if the assumed exposure pathways can be limited by imposing conditions on the implementation of clearance, the number of exposure pathways for the scenario evaluation will be reduced, and for the standard dose higher radionuclide concentration levels can be accepted. Similarly, if the amount of the materials for clearance is smaller, the clearance value will become higher.

As the USNRC did not gain acceptance for their Clearance approach outline in NUREG 1640 they are currently releasing materials under previous rules following the concept of “limited” clearance. There are also a number of other countries where this type of clearance approach has been incorporated into the legal regulations, such as Finland (STUK, 2008) and Germany (Sefzig, 2009).

Obstacles to clearance

Many countries face significant obstacles in adopting and applying clearance standards. The obstacles have been identified in a technical report published by the IAEA. The report deals with recycling of metals, but all of these factors could become obstacles for radioactive materials clearance aswell. Some of the factors are specific to a facility or a country and others are international (IAEA, 1988 b). In the context of clearance of metals these are:

- The availability of regulatory criteria giving activity levels for clearance and alternatives to applying the clearance levels
- The availability of technology and facilities to recycle the metals
- The availability of instrumentation to measure regulatory clearance levels and quality assurance programs to assure compliance with the criteria.
- The effect that recycling of materials will have on the extension of natural resources
- The economic implications including cost of decontamination, waste disposal, market value of recycled materials.
- The socio-political attitudes in the affected country or industry regarding the recycling/reuse of materials or components.

Of these factors the first is a legislative issue, which is for the governments to decide. The next two are technological issues, which are much dependant on the country’s infrastructure. The fourth is an international issue with stakeholder implications regarding sustainable development and conservation of natural resources. The second to last factor is a country specific issue with international economic dimensions. The last factor is a country specific issue which is strongly affected by stakeholder attitudes. In a modern western society it is unlikely that these first two factors would be significant obstacles to radioactive scrap metal recycling as readily available standards exist and there are ongoing operations around the world.

The third factor is a potential obstacle due to detector technology and associated cost implications, but these are discussed in detail in scientific publications and international guidance (Lubenau and Yusko, 1998, Clouvas et al., 2005).

Fourth issue is an international issue with strong stakeholder implications. However, in the current atmosphere of environmental conservation the considerate use of raw materials can be advantageous to radioactive scrap metal recycling if the stakeholders can be convinced of the safety of operations and the quality of the final product.

The fifth factor can become a hindrance if consumers do not accept the use of trace radioactive scrap metal in recycled metals, however the cost implications are unlikely to be an issue if burial cost avoidance is added to the financial calculations. The issue of cost benefit analyses is addressed by a number of scientific and articles and reports as well as national research (Menon et al., 1990, Hill et al., 1996, Yuracko et al., 1996, Rivera et al., 1996, Andreani and Bailo, 2000), the feasibility has also been demonstrated by the operational plants around the world.

The last factor can be, and it is the most serious obstacles to scrap metal recycling. To date a number of stakeholder involvement processes have been undertaken to convince the public of the benefits and safety of radioactive scrap metal recycling, but these stakeholder processes have not been successful in alleviating the concerns of the stakeholders and there is no free market for cleared radioactive scrap metal in the world.

Conclusions

Clearance regulation is provided to ensure the safety of the general public and the environment, and to ensure, that no one suffers health hazards from regulated radioactive materials. To a degree the numerous studies undertaken in developing the current clearance standards have demonstrated that it can be done safely and cost effectively, but the fact remains that significan differences are present in the clearance values eventhough they are working with the same standard dose of 10 µSv/a. This is mainly due to different approximations used in the exposure scenarios from which the limits have been derived.

This inconsistency makes it more difficult for regulators to convince stakeholders of the safety concerns associated with recycling of low activity scrap metal, and it would be more desirable to have consistent standards for materials rather than state of the art science.

With the indications coming from the IAEA and EC that they will be harmonising their clearance standards there seems to be some hope that in the future harmonisation for clearance values can be achieved, but this is still a long way away considering the effort that has been put into researching clearance standards and how jealously the assumptions behind clearance standards are discussed in the international environment. However if harmonised clearance standards can be agreed upon, it is more likely that the industries dealing with cleared materials would be more willing to include cleared materials in international trade.

According to IAEA clearance is: "a logical and well based scientific concept with the potential for avoiding costly and unnecessary regulation", and clearance of materials is demonstrated to be achievable through licensed operations around the world, but making it acceptable requires careful work from the international organisations and governments in justifying clearance and thorough stakeholder engagement and involvement at policy, strategy and facility levels.

Current situation with application of new ICRP system of radiological protection in the Russian Federation: regulation and optimization issues

Shandala, Nataliya[1]; Kiselev, Mikhail[2]
[1] Burnasyan Federal Medical Biophysical Centre, Moscow, RUSSIAN FEDERATION
[2] Federal Medical-Biological Agency, Moscow, RUSSIAN FEDERATION

Abstract
The current Russian basic regulative document, Radiation Safety Standards, needs updating, which must be carried out in accordance with common international practice. In the light of issuing of new ICRP principal recommendations in 2007, review of the IAEA Basic Safety Standards is in progress. In compliance with the national practice, the IAEA member states implement the Basic Safety Standards in a form of national systems of laws, norms and rules. In fact, the current national radiation safety standards can be updated in Russia only after new IAEA standards issuing. Nevertheless, even today, we must take the contemporary principles of development of the radiation safety system postulated in the ICRP recommendations into account. There are no stricter hygienic regulations in ICRP Publication 103 in comparison with those established in Russia, but there are some new conceptual provisions and concepts in it. The paper deals with the frame of national system of radiation safety regulation. Application of optimization and dose constraints in the course of Russian NPP operation is the specific case and its relevance is stressed in terms of future development of nuclear power engineering. Using the nuclear legacy regulation as an example, an importance of application of new exposure situations from ICRP Publication 103 has been shown.

Introduction
Radiation safety regulation consists of:

- Science based knowledge of ionizing radiation effects under development of the United Nations Scientific Committee on the Effects of Atomic Radiation;
- Conceptual model of the human safety and effective control of radiation sources and technologies being generated by the International Commission on Radiological Protection (ICRP);
- Legislative and regulative support of radiation protection and safety for different modes of nuclear energy using and another activity connected with radiation exposure to the human, being developed by the IAEA.

Development or change of each component has resulted in the necessity of the regulation system revision and its adequate submission at the international and national levels. The International Basic Safety Standards (BSS) have always followed the establishment of new ICRP recommendations. For example, the fundamental ICRP recommendations of 1990 issued as Publication 60 were the basis of the revised BSS, published in 1996. Then, in 1999, the Russian national radiation safety standards were developed.

The current Russian fundamental regulatory document – Radiation Safety Standards (NRB, 2009) – requires necessary revision, which must be carried out according to the established world practice. As it is well-known, issuing of the new ICRP fundamental recommendations in 2007 (ICRP, 2007), caused the revision of the IAEA BSS revision (IAEA, 2010). However, just before the official publication of new BSS, we must take into account the up-to-date principles of the radiation safety development as they are postulated in the ICRP recommendations, in our everyday practice.

Regulation of radiation safety and protection in Russia: regulatory bodies, legislative acts and regulative documents

In addition to operators directly responsible for radiological protection in Russia, as it is well known, there are some regulatory bodies, whose functions include regulation, licensing of the appropriate activity and its supervision, fig. 1.

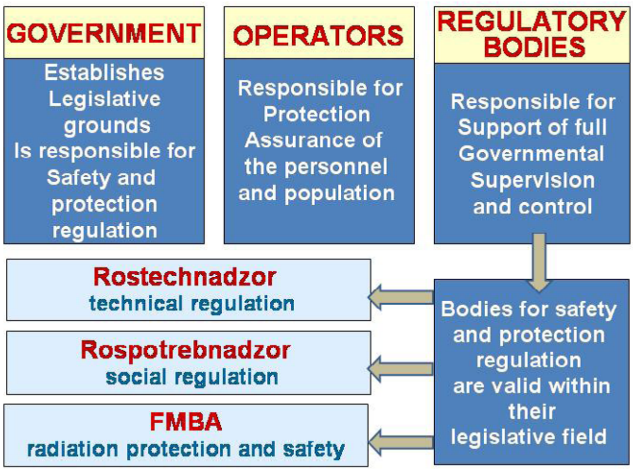

Fig. 1. State regulation of radiological protection in the Russian Federation.

According to the current Russian legislation, the Federal Medical-Biological Agency (FMBA of Russia) is responsible for medical and sanitary support as well as for the state sanitary epidemiological supervision. It covers organizations in some industrial branches with especially hazardous work conditions and the population of some Russian territories according to the list approved by the RF Government. This list includes all radiation hazardous facilities all over Russia (more than 400 facilities). One of the FMBA's principle functions is the state regulatory supervision of safety during nuclear energy using.

At that, some these functions are implemented through the system of the state sanitary and epidemiological regulation, to the extent that approval of the documents developed by the RF State Chief Medical Officer and their following registration in the

RF Ministry of Justice. Such regulations and sanitary rules are obligatory for observation by operators. Over recent 5 years, experts from the FMBA of Russia have developed more than 100 scientific and technical regulatory documents on radiation protection of nuclear workers and the public. 20 of such documents are ascribed to the category of sanitary rules and registered in the RF Ministry of Justice. They include sanitary rules for design and operation of nuclear power plants, including floating ones; regulations for surveillance of radiation safety during overall decommissioning/dismantlement of nuclear submarines; and the requirements for the Russian ports during enter and moorage of ships equipped with nuclear powered installations etc.

Principles of legislative regulation are postulated in laws and directives of the Government of the Russian Federation. National system of radiological protection and radiation safety assurance in the Russian Federation is based on two principal documents: Radiation Safety Standards (NRB, 2009) and Main Sanitary Rules for Radiation Safety and Protection (OSPORB, 1999). Figure 2 shows hierarchical frame of regulative and methodical documents as an example of radiological protection regulation of the personnel and population as applicable for the facilities of the State Atomic Energy Corporation “Rosatom”.

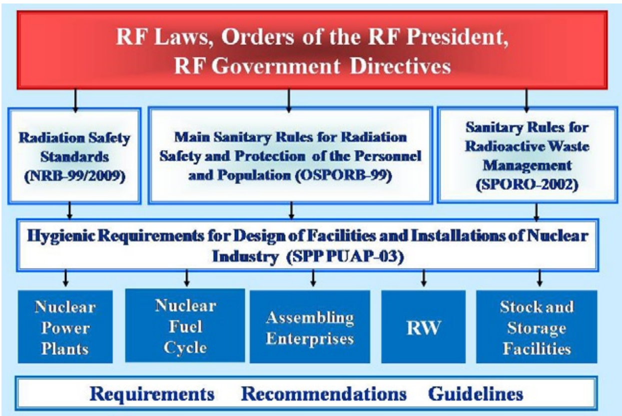

Fig. 2. Normative and methodic support of radiological protection of the personnel and population from the “Rosatom” facilities.

The legislative and regulative background established over the recent decade supports safe operation of nuclear facilities. However, its practical application revealed some problems as well. In the regulative documents, there are difficult questions to be solved connected with operation of the national nuclear industry, such as:

- remediation of sites contaminated due to past nuclear activity and “uranium legacy”;
- decommissioning of nuclear energy using facilities or justification of prolonged operational time of functioning facilities;
- radioactive waste management;
- assurance of effective emergency response;
- difficulties in adequate application of the optimization principle.

The mentioned problems can partially be solved on the base of issued ICRP principal recommendations - Publication 103.

Impact of the new system of the radiological protection on development of radiation safety and protection system in Russia

It is necessary to note that regardless the fact that the final BSS version is not finished so far, the principal Russian regulative document - Russian Radiation Safety Standards (NRB, 2009) has already been revised and is in force since 1 September 2009. Its amendment is due to not only Publication 103 issuing. Such kind of amendments is dictated by the termination of the ten-year operational time.

New version of the Russian Radiation Safety Standards keeps the previous structure. 300 different amendments have been made in total and the following in particular, up-to-date detriment adjusted nominal risk coefficients for stochastic effects after exposure to radiation at low dose rate have been given. In the section «Limitation of natural exposure» in addition to regulation of the construction raw materials, the finished production manufactured on its base has been added together with the mineral raw materials. Regulation of chemical fertilizers and agro-chemicals has been amended. In assessment of drinking water radiation safety the supplement says that regulation is made by adults, and intervention levels for the particular radionuclides are given as a special annex. In the section «Limitation of medical exposure», the criterion on discharge of the patient from the hospital after treatment with radiation sources is amended.

It should be noted that not all provisions of new ICRP system found their reflection in the revised document.

In Russia, the main actual task is to explain, how new ICRP conception of Publication 103 can be effectively and successfully applied in the regulation practice. The following new provisions of the radiation safety and protection system can be important for Russia:

- refusion of “practice and intervention” conception and its replacement by three types of exposure situation: planned, existing and emergency;
- introduction of dose constraint and reference levels for each exposure situation depending upon the category of individuals exposed;
- use of “representative individual” concept instead “critical group”;
- establishing of the eco-centric principle of radiation protection of non-human species and environment.

Some changes of the radiological protection system will cover the following issues as well review of weighting factors for relative radio-sensitivity of organs and tissues, selective use of collective dose value, etc.

Regardless of mentioned changes, together with the above new provisions of the radiological protection system, fundamental revision of current national NRB system is not assumed. Figure 3 illustrates evolution or dynamics of dose limit change in the ICRP documents and in the Russian documents regulated radiation safety, respectively. So, regarding to the professional exposure in planned situation, ICRP continues to advise to present dose limit as 20 mSv a^{-1} effective dose. The public exposure in planned exposure situation is either unchanged: ICRP continues to advise 1 mSv a^{-1} dose limit.

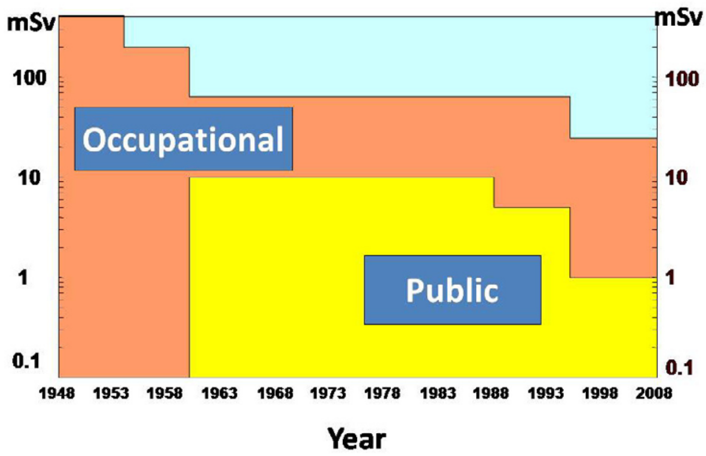

Fig. 3. Evolution of individual dose limits.

Thus, even before issuing of new IAEA international safety standards instead those in use today, it is already evident that national NRB will be the subject of evolutional amendments relating to «reconstruction» of the conceptual background of the radiological protection system, as well as change of digital values of dose coefficients.

In the nearest time, hard work should be performed on introduction of new recommendations into the national system for radiation protection and safety assurance. Therefore, after official issuing of ICRP Publication 103 in Russian, wide discussion is necessary both of the Russian terminology from the "Glossary" section and the whole text translated. Application of new conceptions and terms in the system of regulations must be weighted and one should avoid their formal application. When improving national regulative documents, one should analyze carefully national experience and take into account the up-to-date social and economic circumstances in Russia. The priority of changes from ICRP Publication 103 is to be specified to select those relating to the most important problem in nuclear industry.

Radiological protection optimization in the course of the Russian NPP operation

Information materials on the Russian NPPs operation are being demonstrated as a positive example of good practice of adequate application of the radiological protection optimization principle. In the regulative documents concerning this problem, the dose quote of 25% public dose limit, i.e., 0.25 mSv a^{-1} is written and observed over more than 10 years (SP AS, 2003). The dose quote in the national regulation assumes or is similar to dose constraint in the planned exposure situation. The current NPP 0.25 mSv a^{-1} dose quote value corresponds to the ICRP recommendations for dose constraint (of 0.3 mSv a^{-1}) established in the course of optimization of public radiological protection against existing or potential radiation source. This dose quote also corresponds to practice of other states, where nuclear power engineering is under development.

For the functioning Russian NPP, 250 μSv a^{-1} quote for the public dose is established, while for NPP under design and construction this value is 100 μSv a^{-1}. These quotes are being established for total public exposure due to radioactive gas-aerosol atmospheric discharges and liquid effluents in surface water reservoirs for NPP as a whole, regardless the amount of energy units on the industrial site. Table 1 shows the quote values for the public exposure originated from radiation factors (discharges and effluents) under route operation of the Russian NPPs.

Table 1. Quotes for the public exposure originated from discharges and effluents under route operation of the Russian NPPs, μSv per year.

Radiation factor	Functioning NPP	NPP under design or construction
Gas-aerosol effluents	200	50
Liquid discharges	50	50
Ttal	250	100

According to the regulatory document (SP AS, 2003), the approach is proposed for identification of permissible radionuclide releases into atmosphere based on the optimization principle and on the acceptable risk conception, when the lower border of the risk optimization area for the single radiation source (NPP, in this case) is assumed to be 10^{-6} a^{-1} (that corresponds to annual effective dose of about 10 μSv a^{-1}). For lower values, public doses are not to be reduced, i.e., we mean here application of additional radiation protection. The quote value is considered as upper border of potential public exposure due to radiation factors in the course of optimization of such public protection under condition of route (normal) NPP operation. Figure 4 illustrates the general ides of such approach.

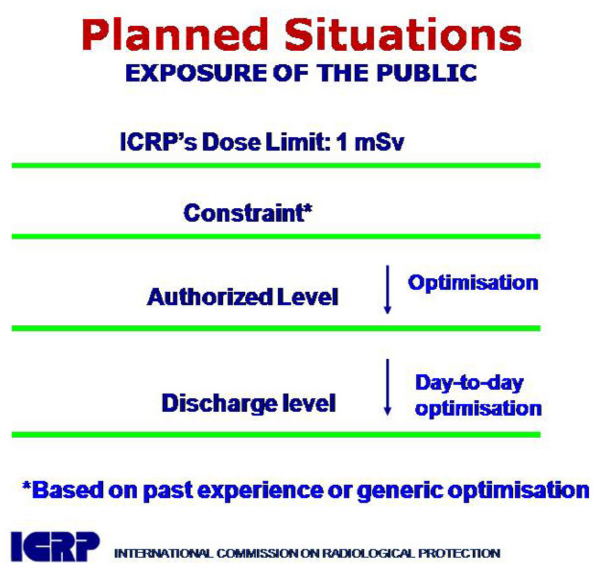

Fig. 4. Radiation protection optimization of the public living nearby the NPP.

Thus, permissible radionuclide releases due to the NPP operation result from optimization approach based on the “benefit-harm” analysis. Here, numerical values of permissible releases vary over the range between the upper and lower borders of optimization and they are not derived levels of dose quotes for the single radiation source (MG, 2004). When establishing the permissible annual releases of radioactive gases and aerosols into atmosphere, the fact was taken into account that noble radioactive gases made the main contribution (more than 98%) into the public dose under route of NPP operation. These are: argon, krypton, xenon and radionuclides ^{131}I, ^{60}Co, ^{134}Cs, ^{137}Cs (^{24}Na –for fast neutron type reactors, BN-600). Limitation and control of other radionuclide activities being detected in the NPP discharges seems to be unreasonable because of their trivial contribution into dose. Table 2 includes values of annual permissible discharges of radionuclides for the NPP equipped with different reactors taking into account ratios of the nuclide activities in such discharge and conditions of the discharge (heights of ventilation pipes).

Table 2. Annual permissible releases of radioactive gases and aerosols from the NPP into atmosphere.

Radionuclide, dimension	T3 with RMBK	T3 with WWR and BN
Noble gases, TBq*	3700	690
^{131}I (gaseous + aerosol forms), GBq**	93	18
^{60}Co, GBq	2.5	7.4
^{134}Cs, GBq	1.4	0.9
^{137}Cs, GBq	4.0	2.0
Note: * 1 TBq = 10^{12} Bq = 27 Ci; ** 1 GBq = 10^{9} Bq = 27 mCi		

The above mentioned permissible discharges are those of minimum significance and they observance guarantees that the public dose during rout operation mode will not be higher 10 μSv per year. Taking into account doses, which are the upper border of optimization, maximum permissible discharges are established for the functioning NPPs at the level of 20 permissible discharges, while for the NPP under design and construction – at the level of 5 permissible discharges. Values of maximum permissible discharges for all NPPs are 5 times higher than the permissible discharge.

If real release (discharge/effluent) from the NPP is lower than maximum permissible values, but higher than the permissible ones, then it is recognized that radiation impact of the NPP on the public and environment does not comply with the optimization principle. This is evidence of the manufacture culture violation and is to be considered with the purpose to eliminate the excess revealed. Excess of maximum permissible discharges or effluents is forbidden under route operation mode of the NPP, because this is violation of the sanitary norms and rules and can justify the suspension of the NPP operation.

Real releases from the Russian NPPs are not higher than 20% of permissible releases. Releases during power unit closures are much higher than those during normal operation at the stable power level (noble (inert) radioactive gases – up to 40%, ^{131}I – up to 70% of gross annual releases). At stable powers of the power units, measurement of the NPP release activities is of illustrative nature because of their low values.

Discharges and effluents due to the NPP operation at the level of about 100% of the permissible releases are undoubtedly acceptable; effective public doses confirm this fact for the population living at the NPP vicinity (Shandala N. et al., 2007). Table 3 includes doses to the public on the example of Volgodonsk NPP.

Table 3. Individual effective public doses at the supervision area of the Volgodon NPP, mSv a^{-1}.

Regions of the supervised area	Years of surveillance				
	2004	2005	2006	2007	2008
Cymlyansky	0.02	0.012	0.021	0.06	0.08
Volgodonsk city	0.015	0.01	0.09	0.017	0.019
Dubovsky	0.09	0.02	0.015	0.013	0.005
Zimovnikovsky	0.012	0.014	0.011	0.01	0.004

Thus, real discharges and effluents originated from the NPP operation are optimized and their reduction is not economically justified. The task is to keep the reached level of atmospheric effluents and discharges into water media, especially in the light of ambitious plans of nuclear power engineering development in Russia.

Optimization and regulation of the Russian nuclear legacy

Optimization of radiological protection in Russia is also important issue in remediation of nuclear legacy of sites and facilities of ex-USSR. Routine operations and discharges from radiation hazardous facilities do not contribute substantially to the public exposure and do not result in any significant consequences for health. In contrast, some legacy radioactive contaminations due to radiological accidents and emergency situations (Techa River, 1949; Kyshtim, 1957; Chernobyl, 1986) resulted in radiation doses to some population groups that significantly exceeded the permissible levels, Table 4 (Balonov M., 2008).

Table 4. Public exposure due to man-made radionuclide releases.

Source	Time period	Significant Nuclides	Mean dose (mGy, mSv)
Global fallout	1950 – 2020	^{137}Cs, ^{90}Sr, ^{131}I, ^{14}C, ^{3}H	1.1
Techa River, PA “Mayak”, Russia	1949 – 2020	^{90}Sr, ^{89}Sr, ^{137}Cs, etc.	50-2000
Chernobyl, USSR	1986 – 2056	^{131}I, ^{134}Cs, ^{137}Cs, ^{90}Sr	Up to 500; Thyroid – up to $10 \cdot 10^3$

Emergency exposure led to adverse health effects, such as, radiation sickness and a long-term increase in the incidence of cancer in the residents of the affected areas. The research institutions under the FMBA of Russia study consequences of contamination of Techa River, Southern Urals, due to both unauthorized radioactive discharges from the PA "Mayak" at the later 1940s and the accident at the "Mayak" in 1957. Following some radiological accidents, significant detriment of human health and environment has been observed. Consequences of defense activity are rather considerable for environmental safety at the sites of nuclear submarine allocation. Such kind of activity resulted in large amounts of the spent nuclear fuel and radioactive waste accumulated at the sites of temporary storage in the Russian Northwest and Far East.

What kinds of problems do arise in optimization context in case of existing exposure? Let us consider them on example the nuclear legacy regulation. The main Russian regulative document (NRB, 2009) presents the guidance (intervention criteria) with respect to the radioactively contaminated areas as a reference Appendix 5. Nevertheless, there is no comprehensive guidance for the existing exposure situation. The optimized protective and remedial measures are recommended at annual dose over the range 1 – 20 mSv; at dose >20 mSv, residence at the territory is forbidden. Prima facie, quite good general compliance with the ICRP Publication 103 is evident; however, application of the lower boundary (1 mSv/year) for the large-scale situation (Chernobyl, Kyshtym, Techa) seems to be inadequate. This can be explained by the Chernobyl Law adopted on the rise of democracy at the early 1990s and by wrong use of the dose limit in case of emergency and existing exposure situations (Shandala N. et al., 2009).

According to the ICRP Publication 103 (ICRP, 2007), environmental remediation can be considered as an existing exposure situation: exposure already exists, when decision is to be made on radiation protection. This kind of exposure situation includes prolonged exposure due to excess radiation background, after radiation accidents, following previous radiation substance handling (including nuclear weapon manufacturing and tests, peaceful nuclear explosions etc.). In many respects, consequences of the Chernobyl accident resulted in generation of such independent exposure situation. The previous ICRP Publication 82 (ICRP, 1999) and the IAEA documents (WS-R-3, WS-G-3.1) recommended the following principal provisions with respect to the remediation situation:

- Dose limits cannot be used, because they cannot be observed in each case.
- Criteria for the human protection – justification and optimization of intervention.
- Generalized criterion of non-intervention – non-exceeding annual effective dose to the public due to all environmental sources (including background) is 10 mSv. Intervention may be grounded above this level.

To develop the above mentioned provisions, the ICRP Publication 103 refuses the "intervention" concept and introduces the reference dose or risk level. The reference level is such level, above which radiation exposure is impermissible, and so optimized protective measures are to be taken, including those at dose below the reference level. The regulatory body establishes the reference level for the specific or typical situation. In case of the existing exposure situation, the reference level of annual effective dose within the range from 1 mSv to 20 mSv is proposed to be established. Higher levels are proposed to be applied in more large-scale situations.

Thus, in addition to review of actual Russian regulatory document (here we mean reasonability of introduction of three exposure situations instead practice and intervention available now), some special criteria of the environmental remediation are to be developed.

Conclusions

1. The ICRP Publication 103 has been translated into Russian.
2. There are no stricter hygienic regulations in ICRP Publication 103 in comparison with those established in Russia, but there are some new conceptual provisions and concepts in it.

3. The safety levels reached due to the optimization principle application in the field of radiation safety and protection at the Russian NPPs and at the areas of their potential impact on the public and environment can be recognized as quite good.
4. The actual Russian radiation protection system is not arranged enough in its documentation basis and differs from the international one, in particular, in inadequate application of dose limit for the planned exposure situations (1 mSv/year) under conditions of emergency and existing exposure situations. Introduction of three exposure situations in the Russian regulation can improve this situation.
5. Recommendations are as follows: 1) To introduce a chapter on radiation protection of the public in the existing (prolonged) exposure situation into the national radiation safety standards and put it in harmony with the international radiation protection system; 2) To promote development of the international connections on studying of good experience in the radiation protection is necessary.

Abstract
A working group of HERCA has reviewed a large variety of examples of stakeholder involvements in medical practices which have already been performed in the member states and in addition looked at possible stakeholder involvements for the future, where a leading role of the national radiation protection authority is needed. The authorities should take the lead to bring stakeholders together to solve today's challenge in a concerted manner. These challenges appear where different professional groups work together on new technologies and/or new processes. Examples can be found in radiation therapy (image guided radiotherapy, dealing with accidents), in nuclear medicine (PET/SPECT-CT), in radiology (going digital, patient dose optimization), screening, the complex of problems through self referral and many others.

Introduction
In diagnostic radiology radiation is used to form an image of a plane or volume, or in nuclear medicine to visualize the function of an organ, and the radiation dose to the patient is just an unwanted side effect. In radiation therapy radiation as such is used to control cancer growth for cure or palliation. We have seen a tremendous technological development both in diagnostic and therapeutic applications of radiation. This growth and development is mainly of great benefit to the patients as individuals and to the society as a whole, but it also causes a strong increase of medical radiation exposure of the population which is of concert for radiation protection reasons. Only a close collaboration between all the stakeholders will allow this dose increase to be understood and kept under control.

Material and methods

The Heads of the European Radiation Control Authorities HERCA have first met in 2007 to discuss the common problems in radiation protection in Europe. 22 member states of the European Union and Norway and Switzerland identified the key issues which needed to be worked on. 5 main topics have been chosen to be looked at more closely in therefore created working groups. The task of Working Group 5 was to analyse the situation of stakeholder involvement in medical practices and give recommendations to national radiation protection authorities of how to identify the relevant stakeholders and how to proceed in involving them in radiation protection issues.

Results

The working group has reviewed a large variety of examples of stakeholder involvements which have already been performed in the member states (see Annex A) and in addition had look on possible stakeholder involvements for the future, where a leading role of the national radiation protection authority is needed.

The participating experts from HERCA member states have discussed the role of the authority in the involvement of stakeholders, have tried to identify relevant parties and to make some recommendations and to give examples of stakeholder involvement.

Definition and identification of stakeholders in medical practices

A stakeholder is someone who is (or should be) entitled to have an interest in radiation protection in medicine. To give a better overview, stakeholders are split into three groups *Justification, Optimization* and *General*.

Justification	• Medical doctors, medical societies and associations • Patients, patient organizations • Legislator
Optimization	• Medical doctors, medical physicists, technicians, other medical staff • Manufacturers and suppliers, staff undertaking installation and maintenance • Hospital directors
General	• Patients and their relatives • Patient ombudsman • members of the public • Insurance and social security • Legislator and health authorities

In the group *Justification* the stakeholders are involved in the process before a prescription has been issued by the medical doctor. Subsequently in the group *Optimization*, the stakeholders are carrying out the procedure.

The overall goals of stakeholders involvement

The national authorities competent in the field of in radiation protection should take the lead in bringing the different stakeholders together (stakeholder platform), analyzing the different interests and needs (stakeholder analysis) and motivate them to participate actively in optimizing medical radiation exposure (stakeholder participation).

The goals, which should be achieved by this process, are summarized in the following table:

Justification	• Specialized Medical doctors in charge of radiotherapy, radiology, nuclear medicine, etc are aware of the principle of justification (ICRP Publication 103 ….) • Specialists and generalists use the guidelines "good practices" (Guide du bon usage, Orientierungshilfe, EU referral criteria RP 118…) • Medical doctors and dentists (generalist) are aware of the justification of radiological examination • Patients are informed of the risks and the benefits of the procedure
Optimization	For the application of the principle of optimization, medical doctors in charge of radiotherapy, radiology and nuclear medicine, physicists and technicians are in charge of : • State-of-the-art technical equipment, quality assurance and maintenance • Optimized procedure for the realization of the examination (i.e. diagnostic reference levels, handbooks of good practice…) • Regularly trained staff • Defined responsibilities in the process (rights and duties) • Resources for radiation protection in all radiological procedures • Feedback culture (safety information system, continuous improvement, self auditing….)
General	• Manufacturers care about radiation protection • Awareness and knowledge in radiation protection (public, patients …) • Well-accepted authorities, who inform, coach and train all users…. • organizations preparing standards are taking care of radiation protection

Discussion

There is no doubt that important benefits can result from interactions between stakeholders and regulatory authorities.

These interactions can vary significantly from one situation to another. Their importance, intensity, purpose and expected outcome depend on well-known factors (benefits, detriments, risks – real as well as perceived). Associated circumstances (e.g. sense of urgency, potential crisis situation, current political engagements of governments) also affect the interactions, as well as socio-economical factors (e.g. need for improved business conditions). In addition, the expertise and resources available to the authorities, as well as the potential need for improved regulatory framework, play a role on the interactions with the stakeholders.

The purposes and expected outcomes of the involvement can be any of these: information exchange, development of tools (books, guidelines, training), advice and expertise, recommendations, legal texts and instruments, direct or indirect involvement in decision making as well as in activities related to authorization and control, prevention of incidents and accidents, preparedness, and response.

The WG agrees with the recommendations concerning stakeholder involvement formulated during the 10th European ALARA Network Workshop:

"Regulatory bodies have an important role to play in facilitating stakeholder involvement, and are encouraged to establish mechanisms for communicating with relevant parties and encouraging their participation. This may for example include seminars, consultation exercises, public meetings, internet forums, etc."

- Stakeholders should be consulted as widely as possible, whenever acceptable (there may be security related restrictions for some types of interactions) and manageable. Authorities should try to be clear on the purpose of the involvement and on the output expected from the interaction (transparency).
- Authorities should try whenever possible to build structural mechanisms for consultation with stakeholders.

One could find several kinds of roles for radiation protection authority when working with stakeholders and getting their involvement to reach an appropriate level of safety. Roles could be for example:

1. Forerunner

The national authorities competent in the field of in radiation protection should initiate, co-ordinate and monitor safety related research and development. The results of the research will support its regulatory functions and also stakeholders in using justified and optimized methods and equipment and to apply and adopt optimized work procedures.

The Radiation protection authority could promote research projects where stakeholders are partners in trying to achieve common goal. The authority could suggest ideas for topics to be investigated and initiate and motivate research projects which will be performed by research groups, universities and research institutions as well. Also small scale studies together with educational institutes and students are valuable.

Especially in the medical sector the opinion leaders are in universities, major hospitals, and educational institutes and in specialized research institutes. Co-operation with these stakeholders will provide a solid base for further work in radiation protection and will grant credibility for radiation protection authority in further actions.

Specialists of the Radiation protection authority should participate in international congresses to get understanding of the newest applications of ionizing radiation.

One has to investigate the needs of education and training together with the users of radiation in discussions and meetings with different kind of specialists and organizations. Surveys together with educational organizations of the needs are valuable as well. Based on this information Radiation protection authority could propose further education for radiation users at universities and training institutions.

2. Rule maker

According to IAEA GR-S-1 "In order to fulfil its statutory obligations, the Regulatory authority shall define policies, safety principles and associated criteria as a basis for regulatory actions". To get commitment from stakeholders for the regulation it is useful to prepare basic regulations using consultation with stakeholders. Sometimes pre-stage in preparing regulation is to perform preliminary study or research project to get better understanding of the status quo. Here you could involve some key stakeholders in the work. The results of the projects could serve as basic information for the foundation of the regulation.

Many times it is practical to invite experts from professional societies to join in to the working groups to prepare specific regulatory documents. Furthermore it is important to call for comments from all involved stakeholders on the drafts of the documents and take these opinions into account in the final version, if appropriate from the point of view of radiation protection.

3. Advisor

Radiation protection authority shall provide guidance to the operator on developing and presenting safety assessments or any other required safety related information. This is according to the IAEA GS-R-1. It is important to make surveys which kind of guidance is needed by license holders and specialists in the field. This is also to get a better mutual understanding of the common goals in radiation protection and to prepare proper guidance. When preparing such guidance and information it is useful to prepare guidance together with the specialists working in actual practices.

4. Communicator

Radiation protection authority shall introduce the regulation and guides for all radiation users (organizations, experts) and involved parties. All radiation users should have information on new regulations and guides soonest possible. Good practice is to mail this information based on the registers of the stakeholders if any. Good service for stake-holders is to provide all kind of general information on radiation protection for stakeholders on the www-pages of the authority.

An effective method is to organize regular discussions and meetings on current topics with different specialists and organizations.

How to communicate risk is a particular challenge, it should be prepared with other stake holders like medical doctor organizations, hospital directors, patient organizations, press bodies. Communicate the risk in advance (booklet), communicate the risk after an incident/accident (info unit important). In some cases (e.g. contamination, permanent source implants), communication should not be limited to explaining what the risk is, but should allow people to contribute to radiation protection (how to behave in order to limit exposure of oneself and/or others and/or environment).

5. Supervisor

Radiation protection authority should have high reputation in its work. To reach this goal authority should have competent experts in all applications of radiation practices with good understanding of radiation protection. The authority should inform all stakeholders of its activities transparently to get a well known status among users of radiation. When recognized status is reached the supervisory work will be more effective and stakeholders will be cooperative to reach optimal radiation protection.

6. Connection to other Health authorities

Radiation protection authority should have a strong connection to health authorities; they are a very important stakeholder. Health authorities obviously have responsibilities for all aspects of health care provision; while the radiation protection authorities have selected duties. There are many different national approaches. In some countries the health authorities are giving expert advice on radiobiology, where in others the competence is within the radiation protection authority. In some countries the responsibility for staff protection and patient protection may be in different authorities.

Where is the justification question set in the national regulatory framework; In the RP legislation, or in a more generic legislation? For example, are other health authorities involved in the justification question? For example breast screening program in Finland, the justification question is judged in a medical – ethical trial.

Examples of areas where other health authorities are involved in addition to the radiation protection authority:

- Justification
- Patient safety
- How patient data are stored, frequency of examinations and treatments, dose data, and other information needed for surveys
- Financing
- Following up of epidemiological data
- International standards

7. Network creator

Information transfer between stakeholders is an important part of a learning process in radiation protection. Users of radiation can learn good practices from each other and also learn from the mistakes of other stakeholders. Radiation protection authority could activate this information transfer by creating discussion forums for example in regular meetings with target groups. Discussion forums on web pages might be useful as well. Data banks of incidents and accidents could be created and made available through the network.

8. Trainer

Radiation protection authority could act as a trainer of trainers on special topics. In this meaning one could educate and train some opinion leaders of stakeholders who can distribute the information on radiation effects, radiation protection and regulation and guides among other specialists.

9. Role to verify and improve radiation protection

Radiation protection authority should verify from time to time the situation at the particular point of time for example by making surveys with stakeholder groups on special topics related to radiation protection. The results of such verification offer useful material to create fruitful discussion with stakeholders in the meetings to improve the process of radiation protection.

Conclusions

The progressively but steadily increasing exposure to ionizing radiation associated with medical applications should be specifically addressed. The lack of awareness of the general public and some medical professions in relation to medical exposures needs to be addressed. Consultations with all stakeholders (medical devices manufacturers, medical staff, hospital managers, structures involved in the organization of national health systems, patients) should be organized in order to address this complex problem and try to find appropriate solutions.

Concerning medical devices, consultations with manufacturers and suppliers should be established to address the radiation protection issue directly at the source. Additionally, a discussion (on a national or international level), allowing better understanding and more transparency concerning the EC specifications for medical devices, should be initiated with the responsible EC structure.

Consultations concerning the notification of medical events and conditions for reporting those events to the medical community and the public should be further developed (medical staff, hospital managers, structures involved in the organization of national health systems, patients).

Health detriment and radiation protection management

Schneider, Thierry; Lochard, Jacques; Vaillant, Ludovic
CEPN, FRANCE

Abstract

Introduced in 1977 by ICRP, the concept of health detriment is a complex construction based on scientific information and on expert judgement. It gives an estimate of the total harm to health to individuals and their descendants as a result of an exposure to radiation, assuming a linear-non-threshold dose-effect relationship. It allows to compare risks induced by different types of radiation exposure situations and to put into perspective with other health risks.

Understanding its meaning is not straightforward, even for experts. It is in fact necessary to analyse its components and associated value judgements, and their evolution to catch this meaning. In addition, the application of this concept for different exposure situations is still a matter of debates in the radiation protection community. For instance: Does it represent a potential number of health effects for an exposed population? Does it give an estimate of the probability of occurrence of a radiation-induced effect for an individual?

The aim of this presentation is to recall the basis of this concept and its evolution and to discuss the key stakes regarding its usefulness in the radiation protection system. For instance, for occupational exposures, although the radiation detriment is no more the central indicator for establishing exposure limits, it is still quite useful to compare the risk associated with these limits with the levels of risk associated with exposure to different carcinogens and with occupational injuries. In addition, it is a key element for addressing the probability of causation for occupational diseases associated with ionizing radiation. Its use is also a matter of debate regarding radioactive waste management or environmental exposures, for which the main concern refers to exposure of future generations and large populations. Nevertheless, this concept is useful in this domain for assessing the level of protection on the basis of the current radiological protection criteria.

Norwegian strategy to fulfil the OSPAR Radioactive Substances Strategy objectives

Natvig, Henning; Nilsen, Mette
Norwegian Radiation Protection Authority, NORWAY

Abstract

At the 1998 Ministerial meeting of the OSPAR Commission, the Contracting Parties agreed to a strategy with regard to radioactive substances, the OSPAR Radioactive Substances Strategy (RSS). It states that the ultimate aim is: substantial and progressive reductions in discharges and to achieve concentrations in the environment near background values for naturally occurring radioactive substances and close to zero for artificial radioactive substances by 2020. Several of the Contracting Parties are far from meeting the 2020 objective. The oil and gas industry represent a substantial part of the TENORM-discharges to the North-East-Atlantic. A substantial part of the discharges come from the Norwegian sector. The Norwegian Radiation Protection Authority (NRPA) regulates the oil and gas industry on the Norwegian sector. NRPA uses a variety of means to contribute to fulfil the RSS objectives by 2020. NRPA collaborate with the competent authorities from the other oil and gas producing countries in the North Sea area to work towards a more harmonized regulation. The Norwegian zero discharge goal for the oil and gas industries has been extended to contain radioactivity, it is also recommended to perform a new assessment of injection of produced water on the two offshore platforms with the highest discharges of radioactive substances. We work towards a strengthened regulation of radioactive waste and discharges by a closer collaboration with the Norwegian Climate and Pollution Agency (former Norwegian Pollution Control Authority). As part of this work the legislation is currently under revision, and a new regulation based on the Pollution Control act is proposed. It is important to continue and develop the national monitoring programme of the industry, as well as investigate possible cleaning technologies and initiate cooperation between industry, regulators and researchers. Norway has at present special focus on TENORM. One of the first repositories for final storage of TENORM waste from the oil and gas industry was commissioned in 2008.

Introduction

Radioactive substances are used or found in several research institutions, hospitals and industries in Norway and on the Norwegian Continental Shelf. Some of these are well known such as the oil and gas industry on the Continental Shelf and in the research reactors at Kjeller and in Halden, the latest is part of an OECD project called OECD

Halden Reactor Proctect, as well as the use in medical diagnostic and therapy in hospitals. In addition NRPA has started a mapping of other industries where there can be discharges of radioactive substances with waste water or generating of radioactive waste of any category as part of the production. The discharges from the oil and gas installations on the Continental Shelf are far the largest radioactive discharges in Norway.

OSPAR

The OSPAR Convention for the Protection of the Marine Environment of the North East Atlantic was agreed in 1992. Countries that either have a North East Atlantic coast or discharge into the OSPAR maritime area via their rivers are Contracting Parties to the Convention. The North Sea including Skagerak, the Norwegian Sea and the Barents Sea are all within the area covered by the Convention. Totally 15 countries and the EU commission have ratified the Convention.

At the 1998 Ministerial meeting of the OSPAR Commission, the Contracting Parties agreed a strategy with regard to radioactive substances (see Box 1).

Box 1: OSPAR Radioactive Substances Strategy (RSS)*

Overall objective:
To prevent pollution of the maritime area, as defined under the Convention, from ionising radiation, through progressive and substantial reductions of discharges, emissions and losses of radioactive substances. The ultimate aim is to achieve concentrations in the environment near background values for naturally accruing radioactive substances and close to zero for artificial radioactive substances. In achieving this objective, the following issues should, inter alia, be taken into account:

- legitimate uses of the sea
- technical feasibility
- radiological impacts to man and biota

Intermediate objective (2020)
By the year 2020, the OSPAR Commission will ensure that the discharges, emissions and losses of radioactive substances are reduced to levels where the additional concentrations in the marine environment above historical levels, resulting from such discharges, emissions and losses, are close to zero.

* Radioactive Substance Strategy of the OSPAR Commission for the Protection of the Marine Environment of the North East Atlantic, 1998.

Norwegian Environmental Policy and Goals

In the Report No 21 (2004 – 2005) to the Storting "The Government's Environmental Policy and the State of the Environment in Norway" one of the national goals says that discharges of radioactive materials from Norwegian sources shall be limited to levels that do not have an adverse effect on the natural environment.

The Report No 8 (2005 – 2006) to the Storting "Integrated Management of the Marine Environment of the Barents Sea and the Sea Areas off Lofoten Islands" states that the targets for limiting inputs and concentrations of radioactive substances in the Barents-Lofoten area are.

> *The environmental concentrations of hazardous and radioactive substances will not exceed the background levels for naturally occurring substances and will be close to zero for man made synthetic substances. Releases and inputs of hazardous or radioactive substances from activity in the area will not cause these levels to exceed.*

In the "Integrated Management of the Marine Environment of the Norwegian Sea", Report No 37 (2008 – 2009) to the Storting is an analogous target is expressed.

With regard to radioactive substances are the goal expressed in these two Reports to the Storting more or less identical with the objective of the OSPAR Strategy. In the report to the Storting 26 (2006 – 2007) "The Government's Environmental Policy and the State of the Environment in Norway" it is referred to the Norwegian obligation to OSPAR, expressed as.

> *As a member of OSPAR Norway have the obligation to prevent pollution of the maritime area from ionising radiation through progressive and substantial reductions of discharges. The goal is that the level of naturally occurring radioactive substances shall be close to the background levels. Norway shall as part in OSPAR before 2020 secure that the discharges of radioactive substances be reduced to levels that contribute to concentrations in the environment beyond historical levels as a result of such discharges are near to zero.*

In the same Report to the Storting the Norwegian government also states that there should be a mapping of discharges, supplies and levels of radioactive materials in the Norwegian Coastal Current and the nearest maritime areas from both oil and gas activities and other sources, and that a need for strengthening of the knowledge of the consequences of the discharges were needed.

Norwegians efforts to reducing the discharges

Acts and regulations

The Norwegian radiation Protection Authority (NRPA) is the competent national authority in the field of radiation protection and nuclear safety in Norway. The NRPA administers two acts along with associated regulations:

- Act of Nuclear Energy Activities (No. 28 of 12 May 1972)
- Act of Radiation Protection and Use of Radiation (No. 36 of 12 May 2000)

- Regulations No.568 of 9 May 2003 on Application of the Act on Radiation Protection and Use of Radiation on Svalbard and Jan Mayen
- Regulation No 1362 of 21 November on Radiation Protection and Use of Radiation (Radiation Protection Regulations)

In addition the NRPA's preparedness mandate is laid down in a Royal Decree of 17 February 2006

When the Norwegian radiation protection legislation was revised at the end of the 1990s, resulting in the Radiation Protection Act of 2000, it was built to a large extent on the prevailing international recommendations. The main focus of radiation protection has traditionally been the protection of man from harmful radiation doses, which also was the main focus in the Radiation Protection Law. However, the Radiation Protection Act also embodied increased environmental awareness of radiation by including the environment in the purpose of the law alongside the goal of preventing the harmful effects of radiation on human health. The Radiation Protection Regulations, adopted pursuant to the Radiation Protection Act, went into effect in 2004. It has special provisions concerning radioactive emissions and waste. Even though the regulations are limited it includes requirements for approval of emissions of radioactive substances, waste facilities, and the export and import of radioactive waste. The Ministry of the Environment was authorised to function as the administrative appeal body under these provisions in 2006.

In recent years, an increased awareness of radiation as an environmental problem has gradually grown both in the international co-operation in the radiation area and in Norway. With respect to the relation between humans and environmental protection, the presumption has long been that as long as people are protected, then the environment is protected. An expression of this prevailing perception is given in the recommendations from International organisations like the Commission on Radiological Protection (ICRP), the International Atomic Energy Agency (IAEA) and the Nuclear Energy Agency (NEA). Corresponding perceptions are also found in EU documents.

As a part of the work of strengthening the radiation protection administration for the external environment, the Norwegian Radiation Protection Authority, Climate and Pollution Agency, the Ministry of Health and Care Services and the Ministry of the Environment have performed a review of the challenges of regulation of radioactive substances in the environment and the roles of the current bodies of regulations. There is a need for a more comprehensive set of regulations than the present regulations on protection of the environment. To meet these challenges a new radiation protection regulation is put forward. The regulation will be under and pursuance of Pollution Control Act. This regulation will result in a regulation of radioactive pollution will be based upon fundamental environmental principles such as prevention and the precautionary principle, the polluter pays and the best possible technologies. This new regulation is proposed to be put into force 1 January 2011.

The zero discharge project

The objective of zero discharges to sea of potentially environmentally hazardous substances from the petroleum activities was established in the Report No. 58 (1997 – 98) to the Storting "Environmental policy for a sustainable development". Based on the petroleum activities' substantial and increasing discharges to sea, the authorities identified a need to formulate a strategic, general objective that could contribute to reducing the discharges beyond that which followed from national and international objectives for reduction of oil and chemical discharges

In the Report No.26 (2006-2007) to the Storting the Norwegian Government announced that in 2009 evaluation of the progress of this project and whether further measures were needed to ensure that the zero discharge targets were achieved for oil and naturally-occurring substances discharged with produced water from the offshore petroleum industry. The Government also wanted to evaluate the need of efforts to reduce the discharges of naturally occurring radioactive materials (TENORM) from the petroleum industry.

To establish a basis to answer this questions the Climate and Pollution Agency and the Norwegian Petroleum Directorate were asked by the Norwegian Ministry of Environment and the Norwegian Ministry of Oil and Energy in 2008 to an evaluation of the above mentioned tasks. This was carried out in cooperation with the Norwegian Radiation Protection Authority. Data prognosis of discharges from the oil and gas installations on the Norwegian Continental shelf were collected from the companies together with estimates of costs for injection of produced water as an alternative to discharges. In addition an evaluation of technical ways to accomplish the injection and The influence of the marine environment of the discharges with special focus on the most vulnerably areas in the North Sea and the Norwegian Sea was also considered together with an evaluation of technical challenges of injection of produced water.

So far no harmful influence on living species in the marine environment can directly be related to discharges of radioactive substances with produced water on the Norwegian Continental Shelf. There is a need for more knowledge of long time effects. It is, however, known that radioactive substances have similar properties and potential environment-related harmful effects such as heavy metals and other environmental toxins.

The concentrations of radioactive substances in produced water can vary considerably between the field and these together with the great variation in the volume of produced water discharged will result in a great variation of the amount of radioactive materials discharged from the fields. The two installations Troll B and Troll C in the northern part of the North Sea are among the installations with the highest discharges of produced water. There is also relative high concentration of radioactive substances in the water discharged from these installations resulting in large discharge of radioactive materials from this field, see figure 1. The discharged radioactive substances from the Troll field count for about 40 % of the total Norwegian discharges.

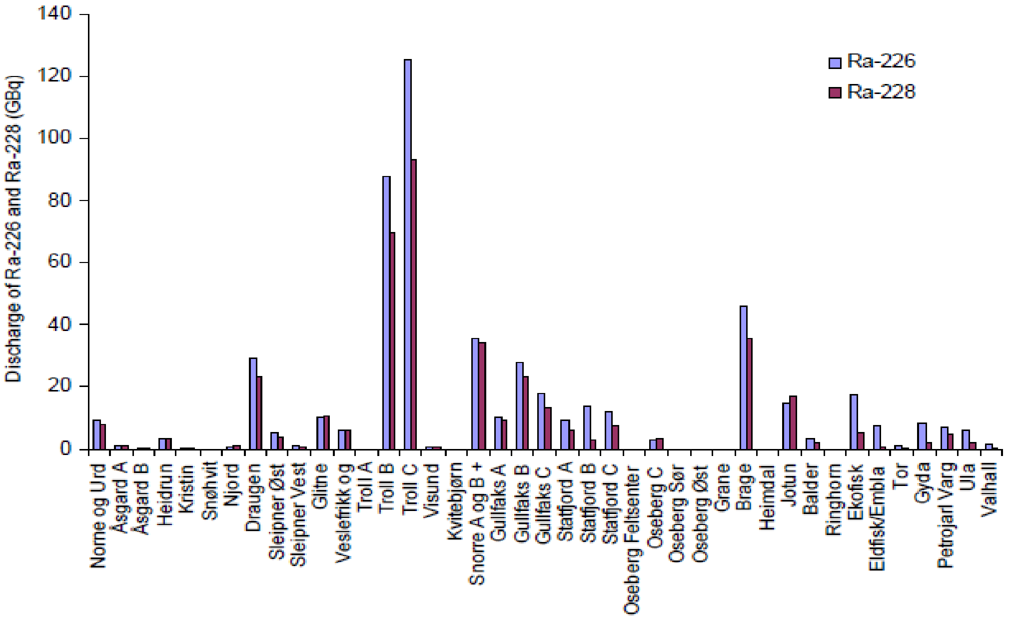

Fig. 1. Estimated discharged activity of ^{226}Ra and ^{228}Ra from Norwegian oil and gas fields in 2007 (NRPA 2009).

Based on the above mentioned evaluations two advices regarding radioactivity in the zero discharge project were given to the Ministry of Environment:

- to include radioactivity (TENORM) in the zero discharges target
- carry out new evaluations of the possibility of injection of produced water from the Troll B and C platforms due to the large amount discharged

Reporting

All activities that hold a permit to discharge radioactive substances to the environment have an obligation to report on the discharges from the activities every year. The reports should include information of the complete discharges of the various nuclides that have been discharges and also the concentration of the nuclides. For land based activities the recipient to which the discharges take place be described too. A description of how the use of best available technology is implemented as well as treatment of radioactive materials before discharges, to reduce the concentration of radioactive substances, should also be included.

Monitoring

National Programme

The Norwegian Radiation Protection Authority has since 1999 had a program for monitoring of radioactivity in the marine environment, both in coastal areas and the open sea (Radioactivity in the Marine Environment, RAME). Samples of seawater, sediments and biota are collected every third year in the North Sea including Skagerak, The Norwegian Sea and the Barents Sea. That is samples are collected from one of the areas each year. In addition samples are collected at permanent coastal stations, at Bear Island, Hopen and Svalbard, and in selected Norwegian fjords. The samples are analysed for both naturally occurring radioactive substances like radium and for some dedicated substances from earlier tests of nuclear weapons in the 1950ies and –60ies, from the accident of Chernobyl and discharges from the reprocessing facility at Sellafield in UK and Cap de La Hauge in France.

In addition the Climate and Pollution Agency is coordinating a task to establish a long-term monitoring programme for the Norwegian maritime areas. The main purpose of this programme is:

- Calculation of the entry of environmental harmful substances including radioactive materials from various sources, divided in up to 12 regions
- Calculation of transport and concentration of these substances in the marine area
- Monitoring of environmental harmful substances in biota and sediments

Monitoring around oil and gas installations on the Norwegian Continental Shelf

The oil and gas companies operating on the Norwegian Continental Shelf have an obligation to carry out monitoring of the water column and the sediments in the neighbourhood of their installations. This monitoring shall give an overview of the environmental conditions and map the development and trends in the environment around the oil and gas installations. The Norwegian Shelf is divided in several regions, see figure 2. Surveys of taking sediment samples is carried out in each region every third year. For the water column the monitoring consist of two parts; condition monitoring in which samples of fish are analysed every third year, and the other part which is being developed is an effect study and the frequency of monitoring near by the different installations is not yet decided. In addition to demonstrate trends the results are the basis for expectations for future developments. In the later years the monitoring programme has included analyses of sediment samples for radioactivity for a few stations.

A process to develop the monitoring of radioactivity around the oil and gas installations has to been started and for 2010 the number of stations where sediment samples will be taken is expanded compared with the previous years.

The results from the monitoring will, among other things, be used for:

- evaluation of the risk for environmental damage and ecological effects
- verification of models for calculating the environmental risk as a function of existing and expected discharge from the offshore industry.
- verification of laboratory based research

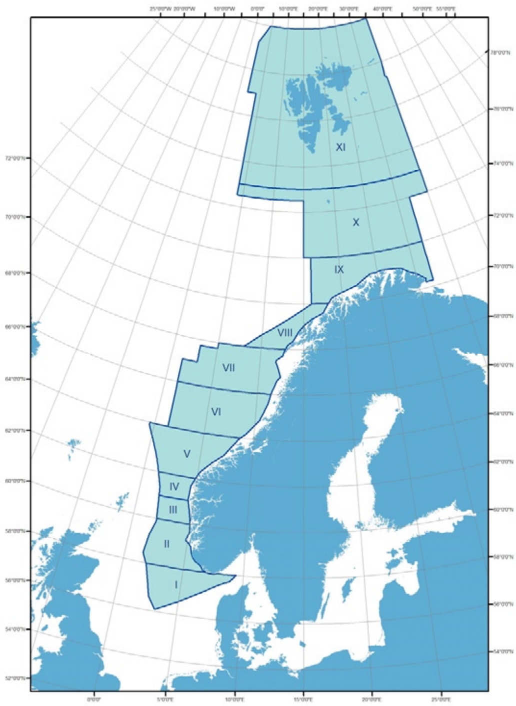

Fig 2. Overview of regions for monitoring of sediments on the Norwegian Continental Shelf.

Regulation of discharges

Generally

All approvals/permissions issued to companies who discharge radioactive substances instruct the companies to examine all their procedures and routines carefully to identify any measure to reduce their discharges of radioactive substances. The results of such an examination should be reported to NRPA within a certain deadline.

NRPA should carry out a total review of all approvals/permissions to secure that the discharges limits are in according to the existing discharges and that they does not open up for significant increase in the future.

If relevant, request for environmental monitoring is a part of the approvals/ permissions, and the results of this monitoring shall be reported to NRPA within a certain deadline.

All approvals/permissions to discharges should contain requests for use of best available technology, to avoid discharges if possible or keep the discharges as low as possible.

Research nuclear reactors

The company responsible for the two Norwegian research reactors (IFE) should be requested to carry out risk analysis of the discharges for both the facility in Halden and at Kjeller. As a part of new discharge permits IFE has to evaluate potential measures to reduce the discharges and by that reduce the radiation doses to the public as well as the environment. In a new discharge permit discharge limits based on the activity of the various nuclides has to be established. As the only Norwegian company IFE have discharge limits given in dose limits, other companies have discharge limits given in nuclide activity.

Oil and gas industry

New fields shall, as a general rule, be developed with the objective of zero discharges of produced water containing radioactive substances under normal operations. For new fields that are developed with a tie in to existing installations discharges of produced water should only be allowed under normal operation if it is needed of serious safety, technical economic or environmental reasons.

On fields in production where injection of produced water is a existing solution it is important that the amount of produced water is kept at the prevailing level or is increased if there is no serious technical, safety, environmental or economical reasons for reducing or stop the injection.

Development of technology for reduce the content of radioactivity in the produced water has to be carried out in a cooperation of operating companies on the Norwegian Continental Shelf, the suppliers of purify technology and research institutions.

Hospitals, universities and research institutions

A joint evaluation of all discharges of radioactive substances from these kinds of institutions to map doses to people and the environment should be carried out. Based on the results of such an evaluation the requirement of further measures to reduce the discharges should be developed.

Waste management

All waste management companies should have a permit with requirements that contribute to as low discharges or other kind of radioactive pollution from the activities as possible. The new regulation mentioned earlier describes procedures for how to handle waste containing radioactive materials with various content of activity. For radioactive waste with origin offshore that have concentrations above certain limits should be sent to a special repository for final disposal. Also for waste with lower activity there are requirements for handling and final disposal.

Mapping of discharge from other sources

NRPA has started several projects to map any discharges or other kinds of radioactive pollution from mines other kinds of industry which may lead to radioactive pollution These projects form a basis for further development of regulations of radioactive waste management and discharge.

Auditing

Inspections and auditing are important to verify that the companies or other institutions that have approvals/permits for discharges or handling radioactive waste from NRPA are operating in conformity with the regulations and permits. These activities should be carried out in accordance to a yearly established plan.

The Integrated Management System – to ensure an overall safety

Ham, Ulla; Lorenz, Bernd
GNS – Gesellschaft für Nuklear-Service mbH, GERMANY

Abstract

GNS (**G**esellschaft für **N**uklear-**S**ervice mbH) as a subsidiary company of the German utilities E.ON, RWE, EnBW and Vattenfall is charged with ensuring the radioactive waste management for their nuclear facilities. Moreover GNS also provides its products and services to foreign customers.

"Safety first" – this is the key note of our vision to ensure sustainable radioactive waste management, meaning first of all the protection of people and the environment.

For this reason GNS has implemented an integrated management system strictly based on the requirements of the IAEA Safety Requirements GS-R-3 "The Management System for Facilities and Activities" /1/ in early 2009.

The management system integrates safety, health, environment protection, security, quality and also economic elements.

Our company policy including the respective guidelines reflects the top-ranking of a strong safety culture within our management system.

An adequate organisational structure and the process organisation needed to fulfil the purpose of our company have been implemented always keeping in mind the meeting of the safety requirements. Continuous improvement of the organisation and processes is guaranteed, especially regarding the further development of our safety culture.

The paper presented in this abstract is to demonstrate in which way an integrated management system, strictly following the requirements of the above mentioned IAEA Safety Requirements, has been developed and implemented. The structure and the daily working of such an integrated system will be illustrated, benefits and advantages will be presented as well as the experiences gained up to the moment. But also challenges that appeared when developing such an integrated system with the emphasis on "safety first" will be addressed.

Introduction

GNS (**G**esellschaft für **N**uklear-**S**ervice mbH) as a subsidiary company of the German utilities E.ON, RWE, EnBW and Vattenfall is charged with ensuring the radioactive waste management for their nuclear facilities. The activities range from the planning, design, manufacturing and services in the field of radioactive waste and nuclear casks to the handling, transport and interim storage of flasks/casks for irradiated fuel as well as the decommissioning/dismantling of nuclear plants or the preparation of final storage. Moreover GNS also provides its products and services to foreign customers.

All these activities are governed by GNS' vision
"as a centre of expertise of the German energy supply companies, to sustainably ensure nuclear waste management while maintaining the highest safety standards at competitive terms".

This vision has been specified by the company's policy taking into account nuclear safety and radiation protection, health and safety, quality and environment factors as well as by the related principles, the very first being "we are aware of our responsibility for safe and reliable waste management". It is supported by the "Code of Conduct" accepted by the management and the employees.

Irrespective of this voluntary commitment GNS also has to satisfy legal requirements, technical rules and standards, requirements defined in licences and approvals all intending to keep safety objectives as e. g. shielding, leak tightness, under criticality, prevention of release of radioactive substances and so to protect men and environment from adverse effects of radioactivity.

But – how to meet these requirements in day-to-day business? Could an adapted management system help? And if yes, what type of management system should it be?

Material and methods

Why an Integrated Management System?

An adapted management system has to provide an instrument to achieve a company's vision and objectives. It defines the organisational structure as well as the process organisation needed to fulfil the company's tasks and the respective requirements. It has to conform to the specific and accepted management rules and standards. It has to integrate already existing procedures and systems or modify them, where necessary, as the already existing quality management system and environmental system, both being accepted for a long time by third parties. And it has to be suitable for day-to-day business.

So GNS decided for the implementation of a – process related - **I**ntegrated **M**anagement **S**ystem (IMS) strictly following the requirements of GS-R-3 /1/ taking into account the requirements of radiation and environmental protection, occupational health and safety, quality control and cost-effectiveness in the planning, design and management of projects and processes. The IMS "covers all specifications, regulations and organisational aids that are provided within the company to manage the relevant tasks for the success of the company under controlled conditions and to control and improve the achievement of objectives" (KTA 1402 /2/). The IMS focuses on the processes that are important to the company.

But – which are the processes important to the company?

Process identification

In co-operation with the management board GNS processes have been identified, the ones classified as being the most important to the company's success as defined in the vision and the policy have then be divided up into management processes, main processes, supporting processes and "other processes".

Management processes are those necessary for the overall regulation of the company and are primarily dedicated directly to the Management Board.

The main processes cover all activities to fulfil the essential tasks in relation to the customers and to a decisive extent determine the economic performance of GNS and the importance of the company for the shareholders in accordance to GNS' vision and policy.

Supporting processes are necessary to achieve the goals of the main processes. The supporting processes provide the prerequisites for the working of the main processes or define procedures which apply to all processes in the same way.

"Other processes" focus on procedures and workflows for other overall elements of the IMS.

Organisation structure to ensure an Integrated Management System

The organisation structure of GNS always follows the essential tasks in relation to the customers and so the main processes. Where necessary the organisation structure has been adapted to other relevant processes within the context of establishing the IMS and therefore focussing on the different interested parties. Persons with special responsibility for elements or processes within the IMS have been authorised.

Documentation of the Integrated Management System

The structure and the processing of the IMS in principle have been described in the IMS Manual /3/. Details are fixed in supplementary documentation.

Results

The processes identified as the most important are shown in figure 1.

The requirements originating from the elements of the IMS (as there are radiation protection and nuclear safety, environmental protection, occupational health and safety, quality and cost-effectiveness) as well as the requirements and the satisfaction of the interested parties (customers as well as shareholders, authorities and experts, employees, suppliers and sub-contractors, members of society) basically determine GNS' processes.

The structure of the processes shown in figure 1 are described in detail in further process visualisations and completed by descriptions or instructions, where necessary. Stipulations are documented to guarantee the keeping of the requirements originating from the different aspects of the IMS. All documents are made available to all employees by an adequate database. The structure of the IMS documentation is shown in figure 2. This figure also demonstrates the correlation between the company's policy or external influences (legal requirements, licences, approvals etc.) and the management system of GNS.

The IMS as means to keep the company's policy and principles has been discussed and communicated to the management and the employees.

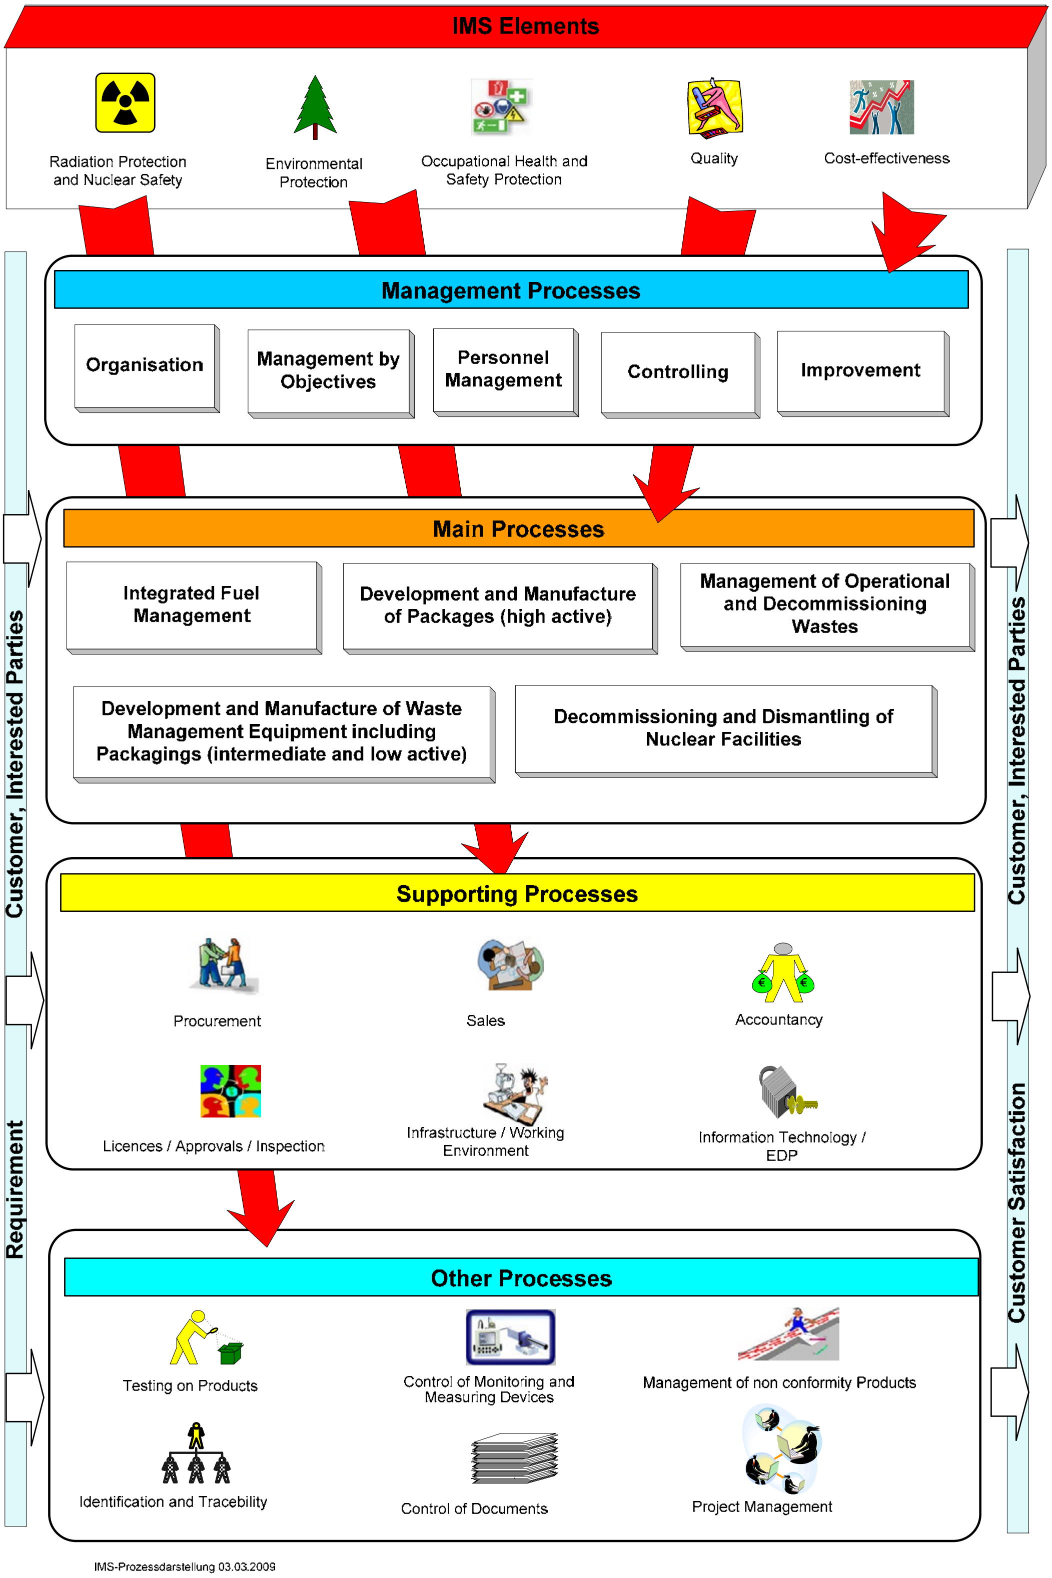

Fig. 1. Process Model of the Integrated Management System.

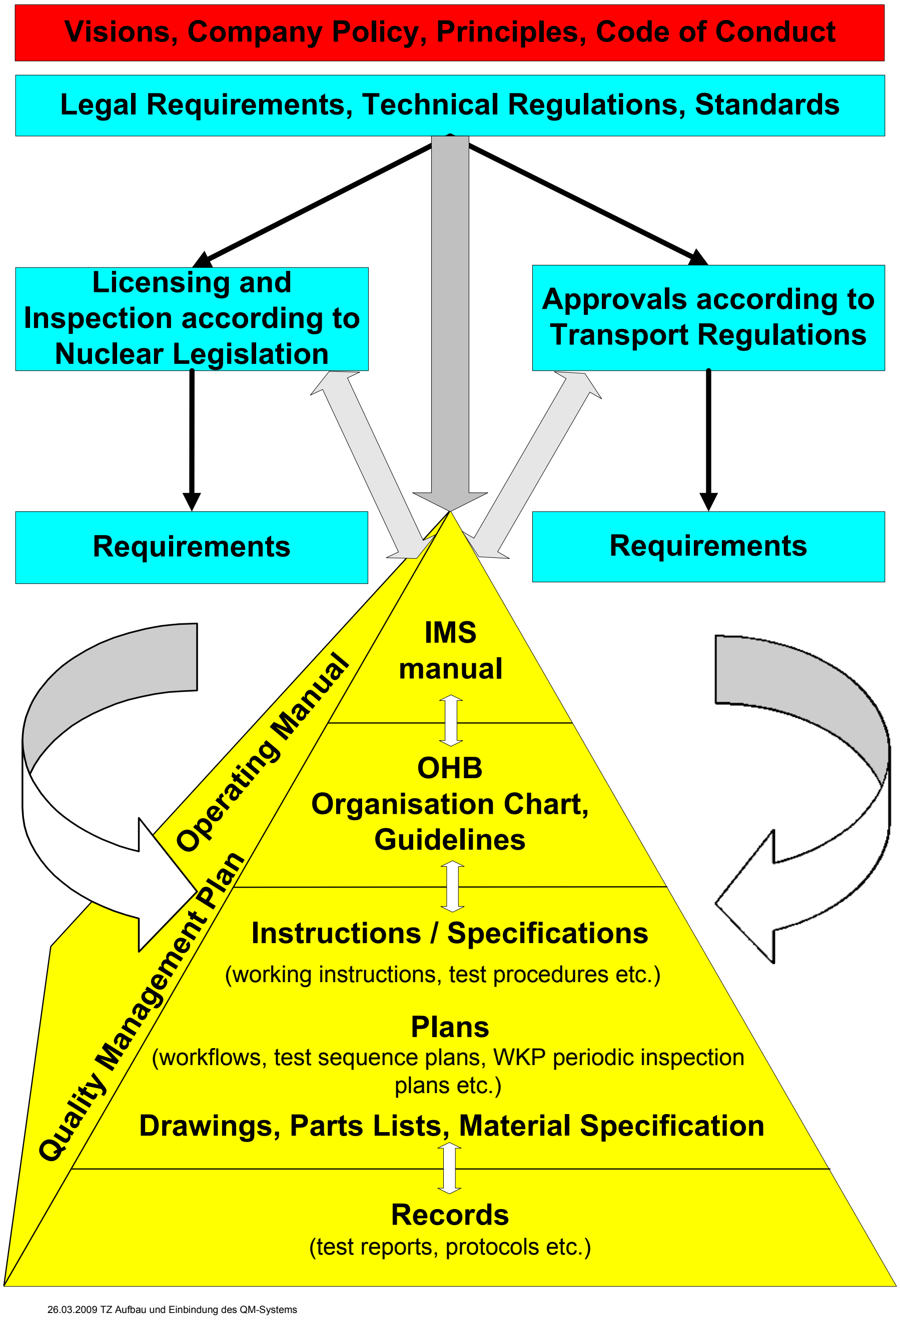

Fig. 2. Structure and Integration of the Management System.

Discussion

What did change regarding the day-to-day business when introducing the integrated management system as presented before?

The IMS is the result of an appropriate combination and continuous development of already existing systems (the quality or environment management system). The principles of the functioning of these systems, proven for a long time, have been adopted and, where necessary, modified according to experiences made. Only the factors systematically to be taken into account when planning, designing and managing processes and projects have been extended according to the company's policy and principles. This fact has supported a high acceptance of the IMS by the management and the employees.

Benefits and advantages of an IMS are highly detectable. The integration of all relevant aspects into the internal procedures has made clear the correlations between them. It has led to a higher sensitivity of the employees for the different requirements and their responsibility for fulfilling them within the frame of their process and project activities. This has also led to a continuous assessment and improvement of the implemented processes and so the management system. Moreover all organisational structures within GNS that could be concerned by a project or a process are involved in the respective planning, designing and managing.

Systematically taking into account all factors that may influence a process, a product or a project also lead to a higher legal certainty with regard to the legal requirements, standards and rules to be kept.

But – how to decide in case of contradictory requirements that originate from the different factors, e. g. aspects of cost-effectiveness versus those of environment protection requirements? The interests have to be balanced, but safety shall never be compromised. The optimum solution has to be found while fulfilling the legal requirements or such coming from licences or approvals. Due to the long lasting experience and practise with operating nuclear facilities or performing activities with radioactive material this spirit was already there in the whole company and its deliberately expression in the IMS Manual was not new for the staff.

Conclusions

The implementation of an integrated management system focussing on the processes important for the company with regard to its policy and principles has been successful. It has been accepted by the management and the employees. Nevertheless continuous sensitisation for as well as discussion and assessment of the needs of such a system as well as of the single factors is required and realised. So it will be and is integral part of continuous improvement.

Regarding the parts of quality management and environment management the IMS has already been accepted as appropriate system by the certification body. The IMS has also been accepted as an adequate system to manage safety (as synonym for quality within the nuclear industry) by third parties as authorities.

Possible implications of new Basic Safety Standards – a Swedish viewpoint

Hellström, Gunilla; Lund, Ingemar
Swedish Radiation Safety Authority, SE-171 16 Stockholm, SWEDEN

Abstract

The 2007 Recommendations of the International Commission on Radiological Protection (ICRP) [1] formally replaced their earlier 1990 Recommendations. The International Atomic Energy Agency and the European Commission presently update and review their *Basic Safety Standards* (BSS) [2, 3] within their frameworks, jurisdiction and international roles. The Swedish regulatory system will be influenced and steered by these emerging documents, especially by the Euratom BSS since these are binding for the Member States. With the proposals existing as of spring 2010 as starting point, we offer our view on the possible implications the new Standards will have on the radiation safety regulations of Sweden.

Introduction

Both the *International BSS* and the *Euratom BSS Directive* relate to the health protection of patients, workers and the public from the dangers of ionising radiation. The standards apply to any planned, existing or emergency exposure situation which involves a risk from exposure to ionising radiation.

The new *Standards* reflect changes introduced in ICRP 2007 main recommendations:

- Updating the radiation detriment based on latest scientific information of the biology and radiation exposure,
- Moving from a process-based protection approach (practices, interventions) to a situation-based approach, basing the system on type of exposure situations (planned, emergency, existing),
- Emphasis on the use of optimisation and dose constraints/reference values in all exposure situations, and
- More focus on the protection of the environment, developing a framework to demonstrate the radiological protection of the environment.

The fundamental principles of radiological protection: *Justification, Optimisation, Application of dose limits*; and the Commission's *dose limits* for effective dose and equivalent dose from all regulated sources in planned exposure situations are kept.

Furthermore, the new *Standards* reflect the societal needs, experience feed-back, and value judgements which have led to inclusion or updates of:

- Requirements on national/regional education, training, and competence,
- Security issues and concerns influence threat analysis and the national emergency planning,
- The justification and treatment of non-medical imaging,
- Regulation of planned or existing exposure situations involving naturally occurring radioactive materials (NORM) and radon in dwellings and workplaces.

Influence on Swedish legislation and regulations

In the following a non-exhaustive treatment of the possible influence of the *Standards* in Sweden is given. Focus is on the Euratom BSS Directive since it is binding for the EU member states.

Exposure Situations

The use of the three exposure situations to identify and determine the appropriate protection needs will influence the present legislation. The control of *planned exposure situations* (includes *practices*) is since earlier well developed and justification and optimisation were required in the Swedish regulation. The new concepts with existing and emergency exposure situations with different approaches to justification and the use of reference levels in the optimisation of protection must be reflected in new legislation. The choice between planned exposure situations and existing exposure situations is not always obvious for all activities which must be taken into account.

Optimisation of the protection and safety in new exposure situations.

For *emergency exposure situations* and *existing exposure situations*, optimisation shall be used to enhance protection. In practice, existing regulations and procedures for emergency preparedness, management of radon exposure and others, classified as existing exposures, will be reviewed. For emergency preparedness this will involve the planning phase (*optimised protection options* related to different events) or decision-making in emergency situations (release of contaminated land, radiation doses to public and emergency workers, etc.). In *existing exposure situations*, protective measures shall be optimised and not merely result in exposure levels below an action value. *Reference values* will have to be developed if they do not already exist. For *existing exposure situations*, any changes in regulatory approach will in Sweden often involve several authorities.

Graded Approach

Especially the *Euratom BSS Directive* now put emphasis on *a graded approach*. The protective measures should be more commensurate with the actual risk estimates. Though for many practices the Swedish authority uses a graded approach in licensing and supervision, it is more of praxis than based on legal documents. This means that a larger diversity of possible legislative and regulatory means must be introduced. In Sweden, the radiation protection legislation will have to introduce the concepts of notification and registration, the existing options of licensing or not licensing are not sufficient. Furthermore, the actual requirements must be proportional; the regulatory body must develop regulations and/or license conditions with a larger degree of versatility. The need for prioritising of practices and sources suitable for registration is obvious and also to more frequently exempt activities or products from control. The proposed general clearance levels are expected to be complemented by authorised release from practices based on the criteria for clearance given in the BSS.

Education and Qualified Experts

Education and good knowledge of sciences and the existing radiation protection philosophy is needed in radiation protection work. Sweden has, as an example, good education in radiation physics. Most of these students become medical physicists and a high number of these are employed in Swedish hospitals but some are employed as qualified experts in the nuclear industry or research institutions. The SSM has issued *general advices* in its Code of Status on suitable educations and competence for operational staff at nuclear facilities and for qualified radiation protection experts. Regulations exist connected to education for the medical and the nuclear sector as well as in many more specific activities (e.g. radiography). However, a general overview of existing advice and regulations must be done and in some cases more specific requirements could be needed. The Euratom BSS directive is now more precise in defining the concepts and tasks of *radiation protection experts* and *radiation protection officers* and this must be accounted for and amendments in regulations introduced as necessary. Another factor that makes education and training important is the on-going generational change at the licensees as well as at the authority.

Regulation of NORM

What earlier was specified as *work practices* in the existing *Euratom BSS Directive*, will now, after the member states have performed national investigations of the needs for regulation and control, require regulation. In many areas, such as radon in residences and work places, Sweden is since many years prepared with regulations. In other areas, changes in legislation and regulations are foreseen. The SSM is for the moment preparing regulations on how NORM material emerging in constructional projects (roads, buildings, tunnels etc…) should be handled if the quantities are smaller than 100 tonnes per year. Further regulatory activities are to be expected; one issue is how the requirement on how optimisation under *reference levels,* is ensured for such *existing exposure situations*.

Justification

An issue of major importance is the justification of activities involving radiation protection. The justification process in the medical field (overall justification of methods and justification of the individual examination, qualifications and responsibilities of referring medical practitioner, radiological medical practitioner) is an unceasing source of importance. The justification of consumer products (e.g. use of smoke detectors) is also a relevant topic and an even more "hot topic" is the justification of non-medical imaging in relation with legal or insurance purposes, theft detection, security or anti-smuggling purposes. The two *Basic Safety Standards* have different approaches to these issues but the common denominator is that such activities, should they occur, must be justified and regulated according to national praxis. The *idea* is to allow for justified use of non-medical imaging however applying strict regulation. How to deal with these complex situations should be further analysed and dealt with, purpose for purpose, situation for situation.

Conclusions

Sweden is well prepared for implementing the new requirements as formulated in the international radiation protection standards, especially the Euratom BSS Directive. Nevertheless quite some work will be needed to review and amend the existing legislation and regulatory framework. Emphasis will have to be put on the new requirements of optimisation in all exposure situations, applying a graded approach and the requirements of education and radiation protection experts. Regarding NORM, some regulations exist but more is foreseen. Finally, we would like to underline that the issue of justification needs emphasising, both in medical as well as in non-medical imaging.

IEC standards for measurement of environmental radiation

Voytchev, Miroslav[1]; Chiaro, Peter[2]
[1] IRSN/DSU/SERAC/BIREN, FRANCE
[2] Oak Ridge National Laboratory, USA

Abstract
This paper presents the IEC/SC 45B "Radiation Protection Instrumentation" and its 15 standards for measurement of environmental radiation that have been published or that are under development or revision. Two types of standards are considered: general standards for environmental measurement instrumentation and standards for airborne radioactivity measurements. The first type covers gamma radiation ratemeters for environmental monitoring (IEC 61017-1&2), equipment for monitoring of radionuclides in liquid effluents and surface waters (IEC 60861), mobile instrumentation for the measurement of photon and neutron radiation in the environment (IEC 62438) and in-situ photon spectrometry systems using a germanium detector (IEC 61275). The second types concerns equipment for continuous monitoring of radioactivity in gaseous effluents (IEC 60761 series), monitoring equipment of atmospheric radioactive iodines (IEC 61171) and radioactive aerosols (IEC 6117) in the environment, radon compensation for radioactive aerosol monitors (IEC 61578) and equipment for monitoring radioactive noble gases (IEC 62302) and airborne tritium (IEC 62303).

Introduction
Different international organizations (ICRP, ICRU, IAEA, ISO, IEC…) develop standards, recommendations, reports or other international documents concerning radiation protection and particularly for measurement of environmental radiation. This paper will present IEC, its Sub Committee 45B "Radiation protection instrumentation" and the scopes of the 15 international standards that IEC/SC 45B has developed for measurement of environmental radiation.

IEC/TC 45/SC 45B
The International Electrotechnical Commission (IEC) was founded in 1906 and is the leading global organization that prepares and publishes international standards for all electrical, electronic and related technologies. These standards serve as basis for national standardization, as references when drafting international tenders and contracts, and for conformity evaluation of instrumentation.

A total of 76 countries are now participating in the IEC family (56 members and 20 affiliates from developing countries). Each country participates through its national committee.

There are 179 Technical Committees (TC) and Subcommittees (SC), and more than 700 working groups (WG) that carry out the standardization work for IEC. The working groups are composed of representatives from all over the world who are experts in their own field and who are members of research and testing laboratories, regulatory agencies, academia, manufacturers, and user organizations.

Technical Committee 45 "Nuclear instrumentation" addresses standard development for instrumentation specific to nuclear applications. Its Sub Committee 45B "Radiation protection instrumentation" covers all the fields of radiation protection instrumentation for measurements under normal and accident conditions of external and internal individual exposure, to workers, the public and in the workplace and environment.

SC 45B has more than 200 experts from 22 participating and 12 observer countries. There are currently 47 publications in force and 14 projects are in development. The SC has liaisons with IAEA, ISO, ICRP and other organizations. Its standards are considered by CENELEC for adoption as European ones.

SC 45B currently has the following active working groups:

- B5: Measurement of environmental radiation;
- B8: Pocket active electronic dose equivalent and dose equivalent rate monitors;
- B9: Installed equipment for radiation and activity monitoring in nuclear facilities;
- B10: Radon and radon decay products measuring instruments;
- B14: Passive integrating dosimetry systems for monitoring of external radiation;
- B15: Illicit trafficking control instrumentation;

SC 45B, through its WGs B5 and B13, was charged with the development of international standards for environmental measurement instrumentation. WG B13 "Measurements of Airborne Radioactivity" was recently disbanded and its activity was transferred to WG B5.

General standards for environmental measurement instrumentation

The general standards for measurement of environmental radiation are developed within WG B5.

IEC 61017 "Portable, transportable or installed X or gamma radiation ratemeters for environmental monitoring"

The first standard to be considered is IEC 61017 "Portable, transportable or installed X or gamma radiation ratemeters for environmental monitoring" published in 1991. This standard has two parts: part 1 "Ratemeters" and Part 2 "Integrating assemblies". Being rather old, a revision of this standard is expected to start in 2010. Both parts will be combined into one standard covering transportable and installed assemblies. Portable (rate) meters are already covered by IEC 60846-1 (2009) developed within WG B8.

IEC 61017 is applicable to portable, transportable or installed assemblies intended to measure environmental air kerma rates from 30 nGy h^{-1} to 10 μGy h^{-1} due to X or gamma radiation of energy between at least 50 keV and 1.5 MeV. If the assembly is to be used to measure air kerma rates in the area surrounding a nuclear reactor producing 6 MeV photons it will be necessary to determine the response at that energy.

For the purpose of radiation protection these assemblies comprise at least a detection sub-assembly (e.g., ionization chamber, GM counter tube, scintillation detector, etc.), a measuring sub-assembly including a display device, which may be connected together either rigidly or by means of a flexible cable or incorporated into a single assembly. The installed assembly may also comprise a continuous recorder (e.g., chart or magnetic cassette recorder or telemetry equipment). The requirements of this standard are also applicable to assemblies that use integration of the ionization current, count-rate, etc. to enable a mean air kerma rate to be indicated or determined.

This standard does not apply to thermoluminescence dosemetry systems or other passive integrating devices and it does not provide for the measurement of beta radiation.

IEC 60861 "Equipment for monitoring of radionuclides in liquid effluents and surface waters"

IEC 60861 Ed. 2 (2006) defines technical requirements for equipment used for monitoring of alpha, beta or gamma emitting radionuclides in liquid effluents and surface waters, provides some general guidance as to the possible detection capability of such equipment and indicates when and where its uses may be practicable.

This standard is applicable to equipment for continuous monitoring of the activity in liquid effluents which could be released in the environment during normal operations and in environmental waters.

It is applicable to water monitors intended to measure the volumetric activity or count rate due to radionuclides in the liquid and its variation with time and to actuate an alarm when a limit value of volumetric activity or count rate in water is exceeded.

IEC 60861 does not apply to equipment specifically for use in accident conditions that may require additional capabilities.

This standard is restricted to equipment for continuous monitoring of gross alpha or gross beta of maximum energy higher than 150 keV or gamma activity in liquid effluent streams and environmental waters. It does not deal with sample extraction and laboratory analysis.

The second edition of this standard from 2006 cancels and replaces the first edition published in 1983 and the first edition of IEC 61311 published in 1995. This edition, with respect to the previous edition, takes into account the main technological evolutions, notably the feasibility of continuous monitoring of alpha radioactivity in liquids and tests for electromagnetic compatibility.

IEC 62438 "Mobile instrumentation for the measurement of photon and neutron radiation in the environment"

IEC 62438 (2010) is applicable to mobile radiation detection systems used for the detection, quantification and identification of photon and/or neutron emitters in the environment. This includes point and distributed radiation sources.

In general, mobile instrumentation systems for nuclear radiation measurements in the environment are comprised of detectors, detector signal processors, position sensing devices, on-board data recording, operational monitoring, and real time display/alarm capabilities. In addition, advanced systems may provide data streams that can be transmitted by telemetry to operation centres.

This standard cancels and replaces IEC 61134, issued in 1992. The scope of IEC 61134 was restricted to exploration for geological deposits of potassium, uranium and thorium. IEC 62438 incorporates the range of currently available detector technologies and incorporates neutron monitoring. This standard also relates to a wide range of mobile platform applications including environmental, emergency response, security, in addition to geological.

IEC 61275 "Measurement of discrete radionuclides in the environment - In-situ photon spectrometry system using a germanium detector"

IEC 61275 (1997) is applicable to a portable or transportable photon spectrometry assembly using a high purity germanium (HPGe) detector to survey in situ, generally at 1 m above ground level, areas in the environment for discrete radionuclides. Such equipment is used to make rapid assessments of activity levels and corresponding free air exposure rates from photon emitting radionuclides. Measurement results may be used to develop guidance for subsequent follow on action including radiological assessments, sampling and monitoring programmes.

This standard does not apply to mobile measurement systems that are covered by IEC 62438.

IEC 61275 is currently in revision on CD level with expected publication in 2012.

Standards concerning the measurements of airborne radioactivity

These standards have been developed for many years within WG B13 of SC 45B before this working group was merged with WG B5.

IEC 60761 series "Equipment for continuous monitoring of radioactivity in gaseous effluents"

IEC 60761 Ed. 2 published in 2002 consists of the following parts, under the general title "Equipment for continuous monitoring of radioactivity in gaseous effluents":

- Part 1: General requirements
- Part 2: Specific requirements for radioactive aerosol monitors including transuranic aerosols
- Part 3: Specific requirements for radioactive noble gas monitors
- Part 4: Specific requirements for radioactive iodine monitors
- Part 5: Specific requirements for tritium monitors

IEC 60761-1 defines acceptable forms of such monitoring, provides general guidance as to the possible range of measurement and capability of such equipment as may be envisaged, and indicates when and where its uses may be practicable. This standard is applicable to equipment for continuous monitoring of radioactivity in gaseous effluents during normal operations and during anticipated operational occurrences. IEC 60761-1 does not apply to equipment specifically for use in accident conditions. Such equipment may require additional capabilities. This standard is restricted to equipment for continuously monitoring radioactivity in gaseous effluent. It does not deal with sample extraction and laboratory analysis.

IEC 60761-2 is applicable to equipment intended for simultaneous, delayed or discrete sequential measurement of aerosols in gaseous effluents discharged into the environment. It is applicable to equipment designed to fulfil the following functions:

- the measurement of the volumetric activity of the aerosols in gaseous effluents and/or the released total activity of aerosols ;
- the actuation of an alarm signal when either a predetermined volumetric activity or a predetermined total released activity of aerosols is exceeded.

This equipment is intended for measurement over a wide range of activity, including very small quantities in the presence of a much larger natural background. The daughters of ^{222}Rn (radon) and ^{220}Rn (thoron) are naturally occurring aerosols contributing to the natural background. The discrimination against natural activity can be an important problem when monitoring low level activity. In order to provide more and better information, complementary or retrospective laboratory analysis of the filters after collection may be performed.

IEC 60761-3 is applicable to equipment intended for simultaneous, delayed or discrete sequential measurement of radioactive noble gas in gaseous effluents discharged into the environment. It is applicable to radioactive noble gas effluent monitors intended to fulfil the following functions:

- the measurement of the volumetric activity of radioactive gases in the gaseous effluents at the discharge point and its variation with time;
- the actuation of an alarm when a predetermined volumetric activity or a predetermined total released radioactivity is exceeded;
- the determination of the gas activity discharged over a given period and/or information on the composition of a mixture of different gases in the discharge.

Radon is a natural radioactive noble gas. Its measurement is not included in this standard. The presence of radon, or its decay products, may interfere with the measurement of other (artificial) radioactive gases.

IEC 60761-4 is applicable to equipment intended for the simultaneous, delayed or discrete sequential measurement of radioactive iodine in all forms. When the effluent is sampled for measurement, iodine bound on aerosols is generally collected on a pre-filter which should be analyzed separately in a laboratory to provide a complete measurement.

It is applicable to equipment designed to fulfil the following functions:

- the measurement of the volumetric activity of iodine and compounds of radioactive iodine in gaseous effluents or of the released iodine total activity;
- the actuation of an alarm signal when either a predetermined concentration or a predetermined total released activity due to iodine or its compounds is exceeded.

This equipment is intended for measurement over a wide range of activity in the presence of other radionuclides in the gaseous effluent, including naturally occurring radioactive nuclides. Discrimination against other radionuclides can be important in measuring low levels of radioactive iodine.

This standard considers both the use of iodine collection media such as activated charcoal and the direct measurement of iodine in stacks or ventilation ducts.

IEC 60761-5 is applicable to equipment intended for the simultaneous, delayed or discrete sequential measurement of tritium in any gaseous form in gaseous effluents discharged into the environment. It is applicable to equipment designed to measure the concentration of tritium in the gaseous effluents at the discharge point and its variation with time and actuate an alarm when a predetermined volumetric activity or a predetermined total released radioactivity is exceeded. The equipment may also be used for the determination of the tritium activity discharge over a given period.

IEC 61171 "Monitoring equipment - Atmospheric radioactive iodines in the environment"

IEC 61171 (1992) is applicable to equipment intended for transportable or installed use for monitoring, as a function of time, airborne radioactive iodines (e.g., ^{131}I, ^{125}I) in the environment (outside of buildings or facilities, at heights typically from one to a few meters above the surface) of a nuclear facility during normal operations, during anticipated operational occurrences or during accident conditions. For the purpose of this standard, monitoring includes the continuous sample collection with, if it is required, the capability to automatically initiate sampling.

This standard does not include equipment intended for monitoring radioactivity associated with gaseous effluents (at the stack). This type of equipment is covered in IEC 60761-1 through IEC 60761-5. This standard does not include monitoring for ^{129}I.

Specific chemical species of radioactive iodines may be selectively collected by specialized sampling equipment according to the requirements specified by agreement between manufacturer and user. Such samples should be in the form appropriate for laboratory analysis. The radioactive iodines may be gaseous, vapour or in aerosol form. IEC 61171 is restricted to equipment for monitoring radioactive iodines in the atmosphere and does not address sample extraction and subsequent laboratory analysis. This standard does not specify tests with atmospheric radioactive nuclides.

IEC 61172 "Monitoring equipment - Radioactive aerosols in the environment"

IEC 61172 (1992) is applicable to transportable or installed equipment for continuous monitoring of radioactive aerosol in the environment for both normal and accident conditions. For the purpose of this standard, monitoring includes the continuous sample collection with, if desired, the capability to automatically initiate sampling. In particular the standard is applicable to equipments designed to fulfil the following functions:

- determination of the activity per unit volume of radionuclides in the form of aerosols, either per unit time together with the variations as a function of time, or integrated over a longer time period, e.g., 24 h and measurement of the volume sampled.
- actuation of an alarm signal when either a predetermined high concentration or a predetermined time integrated concentration of an aerosol activity is exceeded.

The aerosol monitoring can be made both by continuous measurements during sampling and by measurement after collection of the sample. In the measurement after collection, the sample is removed from the air sampler and analysed in a laboratory. This procedure of measurement has to be followed in special cases such as the activity assessment of specific radionuclides and is not within the scope of this standard. The continuous method of measurement is the more widely used and consists in collecting the radioactive samples by drawing air through a filter and measuring the aerosol activity accumulated on it with a detector which is close to the filter. The filters are suitably chosen and periodically changed according to the conditions of use. In some cases automatic filter sequences are used to avoid the build-up of radioactivity or excess of dust on the filter. Also the type of detectors depends on the various conditions such as the type of radiation, its energy and the level of activity.

The discrimination against natural radioactivity (such as airborne radon and thoron daughters) can be an important problem in monitoring low-level radioactivity in air especially with transuranic elements.

IEC 61578 "Effectiveness of radon compensation for radioactive aerosol monitors including transuranic aerosols "

IEC 61578 "Calibration and verification of the effectiveness of radon compensation for alpha and/or beta aerosol measuring instruments - Test methods" was published in 1997 but is currently in revision on CD stage with a new title "Effectiveness of radon compensation for radioactive aerosol monitors including transuranic aerosols".

This standard is applicable to type test methods which allow calibration and measurement of the effectiveness of radon decay product compensation for radioactive aerosol monitors. IEC 61578 in his 2nd edition defines aerosol characteristics used in these tests and applies the following test methods permitting the measurement of:

- the sensitivity of the monitor relative to alpha and/or beta defined man-made aerosols,
- the reference response of the monitor relative to alpha and/or beta defined man-made aerosols,
- the response of the monitor relative to radon decay product aerosols,
- the effectiveness of radon compensation,
- the response of the monitor relative to a mixture of aerosols constituted by natural and man-made radioactive emitters.

IEC 62302 "Equipment for sampling and monitoring radioactive noble gases"

IEC 62302 (2007) directly compliments IEC 60761-1 and IEC 60761-3. This international standard is applicable to equipment used for sampling and continuous measurement of radioactive noble gases in the workplace, in gaseous effluents discharged into the environment as well as in the environment itself. Monitoring by definition is the process of continuous and real-time measurement. The processes of sampling or taking samples for retrospective laboratory analysis are included in this standard.

IEC 60761-3 that will be complimented by IEC 62302, is applicable to installing portable and transportable equipment for sampling and monitoring radioactive noble gases, only in gaseous effluents, while IEC 62302 expands coverage to include monitoring all possible locations where radioactive noble gases could present a radiological hazard. The equipment is designed to be operational during normal operation conditions as well as under emergency conditions, both during and following an accident. Depending on the nature of the emergency conditions it may be necessary to install specially designed equipment for normal operational conditions and other equipment for emergency conditions.

IEC 62303 "Equipment for monitoring airborne tritium"

IEC 62303 (2008) is applicable to equipment used for sampling and continuous measurement of tritium in the workplace, in gaseous effluents discharged into the environment as well as in the environment itself and it is applicable to installed, portable and transportable equipment.

The object of this international standard is to establish mandatory general requirements and to present examples of acceptable methods and equipment for continuously monitoring and/or sampling airborne tritium. IEC 60761-5 which is complemented by IEC 62303, is applicable to equipment for sampling and monitoring tritium only in gaseous effluents, while IEC 62303 expands coverage to include monitoring all possible locations where tritium could present a radiological hazard. The equipment is designed to be in operation during normal operation conditions as well as under emergency conditions, both during and following an accident. Depending of the emergency conditions, it might be necessary to install specially designed equipment for normal operation conditions and other equipment for emergency conditions.

IEC 62303 is applicable to tritium samplers and tritium monitors intended to provide the following functions:

– measurement of the volumetric activity of tritium and its variation with time in the workplace, in gaseous effluents at the discharge point and in the environment;
– actuation of an alarm when a predetermined volumetric tritium activity or tritium concentration or a predetermined total activity of released tritium is exceeded;
– determination of the total tritium activity discharged over a given time;
– sampling and analysis of air or gas containing tritium.

Conclusions

The object of the presented standards is to establish performance requirements, to give examples of acceptable test methods and to specify the general characteristics, general testing procedures, radiological, mechanical, electrical and environmental characteristics of the equipment.

IEC/SC 45B with its 15 published international standards greatly contributes for the high quality of existing instrumentation for measurement of environmental radiation. Compliance with such standard requirements provides the manufacturers with internationally acceptable specifications and the device users with assurance of the rigorous quality and accuracy of the measurements.

Experts from all countries are welcome to contribute to the IEC work (the national committees should be contacted for registration). The next SC 45B meeting will be in October 2010 in Seattle (US).

Acknowledgements

The authors wish to thank all convenors and experts of IEC/SC 45B WG B5 and B13 for their contributions during the preparation of presented standards. They are also thankful to the IEC Central Office staff.

Investigation radiation hygienic monitoring in the Russian NPP vicinity

Shandala, N.; Kiselev, S.; Novikova, N.; Seregin, V.; Filonova, A.; Semenova, M.; Isaev, D.
Burnasyan Federal Medical Biophysical Centre, Moscow, RUSSIA

Abstract
Investigation monitoring in the NPP vicinity includes radiation hygienic monitoring and population health monitoring. Radiation hygienic monitoring is the system of the comprehensive and dynamic surveillance including the long-term continuous control of radiation hygienic situation parameters and doses of residents in the near-by areas of NPP. In the reference points of the NPP surveillance area and in the comparison area, the specialized rules are elaborated. These rules include the types of environmental media, scope and periodicity of sampling, methodological and technical requirements, etc. Two approaches are used for population health assessment: epidemiological and cohort. Medical demography characteristics are based upon indices of the birth rate, general malignant neoplasm mortality, and infant and childhood mortality. Morbidity is used as quantitative and qualitative index of the population health.

The radiation hygienic situation in NPP surveillance areas is generally satisfactory and stable. The individual population risk for all radiation sources in surveillance areas of three examined NPPs is $(2.5\text{-}3.1)\cdot10^{-4}$ cases per year. The individual risk related to the NPP operation is $0.4\cdot10^{-12}$ (Volgodonsk NPP) to $3.2\cdot10^{-8}$ (Novovoronezh NPP) cases per year. Thus, this risk is hundreds and even million times lower if compared to unconditional acceptable risk – $1\cdot10^{-6}$. The assessment of the health baseline as well as in the comparison areas was elaborated applying data of state medical statistics within more than ten years. The peculiar attention was attracted to the malignant neoplasm morbidity, their incidence rate and dynamics. The developed comprehensive investigation monitoring in the NPP vicinity should be the necessary part of the nationwide system of the public radiation protection regulation under nuclear renaissance, because it provides the opportunity to get the modern objective assessment of the NPP impact in the environment and population health.

Introduction
The basic social requirement for the atomic power is the provision of convincible evidences of the safety warrantees of both the plant operation personnel and residents of the NPP affected area. Since the USSR atomic industry start-up, the Burnasyan Federal Medical Biophysical Centre (before 2008 – Institute of Biophysics) of the Federal Medical Biological Agency of Russian Federation was the leading institution

responsible for the medical issues of the industry. One of basic activities of the Burnasyan Federal Medical Biophysical Centre is the scientific support of the radiation protection of the public.

The analysis of medical effects of the Chernobyl accident has obviously demonstrated the high importance of the establishing so-called “zero” baseline of the population health. Such information is necessary to evaluate possible medical effect of many year operation of atomic facilities and to clarify the scale of the health impact. Such assessments require vast comprehensive hygienic studies within the long period of time. Thus, the necessity to organize the rigorous social hygienic monitoring (SHM) in the NPP vicinity is occurred, which is the system of state surveillance, analysis, assessment, and prognosis of the population health and habituated environment as well as the correlation of the population health versus the habituated environment factor exposure. According to the Russian Federation Law on Sanitary and epidemiological well-being of the population, SHM is the major mechanism to regulate this well-being. The SHM implementation is of specific significance, taking into account special document regulates this work and attributes it not only to sanitary and epidemiological authorities and institutions, but also to other ministries and agencies [1]. Present SHM system presumes the development of the unified system of collection, management, and assessment of the information regarding the environmental contamination and population health indices.

The purpose of the present paper is to describe methodology and current status of SHM results obtained in the NPP vicinity. SHM includes radiation hygienic monitoring and population health monitoring.

Ideology & methodology of the research

The main stages of SHM in the NPP vicinity are as follows:

- Conducting of background “zero” examination of public health and radiation hygienic situation before the NPP start-up;
- Dynamic monitoring of important parameters of public health and hygienic parameters (including radiation factor) during the whole NPP operation period;
- Comparison of observed changes of public health and environment against “background” values;
- Observation of changes of public health within 5-10 years after decommissioning NPP or reactor units.

Following eight SHM directions are included for the NPP vicinity:

1. Radiation hygienic situation specifications and population doses
2. Medical demography features of the populations
3. Population morbidity analysis
4. Reproductive health status
5. Endemic diseases
6. Children health status
7. Societal psycho-physiological status of the population and mass media relations
8. Monitoring data bank development.

The scientific ideology of the this research is investigation radiation hygienic monitoring (RHM), which is the system of the comprehensive and dynamic surveillance including the long-term continuous control of radiation hygienic situation parameters and doses of residents in the near-by areas of NPP and other radiation facilities of the first category [2].

The obvious question on the differences between research RHM and radiation control elaborated by different agencies and organizations is occurred. It is clear that radiation situation monitoring in the NPP surveillance area is elaborated by the NPP operator and designer, hydrometeorology service, and sanitary and epidemiological surveillance service. Results of such control attributed to the agency responsibility as well as elaborated under the radiation hygienic certification of territories have some disadvantages. These disadvantages include the rare application of radiochemical techniques, low periodicity of examinations, insignificant number of comparison points, and, in some cases, the absence of the comparison area and significant change of the list of objects subjected to the control. Finally, the radiation factor is not considered together with other non-radiation environmental factors affecting the human and the ranking of these factors is not provided. Unfortunately, low levels of radiation hygienic parameters are not recorded in practice. The indicated disadvantages of the practical radiation monitoring can be corrected by the implementation the detailed investigation RHM.

To elaborate RHM in the reference points of the NPP surveillance area and in the comparison area, the specialized rules are elaborated. These rules include the types of environmental objects, scope and periodicity of sampling, methodological and technical requirements, and inter-relations of interested parties. Table 1 provides a number of aspects of elaborated RHM rules on the sampling and examined parameters of the radiation hygienic situation in the NPP vicinity. RHM rules (environment section) presume the usage of NPP surveillance network data obtained by State Hydrometeorology Committee and Automated System of Radiation Situation Control as well as the original own data [3].

Table 1. Periodicity of sampling and examined parameters in the control points of the NPP surveillance area (routine operation) and in the comparison area.

Supervision object	Periodicity of information receipt	Parameters	Value dimensionality to be measured
Environment			
Gamma background in the area	Random inspection (weekly)	Exposure dose rate of external γ radiation in the area	μR/h
		Effective dose rate of external γ radiation	mSv/y
Atmospheric air (aerosol content in surface air)	Daily, monthly	ß-radioactivity, ^{90}Sr, ^{137}Cs, ^{134}Cs. Content of inert radioactive gases, ^{131}I, ^{60}Co	Bq/m^3
Density of radioactive fallout	Monthly	Total ß-radioactivity, ^{90}Sr, ^{137}Cs, ^{131}I	Bq/m^2/month
Soil	Annually	Total ß-radioactivity, ^{90}Sr, ^{137}Cs, ^{40}K	Bq/kg, kBq/m^2
Gramma grasses or natural growth	Annually (during period of vegetation)	Total ß-radioactivity, ^{90}Sr, ^{137}Cs, ^{40}K, ^{131}I	Bq/kg

Table 1. Continued.

Supervision object	Periodicity of information receipt	Parameters	Value dimensionality to be measured
Environment			
Water of open ponds including water reservoir-cooler	Two times a year (random inspection)	Total α- and ß-radioactivity, ^{90}Sr, ^{137}Cs. In water reservoir-cooler: ^{131}I, ^{60}Co, ^{90}Sr	Bq/l
Underground sources of water (using observation wells)	Monthly (random inspection)	Total α- and ß-radioactivity, ^{90}Sr, ^{137}Cs, ^{3}H	Bq/l
Drinking water (using draw well and water supply systems)	Quarterly	Total α- and ß-radioactivity, ^{90}Sr, ^{137}Cs	Bq/kg
Water-plants and sea-floor sediments of open ponds	Annually (random inspection)	^{90}Sr, ^{137}Cs, ^{40}K in water-plants – total ß-radioactivity	Bq/kg
Foodstuffs of local manufacture			
Bread or bread flour	Annually	^{90}Sr, ^{137}Cs	Bq/kg
Grain (wheat)	Annually	^{90}Sr, ^{137}Cs	Bq/kg
Milk	Two times a year (in summer and in winter)	^{90}Sr, ^{137}Cs, ^{131}I	Bq/l
Meat (pork, beef, mutton)	Annually	^{90}Sr, ^{137}Cs	Bq/kg
Poultry meat	Two times a year	^{90}Sr, ^{137}Cs	Bq/kg
Freshwater fish (river and lake ones)	Annually	^{90}Sr, ^{137}Cs	Bq/kg
Potatoes	Annually (during harvesting)	^{90}Sr, ^{137}Cs	Bq/kg
Edible roots (beet, carrot)	Annually (during harvesting)	^{90}Sr, ^{137}Cs	Bq/kg
Vegetables (cucumbers, tomatoes, onion, cabbage)	Annually (during harvesting)	^{90}Sr, ^{137}Cs	Bq/kg
Gourds (melon, water-melons)	Annually (during harvesting)	^{90}Sr, ^{137}Cs	Bq/kg
Food pot-herbs and leaf vegetables	Two times a year (during period of vegetation)	^{90}Sr, ^{137}Cs, ^{131}I	Bq/kg
Garden fruits and berries (at places of harvest)	Annually (during harvesting)	^{90}Sr, ^{137}Cs	Bq/kg

When choosing the comparison area, following circumstances should be taken into account:

a) hygienic characteristics similarity:
   – soil and sub-soil type;
   – plant species;
   – chemical content of water in superficial reservoirs and underground waters;
   – conditions of foodstuff production;
   – burdens of natural and (or) global fallout radionuclides.

b) the positioning outside the radiation facility affecting area;

c) medical assistance peculiarities (number of specialized medical doctors and availability of medical equipment etc.).

We would like to address population health monitoring, which requires the scientific justification of index selection and population health assessment criteria. These criteria should correspond to the following conditions:

– Applicability for the population assessment;
– Correspondence to the long-term observation tasks, namely, the simplicity, the applicability for the large number of individual examinations, reliable quantification, and objective qualitative characteristics;
– Future possibility for the assessment of possible NPP radiation impact in population health.

Two approaches are used for population health assessment: epidemiological approach based upon the health evaluation via medical statistics data and cohort clinical approach to include health assessments via detailed examination of critical population groups and critical body systems.

Medical demography characteristics are based upon indices of the birth rate, general malignant neoplasm mortality, infant and childhood mortality.

Morbidity is used as quantitative and qualitative index of the population health to assess the dissemination and structure of major diseases in the population of the NPP vicinity. To evaluate health status, medical statistics data are applied and dynamic indices within many years are analyzed.

The index reflecting the population health as a whole is the reproductive health. Reproductive health changes are most specific to the unfavorable factor impact in human health. Basic parameters of the reproductive health are as follows:

a) obstetric and gynecological status (rate and character of the pregnancy termination, gynecological and oncological morbidity)

b) reproduction function state (spontaneous abortions, still birth, early neonatal mortality) and newborn condition (morbidity, inherited developmental defects, etc.).

The child organism at growth and development phase is specific to the peculiar sensitivity, so the children under the radiation risk compose the population critical group. In the framework of the elaborated children health monitoring, statistical data on pediatric assistance are used as well as the detailed clinical examination results in some groups of children.

The “baseline” data on leukemia and thyroid morbidity are essential for the comprehensive assessment of NPP vicinity resident health to use these data as the reference for the following radiation exposure effects. Thyroid examinations presume endocrinologist evaluation and ultrasound imaging to obtain sizes and echo structure as well as the iodine deficiency assessment via urinalysis.

Material and methods

The investigation monitoring been implemented in a number of Russian NPPs including Kalinin, Volgodonsk and Novovoronezh NPPs. When implementing monitoring the following tasks were elaborated:

1. The dynamic acquisition of necessary, sufficient, and confident information on controllable radiation parameters of the environment and on radionuclide burdens in foodstuff and water.
2. Investigation of the foodstuff consumption.
3. Assessment of the external and internal exposure doses in population.
4. Revealing current changes of radiation hygienic situation and prognosis of possible consequences in the population.
5. Providing the information for the managerial decision making to keep radiation doses as low as reasonably achievable.
6. Providing the information for local authorities and local centers of State Sanitary and Epidemiological Surveillance on radiation hygienic situation in the surveyed territory.
7. Forming the databases on the examined parameters.
8. Providing the information for local residents of the NPP vicinity.

More than 670 environmental and foodstuff samples in 48 settlements positioned both in the surveillance areas and in the comparison areas, in cooling ponds and other water reservoirs of the NPP vicinity was investigated (Table 2).

Table 2. The amount of investigations, which were carried out nearby NPPs.

NPP	Quantity of points	Number of proof samples		
		Foodstuffs	Drinking water	Other objects of environment
Volgodonsk	22	270	26	24
Kalinin	15	151	29	20
Novovoronezh	11	98	22	12
	48	519	77	56

Results of the Investigation Monitoring

The comparison to the current standards is also provided. The radiation hygienic situation in NPP surveillance areas is generally satisfactory and stable:

– Outdoors gamma dose rate is in the range of background fluctuations for such territories;
– ^{90}Sr and ^{137}Cs specific activity in outdoor water reservoirs is in the range of radionuclide content in water reservoirs of the Central Russia;
– ^{90}Sr and ^{137}Cs burdens in drinking water is below intervention levels for 135 and almost 300 times, respectively; total alpha and beta activity is below permissible levels;

– ^{90}Sr and ^{137}Cs burdens in foodstuff products and drinking water are 100-1000 times below permissible levels;
– ^{90}Sr and ^{137}Cs burdens in foodstuff products and drinking water (NPP surveillance areas) are similar to these in other regions of the country.

Table 3 provides total doses in NPP vicinity residents due to all sources of ionizing radiation. As it follows from Table 3, the natural background irradiation results to 69-71 % of total effective dose from all sources. The dose impact of global fallout and NPP exposure is 0.2-0.3% in the vicinity of Volgodonsk, Kalinin and Novovoronezh NPPs [4].

Table 3. Total effective doses in the population in the NPP vicinity, mSv/year.

Component of dose, mSv/y	Volgodonsk NPP	Kalinin NPP	Novovoro-nezh NPP	Assessment criteria
^{137}Cs and ^{90}Sr man-caused background	0,007	0,0079	0,010	Russia – 0.022 world – 0.007
NPP	0,0000006	0,00044	0,0017	0.01
Natural sources	2,4	2,9	2,3	2.4
Medical sources	1,0	1,3	1,2	Russia – 1.0 world – 0.4
Sum of all sources	3,4	4,2	3,5	Russia – 3.5 world – 2.8

The assessment of the health baseline in the vicinity of NPPs as well as in the comparison areas was elaborated within more than ten years. The peculiar attention was attracted to the malignant neoplasm morbidity, its incidence rate and dynamics. Specifying children health and the morbidity structure is estimated. Data obtained did not show any significant terms of worse health state of adults and children.

At present time, the radiation hygienic monitoring in the NPP vicinity can provide the radiation risk assessment (Table 4). The individual population risk for all radiation sources in surveillance areas of three examined NPPs is $(2.5\text{-}3.1)\cdot10^{-4}$ cases per year. The individual risk related to the NPP operation is $0.4\cdot10^{-12}$ (Volgodonsk NPP) to $3.2\cdot10^{-8}$ (Novovoronezh NPP) cases per year. Thus, this risk is hundreds and even million times lower if compared to uncondtional acceptable risk – $1\cdot10^{-6}$.

Table 4. Individual life span risk of stochastic effects in residents of the NPP surveillance area, year^{-1}.

Risk due to all the sources	Risk due to NPP operation (R_{NPP})	UAR/ R_{NPP}
Volgodonsk NPP		
$2{,}5\cdot10^{-4}$	$4{,}0\cdot10^{-13}$	2,5 million times
Kalinin NPP		
$3{,}1\cdot10^{-4}$	$6{,}6\cdot10^{-9}$	150 times
Novovoronezh NPP		
$2{,}6\cdot10^{-4}$	$3{,}2\cdot10^{-8}$	30 times

Conclusion

The developed comprehensive investigation monitoring in the NPP vicinity (a) should be the necessary part of the nationwide system of social hygienic monitoring, (b) provides the opportunity to get the modern objective assessment of the NPP impact in the environment and population health, and (c) can be widespread to other radiation facilities in this country.

Abstract

Remediation of the sites for temporary storage (STS) of the Spent Nuclear Fuel (SNF) and Radioactive Waste (RW) is one of the most important challenges for the Russian Northwest region. The prime task is to develop radiation environmental regulations on justification of radiation safety assurance during remedial operations at the STS. According to legislative and normative acts of the Russian Federation regulating management of radioactively contaminated territories after identification of the site contamination level at the radiation facility, one of three decisions can be made: conservation of the site; renovation of the site and buildings (brown lawn);unlimited use of the site (greenfield).The criteria and regulations for the SNF and RW STS facilities and site have been developed, which are suitable for each remediation option. At the same time, the environmental models have been taken into account; reference levels have been developed expressed in radiation parameter units, which could be measured during radiation control and monitoring: surface beta and alpha contamination of the STS buildings, gamma dose rate, radionuclide specific activity in soil, annul activity concentration of ground water, radionuclide contents in hydrobionts.

Introduction

Two technical bases of the Northern Fleet were created in the Russian Northwest in the 1960s at Andreeva Bay in the Kola Peninsula and Gremikha village on the coast of the Barents Sea. They maintained nuclear submarines, performing receipt and storage of radioactive waste (RW) and spent nuclear fuel (SNF). No further waste was received after 1985 and the technical bases have since been re-categorized as sites of temporary storage (STS).

Remediation of sites and facilities of the STS of SNF and RW in Andreeva bay and Gremikha village on the Kola Peninsula is one of regulatory functions of the Federal medical-biological agency (FMBA of Russia). The work has involved the Russian Federation Burnasyan Federal Medical Biophysical Centre, which is technical support organization of the FMBA of Russia. In thus work took part the Norwegian

Radiation Protection Authority (NRPA) in frame of the Norwegian government's Plan of Action to improve radiation and nuclear safety in northwest Russia.

Main tasks within the FMBA – NRPA cooperation consist of:

- Independent detailed analysis of the radiation situation at and near the STSs.
- Radiological threat assessment to determine priority issues for regulatory attention.
- Radiological control and monitoring of the environmental conditions.
- Development of a regulatory documentation system ensuring radiation protection observance of workers and the public, including radiation-hygienic criteria and standards of rehabilitation of contaminated territories.

In order to obtain comprehensive information with respect to current radiation circumstances at STS (independent from regulatory point of view), radiation-hygienic monitoring of STS facilities has been carried out.

Material and methods

Over 2005-2008, more than 180 samples of environmental media, local foods and drinking water were collected in Andreeva Bay and Gremikha village expeditions; moreover, personal dose monitoring was implemented. Gamma-spectrometry and radiochemical methods were applied in sample measurements.

Characterization of SevRAO facilities in Andreeva Bay and Gremikha

The STS Andreeva Bay is located on Kola Peninsula in the Barents Sea coastal strip (Motovsky gulf, west bank of Zapadnaya Litsa bay). The nearby settlements are: Bolshaya Lopatka (2.4 km); Nerpitchie village (1.8 km); Zaozersk city (8 km). The population is 15 700, the majority of which are military estates. The facility holds about $1.3 \cdot 10^{17}$ Bq of SNF and $6{,}0 \cdot 10^{14}$ Bq of RW.

The STS Gremikha is located on Kola Peninsula in Chervyanaya Bay of the Barents Sea. The nearby settlements are: Gremikha village (0.7 km from the site) and Ostrovnoy city (1.2 km). The population is 3500 (mainly, former soldieries and their families). The facility holds about $1.3 \cdot 10^{16}$ Bq of SNF and about $3.3 \cdot 10^{13}$ Bq of RW.

Up to now, a large amount of SNF contained in 88 unloaded cores, as well as 17558 tons of solid radioactive wastes and 3042 tons of liquid radioactive wastes have been accumulated in Andreeva Bay and Gremikha.

Specification of areas within the STS territory

With the purpose of radiation protection of workers and the public, the following areas are specified on-site and around the STS site:

- Controlled access area (CAA) – SNF and RW store facilities are situated here and radiation-hazardous operations are performed here too;
- Uncontrolled (free access) area (UA) – Facilities intended for work supplying in CAA;
- Health protection zone (HPZ) – This is an area of administrative and technical provision of the STS;
- Supervised area (SA) – This is an area surrounding the STS, where radiological monitoring is carried out to guarantee radiation safety and protection for the public.

The member of the public must not stay within the first three areas.

Radiation situation on-site the STS in Andreeva Bay

The accomplished examinations showed that gamma dose rates within the STS territory varied over a wide range: in CAA - from 0.2 to 140 µSv/h-1; in UA - from 0.2 to 12 kBq·kg-1; in HPZ - from 0.1 to 0.2 kBq·kg-1. Within SA, gamma dose rates varies from 0.063 to 0.14 µSv/h-1 with an average value of 0.12 µSv/h-1, which does not differ from the levels typical for the territories of Northwest Russia and in the Murmansk region, in particular. The results of selective personal dose monitoring show that external exposure gamma rates of the public and workers of group B (individuals who are not working directly with the sources of ionizing radiation, but who, due to their working place location, can be exposed to radiation) due to natural and man-made sources of ionizing radiation are, respectively, equal to 0.8 and 0.9 mSv/y. Internal public radiation doses associated with intake of radionuclides with food are 14 µSv·y-1. The total effective radiation doses to the public living in the STS's SA of Andreeva Bay(due to natural and man-made radionuclides) are estimated to be approximately 0.8 – 0.9 mSv·y-1, that is not more than the actual norms.

The highest level radioactive contamination of soil on-site induced by man-made radionuclides is observed in the area of the old technological pier and around some SNF store facilities, where ^{137}Cs specific activity reaches 5.7 107 Bq·kg-1, and that of ^{90}Sr is 5.7 106 Bq·kg-1. ^{137}Cs and ^{90}Sr concentrations in soil within HPZ and SA is at the background level typical for "clean" Russian Northern areas and does not exceed 36 Bq/kg and 4 Bq/kg, respectively.

Radiation situation on-site the STS in Gremikha

Gamma dose rate within CAA varies from 0.2 to 500 µSv·h-1 (maximum values are 4 times more than those in Andreeva bay); in UA – from 0.2 to 12 µSv·h-1 and levels within approximately 80% of the territory do not exceed 5 µSv·h-1. In HPZ and SA (in Ostrovnoy and Gremikha) it varies from 0.09 to 0.2 µSv·h-1, i.e., within fluctuation limits of natural background of this region. The results of selective personal monitoring of the people living and working (workers group B) due to natural and man-made sources of ionizing radiation in the STS area show that the external exposure gamma dose rates are 0.7 mSv·year-1(for public) and 0.9 mSv·y-1 (for worker group B). Internal public radiation doses due to intake of ^{137}Cs and ^{90}Sr with food are approximately 14 µSv·y-1, which is significantly lower than acceptable levels.

Within the industrial site, man-made contamination is observed in top-soil due to ^{137}Cs, ^{90}Sr and, in small concentrations, ^{60}Co, ^{152}Eu, and ^{154}Eu. In SA (including Gremikha and Ostrovnoy), ^{137}Cs and ^{90}Sr contents in soil are mainly within background level (1 – 50 Bq·kg-1). In some cases, at local parts outside the settlements, observed levels exceed background values by up to 100 Bq·kg-1 by ^{137}Cs.

Results of radiation situation assessment at STS in Andreeva bay and Gremikha

Radiation monitoring of the environmental media showed considerable exceeding of typical background values of ^{137}Cs and ^{90}Sr radionuclide concentrations (in the SSZ coastal strip) in seaweeds, bottom sediments and vegetation. An exceeding is also observed in some cases in the STS SA environmental media in comparison with background values. Preliminary results of sorption experiments of radionuclides on local soil and ground waters suggest that radionuclide migration from highly contaminated areas on site, via groundwater flow pathways, is possible. This leads to permanent entry of radioactive substances into the off-shore marine environment.

According to radiation monitoring of catches in the STS off-shore marine environment, the concentration of ^{90}Sr and ^{137}Cs in fish is in the range 0.7 - 13 Bq·kg-1 for ^{90}Sr and 0.4 – 35 Bq·kg-1 for ^{137}Cs, respectively, being significantly lower than actual Russian accepted radiation contamination levels. With the purpose of radiation exposure restriction during large-scale STS remedial work, FMBA established a public radiation dose quota; this quota is 100 µSv·y-1 due to effluents and 30 µSv·y-1 due to radioactive substance discharges (table 1).

Table 1. Public radiation dose quota due to effluents and to radioactive substance discharges under conditions of STS facility normal operation.

Sources of exposure	Quota, µSv·y-1
Gas-aerosol discharges	100
Intake with seafood	300
Reserve for unregistered sources	200

Conclusions

Environmental radiation monitoring demonstrated significant excess (in comparison with typical background values) of ^{137}Cs and ^{90}Sr contents at local parts of the coastal strip of the STS health protection zone in seawater, seaweeds, bottom sediments, vegetation and soil.

Results of radionuclide sorption examination in soil and ground water permit to assume the presence of effective migration from contaminated areas via groundwater, causing radioactive inflow into offshore marine waters. Having in mind a possibility of further contamination of the STS area, dynamic surveillance is needed of the radiation situation both at routine activity, and at SNF and RW removal [2].

The described work carried out under joint FMBA and NRPA Project, devoted to regulation of the public radiation and nuclear safety during STSs operations, current output has included the following documents:

– InitialThreat Assessment for the situation at STS sites.
– Guidance “Criteria and norms on remediation of STS sites and facilities contaminated with man-made radionuclides”.
– Guidance “Hygienic requirements for personnel and public radiation safety guaranteeing at the stage of designing the work with SNF and RW at STSs”.

Quality management system of in-vivo measurement (IVM) lab at Karlsruhe Institute of Technology (KIT) – accreditation and experience

Breustedt, Bastian; Mohr, Ute; Biegard, Nicole; Cordes Gabriele
Institute for Radiation Research, Karlsruhe Institute of Technology, D-76021 Karlsruhe, GERMANY
(contact: bastian.breustedt@kit.edu)

Abstract
The in-vivo monitoring lab (IVM) at Karlsruhe Institute of Technology operates one whole body counter and three partial body counters. IVM is an approved lab for individual monitoring for incorporation according to German regulation. In 2007 a web based quality management system has been set up and all the method and procedures used at IVM have been described in a set of documents. Several document classes are (e.g. standard operation procedures SOP) are used for this. For each class of document a template satisfying the formal requirements is used. In 2007 several internal audits were used for fine-tuning the system before an external audit, which finally granted accreditation to the IVM, was held. The system is kept flexible and can thus be easily adapted to new situations (e.g. organisational changes). Only a sparse amount of the work time needs to be spent to maintain the running system. It also leaves enough freedom in the daily routine work at IVM and found acceptance by the employees, quickly. After two years of working with the quality management we can say it was worth the trouble and time required in setting it up.

Introduction
The in-vivo monitoring laboratory (IVM) at Karlsruhe Institute of Technology (KIT) operates one whole body counter with NaI(Tl) detectors in a stretcher geometry and three partial body counting systems, two with Phoswich and one with HPGe-detectors. Routine monitoring and special measurements of workers at the KIT campus north (either staff of KIT, or of external companies located at the campus) and for external customers are done at IVM. The laboratory is used in scientific studies, e.g. studies on caesium content of the population, and in education and training of students and radiation protection workers. IVM is an approved lab for individual monitoring by direct assessment of incorporated radionuclides according to German regulation. One of the requirements for the approval is an poof of competence via accreditation on ISO/IEC Standard 17025. A quality management system (QMS), which was successfully audited and granted accreditation, has been set up at IVM in 2007.

Material and methods

The quality management system (QMS) is based on ISO9001 certified system of the central safety department. All issues dealing with management requirements (i.e. chapter 4 of ISO 17025) are met by this system. The IVM team added documentation of the routine work and the quality assurance procedures in the lab meeting the technical requirements (i.e. chapter 5 of ISO 17025).

A web based quality management software (CAS Teamworks 2010) is used for handling and controlling of all relevant documents and the workflow for all the steps of document issuing and approval. Employees can log in to the system from their workplaces simply via a web browser. Using an online system ensures that everyone is working with the same revision of a given document. Thus "errors" caused by invalid or expired documentation are minimised. In principle one should work only with the electronic documentation and avoid printing the documents. The latter is not forbidden, but hardcopies are valid only if the revision number on the hardcopies and the revision number in the electronic system are identical. For each controlled document the roles of editor, examiner, approver and the persons that need to acknowledge the final document need to be assigned. In the document properties displayed in the system action links for each step of the document control workflow are provided. The persons involved are informed by the system's messaging interface or via an email with a link to the document in the QMS, when their duty is due. The final approval for the release of a document is given by the quality management representative and a process owner of the procedure involved. This assures a final check of the document and ensures that the system is kept consistent.

Table 1. Main Document Classes in the Quality management system.

Class		Content
QMH	Quality Management Manual (Qualitätsmanagementhandbuch)	Description of formal organization, quality objectives and procedures
MB	Description of Method used (Methodenbeschreibung)	Description of non-standardized methods used in the laboratory
VVP	Protocol of verification of validation of methods (Verifizierungs- und Validierungsprotokoll)	Description of verification and validation of methods used
VA	Generic Procedures (Verfahrensanweisung)	Description of general processes and workflow
SAA	Standard Operating Procedure (Standardarbeitsanleitung)	Operations are described step by step
HMS	Specification of tools and materials (Hilfsmittelspezifikation)	Only tools and materials used in the methods are specified
QA	Reporting Forms (Qualitätsaufzeichnung)	Standardized Reporting Forms for perseverative reporting

Several classes of documents are used in the quality management system, an overview of the most important ones is given in table 1. Central document of the quality management system is a quality management manual (QMH) which provides information of the duties and the formal organization of the institution described (e.g.

ISF or IVM), as well as the quality objectives and policy. The generic processes used are described in process instructions (VAA), more detailed instructions are provided in standard operating procedures (SAA). The tools and materials used in the processes are described in specification sheets (HMS) only if they need to be calibrated or are relevant for the quality of the process or of its product. Templates satisfying all formal requirements of ISO 17025 are provided for each class of documents. Each document is derived from these templates and given a unique ID of the type “Class Lab Number” e.g. “SAA IVM 100” and a meaningful title. Using this ID the documents can easily refer to others and thereby link procedures during a workflow.

The generic principles of our measurements were described in three documents as non-standardized methods:

- Determination of incorporated radionuclides by gamma spectroscopy in the whole body counter
- Determination of incorporated radionuclides by gamma spectroscopy in the partial body counter with Phoswich detector.
- Determination of incorporated radionuclides by gamma spectroscopy in the partial body counter with germanium detectors

The general information and the scientific background of the techniques used in the laboratory is provided in separate documents (MB). These descriptions were required because no reference document (e.g. an ISO standard) on in-vivo monitoring techniques are available. Scientific publications (IAEA 1996, ICRU 2003) were the basis for these documents. Based on past experience and successful participation in intercomparison exercises these methods were verified and validated. This has been documented in a VVP-document.

The full workflow from customer enquiry to final billing including measurement and reporting has been described in a generic procedure (VAA IVM 003). A translated flowchart as provided in this document is shown in figure 1. Two other generic procedures describe the principal workflow for measurements and dose assessments. Detailed step by step descriptions for the single parts of these workflows are given in standard operating procedures, which are linked by their document IDs in the generic procedures. The single documents are focussed on (small) steps of the work (e.g. daily quality assurance measurement), thus only small adoptions of the documentation are required when changes in parts of the procedures are made. The minimum requirements which need to be fulfilled before an enquiry is accepted are described in a standard operation procedure. A counselling interview with a customer is conducted to check these requirements prior to the first measurement ordered. Two documents describe the application of the reference procedure for internal dose assessments as reported in German regulation. All other laboratory (e.g. quality assurance of the balances in the lab) and administrative work (e.g. invoicing, archiving, …) is described in separate SAA documents. An overview of all quality assurance procedures and their frequencies (e.g. daily, weekly, ….) is provided in a document of the quality manual. There all the according standard operating procedures and reporting forms are linked by their document ID. This document provides an overview of the QA procedures at the lab. If changes in on of these procedures are made, only the according SOP (SAA) documents for this special procedure needs to be adapted.

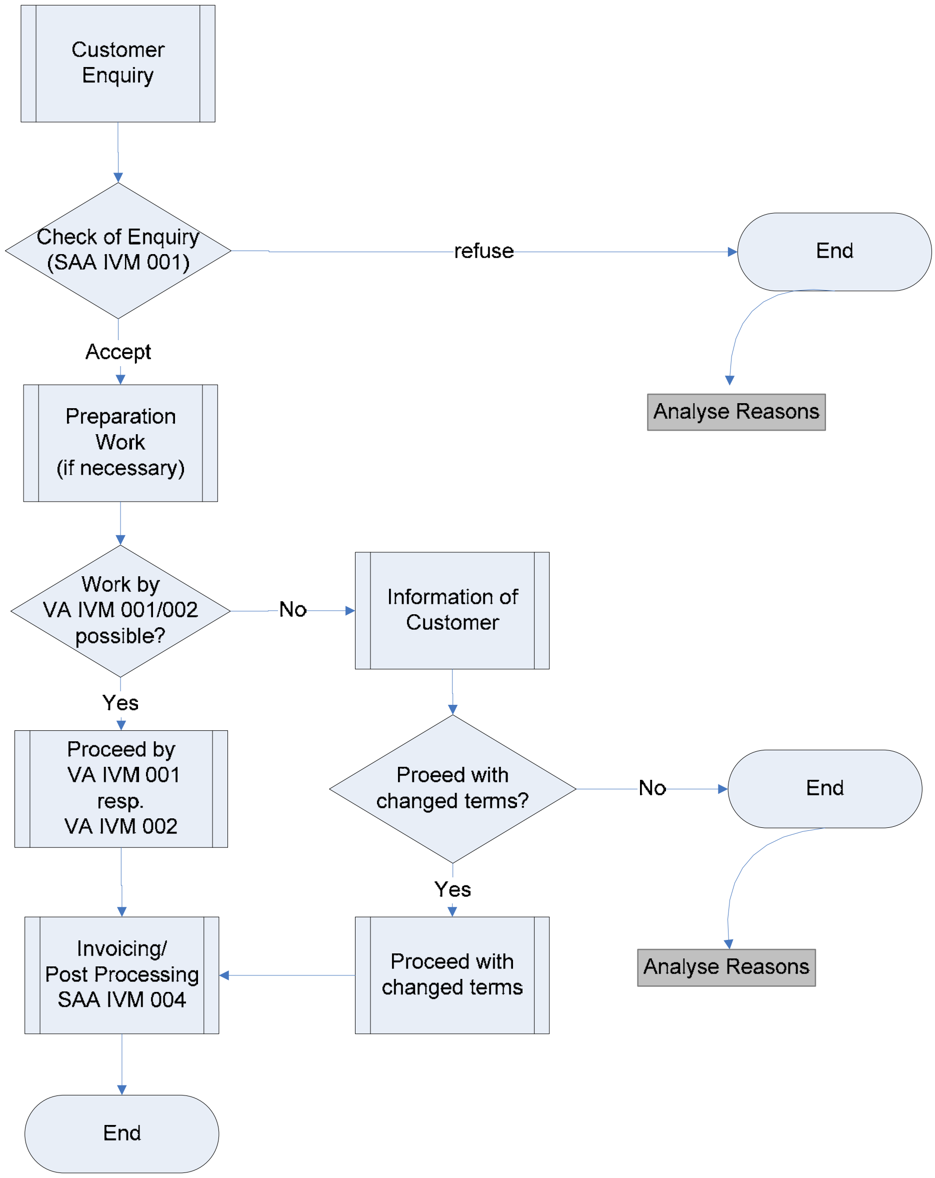

Figure 1. A translation of the flowchart for the generic procedure from customer enquiry to final billing. A short description an the ID of the document providing detailed procedures is given in the VA document.

The whole system including the generic ISO 9001 parts and special documentation of IVM has been set up flexible and could easily be adopted to new situations, like recent organizational changes (e.g. the founding of a new Institute for Radiation Research at KIT to which the IVM was then assigned). Here only minor changes in the existing documentation were needed to adapt the whole system to the new situation.

Conclusions

All the mechanisms required in ISO 17025 chapter 4 are met by the ISO 9001 certified quality management system our accreditation is based on. Thus we "only" needed to add our laboratory specific parts to the system. The experiences from the accreditation of the spectrometry lab in 2006 saved lots of time and discussions to be spent on very basic issues, like e.g. the handling of electronic data. We carefully reviewed and improved our processes during planning and writing the documentation. All processes in the lab are now well documented, the former hidden experiences of the staff are now "publicly" available and are assured against getting lost over time. The quality management documentation now serves as a manual of the work in the laboratory and is under constant review. The discussions and explanations to our quality management team, which was non-expert in the field of in-vivo monitoring, were helpful in putting everything in clear words. Thus our final documentation became more comprehensible for people without in-depth knowledge of the laboratory. The materials developed for the QMS is also used for the education and training of new personnel e.g. the students of Karlsruhe university of cooperative education, who do parts of their practical studies in radiation protection at the in-vivo monitoring laboratory (IVM).

After more than two years of working with the quality management we can say it was worth the trouble and time required in setting it up and gave an overall benefit for the lab. Only a sparse amount of the work time needs to be spent to maintain the running system. It also leaves enough freedom in the daily routine work at IVM and found acceptance by the employees, quickly.

Acknowledgement

Support by the quality management team of HS (now KSM) and the staff of the spectrometry lab is gratefully acknowledged.

Abstract

Molecular imaging techniques have become important tools for the clinical diagnosis of several diseases. These techniques are today in a highly mature state in the clinical field and are now being rapidly developed for use in biomedical (preclinical) research. Among currently available techniques are those allowing acquisition of high resolution anatomical images (CT, MRI), while others offer high sensitivity physiological/ molecular imaging (PET, SPECT, optical). However, used separately each technique offers limited information, and therefore the emphasis of imaging applications for research is on multimodal imaging, wherein images from different techniques are combined to yield an image of high resolution and sensitivity.

Although the use of radioactive isotopes in biomedical research is declining overall, their use in molecular imaging techniques is increasing. Currently, the most developed molecular imaging technique in research, and the most significant from the perspective of radiation protection (RP), is the microPET, combined with anatomical imaging, mainly by CT. In order to set up this technique (or others, such as SPECT) in a biomedical research centre, the RP requirements associated with the handling of high energy gamma sources (PET) and X rays (CT) must be met (equipment, shielding, dosimetry, waste management, training, etc.). These measures also need to be evaluated and adjusted to meet the specific requirements of research centres in terms of biosafety, animal health and welfare, etc. This situation thus complicates RP in this kind of facility.

The aim of this study is to briefly describe the most important imaging techniques and their application in biomedical research, and to present an example of the setting up of a unit or laboratory specialized in these techniques in centres dedicated to pure biomedical research (not associated with a healthcare centre).

This study has been conducted by specialists from the RP and molecular imaging fields.

Introduction

Biomedical research addresses increasingly complex problems related to the biochemical processes that occur in living organisms. As in clinical research, medical imaging techniques are excellent tools to study these processes. A molecular image can be defined as a visual representation, characterization, and quantification of biological processes at the cellular and subcellular levels within living organisms without disturbing the system under study. It has been demonstrated that the visualization and quantification of the function of certain organs of laboratory animals by means of molecular images is a very important tool in the study of human diseases, and also for the discovery and development of new drugs and biochemical probes. As a consequence, animal models are being developed on a translational scale for the generation and the development of tools suitable for the diagnosis and/or treatment of this type of diseases.

Molecular Imaging Techniques with implications for radiation protection

Different Molecular Imaging techniques are combined in this single discipline with a common aim: to change the way in which biological research is carried out. Techniques such as, among others, PET, single photon emission computed tomography (SPECT), digital autoradiography, magnetic resonance (MR), MR with spectroscopy, bioluminescence, fluorescence, and echography, are under constant development. Lately, considerable effort has been directed towards the development of these non-invasive high-resolution imaging techniques for their use in small animals. These miniature systems are not an unnecessary fashionable trend, since they have a better resolution and are generally cheaper than their counterparts for clinical use; several systems can be placed in one laboratory and can be shared among different disciplines. Nevertheless, there are still challenges that need to be solved, such as: trying to obtain an image of a mouse that weighs 30 g and compare it with that of a human who weighs 70 kg, differences in size and volume, the spatial resolution necessary to collect useful anatomical and/or functional data, and the time needed to obtain the images (1). In small animal research the main goal is to obtain the maximum signal possible using the minimum amount of molecular probe, and to locate this signal as precisely as possible in terms of temporal and spatial resolution, using a single system that is able to produce a three-dimensional image that simultaneously presents anatomical and functional information (2). Below, we will evaluate each of the imaging techniques that have major repercussions for radiation protection.

Positron Emission Tomography (MicroPET)

By means of PET the metabolic route can be visualized that a given molecule follows after its incorporation into the organism, generally by means of intravenous administration of a radiolabelled drug. Various biological molecules are labelled with positron-emitting isotopes and follow their normal metabolic route, moving to the sites where they are metabolized (2). Throughout their course, and also from the sites were they are stored and eliminated, they emit a radioactive signal that can be detected from the outside. Detection is done by means of a positron camera or a PET camera. At present, the basic radiolabelled drug used in this technique is fluorodeoxyglucose

(FDG), a glucose analogue labelled with Fluorine-18 (Figure 1). This tracer is relatively unspecific and, although it allows to locate and to study in detail the uptake of the molecule in tissues with high glucose consumption (heart, brain, tumours), deposits may also be produced in other sites that are not of interest, such as points of inflammation. Nevertheless, FDG can be obtained commercially very easily. The use of PET is limited by a poor access to other types of radiolabelled drugs specific for other applications (synthesis of proteins and nucleic acids, hypoxia, immunoPET, etc.); even though such drugs have been developed or are being developed, access to them is difficult if one does not possess a cyclotron or does not have one nearby. Drugs radiolabelled with other isotopes (Ga-68, Cu-64, I-124) are also being developed. At the moment the main applications of PET, both in research and in the clinic, are oncology for localizing and monitoring tumours, and cardiology and neurology for the detection of specific pathologies.

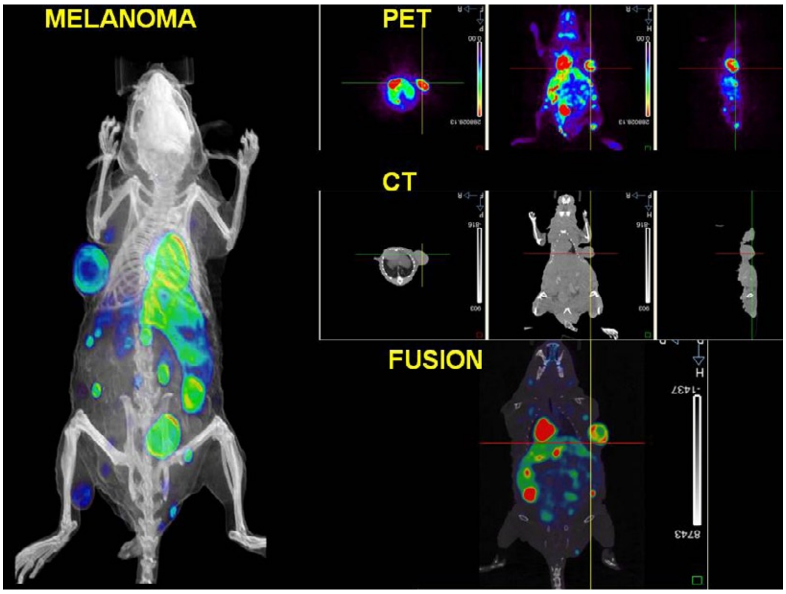

Fig. 1. Image of a study of a transgenic mouse with metastasized melanoma using PET, CT, and a fusion of both. Multiple F18-FDG deposits corresponding to metastases are observed.

Single photon emission computed tomography (MicroSPECT)

SPECT is a technique that is analogous to PET. The difference resides in the type of isotope used, which in the case of SPECT are single photon gamma emitters. Labelling, administration, and acquisition are similar to those for PET, but in this case the technique offers a lower resolution and sensitivity. However, there is a greater variety of tracers and isotopes, since most radiolabelled drugs used for SPECT are obtained using a Tc99m generator, with a longer half life and allowing to work *in situ*. SPECT is applied to the same cases as PET, and in addition for the control of renal and osteoarticular function, but since there is a greater number of approved radiolabelled drugs available, the field of application extends to a larger number of benign pathologies and functional studies.

Computerised Tomography (MicroCT)

The images of computerised tomography are based on the different absorption by tissues when X-rays pass through them. CT is not a technique that provides information at the cellular or molecular level *per se*, and therefore it is not considered a molecular imaging technique. Nevertheless, this technique is of great importance for the anatomical location of functional images (PET and SPECT) and for their reconstruction. This is even more so if one takes into account that the molecular probes are increasingly specific. The radiation deposited in the experimental animals is not insignificant (0.6 Gy/scan, corresponding to 5% of the LD50 in mice), which limits obtaining images in series (3).

Model for applying Molecular Imaging techniques in biomedical research centres

In this part of the paper we will develop a model for the design and management of working with imaging techniques in a research centre not associated with clinical facilities. What is indicated under each point is an option that the authors consider appropriate to be in operation or in phase of development in real centres.

Radioactive Facility

The development of the imaging techniques mentioned above (PET, CT) implies the handling of non-sealed radioactive isotopes and the use of equipment emitting ionizing radiation (RX), which is why, according to the Spanish legislation, it is necessary to have a radioactive facility (RF) authorized by the competent authorities.

In Spain many biological research centres follow a similar RF model. The model includes a central laboratory and authorized areas in the research laboratories. It is a model designed for the use of non-sealed sources both *in vitro* and *in vivo*, although depending on the type of centre and activity it may include equipment emitting ionizing radiation (irradiators, diffractors, imaging equipment, etc.). According to this model, there is a central laboratory designed for the manipulation of high activities (limits of activity per essay from 10 to 30 mCi, depending on the type of isotope) or high-risk isotopes (volatile iodides, high energy gamma emitters). This laboratory is also used for the management and control of the RF and contains the central radioactive waste depots. The RF further includes authorized areas in the research laboratories. These are small areas in each laboratory that requires it, and are specifically placed and equipped for the exclusive handling of limited activities of radioactive isotopes (between 0.5 and 2 mCi per assay, depending on the isotope). In addition to these we may also find areas where emitting equipment is stored; these areas are set up according to the requirements of the equipment (access control, shields, etc.). The Molecular Imaging Unit (MIU) is considered as another authorized area, to which the appropriate measures of control and protection are applied, based on the types of isotopes handled and the techniques developed. The research centres normally have personnel specifically assigned to the management and control of the facility, with an official license (for operation or supervision) granted by the competent authority.

Central Laboratory of the Radioactive Facility

As mentioned before, this laboratory is especially equipped for the development of techniques that imply the handling of high activities or high-risk isotopes. The laboratory should be classified as a controlled area with radiation and contamination hazards. It must have access control and control of atmospheric pressure (negative pressure), as well as activated carbon filtration of all air extracted from the laboratory.

The laboratory has both the basic laboratory equipment and all the necessary means of protection for the development of the established techniques (fixed and movable shields, containers, containment equipment, detectors, emergency devices, etc.).

Since the radioactive waste deposits are included in it, in this laboratory the whole spectrum of registration, preparation, and elimination of radioactive waste or waste material with radioactive contents is realised.

With respect to imaging techniques, in this laboratory the control and registration of the incoming commercial radioactive material is carried out by personnel in charge of Radiation Protection management, and the labelling of tracers is done in situ; these activities are developed by research personnel with specific training in Radiation Protection.

The laboratory has the necessary specific protection equipment to carry out the indicated activities. It must have manipulation cells, movable shields, shielded containers, general laboratory equipment, materials that enable the proper course of action in emergency situations, etc. For manipulation cells, one can opt for mixed and shielded biosafety cabinets. These are conventional biosafety cabinets that have been modified by adding activated carbon filters and the necessary shielding in the outer and frontal panels. They allow working under sterile conditions, and at the same time they protect the operator from radioactive gases or vapours, as well as of aerosols contaminated with pathogenic biological agents that may be used in the research.

This model is being successfully used in various centres.

Molecular Imaging Unit

As mentioned before, a research centre that wants to develop this type of techniques must have a Unit specialized in molecular imaging. The MIU must provide the research groups with the latest imaging techniques. This unit must be in charge of the preparation of the doses, administration to the animals, obtaining the images, and their analysis. It must therefore have specifically trained personnel. Because of the nature of the work done, this unit must be intimately linked to the Animal Facility, ideally being located close to this facility. The unit must also have specific facilities both for handling the animals, which must form part of the Animal Facility, and for the analysis of the images, which should be outside the facility but close to it.

Design of the facility for handling radioactive material and animals

Normally, one starts out with a defined space that must be adapted to the requirements of this type of techniques. Especially with PET isotopes, it is more efficient in economic terms to take advantage of the distances instead of using thicker shields as a means of protection against radiation, or to place the different areas next to low occupation spaces, such as corridors, technical areas, etc. Of course, one should also consider the isotopes to be used and the activities to be manipulated; the latter depends on the study model, since large animals usually require higher activities.

In this space we must establish a room for the imaging equipment, which must fulfil the installation and environmental requirements for operation of the equipment (temperature, humidity, maximum incline, electric power, etc.), and also the requirements for handling animals: space for an anaesthesia table, gas provision, etc. Preferably adjacent to it, there should be a control room from which both the specimen and the equipment can be seen. Close to this area of the facility, to avoid transfers over long distances, a room must be located where the animals are injected and where they will stay during the incorporation of the tracer, and to which they are returned and where they will remain until it can be considered safe to manipulate and house them with the rest of the animals. Normally, this area requires the most shielding of the entire facility and must provide sufficient space for the amount of studies to be done. This is the area with the highest contamination hazard because of the injection procedure and the animal excrements. To avoid transfers of radioactive material over long distances, it is also advisable to locate close to the injection room the area for dose preparation, where the radioactive material from the providing laboratories is received and divided into single doses. The floor of the laboratory must be able to sustain the weight of the of radiation protection material that will be installed in it, which usually is around 1000 kg/m2. Optionally, depending on the characteristics of the isotopes to be used, it may be necessary to have an area for the temporary storage of waste, possibly including animal carcasses until they have decayed. If only PET isotopes are used, storing for 24-48 hrs in wastebaskets may be sufficient. When (e.g. Ge-Ga) generators are used, it will be necessary to have a greater storage capacity.

As a general norm, air of these areas should not be recirculated to the rest of the facility, and the needs of the animals must determine the quality of the air supplied to these areas. All surfaces of the areas described above must be finished in such a way that they allow easy cleaning and decontamination.

Equipment

The area of animal manipulation will have to contain the necessary equipment for the development of these techniques. Below we will list the most important equipment to consider.

- Imaging equipment: select according to the technique to be used. The ideal is to use an integrated multimodal PET/CT or SPECT/CT equipment. At the moment integrated or associated PET/NMR equipment is being developed. The type of studies will determine to a large extent the type of technique and therefore the type of equipment.
- Anaesthesia Table: sized according to the type of study animal.
- Leaded screen for handling the animals, especially rodents. It has to be made in such a way that it can be easily decontaminated.
- Manipulation cell / lead castle: easily decontaminatable, with access for hands and material, shields adapted to the activities to manipulate (30-50 mm Pb is usually sufficient), with an adequate system of air circulation and filtration if the type of isotope to be manipulated requires it, and sufficient illumination. It is very

recommendable to include a properly shielded housing for the ionization chamber of the activimeter.

- Activimeter: appropriate for the isotopes to be used and in the range of the activities handled in the laboratory.
- Radiation Monitor: with a probe sensitive to the levels of design of the facility, typically from 0.1uSv/h to 20 mSv/h
- Contamination Monitor: with a probe suitable for the emission of the isotopes of the facility and with a surface not less than 100cm2.
- Wastebaskets or furnishings for temporary waste storage: easily decontaminatable and with sufficient capacity for the amount of material to be used.

Work norms

For working with PET/SPECT isotopes and the radiation emitting equipment, the general norms for working with radioactive isotopes apply. These include norms regarding the operator: personal protection (gloves, lab coat, etc.), abiding by the norms of hygiene, use of appropriate shields, correct use of the dosimeter, etc.; norms regarding the work area: signposting, order and cleanliness, containment, monitoring, access control, etc.; and norms regarding the surroundings: contamination and radiation monitoring and correct waste management.

Specific norms for PET/SPECT isotopes must also be applied, such as the use of specific movable shields (screens, dose dispenser, syringe protectors, etc.) or the use of means for increasing the distance between source and hands (forceps). Of special importance for labelling animals with PET/SPECT is prior cold training, to carry out the tasks in as little time as possible. Labelled animals must be housed in suitably shielded areas during a period of not less than 24 hours (this can be modified depending on the characteristics of the isotopes used) to allow the isotopes to decay before incorporating the animals again into the colony of the Animal Facility.

To guarantee the correct fulfilment of the norms and hence the protection of the operators, operational monitoring of the facility must be done by means of periodic inspections of control of the fulfilment of the operational norms, both in the central laboratory and in the authorized areas, including the MIU. These inspections include monitoring of contamination, waste management, appropriate conditions of order and cleanliness, filling in of the registers, correct maintenance of the specific monitors, etc. These inspections are carried out by the personnel in charge of the management of Radiation Protection.

Personnel. Functions and classification

The personnel implied in the manipulation of PET isotopes and radiation emitting equipment is as follows (references to degrees and licenses refer to what is established in the Spanish legislation):

- <u>Personnel in charge of Radiation Protection management</u>: Made up of the Responsible of the RF (Supervisor in charge or Head of Radiation Protection), and a team of assigned technicians, all holding an operator license in the application field of the RF at issue. These personnel will be in charge of the reception and registration of the commercial radioactive material and the operations of monitoring and control of the RF.

- Molecular Imaging Unit: Made up of a Person in charge holding a Supervisor license and a team of technicians with operator licenses, all in the field of application of the RF at issue. These personnel will be in charge of the development of the different imaging techniques that involve treating animals with radioactive material or handling radiation emitting equipment, including labelling the animals, the acquisition of images, and their subsequent analysis. This will be the only personnel authorized to carry out this type of techniques.
- Research Personnel: They will carry out the techniques of labelling experimental tracers with PET or SPECT isotopes. Depending on the activities and isotopes handled, they may or may not need to hold an operator license in the field of application of the RF at issue.

As a general norm, all exposed personnel will be considered as exposed workers of category B (according to the Spanish legislation), since it is improbable that they will receive doses above 6 mSv or 3/10 of specific limits in a calendar year. Depending on the animals handled and the doses administered, workers who carry out functions of dispensing and administering radiolabelled drugs may be classified as occupationally exposed personnel of Category A (who may receive doses above 6 mSv or 3/10 of specific limits in a calendar year).

Training

Besides knowledge acquired in training courses for operators or supervisors of Radioactive Facilities, all personnel involved in handling PET or SPECT isotopes must receive specific in-house training. This training will consist of giving different seminars in which information will be included on the general safety norms for working in a laboratory, the handling of radioactive PET/SPECT isotopes (radiological hazard, use of shields, detectors, etc.), operation, and the Emergency Plan of the RF. The personnel of the Imaging Unit dedicated to labelling the animals will receive additional training in handling research animals. These personnel must also first do practical and specific training, developing the techniques of animal handling under the same conditions as when using radioactive material, for example using portable shields (screens, syringe protectors).

Dosimetry

Dosimetry of occupationally exposed personnel of Category A and B must be done by means of individual dosimeters. In our case, we use thermoluminescence dosimeters. The whole body dose must be controlled during the entire working day by means of lapel dosimeters. For the personnel who directly handle the radioactive isotopes, the hand dose must also be controlled by means of ring dosimeters. After an accident an additional control by means of internal dosimetry must be done.

The aim is to keep the doses received by the personnel who handle the animals and the vials or syringes with radiolabelled drugs as low as possible. In the case of handling small animals, whole body dose levels can be obtained that are similar to those of the other exposed workers in research, normally below the public dose (1 mSv/year). Hand doses can be kept at very low levels (100 times below the established annual limit, 500 mSv/year). When working with large animals it is tried to obtain dose levels that are less than those received by the personnel who apply these techniques in the clinical setting, since the doses used for large animals are of the same order as those applied to humans.

Working with research animals. Small and large animals.

Animals used as experimental models for research are, generally, rat, mouse, rabbit, and pig. Mice are the first species of choice in the scientific community for imaging studies. Nevertheless, the study of certain pathologies in mice limits the translation to humans. However, the ease with which genome can be manipulated, the possibility to work with large sample sizes, and the reduced costs make them an ideal species for study. On the other hand, the ease with which they can be handled, the low need for space, and the relatively low doses of radiolabelled drugs they receive in studies simplify the management in radiation protection regarding shielding, housing of the labelled animals, and waste management. In contrast, the use of large animals entails the inoculation of high activities of radiolabelled drugs, to which the difficulty of handling the animal is added, which will have to be anaesthetised and gavaged for the possible collection of contaminated urine (15% of the radiolabelled drug) after injection. Administration of radiolabelled drugs, both to small and to large animals, is best done with the animal under anaesthesia and using appropriate means of protection like shields, or using systems to restrain the animal to reduce the risk of self-inoculation. After the imaging study, there must be a shielded space reserved in the radioactive facility to house the animals until their decay. This module, with peripheral shielding and preferably with individual cells in which movable shields (screen type) must be installed, must have an adequate system for the containment of urine/excrements/ potentially contaminated bedding. Special mention must be made of the handling of urine, which is the major vehicle of elimination of radioactive material. Therefore, a containment system must be implemented adjusted to the volumes and activities used, such as containment tanks or deposits.

Discussion

Molecular imaging techniques are a new and very useful approach in biomedical research. Nevertheless, a technique that is useful for all fields of biomedical research does not exist. The technique must be selected that adjusts best to the needs of each type of disease studied. Multimodality in molecular imaging is the present and the future of these techniques in research and in the clinic. The use of hybrid equipment simplifies and accelerates image analysis and obtaining results.

The use of PET isotopes implies an increased risk with respect to the isotopes used most commonly in research, since it involves handling isotopes with higher energies and higher activities than the ones generally used in research. This becomes even more significant if research is done on large animals, where the doses used are similar to those used in humans. Keeping the doses low is achieved by an appropriate design and application of movable shields, as well as by the specific work norms. Hand doses can also be maintained at very low levels (approximately 100 times less than the annual limits for extremities) by using specific movable shields, by increasing the distance from the source, by avoiding direct handling of the source, and by using accessories (e.g. forceps for the handling of vials) whenever possible. In our case, the facilities for working with large animals (pigs) are in the phase of design and construction, so that we do not have results of the dosimetry of this type of work. The objective is to obtain dose values below those of people working in clinical facilities, using the means indicated above adapted to the type of animal used.

To obtain these results, specific prior "cold" training is vital. For the selection of technicians who are going to do the animal labelling, priority must be given to previous experience in the manipulation of experimental animals, which could be complemented with the appropriate training in radiation protection. Handling laboratory animals and administering drugs to them demand special skills to obtain optimal results (injection in the minimum time possible with the smallest number of attempts and the greatest safety for the operator), that can only be achieved through training and experience. To this the difficulty is added to conduct these operations using specific shielding (syringe protectors). Therefore, the optimal situation would be to have a person with experience in animal manipulation who has sufficient time for prior training in the use of such shieldings. In Spain, training in radiation protection has been regulated for a long time, and it is therefore much more developed than training in animal handling. For this reason it is deemed that it is faster and easier to acquire an extensive and detailed training in radiation protection that complements the experience in animal handling.

Conclusions

At present, PET/CT is the molecular imaging technique that is developed furthest in research, with a greater projection and offering results of higher quality, although other techniques are being developed for specific applications, such as SPECT/CT or PET/MRI.

According to our experience, in the work with small research animals (mice), as far as the dosimetry of the personnel who handle these isotopes is concerned, it is possible to obtain whole body dose levels (lapel dosimetry) similar to the other researchers, which are very much below the annual dose limits of exposed workers and normally close to the public dose levels. Hand dose levels very much below the established annual limits for extremities can also be obtained.

Prior cold training and the selection of personnel are vital to attain the goal of the safe use of these isotopes and to maintain the doses low. It has been observed that it is preferable to prioritize previous experience and training in animal handling, which is then complemented with training in Radiation Protection. Working with large animals complicates the design considerably, and therefore all systems affected must be studied carefully to establish the most appropriate measures to take (shields, housing, control of effluents, etc.) in each case.

Testing of sealed radioactive sources at BAM

Rolle, Annette; Neumeyer, Tino; Droste, Bernhard
Federal Institute for Materials Research and Testing (BAM), GERMANY

Abstract
Requirements and test programs for sealed radioactive sources are specified in international standards for safety in transport and in use.

Sealed sources which are approved as special form radioactive material according to the Transport Regulations, IAEA Safety Standards TS-R-1, must be able to withstand mechanical (9 m drop, percussion and bending) and thermal (800°C heat) tests without loss of radioactive content.

The International Standard ISO 2919 provides a set of tests which classifies the sources for their safety in use. Performance tests specified in this standard are temperature (high and low), external pressure, impact, vibration and puncture tests. Each test can be applied at different levels of intensity depending on typical usage.

As a criterion of pass or fail, leakage testing has to be done after each test.

The poster gives an overview of BAM's comprehensive test equipment and experience in testing sealed radioactive sources.

Introduction
Requirements and test programs for safety evaluation of sealed radioactive sources are specified in international safety standards for transport and for use. BAM is the competent authority for approvals for special form radioactive material and for type testing of devices with inserted radioactive sources and possesses a comprehensive test equipment and experience in testing for many years./1/

Regulations and standards for testing

Transport regulations
Special form radioactive material is defined in IAEA –Regulations TS-R-1 /2/ as an in-dispersible solid material or a sealed capsule containing radioactive material. The design must be able to withstand severe mechanical and thermal tests without undue loss or dispersal of radioactive content. As a consequence the predicted hazards after a severe accident are minimised and the transport of a greater activity in a Type A - package is permitted. Tests specified in Para 705-709 of TS-R-1 are

– impact test
– percussion test
– bending test
– heat test

A different specimen may be used for each test. As a criterion of pass or fail, leakage testing according to ISO 9978 has to be done.

Regulations for use

The International Standard ISO 2919 /3/ provides a set of tests which classifies the sealed source for their safety in use. Performance tests specified in this standard are

– temperature test (high and low),
– external pressure test
– impact test
– vibration test
– puncture test
– bending test.

Each test can be applied at different levels of intensity depending on typical usage (Table 1). The criterion for passing or failing is also the leak-tightness.

Table 1. List of test conditions (ISO 2919:1999).

Table 2 — Classification of sealed source performance (5 digits)

Test	Class						
	1	2	3	4	5	6	X
Temperature	No test	– 40 °C (20 min) + 80 °C (1 h)	– 40 °C (20 min) + 180 °C (1 h)	– 40 °C (20 min) + 400 °C (1 h) and thermal shock to 20 °C	– 40 °C (20 min) + 600 °C (1 h) and thermal shock to 20 °C	– 40 °C (20 min) + 800 °C (1 h) and thermal shock to 20 °C	Special test
External pressure	No test	25 kPa absolute to atmospheric	25 kPa absolute to 2 MPa absolute	25 kPa absolute to 7 MPa absolute	25 kPa absolute to 70 MPa absolute	25 kPa absolute to 170 MPa absolute	Special test
Impact	No test	50 g from 1 m or equivalent imparted energy	200 g from 1 m or equivalent imparted energy	2 kg from 1 m or equivalent imparted energy	5 kg from 1 m or equivalent imparted energy	20 kg from 1 m or equivalent imparted energy	Special test
Vibration	No test	3 times 10 min 25 to 500 Hz at 49 m/s² (5 g_n) 1)	3 times 10 min 25 to 50 Hz at 49 m/s² (5 g_n) 1) and 50 to 90 Hz at 0,635 mm amplitude peak to peak and 90 to 500 Hz at 98 m/s² (10 g_n) 1)	3 times 30 min 25 to 80 Hz at 1,5 mm amplitude peak to peak and 80 to 2 000 Hz at 196 m/s² (20 g_n) 1)	Not used	Not used	Special test
Puncture	No test	1 g from 1 m or equivalent imparted energy	10 g from 1 m or equivalent imparted energy	50 g from 1 m or equivalent imparted energy	300 g from 1 m or equivalent imparted energy	1 kg from 1 m or equivalent imparted energy	Special test

1) Acceleration maximum amplitude

Specimens that comprise special form radioactive material may be subjected alternatively to ISO 2919 tests if these are the more severe ones. The ISO 2919 temperature class 6- test with 1 h at 800°C is in any case more severe than the IAEA TS-R-1 heat test with 10 min at 800°C. Special form radioactive material with a small mass may be except from 9 m drop impact. Capsule designs with a mass less than 200 g may be alternatively subjected to the ISO 2919 impact class 4- test, and for designs with a mass less than 500 g the impact class 5- test may be equally acceptable.

Test methods, equipment and experience

BAM cannot test radioactive samples. All tests have to be done with dummy sealed sources, i.e. the source capsule has the same design, same manufacturing methods and is made from exactly the same material as those of the sealed source that it represents, but containing, in place of radioactive material, a substance resembling it as closely as practical achievable in physical and chemical properties.

Impact test (9 m drop)

For impact test of special form radioactive material the specimen should be dropped from a height of 9 m onto a flat unyielding target so as to suffer maximum damage. Because a definite angle of impact could be important for the damage result BAM use a magnetic release device for a momentum free drop. A high-speed camera (image frequency 5.400/s, 1024x1024 pixel) is used to keep track of the impact position.

Impact test 1 m, percussion test, puncture test

For impact and puncture test according to ISO 2919 and for percussion test according to the IAEA regulations for special form radioactive material the same equipment is used by BAM. (Fig.1)

This test device has also a magnetic release system to assure a momentum free drop, and is suitable for hammer masses up to 5 kg. Impact tests with higher hammer masses are performed at the 9 m drop facility.

Most of the different steel hammers for the tests in different classes (Table 1) are available (Fig.2).

For percussion test with special form designs the specimen shall be placed on a sheet of lead and struck by a steel bar of 1.4 kg from a height of 1 m. A fresh flat surface of lead shall be used for each impact. The bar shall strike the specimen so as to cause maximum damage.

As an example, in case of small welded Ir-192 sources used for the brachy therapy the bar should strike the weld-seam with its rounded edge to cause maximal bending stress by pressing the source only partly into the soft lead (Fig. 1 b).

For ISO 2919 impact test class 4 the specimen is placed on a steel anvil with a mass of at least 20 kg, and is struck by a hammer of 2 kg from a height of 1 m. In most cases strains are much higher than in case of the IAEA percussion test, were an only 1.4 kg hammer drives the specimen in the soft lead sheet, excepting cases with additional bending stress as described above. Beside the striking position, also the form of simulated content can have an influence on damage results. For example Ir-192 sources could be filled with one long iridium wire or several shorter iridium-cylinders. Under impact the edges of the cylinders can partly push trough the thin capsule wall.

Steel hammers for puncture test bear a fixed pin with a diameter of 3 mm and a height of 6 mm and can also be attached at the magnetic release device .The mass depends on the test-class and varies between 1 g and 1 kg. If source design has more than one vulnerable area, tests have to be carried out on each of them.

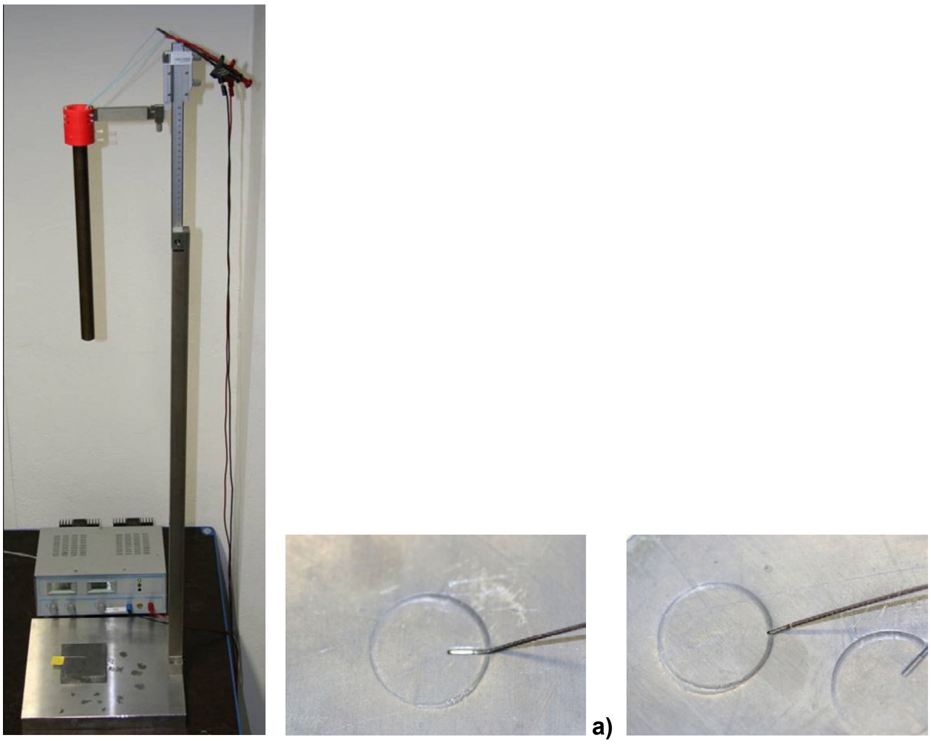

Fig. 1. Percussion test on a Ir-192 source for brachy therapy (1.4 kg from 1 m on a sheet of lead) with different impact positions a) less damage , maximum bending stress in the flexible wire; b) maximum bending stress in weld seam of the source.

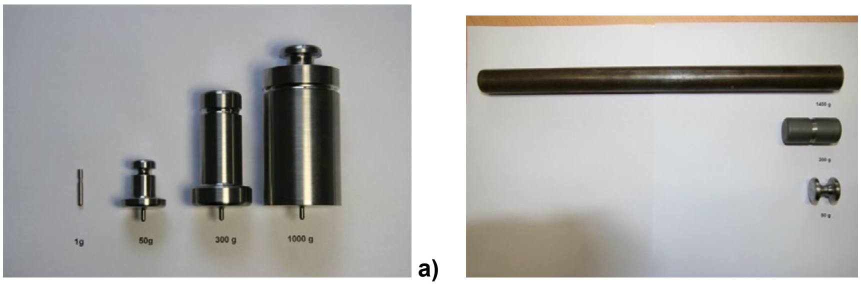

Fig. 2. Examples for steel hammers for a) puncture and b) impact or percussion test.

Temperature tests

An approval for special form radioactive material requires a heat test in air at a temperature of 800°C for 10 min.

Temperature tests according to ISO 2919 include a high–temperature test at temperatures of 80 to 800°C for 1h and a low-temperature test to -40°C for 20 min. The class 6 test (-40°C for 20 min, 800°C for 1 h) as an adequate alternative to the IAEA heat test (800°C for 10 min) is often employed by BAM.

BAM uses for upper temperature test a furnace with a capacity of 10 kW for a maximum temperature of 1200°C to be reached in 2.5 h. Attention should be paid to positioning the specimen in the middle of the furnace and to fitting the thermocouple directly on the specimen surface. In case of designs with a low-melting content, for example distance pieces made of aluminium, an eutectic reaction can happen and can cause a damage of the capsule material and in worst a leakage.

A climate chamber (-80°C until 190°C) is used for low temperature test.

Bending test

Bending tests shall apply only for long, slender sources. IAEA regulations require this for sources with both a minimum length of 100 mm and a length to minimum width ratio of not less than 10. The free end of a rigidly damped specimen has to be struck by a 1.4 kg steel bar. BAM uses a common clamping tool for fixing the specimen and a tripod to adjust the drop height.

Bending tests according to ISO 2919 shall apply to sealed sources having a length to minimum width ratio of 15 or greater. Test procedure is different from this described above. BAM has up to now never carried out this ISO bending test.

Vibration test

BAM features an electro-dynamic shaker with up to 26 kN peak force and frequencies of 5-2000 Hz with acceleration and force control for performing the vibration test according to ISO 2919. Up to now none of the tested sealed sources have shown any signs of damage after these tests done by BAM. Often applicants abstain from this test.

External pressure test

A hydraulic power unit with a maximum operating pressure of 345 MPa , operating medium water, is used for the external pressure test, therewith BAM is able to carry out also tests up to 170 MPa .

Leakage test as criterion for pass or fail

Compliance with all mechanical and thermal tests has to be determined by the ability of the sealed source to maintain its leak-tightness after each test performed.

BAM uses non –radioactive procedures based on a relationship between volumetric leakage rates and loss of radioactive material with test procedures according to the International Standard ISO 9978 /4/.

A volumetric leakage test is only applicable if there is a minimum void within the capsule (Table 2). In particular in the field of medicine sources become smaller and the need for application of volumetric leak test methods with very small void increases.

BAM possesses comprehensive equipment for performing various kinds of helium tests, vacuum bubble and nitrogen bubble tests.

Table 2. Minimum void in capsule for different volumetric leak test methods.

Leak test method	Minimum void in capsule [mm³]
Vacuum bubble	
- glycol or isopropyl alcohol	10
- water	40
- Pressurized bubble with isopropyl alcohol	10
Liquid nitrogen bubble	2
Helium pressurization	10

Conclusions

The International Standards ISO 2919 and the IAEA Safety Standard TS-R-1 provide a set of mechanical and temperature tests for assessing the safety of sealed radioactive sources in transport and use. BAM possesses comprehensive knowledge, experience and equipment for performing nearly all of these tests.

Since BAM is the competent authority for approval of special form radioactive material tests according to the IAEA regulations have always the priority. But depending for their work load test labs are always ready to carry out also the classification tests according to ISO 2919. About four weeks after incoming of specimens, a test program for one source design can be finished in general.

BAM actively works in further development of test methods and regulations and its' representatives take part in national and international working groups and boards dealing with this topic.

Radiological criteria's for patients discharge following a radionuclide therapy or brachytherapy with implanted sealed radionuclide sources

Balonov, Mikhail; Golikov, Vjacheslav; Zvonova, Irina
Research Institute of Radiation Hygiene, RUSSIAN FEDERATION

Abstract

Dose criteria for limitation of exposure incurred by persons helping the patients or living with patients discharged from hospitals following radionuclide therapy or brachytherapy with implanted sealed radionuclide sources have been proposed for national Russian regulation. By means of a conservative dosimetry model, the values of operational radiological criteria for patient discharge from hospital are substantiated basing on the standards of permissible effective dose for population – 1 mSv and for persons helping the patient or living with him – 5 mSv. Two sets of whole body activity for radionuclides I-125, I-131, Sm-153 and Re-188 used in Russia for therapy, as well as dose rate near patient body were received. The smallest one was included in the new Russian Standards for Radiation Safety (SRS-99/2009). Observance of suggested criteria will ensure radiation safety of people in near environment (family, close friends et al.) of the discharged patient.

First lessons from the Montbéliard Radiation Protection Pilot Project: towards the development of a local expertise in radiation protection

Bataille, Céline; Lochard, Jacques; Schneider, Thierry
Centre d'étude sur l'Evaluation de la Protection dans le domaine Nucléaire, FRANCE

Abstract

Since 2004, the Montbéliard Urban Community (CAPM), in cooperation with CEPN, is engaged in a Radiation Protection Pilot Project whose main objectives are to improve the radiation protection of the inhabitants of the Montbéliard Country and to promote the creation of a pole of competence in the field of radiation protection in the territory.

This Project is based on a global approach addressing all aspects of radiation protection. It is divided into five sections: three ones are related to exposure situations (medical exposure, exposure to radon, exposure in case of nuclear or radiological events), two others concern the development of the radiation protection culture among the population.

The Project is designed to promote active participation from various stakeholders at the local level, working in cooperation with national and international experts. In particular, local actors work in close relationships with major radiation protection experts in France: namely the French Institute of Radiation Protection and Nuclear Safety (IRSN) and the French Nuclear Safety Authority (ASN). Besides, CAPM has entrusted CEPN with a number of tasks to help manage and facilitate the project.

In 2009, the main partners of the Radiation Protection Pilot Project decided to analyse the feedback experience from this initiative. This paper focuses on the main results and perspectives of the Project and presents the first lessons that have been drawn. In particular, lessons about the possible involvement of territories in radiation protection management are developed. Conditions needed to favour a local expertise in radiation protection are notably discussed.

Introduction

Everyday, the public is exposed to radioactivity from various sources – radon, medical practices, releases from nuclear facilities… Such exposure, no matter how significant, raises questions and sometimes gives rise to worry or even anxiety. The populations concerned and the professionals and local authorities responsible for risk prevention and management often find it hard to assess the impact that such situations can have. This is largely because they are not involved in the management of their "radiological situation" and have insufficient knowledge of basic principles of radiation protection

That being the case, how can members of the population and professionals working at the local level gauge risk levels and determine what steps need to be taken to control these forms of exposure? How can these people be associated with the assessment and management of radiological risks, with the support of experts and authorities? What can be done to promote a shared radiation protection culture that will allow people to contribute to their own protection?

Based on these observations and questions, local experts in radiation protection from the Montbéliard territory decided in April 2003 to look into the possibility of developing a radiation protection skills centre within the Montbéliard area. A Radiation Protection Pilot Project was then set up in March 2004 with the objectives to improve the radiation protection of the inhabitants of the Montbéliard Urban Community and to promote the creation of a pole of competence in the field of radiation protection in the territory. Considering the absence of nuclear installations in the region, this decision reflected a strong political engagement from the local authorities to address risks related to radiation exposure.

In 2009, five years after the beginning of the Project, it was decided to analyse the feedback experience from this initiative. This paper focuses on the main results and perspectives of the Project and presents the first lessons that have been drawn. In particular, lessons about the possible involvement of territories in radiation protection topics are developed (Bataille et al., 2010).

Structure of the Radiation Protection Pilot Project

The Radiation Protection Pilot Project is based on a global approach designed to tackle all aspects of radiological risks and focuses on any form of radiation exposure, from natural, industrial or medical sources. It is implemented according to thematic sections related to different fields of radiation protection:

- Analysis and management of the risk associated with radon,
- Radiation protection in the medical field,
- Management of radiological risks in the event of a nuclear or a radiological emergency situation,
- Training in radiation protection in the medical field,
- Development of a scientific and technical culture in radiation protection.

The Project is designed to promote active participation from various stakeholders at the local level, working in cooperation with regional, national and international experts. In particular, local actors work in close relationships with major radiation protection experts in France: namely the French Institute of Radiation Protection and Nuclear Safety (IRSN) and the French Nuclear Safety Authority (ASN). The Montbéliard Urban Community (CAPM) coordinates the Project and has entrusted CEPN with a number of tasks to help manage and facilitate the project.

Main results and perspectives of the Radiation Protection Pilot Project

During the last five years, numerous actions have been performed in the framework of each of the sections of the Radiation Protection Pilot Project. Main outputs and perspectives are briefly summarized below.

Analysis and management of the risk associated with radon

The Montbéliard Urban Community is part of the Doubs department, which has been defined by French authorities as a priority area for the control of radon (JO, 1999). In this context, CAPM has wished to launch a specific "radon" section to learn more about radon-related risks on its territory and to initiate any protective action considered as necessary. This section began in 2005 as part of a broader objective aiming at improving the air quality in dwellings.

Work in this section began with awareness campaigns targeting local players likely to be involved in radon measurements as well as the inhabitants of the Montbéliard Urban Community (articles in the local press, distribution of brochures on radon). CAPM then decided to benefit from a "radon map" of its territory to obtain a clear idea of the scale of radon risk. Several measurement campaigns of radon concentration were also performed from the end of 2006, first in dwellings and then in public buildings.

CAPM made the choice to develop its own measurement capacities: both campaigns were performed by inspectors of the CAPM Health Office who were trained by IRSN. Local elected representatives were particularly involved in the organisation of the measurement campaigns: they were solicited to contact inhabitants and owners of public establishments and participated in communicating results of measurements. Through these campaigns, all involved actors gained knowledge and competences in radon risk management.

This approach allowed CAPM benefiting from a better knowledge of the radon risk in its territory and identifying buildings where radon concentration was too high. CAPM has then engaged several actions to help owners to implement remediation actions with the support of experts from IRSN and the Swiss Office of Public Health.

Today, the section "Analysis and management of the risk associated with radon" is continuing through new measurement campaigns that will allow completing the mapping of the territory. Otherwise, it is envisaged that CAPM takes part in a working group whose objectives would be to analyse feedback experiences from local French communities that have decided to deal with radon risk. The aim could be to produce guidance for others communities that would like to initiate a similar approach. Finally, the Montbéliard territory will host the next "radon workshop" organised by the French Society of Radiation Protection (SFRP) in Spring 2011.

Radiation protection in the medical field

This section was launched in 2004 by the Montbéliard hospital management team. It was organised to address problems raised by new regulatory requirements applying to medical physicists and radiation protection experts in two areas: the organisational aspects of radiation protection and medical physics and the optimisation of radiation protection of patients.

In particular, the new requirements imposed the need to have a medical physicist on hand in the nuclear medicine and diagnostic radiology departments (JO, 2004a) and to consult a radiation protection expert (JO, 2003). This triggered the idea of exploring the possibility of setting up a unit dedicated to medical physics and radiation protection. As part of this work, the Montbéliard hospital solicited CEPN to gather and analyse feedback experiences from hospitals where such units were in place. Conclusions of this study are still discussed (Badajoz et al., 2008).

As far as radiation protection of patients is concerned, the Montbéliard hospital and CEPN have participated in a working group created by the French-speaking Swiss Society of Radiation Protection since 2009. The objective is to elaborate new documents to improve information of patients undertaking medical procedures using ionising radiations.

Even if the works described above gave interesting results, the staff from the Montbéliard hospital had difficulties to devote time to the Radiation Protection Pilot Project. The partners of the Project also decided to extend this section beyond the hospital. In this context, the Montbéliard Urban Community now intends to develop, with the help of CEPN, the "Medical Radiation Protection School of the Montbéliard Territory". This project will mainly aim at:

– Supporting initial and continuing radiation protection training and research,
– Informing health professionals and patients,
– Developing a radiation protection culture among health professionals and the public.

The "Medical Radiation Protection School of the Montbéliard Territory" will be opened to any interested structure, in particular:

– Local actors involved in the "health" domain in the Montbéliard territory,
– Regional, national and international institutes/organisms involved in radiation protection in the medical field.

Managing radiological risks in the event of a nuclear or a radiological emergency situation

The objectives of this section are to understand the local stakes associated with the management of a radiological accident and to develop practical actions to improve accident and post-accident preparedness in the Montbéliard territory. This section is implemented from a multiple risk perspective, since the Montbéliard Urban Community has to draft Local Community Emergency Plans (as required by the French law; JO, 2004b) taking into account any risk that could affect its territory.

In order to identify the potential consequences of a nuclear accident or a radiological event on its territory, the CAPM, with the technical support of CEPN and KIT (Germany), is using the Decision Aiding Tools developed over the last decades within the European Framework Programme for emergency and rehabilitation preparedness and management. Simulation results are then coupled with data provided by the CAPM Geographic Information System (GIS), which allows determining practical actions to be better prepared to a radiological event.

To date, first studied scenarios showed that the Montbéliard territory could be quite affected. In case of a medium accident at the Fessenheim Nuclear Power Plant (located at 70 km from Montbéliard), the territory would have to implement foodstuffs restrictions on some products (milk, leafy vegetables) during limited periods of time. In case of a severe accident, it would have to set up emergency countermeasures. Finally, an accident of a truck transporting a caesium-137 source would have very localised consequences, mainly in the nearest agricultural areas and rivers.

As a consequence, the Montbéliard territory engaged some practical actions to be better prepared to a radiological event. Buildings that could accommodate populations that would have to be evacuated have been identified. Their location and characteristics have been entered in the GIS of the Montbéliard territory. An assessment of stocks of iodine tablets, available on the territory, has also been performed.

Today, CAPM is pursuing this project. It will notably take part in the development of the French doctrine on post-accident management (CODIRPA) managed by ASN and become a member of the European Platform on Preparedness for Nuclear and Radiological Emergency Response and Recovery (NERIS), recently launched.

Training on radiation protection in the medical field

This section has been initiated and managed by the University of Franche-Comté with the objective to promote links between training, public research and local competences. Because of the lack of personnel in radiation protection in hospitals in France, the proposed trainings sessions mainly concern radiation protection in the medical field. Two training courses have thus been created:

– A professional degree in medical dosimetry and radiation protection (DORA) was created in 2005. 15 to 20 dosimetrists are trained each year.
– A training module on radiation protection of patients was implemented early 2009, addressing radiographers.

Through the creation of these training courses, the “Training” section allowed a densification of links between the University and IRSN. Today, the University would like to implement a more formal collaboration.

Otherwise, the University envisages to enlarge its training sessions and to develop a “medical radiation protection” option for existing radiation protection masters. All these trainings will be integrated in the “Medical Radiation Protection School of the Montbéliard Territory” described above.

Developing a scientific and technical culture in radiation protection

Drawing on its long experience in promoting scientific culture, the Pavillon des Sciences de Franche-Comté was the driving force behind the implementation of a “Scientific and Technical Culture” section. The objective is to raise the profile of a scientific and technical culture related to radioactivity and radiation protection among the general public and, more specifically, among pupils in the Montbéliard area.

A good example of this section’s activities is the elaboration of the exhibition entitled “Did you say radiation protection?”. This exhibition is the result of a collaboration between artists and radiation protection experts who have produced a number of works of art as well as films that are screened on information terminals. The exhibition was opened in Montbéliard in October 2007. Since this date, it travels all around the world and has already welcomed more than 20,000 visitors.

Since 2007, the work of this section is enhanced through the organisation of “radiation protection workshops” in secondary schools. The goal is to involve pupils in activities approaching radiation protection topics in a concrete manner and favouring an understanding of radiation protection stakes in daily life. The workshops are animated by teachers of the secondary schools in partnership with local and national experts in radiation protection. They favoured a multidisciplinary approach: radiation protection is dealt with through physical and biological sciences, but also through history, philosophy or plastic arts. Every year, all the participating schools gather in a final seminar at the end of the scholar year. The last edition took part in March 2010 in Paris and gathered more than 200 pupils, including children from 7 French schools and 7 foreign schools.

First lessons learned from the Radiation Protection Pilot Project

In addition to the results obtained in the different sections, the activities carried out as part of the Pilot Project have led to a real improvement in the skills of local players involved in various aspects of radiation protection. For example, CAPM employees have acquired new skills and widened their range of expertise: they were trained to radon measurement and were taught to handle simulation tools to be better prepared to radiological events.

Thus, today, several sections of the Radiation Protection Pilot Project have reached a "state of maturity":

– Results acquired in the sections "Analysis and management of the risk associated with radon" and "Managing radiological risks in the event of a nuclear or a radiological emergency situation" allowed a national and international recognition of the competences developed in radiation protection within the territory. Activities will now continue in relationships with national players, particularly IRSN and ASN.
– Activities initiated within the section "Developing a scientific and technical culture" are now developed beyond the frame of the Radiation Protection Pilot Project in an autonomous manner. This section constitutes a major success of the Project and showed that this initiative was answering to a real lack of information and dialogue opportunities on radiation protection topics and stakes.

Besides, other sections, notably the one related to "Radiation protection in the medical field", got restricted results between 2004 and 2009. Today, they benefit from a renewed context and should be further developed from 2010 through the creation of the "Medical Radiation Protection School of the Montbéliard Territory".

Although the experience of the Radiation Protection Pilot Project is not ended, first lessons about the development of a local expertise in radiation protection can be proposed. Indeed, the Project has allowed identifying some elements needed for the development of local competences in radiation protection, among which:

– The importance to benefit from local radiation protection experts, capable of initiating and guiding the various actions. Each section was indeed piloted by a local expert who was involved in the concerned field and benefited from a deep knowledge of local characteristics.
– The necessity to link radiation protection actions with local stakes or projects. For instance, we can remind that: the "Radon" section was initiated as a part of actions concerning the air quality in dwellings; the section about "Managing radiological risks in the event of a nuclear or a radiological emergency situation"

was accomplished in a multi-risk perspective as part of drafting Local Community Emergency Plans.

– The necessity of a definite commitment and support of the local elected representatives. Every year, since 2004, the state of advancement of the Project is presented to local elected representatives. To date, they have always expressed their unanimous support to the Project.
– The importance of a strong articulation with national and international radiation protection experts. Indeed, it is important to underline that the Project could not have been developed in this way if it did not benefit from interactions and help of national and international radiation protection players.

If the experience of the Montbéliard Urban Community has allowed to show that the development of a local expertise in radiation protection is possible, it also allowed to demonstrate that it can lead to convincing results: the different actions performed at the local level have been very well received by the inhabitants of the Montbéliard territory and were all the more efficient. For instance, as far as the management of the radon risk is concerned, owners of houses are listening to advice of the staff of CAPM, because they know them and trust them. Similarly, in the course of the presentation of the exhibition “Did you say radiation protection?” in Montbéliard, visitors were sensitive to the information which, mostly, made echoes to local realities.

However, as mentioned above, it remains to underline the limits of a local expertise related to radiation protection issues: indeed, actions developed by the stakeholders of the Montbéliard territory were sometimes slowed down by a lack of means (equipment to measure radon) or of knowledge (about regulation relating to distribution of iodine tablets). They were also sometimes confronted to public policies that are not well adapted to local actors expectations.

All these elements emphasize the necessity to work on the modalities of articulation between local and national expertises in radiation protection (adaptation of language, definition of roles of each actor…) and on the needs of mediation/facilitation between these two levels, which appear complementary. Drawing on this observation, CAPM and IRSN, with the support of CEPN, have recently decided to officialise their cooperation through the signature of a specific protocol. They engaged to focus their efforts to articulate at best their respective actions and to contribute to a general improvement of radiation protection in the fields already covered by the Radiation Protection Pilot Project.

Abstract
The sustainability of radioactive waste disposals' surveillance systems is a key factor when it comes to long-term surveillance of these facilities. Local stakeholders have shown concerns on this matter, especially when dealing with intergenerational transmission of knowledge and memory of installations.

As a European cooperative research program, COWAM in Practice (CIP) addressed these issues from a practical point of view. From 2007 to 2009, CIP involved a wide range of stakeholders from five countries, including members of NGOs and industry, elected officials, national experts and authorities.

Among CIP outputs were the local stakeholders' expectations regarding long-term surveillance, and considering two main issues: on the one hand the long-term environmental and health surveillance, on the other hand the practical implementation of "reversibility" for geological disposal.

The paper addresses the governance issues associated with the practical implementation of long-term surveillance systems. A sustainable surveillance system, involving local actors in the decision making process, should allow them to monitor the waste inventory, the disposal evolution, the implementation of 'reversibility', the potential environmental and health impacts as well as the financial aspects. Beforehand, an effective involvement requires the identification of concerned local stakeholders, their technical and political empowerment, as well as establishing cooperation between the local and national institutions involved in the surveillance.

The radiation protection community has an important role to play to support local stakeholders' involvement in long-term surveillance, mainly in ways of training, skills and capacity building, but also by taking into account public concerns in the disposal design and for the organisation of its follow-up. Such a support would contribute to improve the sustainability of the surveillance system as well as that of the vigilance.

Introduction

Radioactive waste introduce a new time dimension in the field of risk management. The radioactive period of some radionuclides leads to consider time scales ranging from several thousand to several million years. These time scales imply adapting risk management processes to long or very long-term. Reflections have been led over the past decade on safety as well as societal issues associated with this long-term risk management. In fact, the process of long-term waste management generates new responsibilities that the current generation has to hand over to future generations for pursuing this management, maintaining and organizing a sustainable monitoring system and preserving the waste memory. Although the operator of the waste disposal has the responsibility of developing and implementing a robust monitoring system, the development of a citizen vigilance is a key element for improving the sustainability of the surveillance over the long-term period. This citizen vigilance is notably characterised by the handover of responsibilities of the current generation to the following ones.

Within European projects COWAM[1] and more particularly COWAM in Practice (CIP), dedicated to the improvement of radioactive waste management's governance, working groups involving experts, authorities, waste managers and local stakeholders were set up to discuss the stakes associated with long-term inclusive governance in this field. CIP cooperative investigations helped notably to elaborate local stakeholders' expectations regarding arrangements for long-term vigilance, in the light of two major concerns: first, protection, now and over time, of health and the environment around waste installations; second, practical implementation of 'reversibility' for geological disposal.

This paper presents the main results of these investigations with regard to the involvement of local stakeholders in long-term surveillance systems and discusses some challenges for the radiation protection community to improve and facilitate this involvement, notably through their participation to the building of stakeholder competences in terms of radiation protection.

Long-term surveillance of radioactive waste disposal

Whatever the type of radioactive waste management facility (geological disposal, short-term or long-term storage), the generic term of 'surveillance' can include several aspects of the protection system, which may also vary with time, such as:

- The technical monitoring of the facility environment (control of radionuclides discharges in the environment);
- The technical maintenance of the facility, the reassessment of the safety level over time and the management of any actions on site, including possible retrieval of waste;
- The surveillance of human activity in and around the site;
- The preservation and transmission of know-how concerning waste management;
- The organisation of a multi-level vigilance;

[1] COWAM 1 (2000-2003), COWAM2 (2004-2006), CIP (2007-2009). More information on : www.cowam.com

- The training of the next/new generation(s) who will take over the radioactive waste management facility site.

As it has been shown in the COWAM 2 project, there is no unitary definition of 'long-term'. What 'long-term' means largely depends on the chosen perspectives – who defines it, what the context is, what it is defined for. Therefore, it is essential to first delineate what is at stake in terms of time dimension when dealing with long-term surveillance. Regarding radioactive waste management, two long-term perspectives may be considered: a technical perspective and a societal perspective.

From a technical point of view, long-term is a concern for the operators of radioactive waste disposals, the safety authority and radiation protection community as there is a need to assess the performance of protection systems of the waste disposal over periods of time of about several thousand of years and beyond, that is assessing notably:

- The geological evolution;
- The robustness of waste package and disposal;
- The evolution of radioactivity and thermal characteristics of the waste packages with time, its potential transfer to the environment on long-term periods and the associated safety criteria.

However, from the societal perspective, considering timescales of the order of several thousands of years is meaningless. It is not possible to envisage how the society will be organised in the far future. A reasonable approach to cope with the long-term duration of waste radioactivity is, for the current generation, to create management and governance processes favouring a continuous transmission to the next generation(s) of a "safety heritage" (composed of know-how, protection options, procedures, resources…) in order to ensure the continuity of waste management.

These management processes may evolve with time, but the current generation needs to consider how they can be set up in order to achieve a number of 'missions' to be transmitted to the next generation(s). It will be the responsibility of the next generation(s) to continue and/or reconsider these processes and to adapt them with the aim of ensuring the realisation of these different missions.

Citizen vigilance and local stakeholder involvement in the long-term surveillance system

The COWAM 2 project has shown that the development of citizen vigilance is a key factor for improving the sustainability of surveillance systems over the long-term. This development is achieved through the involvement of local stakeholders in the surveillance system in order to:

- At the planning stage, address their questions and concerns and find a mutual understanding of the issues at stake;
- Identify potential improvements of the monitoring system and management of the nuclear waste installations;
- Favour in this way citizen confidence in the "institutional" monitoring system;
- Work out the specific contributions that citizen vigilance can make, identify the practical aspects of implementation, and, if it is necessary, build up local structures to play this role.

The cooperative research program COWAM in Practice (CIP) allowed revealing the stakeholders' expectations regarding their practical involvement in the surveillance system. The main aspects of interest concern the following aspects:

– Follow-up of the waste inventory;
– Surveillance of the integrity over time of the disposal system (waste packages, installation…);
– Health and environmental surveillance;
– The decision-making process associated with the practical implementation of reversibility for a deep geological waste disposal.

It has to be noticed that the later topic about the role of reversibility on the long-term surveillance was particularly discussed within the CIP project, as the 2006 French law on radioactive waste management asks for a period of reversibility for deep geological disposals.

Follow-up of the waste inventory and the integrity of the disposal system

The issue of keeping an inventory of all radioactive waste contained in the disposal facility is raised at various levels, including:

– From an ethical point of view, ensuring that the memory of the inventory is kept alive over the course of time is seen as a duty of today's generation toward future generations, who have a right to know of their legacy;
– With regard to risk management, it is essential to know with sufficient accuracy what the content of the disposal facility is in order to be able to assess the level of protection provided by the systems according to the health and the environmental aspects.

Special tracking systems are set up by waste management operators to follow-up the content of the disposal facility, throughout the entire operational phase and subsequently to maintain this knowledge in the long-term to ensure that it is passed on to future generations. For example in France, national follow-up of radioactive materials and waste has been mandatory since the 2006 law (JORF, 2006). It gives rise to the elaboration by a pluralistic group of a 'National Plan for Management of Radioactive Materials and Waste' (ASN, 2006).

Beyond the national follow-up, to reinforce the sustainability of this system, the involvement of local stakeholders in the follow-up of the waste inventory is of importance as it creates a 'local knowledge' of the facility, easing the transmission to the future generations. For this purpose, a specific pluralistic body, involving producers of radioactive waste, the disposal facility operator, representatives of institutional and non-institutional actors (safety authorities, expert bodies, associations, etc.) as well as local actors (local associations, elected people…) could be created, allowing the sharing of the information on a regular basis.

For a better efficiency of this local follow-up it appears necessary to create dialogue opportunities between the various actors in charge of elaborating the waste inventory system and the local stakeholders in order to 'co-construct' meaningful indicators. This may be done within a National Plan for Management of Radioactive Materials and Waste, as implemented in France. This means, on the one hand, to facilitate the understanding by the stakeholders of the criteria used by the operator (or authorities) for checking the inventory of waste packages and, on the other hand, to allow these stakeholders to address their expectations concerning indicators making sense for them which could be added to the classical surveillance plan. The followed indicators might cover not only the radiological content of packages but also data on the potential presence of chemicals, package design, how they are positioned in the facility, etc.

The relevance of the followed indicators with regard to long-term surveillance can also be increased by putting them into perspective with the inventory of existing (or future) radioactive waste facilities in their own country and abroad[2].

Another ‘technical aspect’ of the surveillance system concerns the follow-up of the integrity over time of the disposal facility (including waste packages, installation, geological surrounding evolution, etc). Here also, the involvement of local stakeholders will contribute to improve their understanding and knowledge of the waste facility, favouring their participation to the long-term vigilance. This aspect of the surveillance implies to set up a reference point of the disposal system, characterised by a set of indicators that would enable to compare the state of the installation to the evolution planned at the design stage of the disposal. Such follow-up might also be an opportunity to reduce the uncertainties inherent to the predictions of long-term modelling tools.

This follow-up leads questioning related to the diffusion of a radiation protection culture, that is, how to share the assessments made by safety authorities with the local stakeholders. One should note that the meaning of the criteria to be used is currently discussed between ICRP and the radioactive waste management community. Such a discussion will have to be also open to local stakeholders to share a common view on the evaluation of the robustness of the waste management system.

Health and environmental surveillance

Within the CIP project a strong demand on the part of local actors emerged concerning potential health or environmental impacts around nuclear waste installations. In fact, the development of a surveillance system on health and environment can favour the local and national vigilance on the long-term evolution of the site and will provide an assessment of the level of protection achieved for the current period. The follow-up will allow to assess the evolution of this level of protection overtime. It is also an opportunity to define a reference point which could be used in case of incidental situation.

According to the stage of development and operation of the nuclear waste installation, various levels of involvement for the local stakeholders in this surveillance system can imagined: they could participate in the definition of the reference point before the creation of the installation, then key milestones need to be identified in the long-term surveillance programme for which they may be involved and develop more intensive actions.

---

2 For example, during the CIP project, stakeholders have shown great interest in collecting feed-back on the closed disposal of low and intermediate level radioactive waste in France (Centre Manche) as well as the currently operating one (Centre de l’Aube). It can be noticed that good practices and difficulties – and even failures – are equally interesting to learn from past experiences to identify key issues and prepare better technical and governance approaches..

It has to be recognized that health and environmental impacts are quite difficult to evaluate. Among the emerging questions are the following:

– How to estimate the long-term evolution of environment and health?
– How to set up a global approach on health impacts which includes the other nuclear installations and the other exposures to ionising radiation (natural sources and medical exposures)?
– How to identify other causes of health or environmental impacts (potential presence of other industries, presence of chemical releases, pollutions,…)?
– How the results of the waste inventory will have an impact on the surveillance of the integrity of the facility and the waste package?
– How to put the estimated potential impacts into perspective with the regional, national and international situation concerning evolution of health?

To cope with these questions, the local stakeholders expressed a clear interest to establish cooperation / partnership with national institutes in charge of health and environmental surveillance. The creation of these partnerships would contribute to address their concerns and to find a mutual understanding of the issues at stake, to identify indicators making sense for the local stakeholders and to identify potential improvements in the surveillance system and management of the nuclear waste installations.

It was also recognized that it is essential to have access to pluralistic expertise (from national and international levels) when characterizing the reference points (for health and environment) and elaborating the surveillance system. Due to all the difficulties inherent to the impact assessment methodologies (uncertainties, monitoring results interpretation, statistical limits, …), it is thus essential to confront experiences and to share with all the concerned actors (waste operator, authorities, national experts, local and national stakeholders, ….) elements aiming at a better comprehension of these methodologies, their advantages and limits, in view of an evolution of the methodologies if it appears to be necessary.

The decision-making process associated with the practical implementation of reversibility for a deep geological waste disposal

As indicated above, in the French context, any geological disposal of radioactive waste must be designed in order to respect a period of reversibility of at least 100 years. This period of reversibility may have an impact on the long-term surveillance as the storage is maintained ‘opened’ and the waste management process may evolve during this period of time.

Discussions between experts and local stakeholders within the CIP project lead to the proposal that, from a practical point of view, the aim of maintaining a period of reversibility is to be able to choose, throughout this entire period, between three major options: continue to maintain reversibility, retrieve packages or initiate the closure of all or part of the disposal facility (see fig.1). This proposal allowed to shape issues associated with the practical implementation of reversibility, which are now discussed with the waste operator and the authorities.

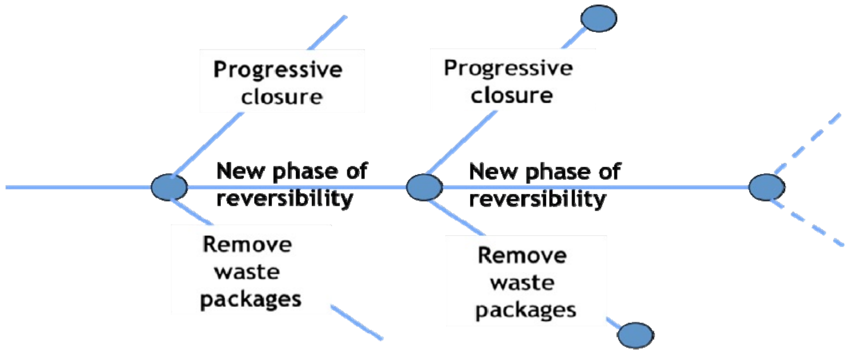

Figure 1. Illustration of the decision-making process throughout the period of reversibility for a geological radioactive waste disposal facility.

The issue of the identification of decision-making criteria for choosing which option to implement is not discussed here. While a first set of criteria will be proposed by the current generation, it will be down to the future generations affected by these decisions to consider or modify these criteria and potentially to draw up other decision-making criteria in view of the context in the future. It is however essential to determine before the start of the operating period what could be the structure of the decision-making process associated with these options: Who will be involved in assessing the situation? Who will make the decision? How often will the situation be reviewed? etc.

There is strong demand on the part of local stakeholders to be involved in the decision-making process associated with reversibility options. They are not asking to take the decision themselves but to be involved in assessing the disposal facility and ensuring that their expectations, especially insofar as they concern decision-making criteria, are effectively taken into account. The involvement of local stakeholders in actually drawing up the assessment and decision-making processes will also serve to make it more effective and, thereby, make the decisions taken more acceptable and sustainable.

The period of reversibility can also be seen as a period during which the disposal is maintained 'opened', giving the opportunity for a close monitoring of the packages, structures and the environment. This period is of particular interest for local stakeholders insofar as it can be used to collect elements aiming at improving the monitoring and surveillance system, reinforce the confidence in the safety scenarios or to clear up any doubts and uncertainties.

During the reversibility period, the inventory of waste packages and the monitoring of the integrity of the waste facility will be all the more important as the results of this surveillance might be an input to decide on the three mentioned options.

Organising regular meetings, within the framework of the decision-making process related to reversibility, to decide between the options for the future of the disposal facility also serves to highlight the question of how new developments in standards should be taken into account (safety standards, radiological protection standards, environmental protection, etc.) and how to ensure the capacity of technical and organisational systems to adapt to such developments. As long as checks are scheduled (and performed) it may also be possible to bring some equipment up to standard (and even replace obsolete equipment) and to some extent make adjustments in the facility in line with new safety requirements or new techniques.

Challenges for the radiation protection community

The radiation protection community has an important role to play to support local stakeholders' involvement in long-term surveillance systems, mainly in ways of training, skills and capacity building.

Thus, with a view to playing an active role when participating to the various aspects of the long-term surveillance system and fulfilling their task of ensuring vigilance, it is essential for local stakeholders to develop the necessary competences to be able to express their expectations and concerns not only about technical issues but also on governance ones. It is also essential to favour the development of governance processes allowing them to participate in the surveillance.

As far as radiation protection is concerned, the main challenge is then to foster the dissemination of a 'radiation protection culture' among the local stakeholders, and engage a cooperation with stakeholders when developing aspects related to long-term surveillance. For this purpose, various types of actions could be foreseen such as:

- Proposing dedicated education and training programmes to the stakeholders aiming at increasing their competences in the various aspects of the surveillance system (basic knowledge of radiation protection, explanation of the criteria used to characterize the waste inventory, what are the key aspects of environmental surveillance etc.);
- Developing, in co-operation with the stakeholders, criteria and indicators to be followed-up for assessing the health and environmental impacts of the waste facility;
- Favouring co-operation and partnership between local stakeholders and radiation protection experts from national institutions or other organisations;
- Setting up a system to ensure intergenerational transfer of knowledge within the local stakeholders (for example, by building specific radiation protection education programmes for local schools, …).

In order to facilitate the involvement of local stakeholders in the waste inventory follow-up, radiation protection professionals could provide them regular reports, invite them to attend periodic inspections of the inventory, propose specific expertises to answer their concerns or even propose to call pluralistic expertises if some specific agreements can be found with operator and authorities to access to the waste inventory files or to directly make complementary measurements.

To assist in the comprehension of long-term surveillance indicators, it could be relevant to propose to local stakeholders (members of the Local Liaison Committee or other concerned representatives of local stakeholders to discuss and analyse with radiation protection professionals the safety reports linked with the radioactive waste facility. The interest of such discussions is both to share the meaning of indicators and the way of assessing the level of protection.

With regards to health and environmental surveillance, radiation protection professionals could be involved in the discussions, with local stakeholders, on the reference levels set up for the impact assessment and take into account local concerns and habits in the elaboration of the exposure scenarios.

Another challenge for the radiation protection community will be to adapt if necessary the monitoring system to respond to the additional surveillance criteria/indicators identified by the local stakeholders.

Acknowledgements

These reflexions have been engaged in the framework of the COWAM 2 (2002-2006, Contract number: FI6W-CT-2003-508856.) and COWAM In Practice (2006-2009, Contract number: FP6/036455) projects, co-funded by the European Commission under the Euratom Research and Training Programme on Nuclear Energy within the sixth Framework Programme. In each of the countries involved in COWAM in Practice a framework was provided for a diversity of stakeholders to cooperate in identifying and investigating what they saw as important issues in RWM governance. Authors would like to thank them for their participation.

Individual response to communication about the August 2008 ^{131}I release in Fleurus: results from a large scale survey with the Belgian population

Carlé, Benny[1]; Perko, Tanja[1,2]; Turcanu, Catrinel[1]; Schröder, Jantine[1]

[2] University of Antwerp, Faculty of Political Sciences, BELGIUM

Abstract
Nuclear and radiological events, such as the one referred to in this article, have taught us that communication is one of the most important challenges in emergency management. In the crisis reported here, communication to local authorities, local actors and population proved to be challenging during this crisis.

On Friday, August 22nd, 2008, a release of 131I started from the Institut des Radioelements (IRE) in Fleurus, Belgium. The release was not noticed until after the weekend, and people living in neighbouring areas were informed no sooner than 6 days after the onset of the incident. It was only then that the Belgian authorities activated a nuclear emergency plan, taking protective actions for the population.

In the summer of 2009, SCK•CEN initiated a large-scale survey on risk perception, using computer assisted personal interviews (CAPI). The survey focused on nuclear risk communication, with one chapter on reception and acceptance of messages during the Fleurus crisis. To the representative sample of the Belgian population, we added a sample of 100 persons living in the zone impacted by the Fleurus incident.

It discusses how people living in the vicinity of Fleurus perceived and evaluated communication the local crisis, and examines the degree to which these perceptions vary according to the information sources attended to, and the media used. Finally, we compare the Fleurus data emergency risk communication with the results for the general population.

Introduction: reconstruction of the event
On Friday, August 22nd, 2008, ^{131}I started to be released from IRE, in Fleurus, Belgium. IRE produces isotopes for the medical sector, by extraction of fission products from highly enriched uranium targets irradiated in reactors such as the BR2 in SCK•CEN in Mol, Belgium. The production is a batch process and, after processing, waste liquids are collected in waste tanks. On that Friday, contents of smaller waste tanks were transferred to a larger tank, starting a chemical reaction and leading to the release of ^{131}I to the stack, through filter batteries. The bulk of the release took place over the weekend, after which smaller quantities kept being discharged for several days,

amounting to a total of 50 GBq ^{131}I. The release was not noticed till after the weekend, when a safety engineer started his work on Monday morning. The problem was first examined in cooperation with the technical support organisation, BEL-V, and the Belgian agency for nuclear control (AFCN-FANC) was not notified about the release until 5:15 p.m. on Monday evening.

On Tuesday, August 26th, the agency made its first mention of the event on its website, announcing that inspectors were being sent to the installation to examine the situation. More details were given in a press release the same afternoon that classified the event as a “serious incident” (INES-3), and that announced that production in the IRE as well as the neighbouring MDS Nordion facility were temporarily stopped. The statement specified the occurrence of a "very small release" to the environment that neither called for activation of the Belgian nuclear emergency plan nor for measures to protect the environment. The press release announced follow-up measurements by the Belgian automatic radiological measurement network TELERAD.

It may be worth mentioning that, in fact, four additional mobile TELERAD stations were placed on and near the Fleurus site that, due to the characteristics of the release, were not able to register the release. The fact that only pure 131 Iodine was discharged at a low concentration during a relatively long period, made it impossible for the TELERAD network to capture dose rates increases.

On Wednesday August 27, AFCN-FANC (the Belgian agency) informed IAEA about the incident, stating *“The waste division of the IRE has performed a transfer of liquid radioactive waste from one tank to another one. Immediately afterwards – for reasons still unknown – radioactivity was released through the stack. The quantity of radioactivity released into the environment is estimated at 45 GBq I-131, which corresponds to a dose of 160 microsievert for a hypothetical person remaining permanently at the site’s enclosure. This incident did not cause a contamination of the personnel, and their dose limits were neither exceeded.”* [BVS 2008]

On Thursday August 28, the first results for three environmental samples became available. These samples, taken by the agency in the close vicinity of the IRE, and analyzed in the lab of the scientific institute of Public Health ISP/WIV, shed new light on the situation. Radioactivity was established at up to 5000 Bq/kg for one grass sample, suggesting that the intervention limits for the food production might have been exceeded and, therefore, activation of the Belgian emergency plan was needed. On Thursday evening governmental web sites issued the first recommendations to the population: People living in a zone of 5 km north east of the IRE were neither to eat fruits and vegetables from their own gardens, nor to use rain water. The press publicized these recommendations. Moreover, local and provincial emergency managers received a FAQ list specifically compiled for the occasion [Crisiscenter 2008]. The local police and the city of Fleurus communicated directly with the concerned population on Friday August 29th and an information phone line was opened. Further characterisation of potential water, air, grass, vegetables and milk contaminations was carried out.

On Saturday August 30th, new measurements somewhat alleviated the concerns. These allowed a reduction of the area for which protective measures were recommended to 3 km-area north east of the IRE. In addition, they confirmed that no significant contamination of milk had occurred. (Maximum measurement was 17

Bq/liter where the intervention level is 500 Bq/liter). Nevertheless, a large-scale campaign to do thyroid measurements was announced to start on Monday, September 1st. These measurements assess a potentially enhanced risk for thyroid cancers and are especially important for children [Public Health 2008].

In the next week, the crisis management team focused on complete certainty that the release had stopped. It requested that the IRE installed extra filters between the waste tank and the stack, and it further monitored the situation by environmental sampling, and active charcoal air sampling. By Saturday September 6th, there were no more uncertainties: No measurements of over 100 samples of vegetables and fruits had been near the intervention levels [FAVV2008], the maximum was 86 Bq/kg, while the intervention level is 2000 Bq/kg, however the WHO has a recommendation to take action when baby food exceeds 100 Bq/kg, and at no time there had been a need to trigger direct protective action for the population (sheltering, evacuation or intake of iodine tablets). Therefore, recommendations to avoid eating fruits and vegetables from the gardens were lifted, and the emergency plan scaled down to a U1 level. Nevertheless, thyroid testing for possible contamination continued to be offered to the local population, with the idea that this could be re-assuring. The medical examinations, performed on Monday September 1st and Tuesday September 2nd, prioritized the most sensitive persons, children and pregnant women. A total of 1320 persons were examined, and no signs of contamination found.

Media coverage of the incident

The event was covered by all mass media in Belgium, both in the French speaking southern part, and in the northern Dutch speaking part of the country. The event was no headline news, but it remained a daily news items for several weeks. The news items were mostly informative, based on the information provided by the crisis management or informed by interviews with the important actors: crisis managers, experts, managers from the installation and local and national politicians. The incident was not sensationalised in the mass media; there was neither amplification of negative messages nor stigmatisation of the technology. Discussions focused on the responsibility for the incident, with a focus on the unacceptable late response of the authorities and the lack of information to the population in the first days. Another issue of discussion was the failure of the automatic measuring network TELERAD to register the release; this failure was interpreted as another instance of poor performance of this network that had received some negative press before. Blame of the IRE management for their lack of communication was another theme, framed as an illustration of the existing problematic relation between IRE, the local authorities and the local population [Fleurus 2008]. Part of the news framing was also on the expected shortage of medical isotopes, a consequence of the incident.

Public opinion survey: material and methods

The Belgian Nuclear Research Centre SCK·CEN conducts periodically large-scale public opinion surveys among a representative sample of the Belgian population [Carlé and Hardeman, 2003; Van Aeken et al., 2007; Perko et al., 2010]. Alongside with recurrent issues such as risk perception, confidence in authorities and other actors, and the use of nuclear energy, the surveys include detailed research sections on topics such as expert functioning, emergency planning, food safety or risk communication.

The data for this study originate from the 2009 SCK•CEN survey.

1. Background Variables
2. Risk perception and confidence in authorities for 17 risk items
3. Attitude towards:
3.1. Science and technology
3.2. Stakeholders engagement in decision process related to industrial installations with risks
3.3 Nuclear energy
4. Acceptance of legal norms for food products
5. Use of different information media
6. Evaluation of different actors in the nuclear domain
7. Risk perception of an accident in a nuclear installation
8. Safety behaviour and anomy
9. Knowledge about the nuclear domain
Newsflash: TV-report about topics related to preparedness for nuclear emergencies
10. Reception & acceptance of messages communicated in the TV-report
11. Reception & acceptance of the iodine predistribution / information campaign
12. Reception & acceptance of messages communicated by authorities during the Fleurus event in 2008
13. Consumer's attitude towards food with radioactive contamination

Fig. 1. Main topics of the SCK•CEN risk barometer survey in 2009.

The content of the entire survey is summarised in Fig.1, more details can be found in Perko et al. (2010). In this paper we present results relevant for the respondents' perception of the communication during the IRE ^{131}I release incident in Fleurus.

Sampling procedure

Field work in the SCK•CEN 2009 survey was performed by a market research bureau using CAPI - computer assisted personal interviews. These interviews were carried out at the home of the respondent; the average duration was 43 minutes.

The bulk data of the 2009 survey consisted of 1031 interviews in French or Dutch. This sample is representative for the Belgian adult population with respect to province, region, level of urbanization, gender, age and professionally active status.

In the general Belgian population, 163 out of the 1031 persons remembered the IRE incident, the questions about what they remembered, to what degree they agreed with the communication during the crisis, and how what media and information sources they used were asked to this subset.

In addition, we asked the same set of questions to a supplementary set of 104 persons from the Fleurus area, the municipality in the French speaking part of Belgium, where the IRE incident happened.

In the next paragraphs, the results for the specific Fleurus group are compared with those from the 16% of the Belgian population who remembered the incident. We provide the results from these directly involved communities as a second line in the graphs, to allow comparison.

Results

Reception of the crisis management communication during the incident

The first set of five questions measures the degree to which people still remember what happened. During the incident, which took place about 11 months prior to this survey, all issues covered in the questionnaire, had received extensive media coverage.

Table 1. What do people remember about the incident?

Question	Sample	Correct answer	Incor. answer	Incor. answer	Incor. answer	No answer
What was the main pollutant?		Radioiodine	Tritium	Caesium	Uranium	
	BE 163	19%	4%	4%	15%	58%
	FL 104	63%	1%	1%	1%	35%
For what purpose was it produced?		Medical	Indus- trial	Energy		
	BE 163	58%	15%	7%		20%
	FL 104	33%	11%	21%		36%
What is the risk of a large intake of Radio-iodine?		Thyroid cancer	Lung cancer	Skin cancer		
	BE 163	68%	7%	2%		23%
	FL 104	77%	3%	0%		20%
What countermeasures were adviced ?		No fresh food from garden	No dairy products	To evacuate		
	BE 163	67%	9%	14%		10%
	FL 104	74%	1%	14%		11%
What was measured in the children?		Radioiodine in thyroid	Blood ana- lysed in lab	Children's urine test		
	BE 163	19%	21%	6%		53%
	FL 104	3%	11%	18%		68%

Less than 20% of the people in Belgium who remember the incident with a radio-active release know it was radio-iodine which was accidently released, but in Fleurus, over 60% remembers the radio-iodine. Remarkably, more people in the general population than in Fleurus connect the incident to the production of radio-iodine for medical purposes. This might be because the subject of a shortage of radio-iodine in the hospitals was in the press during a long time, and it was connected to the incident in Fleurus and the long shutdown of the facility. The majority of the respondents, both in the population in the Fleurus area and also in the part of the population that remembers the incident, are aware of the link between radio-iodine and thyroid cancer. About 80% of both groups remember correctly that people were advised no to consume fruits and vegetables from their gardens if they lived in an area situated up to 5 km north east of the facility. Neither the local population nor the part of the general population, who remembered the incident, appear to have been aware of the thyroid measurement campaign.

Acceptance of the crisis management communication

We asked respondents to indicate their agreement with six statements regarding the information and guidance given during the crisis Six statements were proposed, to which the respondents had to state their agreement degree on a 5-point Likert scale (from 1="strongly disagree" to 5="strongly agree"). Again, the results presented in graph. 1 come from the 16% of the Belgian population who remembered the incident and are compared with the Fleurus sample.

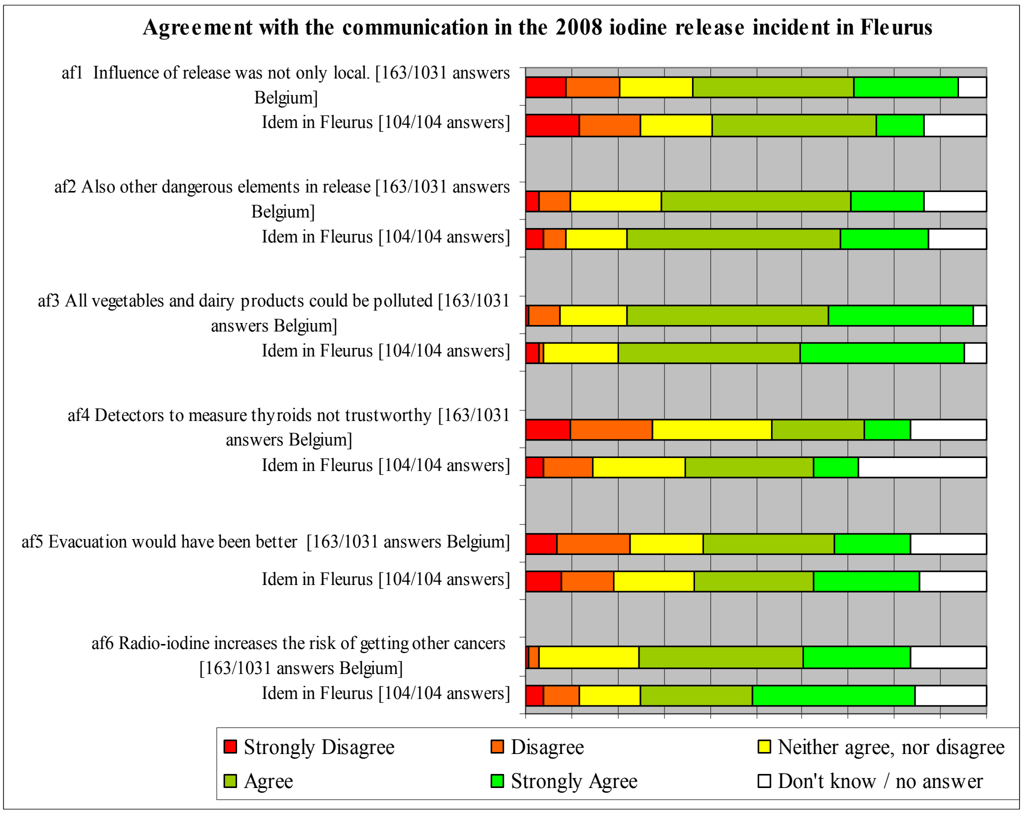

Fig. 1. Agreement with the crisis management communication in the 2008 iodine release incident in Fleurus, Belgium.

Most people think that the incident had consequences for a larger area than was communicated by the authorities (first statement). There is little difference between the people from Fleurus and the general population of Belgium. A large majority of people think that the situation was worse than communicated by the authorities (statements 2 and 3), agreeing with the view that other dangerous elements were released (60% to 80% of the samples), or that other products than garden fruit and vegetables from a larger area could have been affected (50% to 80% of the respondents). Agreement with the last statement also indicates that people think the situation is worse: they believe that other health effects will result from the release.

The population is more balanced on whether evacuation would have been a better countermeasure: about 50% agree, against 20 % disagree and 30 % people with no clear opinion. And finally, statement 4 shows that people don't really trust the physical measurements from the detectors, although the agreement with the statement ".results from detectors used for the measurements of presence of radio-iodine in the thyroid are not completely trustworthy" is lower than for the other statements, between 30 and 40% agree. Remarkably there are no big differences between the general population and the people in Fleurus who were in the affected zone.

Information channels used during the incident.

In this paragraph we look at the media use during the incident in Fleurus. First we ask the respondents what media and information sources they used, and then we ask their appreciation for each information source, specified by how credible, how timely and how extensively they evaluated each source. The first part lists the mass media, the second part personal contacts and other information sources. The results are presented separately for the two parts.

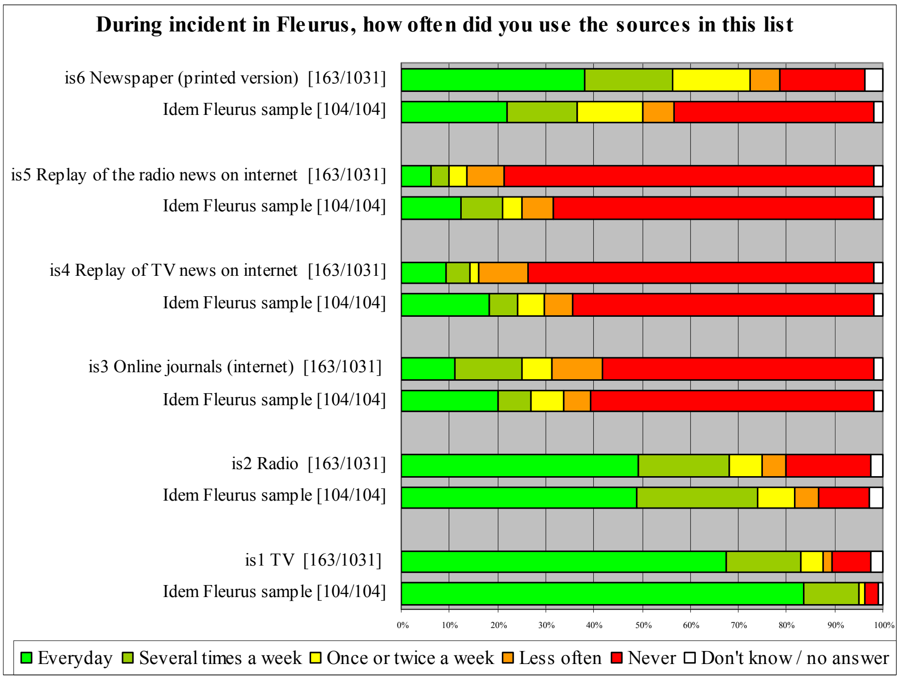

Fig. 2. Information channels used during the 2008 iodine release incident in Fleurus, part A.

In Figure 2 we see that television was the number one mass communication channel, over 80% of the respondents in Fleurus say the watched TV daily, while nearly 70% of the population in the rest of the country indicate they followed the Fleurus incident daily on TV. Radio is clearly the second most important information channel, around 50% both in the local population and in the rest of the country followed the news daily on the radio, and another 20 % did so several times a week.

Newspapers are the third mass communication channel, consulted daily or several times a week by 55% of the general population (or at least by the part of the general population who remembered the incident). For the local population, newspapers were less important, 50 % of the Fleurus population says they read the newspaper never or less than once a week during the incident. We differentiated between 3 types of internet use: internet online journals, replays of TV news on internet and replay of radio news on internet. In general internet is used less than the other media; over 60% of the respondents indicate they never used internet in any of the three ways specified. About 25% of the Fleurus respondents say they used internet journals daily or at least several times a week, and 22% used the replays of TV and radio news as often. The responses for the general population indicate a marginally lower use of the internet sources.

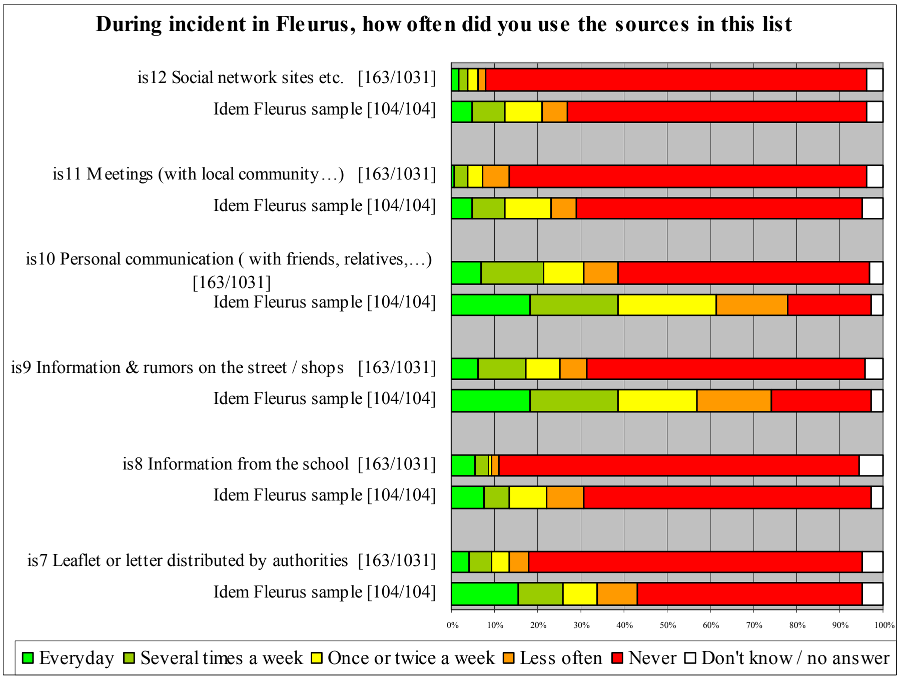

Fig. 3. Information channels used during the 2008 iodine release incident in Fleurus, part B.

While even in Fleurus, TV and radio news were important sources of information, here personal communications such as discussions with friends and relatives, and information and rumours in the street and in local shops etc. were relatively important also: about 40% of the Fleurus sample self-reported to have turned to others daily or several times a week. Other sources, such as letters or leaflets from authorities, local information communications by the schools were used as information by 30 to 40% of the local population at least once a week.

In the next series of questions, we asked the respondents to evaluate the information sources on credibility and being timely. The questions were only asked for the communication sources for which the respondents previously indicated some use, therefore, the total number of answers is different for each source. Results are presented in Tables 2 and 3.

Table 2. Evaluation of credibility and timeliness of media during 2008 iodine release incident in Fleurus Part A.

Sources	#	Credi bility Little	Credibility Average & No Answer	Credi bility Much	Timeli-ness Little	Timeliness Average & No Answer	Timeliness Much
TV (Belgium)	146	14%	39%	47%	13%	37%	50%
TV (Fleurus)	100	46%	30%	24%	49%	26%	25%
Radio (Belgium)	130	10%	42%	48%	9%	42%	48%
Radio (Fleurus)	90	42%	31%	27%	40%	36%	24%
On line Journals (internet) Belgium	68	13%	40%	47%	12%	37%	51%
On line Journals (internet) Fleurus	41	41%	46%	12%	41%	46%	12%
Replay of TV news on internet (Belgium)	43	16%	42%	42%	14%	37%	49%
Replay of TV news on internet (Fleurus)	37	43%	46%	11%	41%	43%	16%
Replay of Radio news on internet (Belgium)	35	14%	46%	40%	17%	43%	40%
Replay of Radio news on internet (Fleurus)	33	36%	48%	15%	30%	55%	15%
Newspaper (printed version) Belgium	128	8%	43%	49%	11%	40%	49%
Newspaper (printed version) Fleurus	59	27%	47%	25%	29%	44%	27%

A first observation is that credibility of the media is considered lower in the Fleurus sample than in the general population. Furthermore, the general population expresses lower confidence in TV and radio news when answering to questions about the Fleurus incident than to more general questions on nuclear accidents, as they occurred earlier in the questionnaire. People from Fleurus have a negative evaluation of the timeliness of news in all media, which may reflect the delay of communication by both authorities and media: It took 5 days after the start of the release before it came first in the news. The general population has a more positive view on how fast the media gave information about the crisis.

Table 3. Evaluation of credibility and timeliness of media during 2008 iodine release incident in Fleurus Part B.

Sources	#	Credi bility Little	Credibility Average & No Answer	Credi bility Much	Timeli-ness Little	Timeliness Average & No Answer	Timeli-ness Much
Leaflets & letters by authorities (Belgium)	29	14%	21%	34%	21%	41%	38%
Leaflets & letters by authorities (Fleurus)	45	46%	24%	58%	24%	58%	18%
Information from the school (Belgium)	18	17%	39%	44%	17%	28%	56%
Information from the school (Fleurus)	32	19%	28%	53%	19%	31%	50%
Information and rumors on the street etc (Belgium)	51	18%	31%	51%	18%	31%	51%
Information and rumors on the street etc (Fleurus)	77	23%	23%	53%	21%	26%	53%
Personal communication (discussion with friends, relatives...) Belgium	63	29%	27%	44%	30%	29%	41%
Personal communication (discussion with friends, relatives...) Fleurus	81	22%	30%	48%	23%	26%	51%
Meetings (with local community…) Belgium	22	18%	36%	45%	18%	59%	23%
Meetings (with local community…) Fleurus	30	37%	50%	13%	40%	47%	13%
Social network sites (facebook,…) Belgium	13	23%	62%	15%	15%	38%	46%
Social network sites (facebook,…) Fleurus	28	21%	50%	29%	21%	57%	21%

Information given by the school is evaluated as the most credible information (over 50% high or very high credibility) by the small subset of the Fleurus sample that indicated schools as a source of information (one third). Informal discussions with friends and rumours on the streets or local shops etc. are considered more credible than the information gained from information spread by the authorities (written information, public meetings). Compared to the general population, those from Fleurus whom the crisis concerned most, evaluate communications by both governmental officials and the press as less credible; they put more trust in information given by the school, and gained from personal conversations.

Direct communication and certainly personal communication is evaluated more as timely than media coverage by radio and TV; an exception forms the “town hall” meeting that was *not* perceived to be timely. The results for the Fleurus sample are for these communications also more consistent with the responses from the people from the general population.

Science and values in radiation protection: Summary of two NEA Workshops

Lazo, Ted
OECD Nuclear Energy Agency, FRANCE

Abstract

For some time the Nuclear Energy Agency (NEA) has been examining the evolution of decision making in radiological protection, studying both the stakeholder involvement aspects, and the judgemental and scientific uncertainty aspects. As part of this work the NEA held a workshop in January 2008 to examine how science, social values and judgement are combined to arrive at acceptable and sustainable radiological protection decisions in a transparent fashion. The second workshop in this series was held in November 2009.

The first workshop addressed three topics of emerging science: individual sensitivity; non-targeted effects; and circulatory diseases. These were discussed in a "*What if?*" format, that is, if research in these areas were to result in significant changes in our understanding of risk, what would we do and how would uncertainty and judgement be taken into account. The results of the dialogue among the attending regulators, scientists and NGOs were seen as having very positively improved mutual understanding of issues, viewpoints and possible implications, and as beginning to identify elements of a process and framework for the better integration of the social and scientific dimensions of radiation protection.

The second science and values workshop will take a similar approach to the first, but addressed three topics that are currently presenting challenges to radiological protection policy, regulation and application in a "*What now?*" format: management of medical exposures; management of radon exposures; and implications of new scientific evidence on cardiovascular disease risks from radiation exposure. These topics represent areas where current approaches to radiation protection have either not fully yielded the desired results (i.e. radon and medical exposures), and/or have not yet been perceived as being sufficiently scientifically supported to warrant change in the current approach (i.e. cardiovascular diseases). Thus, while the objective of this workshop was not to develop detailed recommendations as to new approaches, it did develop significant results:

- Relevant stakeholders in each area presented and exchanged experience related to their viewpoints and relevant values, increasing their levels of mutual understanding to facilitate development of common approaches forward;
- Social and scientific rationale and justification for adopting new approaches to radiation protection in each of these areas was discussed (tipping point);

- Practical approaches to improving radiation protection in each area was discussed based on national experience, and in relation with public health issues; and
- Process and framework elements that could enhance radiation protection in these three areas by better integration of social and scientific aspects were identified.

This paper will summarise the results of this workshop, and indicate what further work could be pursued in this area.

Introduction

Radiological protection was founded on and continues to be a combination of science and value judgments. As described by Lauriston S. Taylor, radiation physicist and pioneer in the field of radiation safety, and founding member of both the International Commission on Radiation Units and Measurements (ICRO) and the International Commission on Radiological Protection (ICRP), radiological protection is *"... not only a matter for science. It is a problem of philosophy, and morality, and the utmost wisdom."* (Taylor 1957).

In the development of radiological protection policy and its practical application there is always a need for radiological protection policy makers, practitioners and other stakeholders to better understand the evolving interactions between science and values. At the same time, there is also a need for radiological protection scientists to better understand the broad processes of radiological protection decision making and to better interact with these processes particularly by furnishing input coming from their research. Rolf M. Sievert, the Swedish physicist who laid the foundations of modern radiation physics, expressed clearly the dynamic link between policy, research and application: *"The establishment of maximum permissible radiation levels is a non scientific task, which must be based primarily on scientific knowledge and judgment."* (United Nations 1958).

Achieving such a mutual understanding among radiological protection policy makers, practitioners, researchers, industry, non-governmental organisations, etc. is expected to facilitate prioritisation of research and framing of decision making in the future and to improve the quality and robustness of radiological protection.

The Committee on Radiation Protection and Public Health (CRPPH), a standing technical committee of the OECD Nuclear Energy Agency, has long been aware of a need to develop a shared understanding of emerging challenges for radiological protection among scientific and regulatory communities and other concerned stakeholders. In 2007 the CRPPH Expert Group on the Implications of Radiological Protection Science (EGIS) published a report on "Scientific Issues and Emerging Challenges for Radiation Protection" (OECD-NEA 2007). This report represents a broad summary of key scientific challenges that could arise from ongoing research on radiological protection. Additionally, the CRPPH Expert Group on the Collective Opinion (EGCO) published its report on "Radiation Protection in Today's World - Towards Sustainability" (OECD-NEA 2007). That report identifies key emerging challenges to the radiological protection system in order to assist decision makers at all levels to better address these within their relevant contexts.

In follow-up to these activities and in response to the existing need to foster mutual understanding among all concerned stakeholders, the CRPPH initiated a longer-term process of reflection on scientific and societal issues that might challenge radiological protection in the coming decade. The first step in this process was a workshop organised in collaboration with the Radiation and Nuclear Safety Authority of Finland (STUK) to address some of these issues. This first workshop entitled "Science and Values in Radiological Protection" took place on January 15-17, 2008 in Helsinki, Finland1. In this workshop more than 60 scientists, researchers, representatives of regulatory authorities, political decision-makers and other experts from 22 countries (including countries not members of the OECD) gathered together to discuss new trends in radiological protection.

A second workshop in the series was then organised in collaboration with France's IRSN (Institut de Radioprotection et de Sûreté Nucléaire) and sponsored by the French Ministry of Ecology, Energy, Sustainable Development and Land Use Planning (MEEDDAT). This second "Science and Values" workshop took place on 30 November - 2 December 2009 in Vaux-de-Cernay, France2. Attending were more than 70 participants from 19 countries. The following types of institution were represented: public health authorities; regulators; international bodies; industry; hospitals; scientific expert organisations; universities.

The objective of these meetings was to develop a more shared understanding between the various stakeholders with regard to the mixing of science and its uncertainty with social values and their diversity in achieving decisions that are sustainable and acceptable when radiological risks are involved. At both Helsinki and Vaux-de-Cernay, selected key challenges to radiation protection were explored by plenary presentations3. In-depth discussion then took place among participants in topical break out sessions. The present report introduces the objectives, aims and topics of each workshop, and then summarises findings and outcomes of the respective break out sessions.

Material and methods

Each workshop was structured to foster participants having a complete overview of the "state-of-the-art" with respect to the subjects addressed, and to allow a significant amount of time dedicated to discussion of the value issues involved in decisions regarding these topics. To achieve this, each workshop was structured around a number of invited plenary presentations addressing selected emerging challenges to radiological protection. These presentations were followed by facilitated break out sessions that examined those challenges in greater detail, in particular their potential implications from the perspectives of science, values and interpretation. Participation in each break out session was predetermined so as to achieve balance in terms of the spectrum of stakeholders participating in the workshop.

Each workshop was structured around a few scientific and regulatory issues. The 1st Science and Values Workshop addressed the following three topics, which had been identified in the EGIS report (OECD-NEA 2007):

- Non-targeted effects.
- Individual sensitivity.
- Circulatory diseases.

[1] http://www.nea.fr/html/rp/helsinki08/welcome.html
[2] http://www.nea.fr/html/rp/vaulx_de_cernay09/welcome.html
[3] A subset of the plenary presentations from each workshop can be viewed online at the hyperlinks provided in footnotes 1 and 2 of this document. The remaining presentations were based on preliminary data, or on data awaiting journal publication elsewhere, and were thus unsuited for online publication.

The moderated breakout session discussions followed a "*what if*" approach to determine the nature and significance of the potential implications of the various emerging issues or challenges. Where appropriate, participants identified the need for further research and/or analysis to aid in better understanding the challenge and how/if it may be accommodated. Discussion was facilitated by a set of proposed questions adapted to each "challenge" topic, reproduced below for the topic of "non-targeted effects":

- Why are non-targeted effects a relevant topic?
- What do we know now about non-targeted effects?
- What do we not know now about non-targeted effects that we would like to know?
- What are the scientific issues?
- What are the regulatory issues?
- What approach(es) should be followed to address scientific issues raised above?
- What would we do differently if we knew now what we would like to know?
- What could or should we do now while we wait for the answers to these questions?

During the 1st workshop a "*What if?*" approach was used to discuss the scientific aspects in some key areas of emerging radiological protection science. The results of the dialogue among the attending regulators, scientists and NGOs were seen as having very positively improved mutual understanding of issues, viewpoints and possible implications. The discussion was also seen as having begun to identify elements of a process and framework for the better integration of the social and scientific dimensions of radiological protection.

Re-emphasising that radiological protection is a combination of science and value judgments, the CRPPH agreed at its sixty-sixth annual meeting to continue the useful discussions begun in Helsinki by organising the second workshop. Here, however, the committee agreed to focus on radiological protection issues that are currently facing us, and that continue to pose challenges to our world today. As such, the second workshop in this series was designed to address a series of current radiological protection issues from the standpoint not of "*What if?*", but rather, "*What now?*". With this, the 2nd Science and Values workshop continued along these lines, and addressed the following three topics:

- Radon as a public health issue.
- Medical exposures in diagnostic and screening procedures.
- Radiation-induced vascular effects.

During the discussion of these issues participants presented and discussed their relevant national objectives and experience in the designated area, and brainstormed on approaches to better achieve their objectives when faced with emerging data. The break out sessions engaged participants in addressing the following central questions:

1. Which issues need further elaboration before deciding whether it is necessary or appropriate to change the current approach?
    - Identification and discussion of science issues
        - What level of effect is being discussed?
        - What are the uncertainties involved and how well characterised are they?
    - Identification and discussion of practical issues
        - What would a change in regulation impact?
        - What would be the magnitude of such changes?
    - Identification and discussion of value issues
        - Balance of risks and benefits?
        - Precautionary judgement?
2. What aspects weigh on decisions regarding possible change?
    - Implications for regulation, industry and health care sectors
    - Practical implications for application
        - Resources needed.
        - Adapting to a significant change in approach.
        - Education and training needs.

Results

The results of these two workshops are being summarised in an NEA report that will be published in the fall of 2010, however the most significant conclusions are presented briefly here.

Non-targeted Effects (1st Science and Values Workshop)

Non-targeted effects referred to those effects seen in cells not directly hit by radiation, such as the so-called bystander effects and genetic instability. These effects were characterised as being seen mostly at a cellular level, and as such having a somewhat uncertain effect on the overall detriment to the organism. It was felt that better understanding of non-targeted effects would very likely not affect the overall level of risk, but rather would better explain the point of origin of the risk.

Individual Sensitivity (1st Science and Values Workshop)

At this workshop the individual sensitivity that was discussed referred broadly to the sensitivity that may be caused by genetic imperfections, rather than the sensitivity differences seen between men and women, or between children and adults. As a result of discussions, there seemed to be no need to radically modify the current approach RP. However, in emergency situations and in medical diagnostic and therapy situations, it was suggested that some consideration be given to refocusing protective actions taking individual sensitivity into account.

Cardiovascular Disease
(1st Science and Values Workshop)

The discussion of cardiovascular disease at the 1st Science and Values workshop suggested that new epidemiological data, in particular from the Mayak workers, would be published not long after the workshop, and would broadly show agreement with data from the Hiroshima / Nagasaki Lifespan study, suggesting that cardiovascular diseases could be provoked by both acute and chronic exposures. Taking this detriment into account, at that point simply based on LSS data, there could be a need to lower current dose limits by 30-50%, with strong emphasis on optimization. However, the workshop concluded that the science is still evolving and there was no need at that point to recommend change to the system of radiological protection.

Management of Domestic Radon Exposure
(2nd Science and Values Workshop)

In discussing this topic and exchanging experience regarding national approaches, it was noted that most countries focus actions on high-concentration homes. This suggests that the "values" aspect of the management decision has focused on protecting those most exposed. Epidemiology suggests, however, that most lung cancers occur in homes with lower concentrations, such that revisiting national protection strategies could be of value. Optimisation actions could include the promotion of protective actions for new buildings (e.g. building codes, pre-sale criteria), tying radon strategy to other programmes (e.g. smoking, energy efficiency, indoor-air quality), integrating radon exposure management into the public health system, rather than the other way around. It was noted that remediation of radon in dwellings is a long-term process

Management of Diagnostic Medical Exposures
(2nd Science and Values Workshop)

With the significant increase of patient exposures in many countries, the justification of diagnostic procedures, and the optimisation of protection were seen as key issues to discuss and improve. It was suggested that physicians tend to focus very strongly on the diagnosis and treatment of an individual's health issues, suggesting that the driving value is to give priority to health risks today. There is evidence, however, that a significant fraction of diagnostic procedures are not justified at the individual level, and that protection is not optimised. Justification seems to be the critical step. Greater awareness and use of exiting tools (e.g. diagnostic guidelines), and focus on sensitive populations (e.g. children) seem to be the areas of focus

Cardiovascular Disease
(2nd Science and Values Workshop)

Because the scientific study of cardiovascular diseases seemed to be evolving rapidly, this topic was chosen to be revisited at the 2nd Science and Values workshop. Radiation-induced cardiovascular disease is well known in high-dose radiation-therapy patients, however risks are broadly viewed as deterministic, without sufficient scientific knowledge to categorise otherwise. As such, the value driving decisions seems again to be to give priority to health risks today, in particular since these effects seem to be deterministic rather than stochastic. However, new epidemiological studies suggest that chronic, lifetime exposures may, at somewhat lower doses, cause cardiovascular diseases. Mechanisms of such damage, and identification of “target organ” are still topics of research. Again, it was judged that the science is still evolving and there was no need at that point to recommend change to the system of radiological protection. It was, however noted, that with the same level of knowledge regarding stochastic effects of radiation in the 1950s, a precautionary approach was none-the-less adopted at that point, without the need for science to “prove” that a risk existed. As such, the workshop suggested that there is a need to increase awareness of this issue, and to reinforce scientific studies.

Conclusions

The CRPPH has recognised that mutual understanding on the scientific evidence and on the radiological protection values and practice is important both for obtaining optimal protection, and for identifying the gaps in knowledge that are most relevant for radiological protection. Most of the participants at both Science and Values workshops agreed that while there is no immediate need to change the current principles, extended dialogue among all concerned stakeholders is necessary in order to facilitate integration of challenging scientific phenomena into existing regulatory frameworks. This type of exchange forum between regulators and scientists was welcomed and could serve as a model way of moving forward. As such, the CRPPH is preparing the 3rd Science and Values workshop, to be held in the second half of 2011 in Japan, hosted by the Japanese government.

Lessons learned in radiological protection during the dismantling of nuclear facilities

González, Oscar; Ortiz, Teresa
ENRESA, SPAIN

Abstract
This paper presents the lessons learned and recommendations deriving therefrom in relation to radiological protection and the application of ALARA programmes during the performance of dismantling projects. It also identifies specific problems arising and the result of the solutions designed.

Introduction
The Spanish national radioactive waste management agency Empresa Nacional de Residuos Radiactivos (ENRESA) has carried out the dismantling of the Vandellós 1 Nuclear Power Plant and the experimental reactor and other research facilities at the Centre for Energy-Related, Environmental and Technological Research (CIEMAT).

During dismantling work various radiological protection challenges arise; application of the ALARA principle is fundamental.

The principles governing the application of the ENRESA ALARA policy in the projects and activities under its responsibility are established in the AL (G) document, "Manual for application of the ALARA principle in ENRESA projects and activities", and in the ALARA programmes specific to the different projects. These documents establish the methods for the development, implementation and evaluation of the ALARA programmes applicable to the engineering and work performance phases of the facility Dismantling and Decommissioning Plans.

The application of this programme is carried out by introducing recommendations during the phase of drawing up of the documentation of interest, as well as through the performance of ALARA audits during the different activities and phases of the project.

The radiological criteria (collective dose, individual dose, dose rates and levels of surface and airborne contamination) for the detailed application of the ALARA methodology to a specific task are specified in the ALARA work control and management and dose reduction and minimisation procedures.

Specific aspects of dismantling
The objectives of Radiological Protection and ALARA, the basic criteria for application and the regulatory responsibilities are the same in normal operation of the facilities as in dismantling; however, the aspects relating to the licensing documentation, planning, adaptation of the organisation, production objectives, regulatory requirements, the

necessary human and material resources and the mechanisms for coordination with the rest of the organisation have clearly differentiated characteristics that must be taken into account.

Furthermore, there are initial conditioning factors that fundamentally shape the approach and methodology for the application of Radiological Protection, these being the type of facility, the time elapsing since shutdown, the final level of dismantling foreseen, the remaining surveillance systems and the possibilities of their being reused during the project.

All this requires adaptation of the organisation to the project objectives, this implying the organisation operating in a matrix configuration, an increase in the number and diversity of the participating organisations and the involvement of agents and workers not used to working in radiological scenarios.

As regards the Radiological Protection (RP) personnel, these conditioning factors materialise through a multiplication of interfaces and dependences, this including involvement in the "production process", which is not habitual at operating facilities.

For RP these initial conditions imply assessment of the usefulness of the available equipment and of the possible need for them to be adapted or complemented, specifically as regards documentation, facilities and instrumentation.

These conditioning factors pose various specific challenges, such as the following:

- Dismantling implies modifying the physical configuration of the systems existing at the installation (ventilation, effluents, etc.); variation of the routes for equipment, wastes and materials; the loss of auxiliary media (cranes, hoisting devices, etc.); the appearance of new radiological zones (stores, decontamination workshops, radioactive waste collection areas, etc.).
- Dismantling implies continuous variation of the radiological status of the installation due to the rupturing of system confinements, continuous work in areas of radiological risk and the appearance of new radiological zones (due to the movement and storage of the radioactive material generated).
- Dismantling implies modifying the working techniques due to the use of industrial cutting and demolition equipment, equipment for the moving of large loads and large-scale decontamination techniques not used during normal operation.
- Dismantling implies a variation of the radiological risks: the risk of exposure to transuranic elements increases, as does the variety of the chemical forms and sizes of contaminant particles, although the risk of exposure to other radionuclides, such as radioiodines, noble gases and, in general, all short-lived radionuclides, is reduced.
- Dismantling implies adapting the application criteria to the ALARA criterion. Converting classical criteria into a tool for efficiency is an essential objective, and for this the most practical approach is to require that contractors and the organisation overall fulfil their part of overall responsibility, offering the help required to simplify the methods for the analysis and assessment of alternatives, prioritising the optimisation criteria regarding strict compliance with the initial dose objectives.

- Dismantling implies contemplating the risk of internal contamination by alpha emitters, for which reason this should be taken into account: special individual perception of this risk; the existence of strict regulatory requirements; the significant dosimetry repercussion in the event of incorporation; the repercussion on external doses of using protective equipment slowing down job performance; the need for specific protective and measuring equipment; the need to implement complex internal contamination controls through the bioanalysis of urine and excreta.
- Dismantling implies adapting the radiological protection training of the workers, taking into account that many of them will never have worked before with ionising radiations and that disassembly, cutting, demolition and decontamination tasks require non-habitual behaviour patterns, precautions and protections. Likewise, the workers should understand the risk of internal contamination and not underestimate its importance.
- Dismantling implies a combination of radiological and conventional risks due to the existence of radiological environmental contamination and the presence of toxic materials and fumes. Likewise, the use of radiological protection equipment may increase the risk of accidents due to diminished visual or hearing capacity.
- Dismantling implies the extended use of radiological protection equipment and resources, both human and instrumental. The equipment is required to be robust and transportable and to provide extended detection capabilities allowing for the real-time measurement of airborne contamination and for remote control and data acquisition.

Lessons learned and recommendations

Indicated below are certain of the problems specific to dismantling detected and the solutions successfully developed and applied. The experience acquired during the dismantling of Vandellós I and of the facilities included in the PIMIC dismantling project constitutes the main source of information.

Administrative and organisational aspects

The main problem detected is that the contracting specifications do not establish sufficiently the ALARA responsibilities of the contractor and that ALARA aspects are not adequately considered in assessment of the bids. These shortcomings must be overcome when performing the work.

Furthermore, as ALARA solutions are not taken into account in the specifications, the collective doses assessed are overestimated and at times it is difficult to justify the variations between the estimated and actual doses before the Regulatory Authority.

The solution consists of establishing the ALARA commitments and requirements in the specifications and bids and of taking into account ALARA proposals in the licensing documentation dose estimates.

Other organisational aspects have also been observed relating to the documentation required of the exposed workers. These lead to delays in the process of registering the worker at the facility for him to perform his work.

This might be solved by including the requirements and the obligation of the contractor to meet them in the specifications and contracts, including penalties for cases of non-compliance.

Another aspect that needs to be improved is training; on the one hand to provide better understanding of the project documentation by the works organisation and, on the other, to provide better basic training on radiological protection for the workers performing the work.

In the dismantling operations managed by ENRESA, enormous efforts have been made regarding overall accountability, analysis, multidisciplinary planning, the involvement of the contractors and specific initial and on-going training, with highly positive results. Likewise, the contractors have been required to make available technical personnel with ALARA training and experience, this having facilitated coordination in this respect with the organisation.

Technical aspects

The following are particularly significant as regards the technical aspects to be taken into account:

- Initial radiological characterisation of the site: this is not normally oriented towards radiological protection needs for performance of the work, but towards estimation of residual activity, isotopic streams and scaling factors. Although an initial radiological classification is established, this is not valid since it corresponds to a static situation that might vary a great deal when disassembly work begins, with unforeseen areas of radiological risk emerging. It is necessary to extend and intensify the initial campaigns when the work begins, especially in those areas in which there is little historic know-how.
- Control of airborne contamination. The special characteristics of dismantling activities (cutting, breakdown, scarification, demolition, opening of active systems, transfer, transit storage, etc.) very often imply the release and dispersal of contaminants in the form of aerosols in the working environment. Occasionally this contamination poses non-habitual problems such as the presence of alpha particles, this requiring special controls implying sampling, detection and the implementation of exhaustive precautions, confinement and the use of special individual protective equipment.
- Confinement and ventilation: The technique of constructing and deploying rigid confined enclosures (SAS) (figure 1.) is efficient for the confinement of contamination when work is performed with important levels of negative pressure and air renewal. The elimination of releases of airborne contamination outside these SAS during work underlines this. These enclosures must guarantee an important level of negative pressure with respect to the adjacent areas, also ensuring a flow of air from clean compartments to more contaminated areas. There must also be conditioned areas for the loading, closure and removal of the containers and drums used for dismantling and secondary wastes. The use of transparent materials for their construction facilitates supervision, control and communications between the interior and the exterior of the enclosure. Personnel accesses and exits should be provided, with sufficient space for the implementation of sequential dressing and undressing stages, with the

corresponding stepwise arrangement, allowing for action with sufficient convenience and safety (these are the phases implying the highest radiological risk). In this same respect it is essential that there be a rigorous individual discipline as regards the sequence of undressing, for which reason increasing the awareness of all the participating workers becomes especially relevant.

Fig. 1. Rigid confined enclosure.

- Working techniques: The introduction of improvements in working techniques in the performance of tasks potentially generating or increasing the generation of surface and airborne contamination is another aspect for which important efforts have been made.
  - The use of special equipment for the removal and pre-conditioning of active liquids is to be recommended, as is the use of breathing equipment and systems for the filtering of contaminated dust, guaranteeing confinement of the particles and preventing subsequent risks of exposure to internal contamination.
  - The removal of liquids remaining in the bottom of tanks using venturi suction systems transferring the liquid and sludges directly to a confined drum, in which the air extracted passes through a HEPA filter before being vented, and the use of a similar system for the removal of highly contaminated dust, replacing the drum with a system equipped either with a sleeve filter or a cartridge filter in a plastic case (disposable without the need for handling) and a final HEPA stage, both easily disassembled and replaced, has proven to be much safer than the normal practice of using vacuum cleaners, the operation of which may pose considerable risks.
  - Also identified as a moment for special attention is the replacement of spent filters from portable ventilation units, and ventilation systems in general, especially when they have been used in areas with alpha contamination. Certain cutting techniques generate large quantities of smoke and aerosols that saturate the filters in a short time, making it necessary to replace them very frequently, a process that if carried out without protection or with inadequate handling may lead to the external or internal contamination of the workers.

- It would be interesting to study the possibility of improving the service lifetime of PVU filters by incorporating a coarse pre-filtering system of some kind, capable of retaining coarse particles and part of the contamination. This would the need for filter replacement operations and the associated risks. Reducing the number of spent filters with high levels of contamination (specifically alpha) would also reduce the risks associated with the necessary subsequent processes of disassembly and conditioning as waste.
- The objective of necessarily limiting the use of rotary or thermal cutting equipment or methods is to reduce the risk of dispersal and resuspension of contaminated aerosols. However, following assessment of the operational profitability of applying thermal cutting and its authorisation on the basis of tests performed for the purpose, it has been demonstrated that this may be used if adequate protection and efficient ventilation systems are available. The effectiveness of these aggressive but extraordinarily fast techniques makes them an interesting and controllable option from the radiological point of view, as long as the personnel are duly capacitated in their use. In the specific case of breaking down tanks, the solution to make thermal cutting compatible with the confinement of the contaminated fumes generated consisted of incorporating suction systems inside the tanks themselves, such that practically all the fumes and aerosols generated are immediately absorbed and filtered. To optimise the process, all the incomplete cuts were initially addressed, maintaining the geometric integrity of the tanks as long as possible in order to make the vacuuming more effective. This system kept the areas outside the SAS free from airborne contamination throughout all the work.
- The use of peelable paints (figure 2.) has been effective to fix the existing surface contamination and to protect already decontaminated areas. Their application and handling has not posed any problems.

Fig. 2. Peelable paint applicated.

  - As an alternative to thermal or rotary methods (plasma, blowtorch, cutting disk) for highly contaminated items, hydraulically operated manual shearing devices of different capacity have been used successfully for the cutting of pipes and profiles of small and intermediate dimensions. This system reduces the risk of resuspension , provides an initial sealing of the cut edges of the pipes and allows for a far better rate of work than manual disassembly and de-flanging and cutting with saws. It also reduces the risk of fire and does not produce fumes.

- Special protective equipment (figure 3): on the basis of analysis of the radiological characteristics and risks associated with work with high levels of surface and/or airborne contamination (especially if artificial alpha contaminants are included), the following is deemed to be necessary:
  - Availability and use of personal means to protect against contamination (surface and airborne), guaranteeing a sufficient degree of isolation under any conditions. For this reason, the use of special protective equipment of known characteristics and methods of use has been widespread for certain activities, this having proven to be useful in installations and tasks of comparable characteristics. In our case, this has consisted of the use of integral semi-autonomous systems with a supply of exterior breathable air and incorporating a mask and P3 filter connected to the supply line. This equipment allows a continuous level of protection to be afforded during the process of removing protections, guaranteeing that at no time during the undressing phase is the worker exposed to contamination by inhaling.

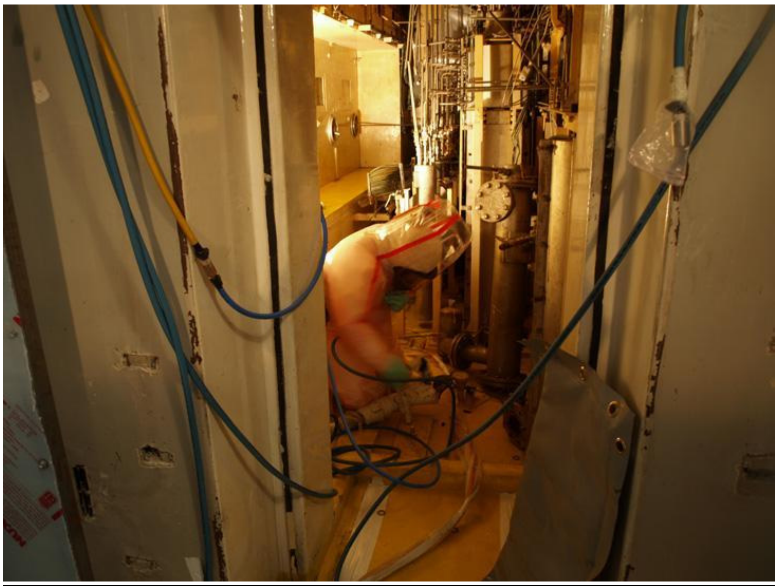

Fig. 3. Special protective equipment.

  - The specific conditions of use of this equipment, and the use of a breathable air system, make it advisable to deliver specific training to the personnel intervening in the different phases of the work.

- Special surveillance techniques: continuous airborne alpha and beta contamination measuring equipment has been used. This equipment was used for the dismantling of equipment that had been directly affected by operational activities implying the handling, reprocessing or storage of irradiated nuclear fuel. The advantage of using equipment of this type has been the possibility of remotely and centrally controlling the environmental conditions of the work places, with real-time display. The equipment has been of great help in tasks involving a specific risk of alpha contamination, since it immediately warns of any unexpected increase in the levels of airborne contamination, facilitating interruption of the work and the evacuation of the affected personnel. As a complement to the use of this equipment, environmental volumetric sampling has been performed, analysing the filters in the laboratory to confirm the alarms. It is recommended that nasal swabs be performed periodically and whenever there are incidents involving possible personal contamination affecting the face.
- Precautions in the handling of radioactive waste and materials: Management, including the handling and conditioning of radioactive materials and waste, constitutes one of the most important scopes of work during dismantling. It is essential to take into account that many of the radiological risks identified in the performance of tasks with materials are reproduced, with specific characteristics, in many of the activities relating to their management once they have become wastes. The experience acquired makes it possible to identify certain processes in which these risks are clearly manifested, and for which preventive and control measures should be established. Among the most significant are the inspection of containers, the immobilisation of non-compactable wastes and the compacting of wastes.
- Hot particles (discrete radioactive particles): The presence of discrete high specific activity radioactive particles has not been a risk detected in the dismantling of Vandellós and PIMIC, due to the type of facility and the time elapsing between the shutdown of the installations and the initiation of dismantling activities. However, in future light water NPP dismantling projects, the appearance of this radiological problem is highly likely due to the essential task of cutting highly activated metallic materials (reactor internals). This should be taken into account from the very design phase and consideration should be given to the need to develop programmes and procedures for the prevention, location, characterisation, control and elimination of the problem (specific portable detectors, integral checking gate monitors on two levels), as well as to dose calculation tools. In accordance with the international recommendations, the control programmes set up should be aimed at preventing equivalent organ dose limits from being exceeded (fundamentally the skin) and at preventing the appearance of deterministic effects such as inadvertent exposure to hot particles.

Conclusions

– The dismantling of a nuclear power plant requires the RP programme set up during normal operation to be entirely adapted. This adaptation covers from documentary aspects to increased human and technical resources and the reorientation of operating practices.

- The changing situation during work performance means that RP control must be continuous, without forgetting the importance of ensuring the commitment of the entire organisation to minimising doses.
- The ALARA principle should be taken into account from the moment of planning the work, and all the players involved should participate in its application.

- Regardless of the level of risk of external radiation that might exist at the facility, maximum attention should be paid to the risk of internal contamination, which increases greatly with respect to normal operation because of the disassembly tasks themselves, the removal from service of the ventilation and confinement systems and interventions on equipment and components never before touched.
- Adequate planning of the tasks requires an in-depth understanding of the operating and radiological history of the facility, although in all cases the radiological status of the installation needs to be updated when addressing its dismantling.

With due consideration given to the above, it may be stated that the RP applied will be effective and that doses will be as low as reasonably achievable.

Remediation of TENORM residues: Professional risk assessment and public risk perception

König, Claudia[1]; Riebe, Beate[1]; Rieger, Matthias[2]
[1] Institut für Radioökologie und Strahlenschutz, Leibniz Universität Hannover, GERMANY
[2] Institut für Soziologie, Leibniz Universität Hannover, GERMANY

Abstract

In the last three decades, members of different disciplines (such as sociology, radiation protection) have published a vast number of studies on risk perception and acceptance with respect to nuclear power plants and nuclear waste repositories.

However, bridging the gap between what radiation protection experts consider to be an objective risk and the subjective risk perception by non-scientists is a challenging task. This is especially true for perception of radiation risks which might derive from so-called TENORM (Technologically Enhanced Naturally Occuring Radioactive Materials) during the remediation process of polluted industrial sites.

In many cases, remediation of TENORM residues is affected by the people concerned facing inconsistent information (on the actual risks) and/or overlapping legal regulations. The remedial actions aimed at the protection of the residents often raise further concerns. As a consequence even the radiation monitoring required might cause distrust.

This research project was established to elucidate the underlying reasons for communication problems between experts and affected members of the public.

In case studies from two remediation sites in Germany (a residential area on a polluted former industrial site in Hanover and remediation of uranium tailings by WISMUT in Saxony) the risk assessment of experts and the risk perception of laypersons, resp., are analysed on the basis of interviews conducted with experts in the field of radiation protection and remediation, as well as with residents living on former industrial sites polluted with radioactive substances.

Furthermore, primary sources including governmental documents and radiation protection regulations, and press coverage are investigated.

The first results from the analysis of the data collected in this qualitative approach are presented here.

Introduction

Everyday perception of radioactivity is often shaped by the discussion on how safe or risky nuclear power plants or nuclear waste repositories are (Renn 1998; Sjöberg and Drottz-Sjöberg 2009; Slovic 1996). Only when ionising radiation occurs in people's living environment, their houses or gardens, they realise that also other forms of radioactive substances exists, the so-called technically enhanced naturally occuring radioactive materials (TENORM).

The management of TENORM residues is affected by a number of conflicts between the several dimensions of a remediation (Fig. 1).

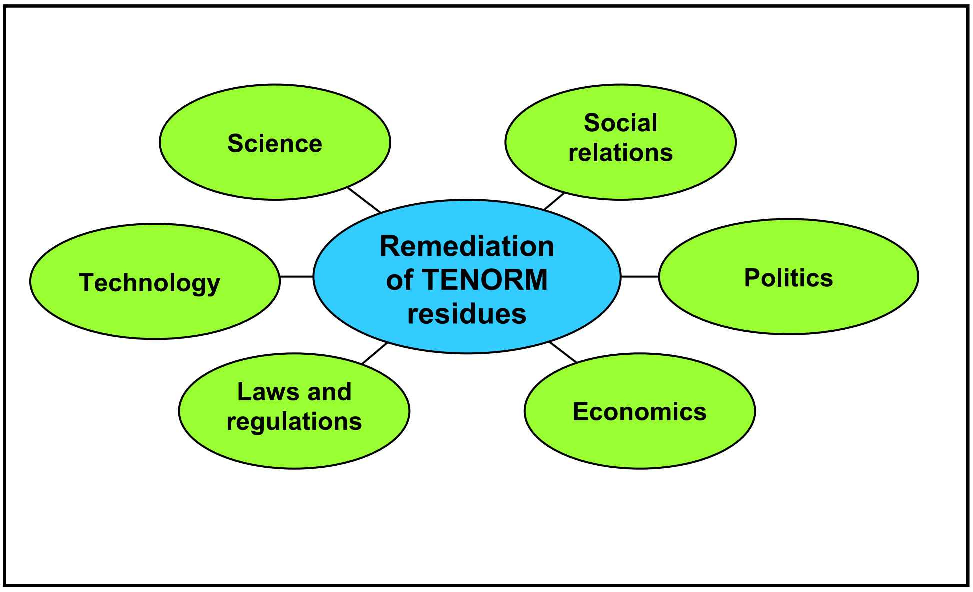

Fig. 1. Dimensions of remediation of TENORM residues.

For example: Contradictory statements by experts and media reports lead to reservations on the part of the residents affected. Errant communication between experts and politicians, and overlapping legal framework raise further confusion. As a consequence, the residents experience remediation actions as new dangers. Whenever authorities or experts try to protect the residents of polluted areas, the residents often consider the actions as unsettling rather than of avail (Wynne 1987).

In the field of radiology as well as sociology, many researchers account the fact that residents and experts often percceive the risk of radiation in very different ways (Slovic 2002). But until now, research on TENORM remediation lacks a clear concept for the management of TENORM residues which combines the professional risk assessment of the experts with the the risk perception of the residents.

In our project, funded by the German Federal Ministry of Education and Research (BMBF), we work out criteria for an evaluation of TENORM remediation. These criteria do not only include radiological but also societal aspects. Using as examples the remediation of an urban district of the provincial capital Hanover and the remediation process of the former area of the uranium mining industry in Saxony, Germany, we study the risk assessement and risk perception of TENORM-remediation. Our aim is to investigate the following questions:

- What are the different understandings of risk and safety for experts and lay persons involved?
- Which basic assumptions underly the predictions of experts?
- How does the familiarisation with ionising radiation, like in an uranium mining area, influence the perception of radiation risk?
- Which social factors determine an appropriate and accepted remediation of TENORM?
- And which interactions between the stakeholders have a recognisable impact on TENORM remediation?

Material and methods

We have chosen a transdisciplinary approach which combines the examination of the scientific as well as the social factors of remediation processes. The collaboration of the Insitute for Radioecology and Radiation Protection and the Institute of Sociology allows to combine scientific and sociological expertise for the examination of the perception and assessment of risk.

Based on analyses of the stakeholders` network of residents, experts, administrators, journalists, politicians etc. we focus on two contrasting cases for remediation of TENORM. The first case concerns the contamination of parts of an urban area in Hanover. The polluted area lies in the very center of the city and strikes one of the most favourable residential areas. Parts of the district were built on the property of an abandoned chemical plant, in which, among other things, uranium and thorium had been processed. In 2008, more than one hundred years after the demolition of the plant, the industrial inspectorate found residues of uranium, thorium and their daughter products in the soil, as well as heavy metals in remarkable concentrations.

The second case refers to the remediation of one of the world`s-biggest uranium minig sites in the last century. From 1946 to the end of 1990 extensive uranium mining operations took place in Saxony and Thuringia (eastern Germany). 220.000 tonnes of uranium were produced and supplied to the former Soviet Union. At the mining and milling sites, 48 waste rock piles were accumulated, containing a total of 300 million cubic meters of mine spoils. Furthermore, 160 cubic meters of suspended ore-processing residues were disposed of in 14 slurry ponds. Due to the fact that uranium was mined in a densely populated and intensively used agricultural area, living conditions for many people in the affected area were impaired significantly. After almost fifteen years of remediation, this process is a striking example for the chances, but also for the pitfalls, deriving from TENORM remediation in Germany (Hagen and Jakubick 2006).

We chose these two cases to compare the impact of an unforeseen confrontation with TENORM like in Hanover with the effects of familiarisation to TENORM residues like in Saxony and Thuringia.

Our research is based on three interconnected methodological approaches. First, we analyse different standard texts in use by the involved experts, e.g. manuals and other standard works on radiation protection, environmental law and occupational health. The analysis of these documents is crucial for a deeper understanding of the experts` risk assessment, their basic assumptions and terminology. Secondly, we will conduct interviews with selected experts who are directly involved. Thirdly, qualitative interviews with residents in the affected areas will complete these analyses.

First results

A first analysis of interviews, media reports and other material already depicts several obstacles constricting the interaction between the different stakeholders.

First, stakeholders use scientific terms such as ´risk`, ´hot spot`, ´contamination` and `remediation` in very different ways. 'Hot spot' e.g.; is a good example for how a term changes its meaning in different contexts. We can see in our case that investigating radiologists use 'hot spot' to name locations with radiation levels higher than the surrounding areas. But when politicians or journalists use 'hot spot' in public discussion, they connect the term with 'danger`. Thus, politicians and residents demand removal of every 'hot spot', even if there is no need from the scientific point of view.

Another area of conflict are the lacks in the legal framework in NORM-regulations in Germany. For instance, there are no specific constraints or even reference levels for indoor radon concentrations. The scientific discussion about the level from which on radon causes cancer is still going on. Therefore, the decision makers involved in remediation processes have to rely on diverging recommendations given by different organisations such as WHO, the German Federal Office for Radiation Protection (BfS) and the ICRP, respectively.

Regarding residents` risk perception we observe that two main factors having a substantial impact – factors beyond concerns about physical damage. First, residents fear economic damage, namely the reduction in value that their properties suffer. As a consequence they are also worried about the impending social decline of their neighborhood, and therefore a recognisable damage in their social status.

Conclusion and future work

Having started our project in January 2010 the first results already indicate that communication problems exist on different levels of the stakeholder interactions in an on-going TENORM remediation process. Barriers become prominent between radiation experts and politicians, between radiation experts and decision makers in the administration, and between scientific risk experts and residents, respectively. In our future work we will try to reveal further relevant communication obstacles, and track to which extent the different obstacles are interconnected.

Abstract

On August 22, 2008, a cloud of ^{131}I was released from the Institut des Radioelements (IRE), a producer of medical isotopes located in Fleurus, Belgium. The peak of the release took place in the weekend of 23-24 August and was followed by a smaller, continuous release which lasted for several weeks.

After reports of the incident in the press, concern grew among the local population about possible health effects of this release of radioactivity.

As a consequence of this concern, the Belgian public health authorities organised a thyroid measurement campaign for the local public to reassure the public that no detectable dose was acquired in the thyroid, especially for small children and pregnant women.

The Belgian Nuclear Research Centre SCK•CEN made a very substantial contribution to the thyroid measurement campaign. It provided 4 of the 5 measurement teams, each one equipped with a high-purity germanium detector and the necessary hardware and software. The University of Liège provided another team with a NaI detector.

All detectors had been calibrated in advance and were checked regularly during the measurement campaign.

The thyroid measurement campaign took place on Monday September 1st and Tuesday, September 2nd 2008 in the village of Lambusart close to Fleurus. More than 1000 people were measured, including all children from the local schools. No thyroid contamination was detected.

This paper elaborates on the preparation of this measurement campaign and the practical execution. It draws important lessons for the preparedness for similar situations in the future, both with respect to public information and technical and organisational aspects.

Introduction

During a radiological or nuclear emergency, it is of utmost importance to maintain (or establish) public thrust in the authorities for a good implementation of countermeasures and to prevent ill-based panic.

On August 22, 2008, a cloud of ^{131}I was released from the Institut des Radioelements (IRE), a producer of medical isotopes located in Fleurus, Belgium. The peak of the release took place in the weekend of 23-24 August and was followed by a smaller, continuous release which lasted for several weeks.

After reports of the incident in the press, concern grew among the local population about possible health effects caused by this release of radioactivity.

As a consequence the Belgian public health authorities decided to organise a thyroid measurement campaign for the local public to reassure the public that no detectable dose was acquired in the thyroid. Especially small children and pregnant women, the most sensitive group, were envisaged.

The Belgian Nuclear Research Centre SCK•CEN and the University of Liège were asked to execute the technical part of the thyroid measurement campaign. SCK•CEN provided 4 out of 5 measurement teams, each one equipped with a high-purity germanium detector and the necessary hardware and software. The University of Liège provided another team with a NaI detector and associated hardware and software.

Description of the measurement campaign

Goal (technical and societal)

The technical goal of the measurements was to measure at least a ^{131}I contamination in the thyroid that would result in an effective dose of 2 mSv for a child.

Based on the assumption that the intake of ^{131}I took place via inhalation, Absorption Type F, the predicted values for activity in the thyroid per inhaled activity [ICRP 78] and the ICRP dose conversion factor for ^{131}I in the thyroid (inhalation, AMAD 1 µm, Absorption Type F [ICRP 71]) a measurement time of 1 minute was derived in order to be able to measure a 2 mSv thyroid equivalent dose for a child, equivalent to a 100 Bq activity in the thyroid 8 days after the major release.

An analysis of the measured gamma-spectra after the measurement campaign revealed that the obtained detection limits were in the range of 20-90 Bq. The observed variation is due to differences in the detectors, mainly the efficiency.

The maximum detection limit of 2 mSv is well below the Belgian intervention level of 10 mSv thyroid equivalent dose for children and pregnant women.

Based on the known release of ^{131}I, it was considered as extremely unlikely that a measurable contamination could have occurred. However, in view of the concern among the local population, it was decided by the authorities to organise this measurement campaign in order to reassure the public. The campaign focussed on children, but adults that desired to be checked were given the opportunity to be measured after the children were measured.

Used equipment

Four detectors were used:

- 1 LEGe detector with electronics and Genie2000 analysis software
- 1 MAC Ge detector with electronics and Genie2000 analysis software
- 2 Ge detectors with ISOCS efficiency calibration.

The acquisition, analysis and calculation of the detection limits was done with Genie2000 (Canberra) software. Detection limits were calculated with the Currie method. The detection limit is stated as the smallest net signal that can reliably be quantified. It can be calculated for the radionuclides not found in the spectrum, as well as for those that have been found. Under ideal laboratory conditions (low background, long measurement time), a detection limit as low as 1 Bq can be achieved, but this was not the case for this measurement campaign as explained below.

Calibration was performed with a ^{133}Ba source in a thyroid neck phantom as shown in figure 1. The measurement setup of the University of Liège was also checked with this calibration phantom for consistency of the measurement results.

Figure 1. IRSN thyroid phantom for intercomparison (left), SCK•CEN thyroid phantom for calibration (right).

Practical execution of the measurements

The 4 detectors were placed in two changing rooms of the sports hall *'Salle Omnisport'* of the village of Lambusart, close to Fleurus. This village is located in the main wind direction of the release. The setup for the measurements consisted of placing the person with his/her thyroid gland (located just under the Adam's apple in the neck) in front of the detector at 2-5 cm distance (figure 2). A measurement was then started for 1 minute during which the person had to stay as still as possible. The measurement is based on the detection of the 364.5 keV gamma peak of ^{131}I.

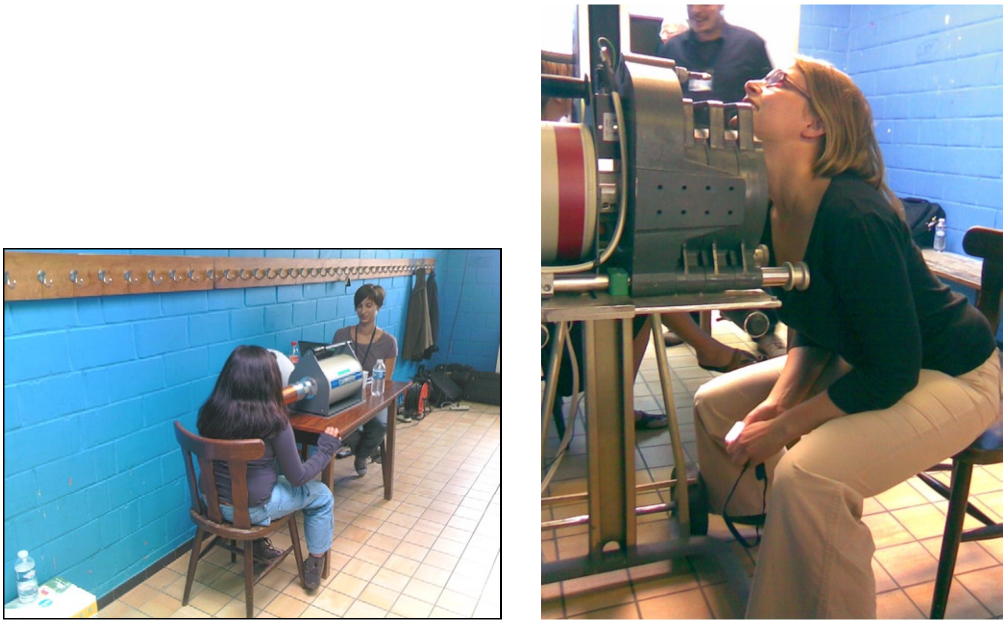

Figure 2. Thyroid measurement setup

After the gammaspectrum is acquired, the analysis is done immediately and indicates if any activity of ^{131}I was detected in the thyroid. No activity detected means that with a confidence of 95%, the activity in the thyroid is lower than the calculated detection limit.

Measuring in an unshielded room and reducing the measurement time to 1 minute increased the detection limits considerably compared to the above-mentioned ideal laboratory conditions. The use of different detectors and the varying background activity in the environment resulted in detection limits ranging from 20 to 90 Bq for the detection of ^{131}I..

The result of the measurement was immediately communicated to the person involved and it was indicated on the result sheet with an identification number. 'SCK•CEN' was written on the results sheets of persons measured by any setup of SCK•CEN. When no activity was detected, a result of 'risque nul' (zero risk) was indicated on the result sheet of the measured person. This was done on demand of the responsible from Public Health although scientifically we could not state the activity was zero.

Target group

The authorities decided to focus first on the most vulnerable group, children and pregnant women. All children from the schools in the vicinity of Lambusart were transported to the sports hall to be measured, while also all pregnant women were requested to come to the measurement location.

After these groups had been measured, the other members of the local public could come and let themselves be measured.

SCK•CEN performed 876 recorded measurements, all with a negative result. Additionally about 200 persons were monitored with equally negative results, but without recording the results in writing. This was done at their explicit request.

Chronology

On Friday August 29th the public health authorities asked the SCK•CEN representative at the federal crisis centre whether SCK•CEN would be capable to organise a thyroid measurement campaign for the local population of Lambusart, with an estimated 3000 inhabitants. The same date SCK•CEN wrote a note that stated that such a campaign would be possible.

On Saturday August 30th SCK•CEN received an order of the Ministry of Public Health to provide measurement teams for the thyroid measurement campaign. The same day the relevant experts were contacted to prepare this campaign.

On Sunday August 31st two available measurement chains were prepared. Soon it was realised that these two setups would not be sufficient to measure 3000 people and it was decided to include the two additional ISOCS systems to have four systems available. The complete team was assembled, consisting of 4 measurement teams with one operator and one guide, an expert in electronics, a team leader and a radiological expert for informing people.

Monday September 1st at 5:45 a.m. arrival of the team at SCK•CEN for the last preparations. Departure to Lambusart at 6:30 a.m.for arrival at Lambusart at 8:30 a.m.. Set up of equipment took 1 hour and final briefing of the teams at 9:30 a.m. Start of the measurements at 10:00 a.m. From 10:00 a.m till 01:00 p.m. measurement of limited numbers of children and pregnant women. After 13:00 all inhabitants could come and have themselves measured. Between 16:00 and 19:30 there was a peak, resulting in relatively long queues. After 20:00 the campaign was finished. Several team members had to stay for an information session for the local population from 21:00 till 23:00. After this session the public health authorities decided to extend the measurement campaign at the next day. Departure at 24:00.

Tuesday September 2nd, two measurement teams were sent instead of four. Measurement campaign was executed from 16:00 till 20:00. The team consisted of two measurement teams of two persons, a team leader, a radiological expert and a communication expert. No electronics expert was present, but a third Ge detector was present in case replacement is necessary.

Interactions with/reactions of the public

Most members of the public did not ask more information. However, when an initiative was taken to provide them with more information, the majority reacted positively and asked for more information. A considerable minority considered the campaign as a cover-up of the authorities, but nevertheless accepted a measurement.

The minority that asked more information on its own initiative was concerned whether the measurements itself could harm them and wanted to know more about the health effects of ^{131}I. Less questions were asked about how the measurements were performed and how reliable the measurements were.

Performing measurements on small children is a trick on its own. The size of the Ge detectors was rather impressive for the youngest (0-5 years) and required distractors like laboratory gloves blown as balloons. For that group, the NaI detector of the University of Liège was less frightening since its size was much smaller, but its efficiency was also lower.

An additional disadvantage was that September 1st is the first schoolday, so most teachers were not yet acquainted with the children and had not yet established a bond of trust.

The vast majority considered SCK•CEN and the University of Liège as impartial and therefore trusted the quality and outcome of the measurements. This would not have been the case if IRE, which caused the release, would have carried out the measurements.

The vast majority of the team on the first day consisted of native Dutch-speaking people, with one exception. Although many of them spoke reasonably well French, communication with the French-speaking population led sometimes to misunderstandings, certainly when it concerned children. It was decided for the second day to compose teams with a better French-speaking ability.

Possible improvements

It has to be admitted that the existing measurement equipment just had been calibrated for thyroid measurements, rather as a coincidence. Actions are ongoing now to extend calibrations for a range of isotopes (^{131}I, ^{137}Cs, ^{60}Co, ^{235}U and ^{238}U) and contamination types (thyroid, whole body, lungs).

There was a clear demand of the general public to be informed, but the initiative should come from the experts. The public is reluctant to ask experts about their expertise, but is eager to listen and learn when something is explained. Therefore communication to the public should be part of the overall strategy, explaining first of all of the health effects of radiation and secondly of the principles of the measurement method.

To establish and maintain experience in these kind of campaigns, regular exercises should be undertaken as part of the overall emergency planning exercises. The different types of measurements (thyroid, Whole Body Counting, lungs) should be trained to understand the specific problems that occur in practice.

Conclusions

During a measurement campaign, the public needs to be informed actively, since the majority will not ask information, but is nevertheless interested when more information is provided. The information given should focus first on the health effects of radiation and secondly on the radiation measurement principles.

Very young children (age 0-5 years) should be measured in a reassuring environment. Toys, ballons and lively colours will distract their attention from the impressive measurement equipment.

Measurements should be executed by institutes that are not related with the institute responsible for the radiological problem and that are considered by the general public as independent and impartial.

Calibrations of existing measurement equipment for specific cases are time-consuming and cannot be performed in times of crisis. These calibrations should be performed for all different types well beforehand and should be checked by intercomparison exercises.

To maintain the operationality of the measurement teams, exercises should regularly be organised to test also the aspect of measuring large number of people.

In a multilingual country measurement teams should be partly composed of native speakers of the local language to provide a clear communication with them.

Abstract

In order to develop trustful relations and to harmonize with society for the use of nuclear energy and the operation of nuclear facilities, it is essential for the state governments and electric power utilities to design the appropriate measures for communication and dialogue with stakeholders. The one-way information distribution should be avoided and the two-way information exchange system should be build up between the administration and the public.

In this paper, we focused on the designing of the stakeholder meetings and comparatively studied the cases in Japan, France and UK. As the result, it is found that there are differences in the selection of stakeholders and the designing of the meetings. These differences are probably relating with the social backgrounds and cultural differences in the countries. The experiences in the French system would be informative for the Japanese stakeholder meetings.

In Japan, one of the biggest issues has been the finding of the candidate site for the high-level waste disposal facility. Toyo town in Kochi prefecture applied as the candidate, for the first time in January 2007. However, due to the strong opposition movement developed in Toyo town and Kochi prefecture, the application was cancelled. Based on the results of this case, we considered the problems of the stakeholder involvements and the differences in the designs of the stakeholder meeting between the existing nuclear facilities and the planning facilities.

Introduction

In the past one and half decades, a number of troubles, failures, accidents and manipulations have occurred in the nuclear industries in Japan. In spite of the world wide nuclear Renaissance, good relationship between the public and the nuclear industries has not yet been created in Japan. To eliminate the distrustful concern of the public against the operations of nuclear facilities, and to develop good social relations, it is important to facilitate the communications of two-way talks among stakeholders. In the present work, we comparatively analyze the stakeholder meetings established with the aim of safety assurance of the nuclear facilities in the hosting region in France, Japan and UK, paying attention to the designing of the stakeholder meeting.

Subject of Analysis

The approaches and the efforts have been made in various countries to establish and to run the stakeholder meetings in order to ensure the safety and the transparency on the operation of the nuclear facilities in the local area. The present study surveys and analyzes the designing of the stakeholder meetings developed. We selected the following stakeholder meetings for the analysis in the present work, paying attention to the participating members.

Stakeholder meetings in Japan

– Community Meeting for Securing Transparency of Kashiwazaki-Kariwa Nuclear Power Station (hereinafter referred to as "The Community Meeting")
– Monitoring and Evaluation Conference on Environmental Radiation

Stakeholder meetings in France

– CLI AREVA NC La Hague
– CLIS de Fessenheim

Stakeholder meetings in UK

– West Cumbria Sites Stakeholder Group (WCSSG)
– Sizewell A&B Stakeholder Group

Method for Investigation

We conducted the literature survey on the design and the laws and regulations relating to the stakeholder meetings in Japan, France and UK.

We also conducted the interviews to survey the activities, the membership and the regulations for the following stakeholder meetings: The Community Meeting (Japan); CLI AREVA NC La Hague (France); CLIS de Fessenheim (France); West Cumbria Sites Stakeholder Group (WCSSG) (UK).

Analysis

Japan

The establishment of the stakeholder meetings is not required by laws and regulations for the operation of nuclear facilities in Japan. The municipalities hosting nuclear facilities establish the Regional Committee for Monitoring and Evaluation of Environmental Radiation, in order to protect health and safety of local residents. Its purpose is to evaluate the results of the monitoring data around the nuclear facilities. In addition, Niigata prefecture and other local authorities establish a stakeholder meeting in the area located Kashiwazaki-Kariwa Nuclear Power Station.

1. Community Meeting for Securing Transparency of Kashiwazaki-Kariwa Nuclear Power Station (The Community Meeting)

In July 2000, a former employee of an affiliate company of General Electric reported the Ministry of Trade and Industry the dishonesty in the inspection records of Unit No.1 of Tokyo Electric Power Company's Fukushima Daiichi Nuclear Power Plant. In August 2002, the Nuclear and Industrial Safety Agency announced to the public that there were a total of 29 improper inspection records, in which the four cases occurred in Kashiwazaki-Kariwa Nuclear Power Plant (Community Meeting 2002, 2003a).

In order to prevent the reproduction of the occurrence and to restore the trustful relations, Tokyo Electric Power Company proposed to set up a third party organization in both Fukushima and Niigata Prefectures, where nuclear power plants are located. However, Niigata Prefecture, as well as the municipalities of Kashiwazaki-city, Nishiyama-town, and Kariwa-village, had misgivings about the proposal, sensing that the electric power utilities might be using it as nothing more than a public relations activity. They came to the realization that a public-participation type conference in the host region was necessary to prevent future dishonest actions by the electric power utilities and to enhance transparency in the operation of nuclear power plants. Thus, in 2003, the "Community Meeting for Securing Transparency of Kashiwazaki-Kariwa Nuclear Power Station" (hereinafter referred to as "The Community Meeting") was established on a voluntary basis by local authorities (Community Meeting 2002).

The purpose of The Community Meeting is to conduct monitoring from the viewpoint of local residents, placing emphasis on securing transparency of the activities at the power station, in order to prevent the re-occurrence of dishonest actions in Kashiwazaki-Kariwa Nuclear Power Plants.

Membership of The Community Meeting is to be composed of a maximum of 25 members residing in Kashiwazaki City or Kariwa Village, recommended by the 21 organizations approved by the regional community (Community Meeting 2003a, 2003b, 2008).

These organizations include in Kashiwazaki-city, the Energy Forum in Kashiwazaki, the Kariwa village Society of Commerce and Industry, Association to protect Kariwa village from nuclear power plant, and so on. The membership of The Community Meeting consists of nuclear power promoters, neutral parties, and opponents. This is characteristic of The Community Meeting. The site operator (Tokyo Electric Power Company) and the regulatory bodies participate as elucidators in the regular conference of The Community Meeting.

2. Monitoring and Evaluation Conference on Environmental Radiation

As the prefectures that host nuclear facilities have a duty to protect the health and safety of their residents, they are involved in surveying environmental radiation in the vicinity of these facilities. The "Guidelines for Monitoring Environmental Radiation" stipulate that monitoring shall be uniform between local public entities and electric power utilities, and that evaluation of monitoring results should, depending on local situations, be made by a monitoring and evaluation organization consisting of stakeholders, including local public entities and residents. In accordance with these regulations, monitoring and evaluation conferences on environmental radiation have been organized in the prefectures hosting the nuclear facilities. Japanese laws do not stipulate the membership and number of members of Monitoring and Evaluation Conference on Environmental Radiation.

The membership of these conferences consist of key players, mayors of cities, towns, and villages in the region, and representatives of local industries (Monitoring and Evaluation Conference on Environmental Radiation 2007). The memberships of

Monitoring and Evaluation Conference on Environmental Radiation in Aomori-prefecture and Niigata-prefecture are shown in Table 1.

France

The local information committees (CLI: Commission Locale d'Information) are established in the area where the nuclear facilities are located in France. The purpose is to engage in dialogue and communicate with stakeholders, in order to nurture a committed relationship among stakeholders. CLIs was established on the basis of the notification dated 4 September 1981 from the minister of industry and the notification dated 15 December 1981 from the Prime minister. Then, the establishment of CLI is required under article 22 of Nuclear Security and Transparency Act in 2006. There are about 30 CLIs around the civil nuclear facilities in France. This study chooses 2 CLIs as the subjects of analysis: CLI AREVA NC La Hague and CLIS de Fessenheim. That is because they have operated for about 30 years and they are still active.

The constitution of CLI is stipulated in the legislative decree dated 12 March 2008 (No. 2008-251). The membership and their component ratio are defined under article 5.

1. CLI AREVA NC La Hague

CLI AREVA NC La Hague was established on the basis of the notification dated 4 September 1981 from the minister of industry (Hervé 1981). Originally its name was CSPI (Commission Spéciale et Permanente d'Information). CSPI changed its name to CLI AREVA NC de La Hague after enacting Nuclear Security and Transparency Act in 2006.

As of 2010, CLI AREVA NC La Hague consists of 23 local assembly members, 6 representatives of environmental protection groups, 6 representatives of labour unions, 3 representatives of chamber of commerce, 1 representative of constabulary, 6 certified person in nuclear engineering and communication. Total number is 45. The site operator (AREVA) and safety authority are not members but observers. The membership and the component ratio are defined under article 5 of the legislative decree dated 12 March 2008 (No. 2008-251).

2. CLIS de Fessenheim

CLIS de Fessenheim was established in 1977. This was before the notification dated 15 December 1981 from the Prime minister (Mauroy 1981). Fessenheim nuclear power station is the first site where a PWR was constructed in France. At that time, local residents concerned about the PWR which was different from the existing gas-cooled reactor. Therefore CLIS de Fessenheim has the purpose to respond the concerns among local residents and to conduct surveillance of Fessenheim nuclear power station. This is because CLIS de Fessenheim has a character "S" which means "surveillance."

There are 40 members in CLIS de Fessenheim as of 2010. The membership and the component ratio are defined under article 5 of the legislative decree dated 12 March 2008 (No. 2008-251).

The feature of membership of CLIS de Fessenheim is participation from other country. Fessenheim nuclear power station is located near the German border, so that 2 members from Germany participate (Conseil Général Hault-Rhin 2008).

UK

In UK, Local Liaison Committee (LLC) and/or Site Stakeholder Group (SSG) are established around the area where nuclear facilities are located. Various stakeholders (municipalities, labour unions, environmental protection groups, and so on) are included in the members of LLC and SSG. The purposes are to share the information, to have a dialogue and to communicate among stakeholders. This study chooses 2 SSGs as the subjects of analysis: West Cumbria Sites Stakeholder Group (WCSSG) and Sizewell A&B Stakeholder Group.

1. *West Cumbria Sites Stakeholder Group (WCSSG)*

The Sellafiled Local Liaison Committee (SLLC) was established to provide information and a forum of local community around the area of the Sellafiled reprocessing plant. It was replaced to the West Cumbria Sites Stakeholder Group (WCSSG) in April 2005. WCSSG provides a forum for representation of local community interests and is the interface between the community, the site operators and the Nuclear Decommissioning Authority (NDA). The establishment of WCSSG is on the basis of NDA Guidance (NDA 2009). It is not a law or a regulation.

WCSSG has six sub-committees, detailed aspects of the Sellafield and Low Level Waste Repository sites, including operational issues, environment health, emergency planning and socio-economic impacts.

WCSSG membership reflects the representational structure of the local community and its interests. The membership is as follows:

- Elected representatives of the local community.
- Appointed representatives of relevant organisations such as regulators, local authorities, unions, emergency and health services.
- A representative of the NDA.
- Representatives of the site contractor/operator.
- Independent advice to support members as appropriate.
- Representation from members of the public and local environmental groups.

The core membership of WCSSG is shown in Table 1. It consists of the representatives of the site operators, regulators, local councils, fire services, police, farmers union and so on (WCSSG 2006).

2. *Sizewell A&B Stakeholder Group*

The Sizewell A&B Stakeholder Group was established and run around the area of Sizewell A&B Nuclear Power Station. The purpose of the Sizewell A&B Stakeholder Group is to:

- inform the public of activities of Sizewell site,
- act as a conduct for two-way information provision and flow,
- act as a “clearing-house” for community concerns by providing independent interpretation of information.

The membership list of the Sizewell A&B Stakeholder Group is shown in Table 1. The Sizewell A&B Stakeholder Group is characterized by inclusion of the representatives of local council and the site operator, as well as WCSSG.

Results

Table 1 shows the design of the stakeholder meetings already-described.

Table 1. Design of the stakeholder meetings around the local areas of the nuclear facilities in Japan, France and UK.

Stakeholder meeting	Country	Numbers	Membership
The Community Meeting	Japan	within 25	Local residents living in Kashiwazaki City or Kariwa Village, recommended by the 21 organizations approved by the regional community
Monitoring and Evaluation Conference on Environmental Radiation in Aomori-prefecture	Japan	within 80	25 experts 8 local key figures 2 prefectural assembly members 8 mayors in municipalities 21 representatives of concerned associations 6 prefectural government's employments
Monitoring and Evaluation Conference on Environmental Radiation in Niigata-prefecture	Japan	21	10 experts 5 representatives of concerned associations* 1 governor of Niigata Prefecture 1 mayor of Kashiwazaki city 3 prefectural government's employments
CLI AREVA NC La Hague	France	45	23 local assembly members 6 representatives of environmental protection groups 6 representatives of labour unions 3 representatives of chamber of commerce 1 representavie of constabulary 6 certified person in nuclear engineering and communication
CLIS de Fessenheim	France	40	20 local assembly members 6 representatives of labour unions 7 representatives in the business community and experts 7 representatives of environmental protection groups
West Cumbria Sites Stakeholder Group (WCSSG)	UK	51	Members and officers of the local councils Representatives of the local parish councils Representative of the local supply chain Representative of the economic regeneration programme Representative of local NGO groups Representatives of Health Authorities Representative of Cumbria Constabulary Representative of Cumbria Fire Service Representative of Isle of Man Department of Local Government and the Environment Representative of Health and Safety Executive (NII) Representative of Environment Agency Representative of DEFRA Representative of FSA Representative of Government Office North West Representative of United Utilities Representative of National Farmers Union Representative of Whitehaven and District Trades Council Representatives of Site Operators (ie: Sellafield Ltd, LLWR) Representatives of labour unions

* The concerned associations are local medical association, the local chamber of commerce, the fishery association, the farmers cooperative association and so on.

Table 1. Continued.

Stakeholder meeting	Country	Numbers	Membership
Sizewell A&B Stakeholder Group	UK	22	2 representatives of Leiston-cum-Sizewell Town Council 1 representatives of Aldeburgh Town Council 1 representatives of Saxmundham Town Council 1 representatives of Aldringham-cum-Thorpe and Knodishall Parish Councils jointly 1 representatives of Middleton and Theberton Parish Councils jointly 1 representatives of Westleton Parish Council and Dunwich Parish Meeting jointly 1 representatives of Suffolk Coastal District Council 1 representatives of Suffolk County Council The Member of Parliament for Suffolk Coastal Parliamentary Constituency or their representative 1 representatives of the Suffolk Association of Local Councils 1 representatives of the Sizewell Residents 1 representatives of the Leiston Business Association 1 representatives ofg the National Farmer's Union and Country Landowners' & Business Association jointly 2 representatives of the staff of Sizewell A 2 representatives of the staff of Sizewell B

The feature of The Community Meeting is inclusion of anti-nuclear groups in membership. On the other hand, Monitoring and Evaluation Conference on Environmental Radiation do not have any members of anti-nuclear groups. But it is charactered by consideration to local industries, because many representatives of the local industry associations participate in the Conference.

In France, the membership and the component ratio are defined under article 5 of the legislative decree dated 12 March 2008 (No. 2008-251). The result of analysis found that the ratio adhere fundamentally to the composition of the notification dated 15 December 1981 from the Prime minister. CLI consists of local assembly members, representatives of environmental protection groups, labour unions, certified person in nuclear engineering and communication, and so on. Local assembly members are as the position of representatives from local residents.

The memberships between a nuclear power station and a spent fuel reprocessing plant are the same in France.

WCSSG has the members of local fire services and police. WCSSG has a sub-committee on the emergency plan. At the nuclear emergency in UK, Police has to play a central role, so that WCSSG has the members of police. On the other hand, fire services and police are not the core members of Sizewell A&B SSG and CLI, because they do not work with them in the emergency situation.

The participants of these stakeholder meetings in Table 1 are not selected by independent organizations.

Discussion

As the result of analysis, the following characteristics are found.

- Each stakeholder meetings has the members as the representatives from local residents, who are affected by the consequence of the facility accidents and concerned with the activities of nuclear facilities.
- The Community Meeting intentionally excludes the representatives of labour unions and the site operator from membership. This is because that the role of The Community Meeting is to represent the opinions of the residents.
- Anti-nuclear groups are not participating in Monitoring and Evaluation Conference on Environmental Radiation.
- The experts participate in CLI and Monitoring and Evaluation Conference on Environmental Radiation. OECD/NEA points out the necessity of participation of neutral persons who are reliable and having high expertise in relating technical fields (OECD/NEA 2004).
- In CLIS de Fessenheim, 2 members are from Germany, reflecting the regional situation.

We think that following items are important at the designing of the stakeholder meetings: well-balanced selection of various stakeholders and the consideration of local characteristics and individual situations.

In Japan, one of the biggest issues has been the finding of the candidate site for the high-level waste disposal facility. Nuclear Waste Management Organization of Japan (NUMO) has been in charge of disposal business. Toyo town in Kochi prefecture applied to NUMO as the candidate of the study area, for the first time in January 2007. The Japanese government approved the initiation of preliminary literature investigations to survey the previous records of the earthquakes and so on. However, due to the strong opposition movement developed in Toyo town and Kochi prefecture, the application was cancelled. A number of opponents gathered in Toyo town from distant areas. The results indicates that multi stakeholders meeting is needed in the site area, to develop appropriate consensus among stakeholders. In the designing, the stakeholder meeting should have the core stakeholder which represent the core area of the region hosting the facilities. The distance from the nuclear facilities would be one of the factors to define core stakeholders.

The membership constitution of CLI is the same as one for other nuclear facilities. In France, the design of the stakeholder meeting for the construction of a future new reactor is the same as that of existing nuclear facilities. In the case of a future new nuclear facility, just like the high-level waste disposal facility, based on the result of Toyo town case, it may be necessary to design the core stakeholders and distinguish it from other stakeholders in the future energy policy making.

Conclusion

The result of analysis from this study reveals that the designing and selection of participating stakeholders should be different facility by facility in accordance with the purpose and expecting roles of stakeholder meetings.

We think a diversity of stakeholders and its selection are important to realize the broad-ranging discussion and dialogue. If the stakeholder meeting like CLI and SSG will be introduced into Japan, it is deemed desirable to flexibly design the meeting and the membership reflecting local characteristics, like CLIS de Fessenheim and Monitoring and Evaluation Conference on Environmental Radiation in Aomori and Niigata prefectures.

The study on the stakeholder meetings in other counties such as North European countries would be interesting.

Note

For this survey, we contacted the secretariat of the Community Meeting on 28 September and 5 October 2007, by e-mails. We interviewed the president of the Community Meeting on 29 October 2007 in Yokohama, and on 8 August 2008 in Tokyo. We interviewed the secretariat of CLI AREVA NC La Hague in Cherbourg on 21 February, 2008. We participate sat in on a regular conference on 17 December 2009 in order to grasp the situation. We interviewed the secretariat of CLIS de Fessenheim in Colmar on 15 January, 2009. We interviewed 2 members of WCSSG in Cleator near Sellafield reprocessing plant on 2 March 2010. We are thankful for the help of all concerned.

Information technologies in radiation protection legal regulative in Serbia

Spasic-Jokic, Vesna[1]; Jokic, Milica[2]
[1] Faculty of Technical Sciences, University of Novi Sad, SERBIA
[2] Faculty of Law, SERBIA

Abstract
Books, documents, lows and other regulatory papers were accessible only for the limited number of users. Development of information technologies enable easy and quick access to radiation protection regulatory as well as to the other documents not only to the experts but also to the public. In this paper we gave example of information technology application in radiation protection regulative of Serbia

Introduction
Books, reports, texts of laws and accompanying documents were available only for restricted number of experts and governmental clerks. Development of information technologies (IT) enabled digitalization of libraries and archives and made them also available to the lawyers, journalists and to general public. From mid 1990 legislature started with internet communication in aim to enable free or semi-free access to their activities and documents not only for employees but also to the public. Internet is only a part in evolution of so called E-government and two-way communication between governmental structures and citizens.

Investigations in our country have shown that citizens were generally satisfied with electronic services which also have included possibility of getting information about document drafts, radiological situation in the country as well as about some actions with direct impact of public security. Investigations also have shown that there was some doubt about security information. In building of Information system we started from EU good practice in European Parliament, US Congress and House of Commons in UK. We gave a copies of web sites relevant for the radiation protection.(EC,2005)

Material and methods

Legislative bodies and Web
At the very beginning legislative webs have been created to support the three main goals: Activities and distribution of the documents; Communication with citizens and Transparency. It was the big step forward as at the time of Chernobyl accident there was a strict state embargo on all information. From the internal point of view webs allow to the staff and members of legislative bodies to improve organization and

responsibility hierarchy and also to be inform in time about all meetings, agendas, documentations and monitoring data. In the other side citizens can be better informed about all relevant legislation, final documents, drafts and changes, monitoring data which could be freely shared but also they can find brief description about the legislative procedures, voting and possibility to ask a questions. Some political parties have their own sites dedicated to radiation protection but they are not the part of official information system and their data are not valid for taking an actions and preventive measures. Pressures of press, various lobbyists as well as general public have a great influence on amount of data and information available to the public which enable continuous transparency in legislative bodies work.

Citizens and E-government

Generally, about 62 % of citizens which have internet assess used web site of National assembly to find published or drafted laws and rules of procedures. Less than 20 % know that there is a possibility to find monitoring data at the site of the Ministry of the Environment. Unfortunately, only about 25 % citizens of Serbia have internet access. Although the internet became the central part of civilize society it is obvious that the further development is necessary. This development must offer interactive approach and enable to the public to have more active role in legislative process. In radiation protection it is not so easy as the citizens, journalist and other interested groups must have at least basic knowledge in radiation protection quantities and units and dose limits. Such educative materials are not available at our official sites linked to the governmental institutions. Citizens expect not only to have information about radiation protection legislative but also to expose their own opinion and to debate. Truly the possibility of interactive approach is very poor at governmental official sites. From that point of view it is necessary to look critically on interactivity and some proposals and remarks given during the public discussion of vital radiation protection law: Law of radiation protection and nuclear security.

New standards for information systems in radiation protection

Information and documents available at official sites have to fulfilled some basic standards: accuracy, timeliness, completeness, clarity and content and links. Design of information system must fulfilled five basic criteria but also have to estimate the basic requirements for links between E-government and citizens and to identify the best possible practice.

Interactive two-way approach has a challenge in the nature of inputs and the fate of all remarks and numerous questions of citizens. Some questions are easy to be answered but some of them are complex and take a lot of time and engagement of experts. Additional complication is terminology as laws and accompanying documents use special juristic and professional terminology hardly understandable to average citizen. Users of information system are very differ in knowledge, juristic education and in capability to understand legal processes., therefore Information system have to be built in multiple layers "in depth" suitable for all categories of users: members of legislative bodies, students, professors, various lobbyists, pres, Citizens Associations, foreign governments and their accredited representatives as well as average citizens. This system is not built jet in our country.

Sites are multilingual, in Serbian (Latin and Cyrillic) and in English.

Objectives of designed information system in radiation protection legislation based upon (Griffith, 2006) can be summarized in eight points:

1. Development of coordinated system which fulfill all requirements of legislator and accompanying agencies and bodies.
2. Assurance of free or semi-free access to information and texts obtained from authorized sources,
3. Assurance of integrated system for location of the most important data in legislative
4. Assurance of coordinated interactive system which will avoid duplicating
5. Assurance of tracking the new technologies and continuous site innovation
6. Assurance of reliable and safety technical environment for interactive system
7. Establishment of systems and procedures for long-life stability and reliability of information system in legislation
8. Assurance of appropriate support of new and temporary users as well as experts

Results

Tracking system recommended by legislator is tracking from the initiative (in Ministry) to adoption in National Assembly. Tracking system gives also the short or complete text of legal document. The tracking is realized through: internal portal for lawyers, constitutional court site, competent ministries, National Assembly of Republic of Serbia official site and VINCA Institute of Nuclear Sciences site.

Internal portal for lawyers is dedicated portal for professionals which offers information about: primary and secondary juristic sources (legislative, court decisions, journals, data base, libraries and browsers etc), relevant institutions (faculties of law, NGOs, institutes, lawyers bars and chambers, courts, international institutions and individuals. The most important portal is *find a law* www.pronadjipravo.com.

Fig. 1. Home page of Portal for lawyers (www.pronadjipravo.com).

Constitutional court side offers information related to competence of this court and gives short educative texts about processing cases at this court. www.ustavni.sud.rs

Fig. 2. Home page of Constitutional court (www.ustavni.sud.rs).

Agency for Radiation Protection and Nuclear Security is in the process of establishing. All activities related to radiation protection and nuclear security regulation are still in competence of the Ministry of Science and Technological Development. This Ministry was a proponent of all laws and legal documents dedicated to radiation protection.

Fig. 3. Home page of Ministry of Science and Technological development (www.mntr.gov.rs).

National Assembly of Republic of Serbia is the prime legislative body which adopts all laws and legal documents. Assembly site gives a numerous information and data about assembly activities including complete text of laws in procedures and adopted laws, The disadvantage of this site is extremely poor and non-updated interactivity. www.parlament.rs

Fig. 4. Home page of National assembly (www.parlament.rs).

Carrier of supervisory functions in radiation protection and nuclear security is Ministry of Environment and Spatial Planning. The most important part of this site is link to the System of early warning of radiation accident which gives data about ambient dose equivalent rate at every 30 minutes.

Fig. 5. Home page of Ministry of Environment and Spatial Planning (www.ekoserb.gov.rs).

Significant link bank in chain of radiation protection legislation is the only nuclear institute on our country: VINCA Institute of nuclear sciences. On Vinca site it is possible to find a lot of useful information related to Institute activities. In this very moment when the decommission of one reactor is in progress it is possible to find monitoring data from the Institute territory which are complementary with previous data.

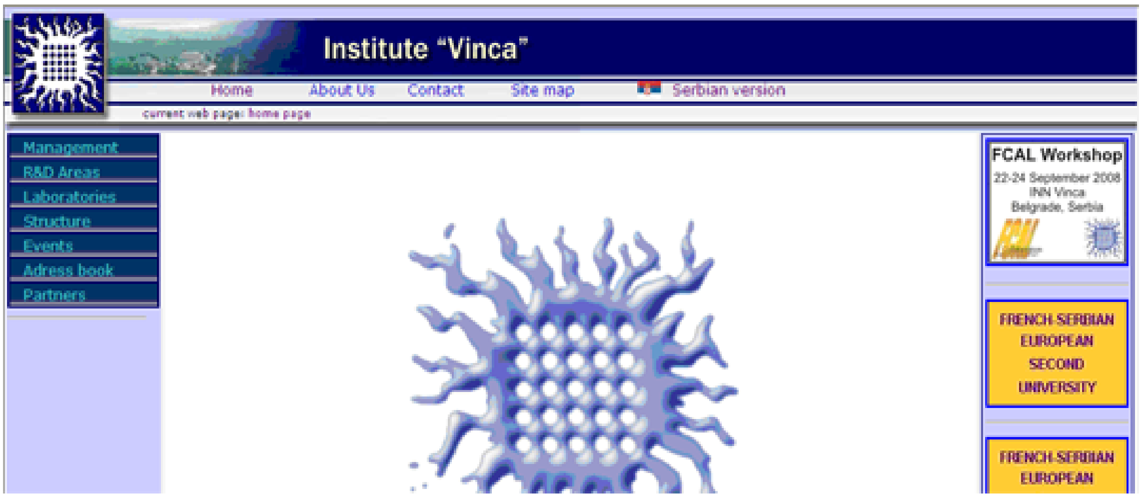

Fig. 6. Home page of VINCA Institute of Nuclear Sciences (www.vinca.rs).

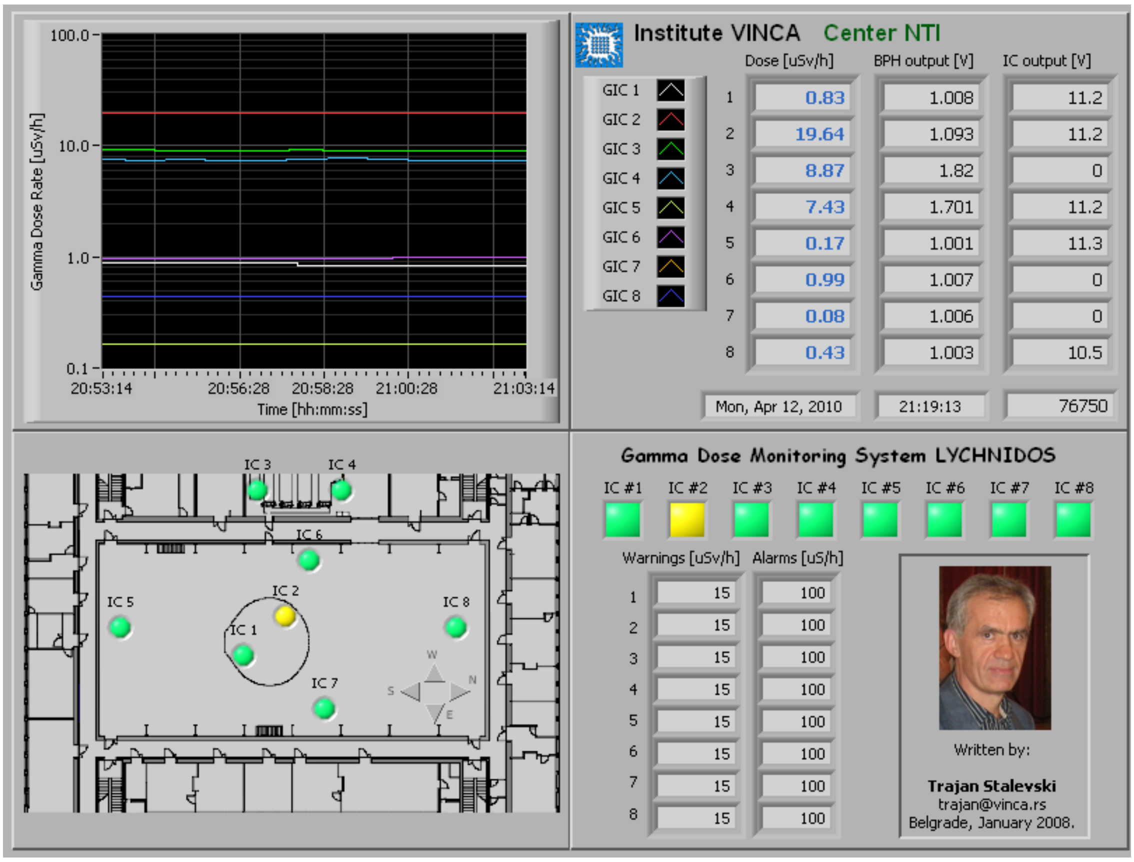

Fig. 7. Home page of VINCA Institute of Nuclear Sciences Reactor monitoring system (www.vinca.rs).

Discussion and conclusion

Source of information in Serbian radiation protection legislation can be summarized in five points: Resumes given at Ministries and National Assembly sites related to short information, explanations and short texts; Proposals of Commissions and Boards; Reports of the Boards; Home Page of National Assembly with new information and education resources. The necessity of information system in legislative actions is obvious and only question is how this system has to designed and implemented. Implementation of good practice means realization of four elements: Resumes of law proposals; Integration of all available sources; Implementation of mechanisms of data management and Continuous testing and improvement of all services. 30 years of the Croatian Radiation Protection Association

Krajcar Bronić, Ines; Miljanić, Saveta; Ranogajec-Komor, Mária
Rudjer Bošković Institute, Zagreb, CROATIA

Abstract
Croatian Radiation Protection Association (CRPA, www.hdzz.hr/) was founded in 1979 and in 1992 became a regular member of the International Radiation Protection Association (IRPA). The 30th anniversary of CRPA is an opportunity to review the work of the society and to point out the main goals for the future. Seven national symposia of CRPA with international participation were organized after 1991. All presentations were published as full papers in printed Proceedings. In 2001 CRPA organized the IRPA Regional Congress in Dubrovnik, Croatia. Members of CRPA take part in organization of international IRPA congresses and in the work of IRPA General Assembly. CRPA has been actively involved in the meetings of the European radiation protection societies since 2004 and organized the 6th meeting in Zagreb in 2009. On the celebration of the 30th birthday of CRPA the first award for best work in the field of radiation protection was given to the young scientist.

Introduction
The Croatian Radiation Protection Association (CRPA) was founded in 1979 in the frame of the Yugoslav Radiation Protection Association. Since 1991 CRPA has been an independent organization and in 1992 became a regular member of the International Radiation Protection Association (IRPA). CRPA adopted the IRPA Code of Ethics. CRPA has today a membership of more than 150 scientists and specialists from Croatia from various areas of radiation science.

CRPA is a public organization with the purpose of promoting and developing scientific, educational and cultural activities in the field of radiation protection and related fields of science. The main activities are organisation of scientific and popular lectures, organisation of national symposia, co-organisation of regional meetings, and participation at international meetings and conferences.

The main goals of all these activities are stimulation and support of basic and applied scientific research; stimulation and support of the application of scientific results in commercial and non-commercial activities; initiatives and execution of improvement of education in schools, colleges and universities in Croatia; popularization of science, its results and their applications; and affirmation of the scientific method and manner of thought.

National symposia

Seven national symposia of the Croatian Radiation Protection Association with international participation were organized after 1991: in 1992, 1994, 1996, 1998, all in Zagreb, in 2003 and 2005 in a small resort nearby, Stubičke Toplice, and in 2008 in the North-Adriatic sea-side resort Opatija. The proceedings of all symposia were printed in Croatian with extended abstracts in English [CRPA, 1992; 1994; 1996; 1998, 2003, 2005, 2008]. The next, 8^{th} Symposium of CRPA with international participation will be held in the Koralj Hotel, Krk, Island Krk, 13 – 15 April 2011.

The topics of interest for the the radiation protection community can be observed through the relative abundance of papers grouped in various research subjects (Fig. 1). All papers presented at the first four symposia (1992 – 1998) are grouped together and then compared with the papers of the 5th, 6th and 7th Symposia.

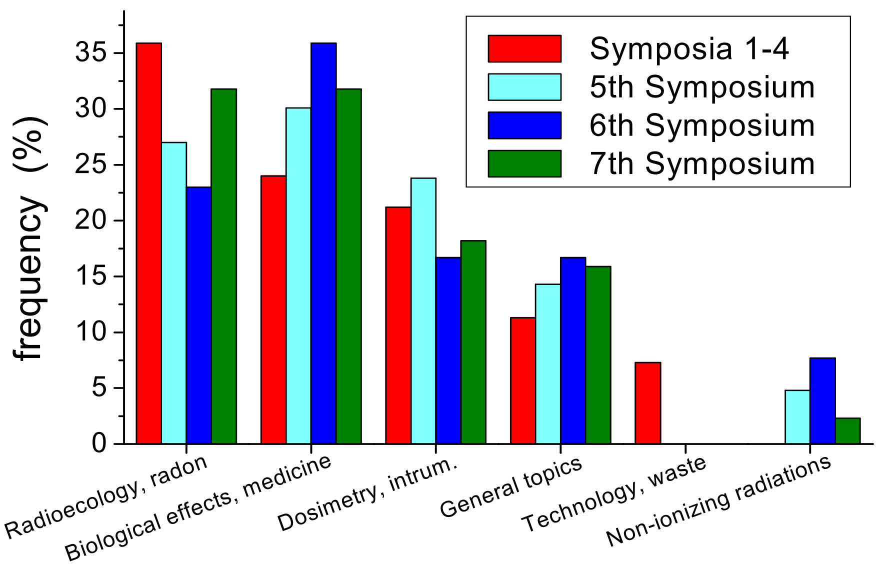

Fig. 1. Relative abundance of topics in CRPA proceedings.

Radioecology (including radon and related topics) and biological effects of radiation and medicine are the most abundant subject areas, each representing about 30% (with slight variations, ±5%) of all contributions. Dosimetry (including radiation physics and chemistry, methods and instrumentation) is represented by about 20% of the contributed papers, and general topics (including legislation, education, public awareness) by 15%.

At the first four symposia problems concerning radioactive waste technology and disposal were represented by 5% of the papers, but no papers on these topics are presented at the last three symposia. Instead, papers dealing with non-ionizing radiations represent about 5% of contributions. Non-ionizing radiations, their effects and medical/health implications became more abundant mostly due to huge expansion of cellular telephony and other applications of non-ionizing radiations (ultra sound, microwave, photo-therapy, etc), as well as due to our ever increasing awareness of their possible damage.

IRPA congresses

Members of CRPA regularly participate at regional, European and world IRPA congresses. Seven regional IRPA congresses for Central and Eastern Europe were held in the period 1992 – 2008 and the average number of Croatian participants (excluding the one in Dubrovnik 2001) is 10, as well as the number of contributed abstracts. The average number of Croatian participants at the four world IRPA congresses since 1996 (IRPA-9 through IRPA-12) and two European IRPA congresses is 15 with 16 presentations on the average.

CRPA organized the IRPA Regional Congress on Radiation Protection in Central Europe with the theme "Radiation Protection and Health" in Dubrovnik, Croatia, in 2001, with 180 presentations and 229 participants from 29 countries [CRPA, 2001]. Full papers were published as proceedings on CD-ROM [CRPA, 2002].

International cooperation

CRPA has been actively involved in the meetings of the European radiation protection societies since 2004 and organized the 6th meeting of this kind in Zagreb, October 26, 2009 with participation of 23 representatives of 13 European radiation protection societies. The topics included reports on current IRPA activities and IRPA-12 Congress (Buenos Aires, Argentina, 2008), status of the Radiation Protection Culture initiative, announcements of several training courses and workshops, current status of organization of 3rd European IRPA Congress and IRPA-13 Congress (Glasgow, 2012), as well as the status of national awards for young scientist and professionals in the field of radiation protection and radiation science.

30th Anniversary of CRPA

The main celebration of the 30th birthday of CRPA was held on October 27, 2010. The program included presentations of activities of the CRPA and a very interesting lecture on the early days of radiation protection in Croatia. All former president of the CRPA were awarded and Prof. dr. Božo Metzger has been elected as the first Honorary member of CRPA. The first award for the best paper of a young scientist published in 2008 – 2009 was officially given to Martina Rožmarić-Mačefat who is going to compete for the first European award for young scientists at the 3rd European IRPA Congress. Exhibition of scientific equipment and publications related to radiation protection was also organized.

Concluding remarks

In future CRPA will continue to organize regular national symposia and encourage its members to participate at IRPA congresses. It will increase the efforts in organization of lectures for both scientific community and general population. It will also keep its presence in various international activities of radiation protection societies with emphasis on improvement of cooperation with the societies in the neighbouring countries.

Acknowledgments

We are grateful to all members of CRPA who actively participate in the activities of the society.

Public acceptance of radiocontamination in food products: what can we learn for a better decision-making?

Turcanu, Catrinel[1]; Perko, Tanja[1,2]; Carlé, Benny[1]; Schröder, Jantine[1]
[1] Belgian Nuclear Research Centre SCK•CEN, BELGIUM
[2] University of Antwerp, Faculty of Political Sciences, BELGIUM

Abstract

This contribution investigates consumer's risk perception and attitude towards food products containing residual radioactivity. The data originate from a large-scale public opinion survey carried out in Belgium in the summer of 2009 on the basis of computer assisted personal interviews. It is assumed that the products under discussion satisfy the legal norms concerning the maximal allowable levels of radioactive substances in food.

Risk perception of residues of radioactivity in food products, consumer's attitude and a number of factors that could influence it are explored in our study: acceptance of food legal norms, attitude towards nuclear energy and psychometric factors such as disaster potential and tampering with nature. The results are interpreted in the context of practical implications for the decision making process in nuclear emergency management.

Introduction

After a nuclear event with subsequent contamination of the environment, one of the key issues to be dealt with is management of contaminated food production systems. The main challenges are mitigating the health effects to the population consuming such products and bringing social reassurance, while limiting economic loss and restoring normal life.

The European norms (also adopted in the Belgian legislation) for marketing food products after a future radiological accident are the Council Food Intervention Levels (CEC, 1989). These are subject to approval or modification by the experts of Article 31 of the EURATOM Treaty in the first 3 months after the accident. In practice, it is likely that the type and scale of the release, as well as various socio-economic factors, will bear a heavy influence on the decisions taken with regards to food safety. While public acceptance of the policy is important for the obvious social and political reasons, consumer's attitude towards potentially affected food products may have important economic consequences. A better insight in consumer's attitude can thus contribute to a better preparedness and a more efficient decision-making.

Residual radioactivity in food is not a matter of daily concern for the consumer. Some lessons can yet be drawn from past experiences with food contaminations of other nature, which show that consumption levels for products affected by a food chain crisis decreased in both claimed and reported consumer behaviour (Verbeke, 2001).

The first aim of this study is to investigate general risk perception of residual radioactivity in food. The second is to explore related consumer's attitude in a post-accidental framework. We thus tackle the following research questions:

- are risk perception or confidence in authorities for managing risks from residues of radioactivity in food different than for harmful substances in food in general?
- what is the consumer's attitude towards radioactive contamination of meat?
- what is the relationship between consumer's attitude and potentially explanatory variables, such as acceptance of food legal norms, attitude towards nuclear energy or psychometric risk characteristics.

Throughout the paper, it is assumed that the food products under discussion satisfy legal norms concerning maximal allowable levels of radioactive substances in food and therefore can be freely marketed.

The interpretation of results aims at highlighting practical implications for nuclear emergency management and for the associated decision-making process.

Material and methods

Starting from 2002, the Belgian Nuclear Research Centre SCK·CEN conducts periodically large-scale public opinion surveys among a representative sample of the Belgian population (Carlé and Hardeman, 2003; Van Aeken et al., 2007; Perko et al., 2010). Alongside with recurrent issues such as perception of various risks, confidence in risk regulators or the use of nuclear energy, the surveys include detailed research sections on topics such as emergency planning, food safety or communication.

The data in this study originate from the SCK•CEN survey carried out in 2009.

1. Background Variables
2. Risk perception and confidence in authorities for 17 risk items
3. Attitude towards:
    - 3.1. Science and technology
    - 3.2. Stakeholders engagement in decision process related to industrial installations with risks
    - 3.3 Nuclear energy
4. Acceptance of legal norms for food products
5. Use of different information media
6. Evaluation of different actors in the nuclear domain
    - 6.1. Knowledge, competence and confidence in various actors
    - 6.2. Confidence in authorities for management of nuclear installations
    - 6.3. Confidence in authorities for radioactive waste management
7. Risk perception of an accident in a nuclear installation
8. Safety behaviour and anomy
9. Knowledge about the nuclear domain
    - 9.1 Protective measures in nuclear emergencies
    - 9.2 General knowledge about nuclear technology and nuclear energy
    - 9.3 Experiences with the 'nuclear'

Newsflash: TV-report about topics related to preparedness for nuclear emergencies

10. Reception & acceptance of messages communicated in the TV-report
11. Reception & acceptance of the iodine predistribution / information campaign
12. Reception & acceptance of messages communicated by authorities during the Fleurus event in 2008
13. Consumer's attitude towards food with radioactive contamination

Fig. 1. Main topics of the SCK•CEN risk barometer survey in 2009.

The content of the entire survey is summarised in Fig.1, but more details can be found in Perko et al. (2010). In this paper we resume to presenting results relevant for consumers' risk perception and attitude towards food with radioactive contamination.

Sampling procedure

The field work in the SCK•CEN 2009 survey was performed by a market research bureau using CAPI - computer assisted personal interviews. These interviews were carried out at the home of the respondent, the answers being directly recoded and stored on a portable computer's hard disk. The bulk data of the 2009 survey consisted of 1031 interviews in a chosen language (French or Dutch). This sample is representative for the Belgian adult population with respect to province, region, level of urbanization, gender, age and professionally active status. Stratified sampling was applied by i) cross-tabulating the 11 Belgian provinces with four levels of urbanisation; ii) drawing a selected sample of communities from each resulting cell; and iii) random selection of dwellings in the 108 communities. Interviews were organised such that predefined quota were respected for gender, age (divided in three categories), professionally active status and social class.

In addition, the 2009 edition included 104 interviews organized in the Fleurus area (commune in Wallonia, the French speaking part of Belgium), where the authorities advised against eating fresh vegetables and fruit from the gardens after the iodine release event in August 2008. Results for this specific population group will be compared -where appropriate- with those obtained for the French-speaking part of the Belgian population and the region of Wallonia, respectively.

Scaling

Wherever latent concepts were measured by more than one item, in order to reduce measurement errors and/or to capture multiple aspects of that concept, exploratory factor analysis using principal axis factoring was performed to examine each of the scales. In addition, the reliability of the scales was assessed with Cronbach's alpha reliability coefficient. The high reliability estimates (> 0.7) and factor loadings (> 0.5) obtained for each of these scales suggest high construct validity. The content of the constructed scales will be discussed in later subsections.

Risk perception and confidence in authorities

Perception of risk from "*residues of radioactivity in food"* and confidence in authorities for managing this risk were measured by direct questions, alongside with other risk topics: "*How do you evaluate the risks for an ordinary citizen of Belgium for …"* and "*Please state how much confidence you have in the authorities for the actions they undertake to protect the population for …*". In the results section these shall be presented and discussed in comparison with risks from harmful substances in food in general.

Acceptance of food legal norms

The term "food legal norms" was used with the meaning of maximal amounts of toxic substances allowed in that food products. This was briefly explained by the interviewer through a short introductory text: "*The government plays an active role by limiting the* *quantity of toxic substances a particular foodstuff may contain. These upper limits are laid down by the government as legal norms. Such a norm may tell us for instance how much dioxin may chicken meat contain or how much preservatives may be present in cookies*".

Based on previous research (Van Aeken et al., 2006), a set of six items related to legal norms was used, reflecting the content, the enforcement and the legitimacy of the norms. These items were formulated as statements with respect to which the respondents expressed their level of agreement on a 5-point Likert scale, ranging from 1="strongly disagree" to 5="strongly agree". Kaiser-Meyer-Olkin measure of sample adequacy (0.81) and Bartlett's test of sphericity (χ^2=2585, df = 15, Sig.<0.001) suggest that conducting a factor analysis on these items is appropriate (see results in Table 1). Two norm items were inverted to enable the calculation of the reliability coefficient. Factor analysis revealed one factor, all items having loadings larger than the cut-off value 0.5.

Table 1. Factor loadings and scale reliability for the acceptance of food legal norms.

Acceptance of food legal norms (N=935)	Factor loading Principal axis factoring Rotation: Oblimin	Reliability Cronbach's alpha
Legal norms for food products offer sufficient protection to all citizens, including children and the elderly.	.818	
A food product that complies with the legal norms can be safely consumed.	.772	
Legal norms for food products are the result of sound reasoning by the government.	.745	0.85
There is sufficient control on food products.	.728	
(inv) The legal norms are not strict enough.	.575	
(inv) The government is inadequately organized to secure food safety	.530	

Attitude towards nuclear energy

Attitude towards nuclear energy was first assessed by three general statements to which the respondents had to state their agreement degree on a 5-point Likert scale (from 1="strongly disagree" to 5="strongly agree").

Table 2. Factor loadings and scale reliability for the attitude towards nuclear energy.

Attitude towards nuclear energy (N=892)	Factor loading Principal axis factoring Rotation: Oblimin	Reliability Cronbach's alpha
(inv) Opinion about nuclear energy (INVERTED scale)	.818	
Benefits of nuclear energy outweigh disadvantages	.772	0.84
Keeping NPP's open necessary for a secure energy supply	.745	
(inv) Reduction of NPP's is good cause	.728	

These items assessed the extent to which the respondents agreed that benefits/advantages of nuclear energy outweigh the disadvantages, that keeping NPP's open secures energy supply and that reduction of the number of NPP's in the E.U. is a good cause (first three items in Table 2). Subsequently, opinion about nuclear energy was measured through a direct question whether the respondent was in favour of nuclear energy or not (from "1=very much in favour" to 5="very much opposed").

Before conducting a factor analysis (see results in Table 2), two items were inverted such that high scores indicate always a strong support for nuclear energy. A scale was formed with these items using the resulting factor.

Consumer's attitude towards meat products with radioactive contamination below legal norms, after a nuclear accident

In 2006 an extensive study (Van Aeken et al, 2007; Turcanu et al., 2007; Turcanu et al., 2008) was dedicated to the management of contaminated milk. In the 2009 edition of the SCK•CEN barometer, the focus was on meat products. These generally represent an important part of the daily diet in Belgium: almost half (47%) of the respondents consider meat as important or very important daily food product, whereas 29% think it is moderately important.

In order to assess consumer's attitude towards meat products with residual radioactivity, a short introductory text was used to set the framework: "*Suppose that after a nuclear accident there is a contamination of meat with radioactive substances, and that the authorities ensure that radioactivity level is below the legal norms*". Consumer's attitude was then measured by the level of agreement with the statement: "*I would buy meat and consume it as usual in the first few months after the accident*", on a 5-point Likert scale ranging from 1="strongly disagree" to 5="strongly agree".

Characteristics of risk perception of meat products with radioactive contamination below legal norms, after a nuclear accident

Ten items selected and adapted from the extended psychometric model (Sjöberg, 2000) were used to asses the latent constructs behind risk perception of radioactive contamination in meat products after an accident in a nuclear installation. Respondents were asked to express their level of agreement with these statements, introduced with the following text "*Even for a contamination below legal norms, the presence of radioactivity in meat after an accident in a nuclear power plant…*"

Measurements were done on a 5-point scale ranging from 1="strongly disagree" to 5="strongly agree", high scores indicating strong adherence to a psychometric risk characteristic. Three characteristics of risk were measured: "Disaster potential" (four items), "Tampering with nature" (three items) and "New and unknown risk" (three items).

Kaiser-Meyer-Olkin measure of sample adequacy (0.92) and Bartlett's test of sphericity (χ^2=7298, df=45, Sig.<0.001) indicate the suitability of conducting a factor analysis. Three factors were extracted (see Table 3), based on the theory (Sjöberg, 2000), scree plots analysis, explained variance in the data and eigenvalues larger than or close to 1.

Table 3. Factor loadings and scale reliability for psychometric characteristics of risk perception of meat products with radioactive contamination below legal norms, after a nuclear accident.

Psychometric risk characteristic	Factor loading Principal axis factoring Rotation: Varimax	Reliability Cronbach's alpha
Disaster potential (N=917)		
Has large consequences for consumers	.782	
Will cause cancer for consumers	.802	0.95
Will harm children and future generations	.804	
Will have effects that cannot be reversed for consumers	.775	
Tampering with nature (N=942)		
Is the result of an activity which is contrary to nature	.738	
Is the result of humans trying to influence the basic processes and structures of nature	.874	0.89
Is a warning that much worse things might happen	.572	
New and unknown (N=944)		
Has effects that are hard to understand for consumers	.667	0.81
Has effects that are not sufficiently known by science	.652	
Would be something new and unknown to consumers	.690	

Results

Risk perception and confidence in authorities for residues of radioactivity in food

Outside of the context of a nuclear accident, "*residues of radioactivity in food*" are generally perceived as a low to moderate risk for an ordinary citizen of Belgium: 47% of the respondents perceive it as a low or very low risk and 27% as a moderate risk.

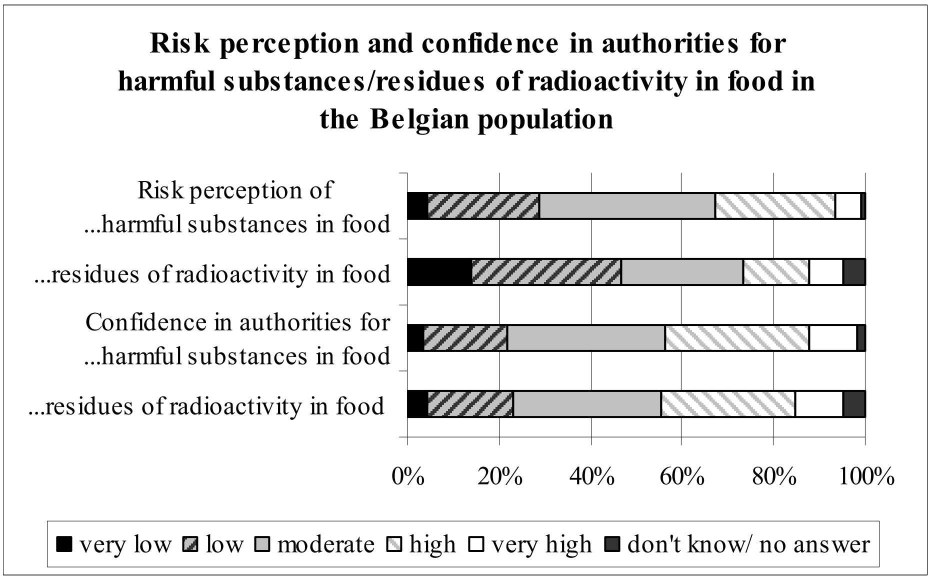

Fig. 2. Risk perception and confidence in authorities for harmful substances/ residues of radioactivity in food in the Belgian population.

Compared to this, perception of harmful substances in food (in general) is slightly higher (see Fig. 2), which suggests that there is no a priori fear of radioactivity in food.

Concerning confidence in authorities for managing risks from residues of radioactivity in food, 40% of the respondents expressed high or very high confidence, while 32% a moderate level of confidence. The difference compared to “harmful substances in food” is considerably smaller than for risk perception (see also Fig. 2).

The same analysis for the population sampled in the area of Fleurus (Fig. 3) reveals that risk perception is more clearly outspoken for “radioactivity in food” than for “harmful substances in food” in general: the percentage of people with a moderate risk perception is lower for risks from residual radioactivity in food. However no clear tendency towards a high or a low risk perception is observed.

Confidence in authorities is again similar for the two types of food risks.

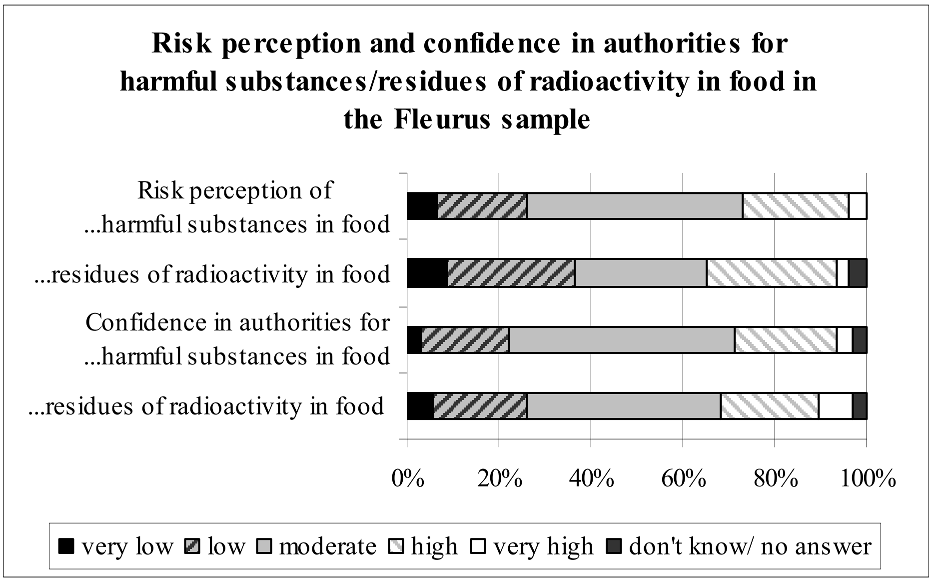

Fig. 3. Risk perception and confidence in authorities for harmful substances/ residues of radioactivity in food in the Fleurus area.

Looking at residues of radioactivity in food, we notice that only 36% of the respondents from the Fleurus sample have low or very low risk perception compared to 43.8% in the French speaking part of the population and 51% in Wallonia; 30% of the respondents from the Fleurus sample have high or very high risk perception against only 9.1% in the French speaking population and 18% in Wallonia. With respect to the confidence in authorities, this accounts for 26% of respondents with low or very low confidence and 29% with high or very high confidence in authorities in the Fleurus area, which is quite in line with results from the French speaking population and Wallonia region: 29% with low or very low confidence among the French speaking and 31% in Wallonia, against and 30% with high or very high confidence in authorities among the French speaking and 33% in Wallonia.

Consumer's attitude towards meat with radioactive contamination

Almost half of the respondents (48%) stated their disagreement with buying and consuming meat as usual, even if authorities ensure that contamination is below legal norms (see Fig. 4). About 17% of the respondents do not have a definite opinion, while 30% agree or strongly agree with buying and consuming such meat products as usual.

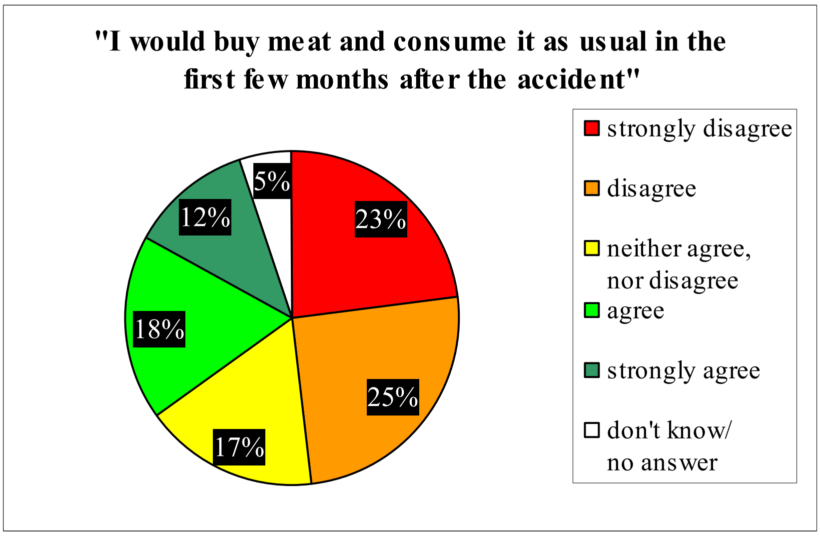

Fig. 4. Consumer's attitude towards meat with radioactive contamination below legal norms.

The study of potential associations between consumer's attitude and socio-demographic characteristics revealed significant associations with language (χ^2=50.10, p<0.001), education level (χ^2=51.24, p<0.001), region (χ^2=56.45, p<0.001), habitat (χ^2=47.96, p=0.001) and importance of meat in the daily diet (χ^2=137.6, p=0.001).We note that no significant associations with gender, social class or age were detected.

Respondents with primary education or with university degree strongly disagree with buying and consuming meat products with radioactive contamination below legal norms more often than people with other education levels: 40.5% with university education and 31.5% with primary education strongly disagree with buying and consuming meat with radioactive contamination, while for other education levels this is only between 20 and 25%. However, strong agreement decreases with the education level (from 20.2% for primary school to 4.1% among the holders of a university diploma) and increases when moving from urban to rural environment. In large cities only 18.1% respondents agree or strongly agree with consuming such meat products, while in other habitats this accounts to more than 35%. Brussels stands out as expressing the strongest disagreement (33.7% strongly disagree) with buying and consuming meat products as usual, followed by Wallonia (27.5%) and Flanders (21%).

Strong agreement with buying and consuming meat products as usual when contamination is below legal norms also grows with the importance of meat in the daily diet, e.g. 30.8% of those for whom meat is a very important food product strongly agree with buying and consuming meat as usual, while this is valid for only 5.2% of the respondents who state that meat is moderately important in the daily diet.

Potential predictors for consumer's attitude towards meat with radioactive contamination

Ordinal logistic regression was employed to study potential predictors for the consumer's attitude using the R package (library Design). The regression coefficients and the results of the Wald test for significance of the coefficients are presented in Table 4.

Table 4. Results of ordinal logistic regression for consumer's attitude (N=722)

Cut-off point/ Independent variable	Coefficient	Std. error	Wald Z stat.	P
y>=disagree	0.14	0.24		
y>=neither agree, nor disagree	-1.28	0.24		
y>=agree	-2.18	0.25		
y>=strongly agree	-3.62	0.27		
Importance of meat in daily diet	0.376	0.068	5.51	<0.001
Acceptance of food legal norms	0.289	0.083	3.48	<0.001
Attitude towards nuclear energy	0.202	0.084	2.41	0.016
Disaster potential	-0.756	0.082	-9.18	<0.001
Tampering with nature	-0.549	0.076	-7.19	<0.001
New	-0.329	0.085	-3.88	<0.001
Likelihood ratio χ^2=283; df=6; Sig.<0.001(statistically significant model); c-statistic C=0.74; Pseudo-R^2 = 0.35 (moderate effect size).				

Psychometric risk characteristics are negatively associated with the tendency to accept food products with contamination below legal norms, whereas e.g., importance of meat in the daily diet is positively associated with the latter. For every unit increase in the importance of meat in daily diet, we expect a 0.4 increase in the expected log odds to move to a higher category of consumer's attitude (more acceptance), i.e. an increase in odds by a factor exp(0.376)= 1.45[1].

Discussion

The study of general risk perception of residual radioactivity in food shows that this risk is not a matter of special concern in the Belgian population. In the Fleurus sample, perception of this risk is slightly higher than overall in the French speaking population or in Wallonia. However, this cannot be pinpointed as a direct effect of the radioactive iodine release incident in 2008, since no measurements of risk perception were performed prior to the incident. In what concerns confidence in authorities, similar results were obtained for risks from residues of radioactivity in food and harmful substances in food, both for the Belgian population and for the Fleurus sample.

In a post-accidental situation, even if food products complying with legal norms may be deemed as fit for consumption, this does not necessarily lead to consumer's willingness to buy food products with residual radioactive contamination, which confirms the findings of the 2006 survey (Turcanu et al, 2007). When asked if a food product complying with legal norms can be safely consumed, an overwhelming 68% of the respondents agree or strongly agree with this statement. However, only 30% agree

[1] The log odds scale is given by logit(p)=log(p/(1-p)), where p/(1-p)= odds of an event with probability p

or strongly agree with buying and consuming meat products with radioactive contamination below legal norms after a nuclear accident.

Significant effects on consumer's attitude towards meat products with contamination below legal norms in a post-accidental context were detected for psychometric risk characteristics, importance of meat in daily diet, acceptance of food legal norms and attitude towards nuclear energy. For instance, respondents with higher acceptance of food legal norms or less adherence to the psychometric risk characteristics studied are more likely to agree with consumption of such food products.

Conclusions

A good preparedness is the cornerstone of an efficient response to emergencies, one of the important issues to be dealt with being the management of contaminated food. Our study aimed at gaining a better insight in consumer's attitude towards food products with radioactive contamination. Results show that, although radioactivity in food is generally not perceived as a high risk, a large scale post-accidental contamination would bring about complex policy issues. Effective communication and information of the public in such a circumstance are certainly needed and could help alleviate social concerns.

Unjustified CT examination in young patients: a survey at Oulu University Hospital

Introduction

Shortly after publication of the European Commission's directive 97/43/EURATOM, justification was considered to be the challenge of the decade (1). Ten years later, it has been speculated that the process of justification is sometimes weak or even nonexistent (2).

The radiation doses from computed tomography (CT) examinations are among the highest in diagnostic radiology, yet CT is being increasingly utilized. According to the referral criteria for imaging recommended by the European Commission, imaging methods without ionizing radiation, such as ultrasound (US) and magnetic resonance imaging (MRI), or methods with low-dose radiation should be considered whenever justified (3). Particular attention should be paid to young patients, since the radiation-induced lifetime risk of cancer mortality is higher at younger age until approximately 35 years of age (4).

The basic aim of our study was to determine whether previous CT examinations done at our university hospital on patients under the age of 35 years had been justified, and if not, whether other, more justifiable imaging modalities had been available, or if any modality was needed. Based on the study, a more comprehensive development project related to justification assessment was implemented.

Materials and Methods

Altogether 148,988 examinations were performed in the Department of Diagnostic Radiology of Oulu University Hospital, Oulu, Finland, in 2005. 16,975 of the examinations (11%) were done using CT, and 2,367 (14%) of the CT examinations were done on patients under the age of 35 years. The main groups of examinations were CT of the head, thorax or lungs, lumbar (and sacral) spine, abdomen or upper abdomen, trauma, cervical spine, nasal sinuses and body (thorax and abdomen) (Table 1).

The examinations analysed in this study were CTs of the head (50 patients), lumbar (and sacral) spine (30), abdomen or upper abdomen (30), trauma (30), cervical spine (30) and nasal sinuses (30) (Table 1). The final study thus included 200 examinations. Images falling in these categories were extracted from the electronic patient files of our hospital consecutively from the beginning of the year 2005. CTs of the thorax or lungs and body were excluded from the study because there is no good alternative for these examinations.

Patient files, clinicians' referrals and indications of the examinations were analysed by a specialist in radiology with good experience. Using this information and the referral criteria for imaging recommended by the European Commission (3), it was decided whether the examinations had been justified, and if not, whether some other, more justifiable imaging modalities would have been available. After that, other specialists in radiology went through the information collected and expressed their opinion; if necessary, consensus was used.

Table 1. CT examinations performed on patients under the age of 35 years in 2005 and the number of cases analysed in the study.

CT examinations	Number of CT examinations n	CT examinations analysed n
Head	1,063	50
Thorax or lungs	241	
Lumbar and sacral spine	130	30
Abdomen or upper abdomen	123	30
Trauma	117	30
Cervical spine	110	30
Nasal sinuses	100	30
Body	80	
Other	403	
Total	**2,367**	**200**

Results

About 30 per cent of all the 200 examinations evaluated were non-justified (Table 2). Twenty-three of the 30 CT examinations of the lumbar spine (77%) were considered not justified. Twenty cases could have been replaced by MRI, and three patients would not have needed any radiological examination (Table 2). Symptoms of disk syndrome, suspicion of spinal stenosis and control of spinal lymphoma in young patients may indicate MRI. Trauma and control of fixation indicate CT.

Eighteen of the 50 CT examinations of the head (36%) were not justified. All of them could have been replaced by MRI. MRI should have been performed in elective cases. CT is indicated in trauma or some other acute cases, such as suspicion of intracranial bleeding or acute stroke.

CT was not justified in 11 of the 30 CT examinations of the abdomen or upper abdomen (37%). Five of the cases could have been replaced by MRI, four by US and one by fluoroscopy. One patient would not have needed any radiological examination. Two patients had unspecific hepatic lesions at US, which should have indicated MRI instead of CT. Other patients in this group were so variable that no classification could be done; the analysis had to be done on a case-by-case basis.

Six of the 30 CT examinations of the nasal sinuses (20%) were not justified. Five of them could have been replaced by MRI, while one would not have needed any other examination but CT of the head. CT was considered to be justified especially if operation of the sinuses was being planned, since there is a need for accurate delineation of the bony structures for functional endoscopic sinus surgery (FESS). However, five of the unjustified cases also had rhinitis or sinusitis, but there was no information about operation plans in the referral.

Only one of the 30 CT examinations of the cervical spine was not justified. The patient would not have needed any CT examination of the cervical spine in addition to one of the lumbar spine. Other cases were traumas and a control of fixation, which indicated CT. All the 30 CT examinations of trauma were justified because the traumas were high-energy ones.

In our study 21 out of the 200 patients were children (15 or under 15 years old) (11%). There were three unjustified cases in this group (3/21, 14%).

Table 2. The number of unjustified CT examinations out of total number of cases analysed and the possibility of other modalities to replace CT.

CT examination	Unjustified / All n (%)	Possibility of other modalities to replace CT			
		MRI n	US n	Fluoroscopy n	No examination needed n
Lumbar spine	23 / 30 (77%)	20			3
Abdomen	11 / 30 (37%)	5	4	1	1
Head	18 / 50 (36%)	18			
Nasal sinuses	6 / 30 (20%)	5			1
Cervical spine	1 / 30				1
Trauma	0 / 30				
Total	**59 / 200 (30%)**	**48**	**4**	**1**	**6**

New interventions and follow-up

As a consequence of our study, we wanted to change our practice and introduced various interventions and organized follow-up of the project. The interventions were mostly introduced in 2006-2007.

We provided education for the staff of the Department of Radiology, other personnel working with ionizing radiation in our area and the referring practitioners in our hospital. The education consisted of the risks and doses of radiation, indications of different examinations, the process of justification and legislation on radiation protection. The radiology staff in other hospitals in Northern Finland could also be reached through videoconferences. We also provided info cards containing information on radiation and justification for the referring practitioners in the Oulu area and for the people working with radiation in our hospital, and the cards will be handed out to medical students every year.

The referral criteria for imaging recommended by the European Commission were distributed into the different areas of the Department of Radiology. We also made some new recommendations for the use of CT for the referring practitioners and the radiologists at our hospital. Their content is roughly the following: 1. MRI is the primary examination of the head. CT examination is only indicated in acute cases. 2. MRI is usually the primary examination of the lumbar spine in young patients. 3. Clinicians are recommended to consult a radiologist before sending a request form for abdominal CT in the case of a young patient.

Our study revealed that most of the unjustified cases could have been replaced by MRI. Shortage of MRI capacity may partly have contributed to the poor results of justification. We addressed this by purchasing a new MR system. We have also reported about the project at conferences and in medical journals both in Finland and abroad (5).

We have followed up justification of the CT of the lumbar spine in our department. We wanted to monitor that area in particular, as it showed the poorest justification in our study. The total number of CTs of the lumbar spine has decreased and the justification has improved in patients under the age of 35 years during the years 2007-2009 when compared to the levels in 2005 (Table 3). We have also followed up the ratio of examinations with and without ionizing radiation in our department. Since 2006, the ratio also improved towards examinations without radiation until the year 2008. There was a slight opposite change again in 2009 (Table 4).

Table 3. CT examinations of the lumbar spine performed on patients under the age of 35 years in 2005 and in 2007-2009 and the number of unjustified lumbar CTs out of total number of cases analysed during the same years.

	2005	2007	2008	2009
CT of the lumbar spine (n)	130	37	38	24
Unjustified lumbar CT (n) / All (n) (%)	23/30 (77%)	2/4*/** 11/19 (58%)*/**	2/4*/** 5/20 (25%)*	1/1*/** 2/20 (10%)*

* in different units of the department; time period for the control audit varied between 9-11 months in different years
** less than 20 patients found for the control

Table 4. The ratio of examinations with and without ionizing radiation in the follow-up.

	2005 %	2006 %	2007 %	2008 %	2009
Ratio	77:23	76:24	74:26	74:26	75:25

Discussion

It is estimated that about 50% of the global collective dose of radiation is caused by CT with its relatively high doses (3). There were about 3.9 million medical x-ray examinations performed in Finland in 2005. About 7% were CT scans, and there were 30% more CT examinations in Finland in 2005 compared to 2000 (6). At Oulu

University Hospital, there were 19% more CT examinations in 2005 compared to 2000. It has been assumed that although the risk of radiological examination to a single individual is small, the exposed global population is large and increasing, which may result in significant long-term public health problems (7). It is therefore important to have good indications for CT or to utilize US or MRI or examinations with lower doses whenever possible.

The utilization of radiology is accepted as part of medicine, especially after careful justification. Despite the rules and recommendations defined in the legislation on medical radiation, suspicions of inappropriate use of radiological examinations and less selective use of diagnostic CT have been reported. Some paediatric radiologists have estimated that about one-third of CT examinations are unnecessary (7,8). With the help of the retrospective analysis we wanted to find out whether the number of CT examinations done on young patients could have been reduced with better justification. For the analysis, we chose CT examinations that could be replaced by other investigations, even ones not involving any radiation.

Most of the unjustified examinations, 77%, appeared to fall into the group of lumbar CT. The dose of radiation from lumbar CT is about 300 times the level of thorax PA x-ray. Most of these unjustified cases could have been replaced by MRI. Thirty-seven per cent of the cases in the group of abdominal CT were unjustified. The dose of radiation from abdominal CT examination is about 500 times that of a single thorax PA x-ray (3). Five of the unjustified cases could have been replaced by MRI, four by US and one by fluoroscopy. Thirty-six per cent of the cranial CT studies were deemed unjustified. All these 18 examinations should have been replaced by MRI. The dose of radiation from CT of the head is also about 115 times that of a thorax PA x-ray (3). There were fewer unjustified cases in the group of CT examinations of the nasal sinuses or the cervical spine, and all cases in the trauma group were justified.

To our knowledge, there are only few other studies about the justification of examinations causing radiation. In 2001, Clarke et al. reported about the possibilities of MRI to replace CT examinations. This team had more patients and subgroups than we did, and more than 70% of the CT examinations could have been replaced by MRI (9). In another report concerning CT examinations of the abdomen, pelvis and lumbar spine, the last of these was often recommended to be replaced by MRI (10). One study reports about 60% justification of CT examinations according to the request forms; in particular, US could have been useful as a preceding or alternative investigation (11). According to the Swedish national survey on justification of CT examinations approximately 20% of all examinations were not justified. The degree of justification varied strongly with the organ examined, moderately with prescriber affiliation and weakly with geographical region (12).

In our study, 21 out of the 200 patients were children. There were three unjustified cases in this group (14%). Ionizing radiation always increases the statistical risk of cancer mortality. The risk is higher at younger age because the expected lifetime is longer than at older age. Division of the cells is also fast and the organs are particularly sensitive to radiation at a younger age (4,13). There are only few published audits of justification of radiological examinations in children. The Swedish national survey on justification of CT examinations reported that the degree of justification is lower for younger patients. However, the total number of paediatric examinations was small in that study (12). There is also an audit of CT for the evaluation of mild to moderate paediatric trauma. Paediatric patients had significantly more CT scans than adults (14).

As a consequence of our study, we wanted to change our practice by introducing new interventions. It is known that awareness of radiation is often deficient and that radiation risks are frequently underestimated (15). We provided education and an info card containing information on radiation and justification for the staff of the Department of Radiology, other personnel working with ionizing radiation in our area and the referring practitioners.

The referral criteria for imaging recommended by the European Commission were distributed to different areas of the Department of Radiology. We also made some new recommendations for the use of CT for the referring practitioners and the radiologists at our hospital. Regular use of referral guidelines can also lead to a reduction in the number of request forms and ultimately to a reduction in patient exposure to ionizing radiation (3). Our study revealed that most of the unjustified cases could have been replaced by MRI. Because shortage of MRI capacity may partly have contributed to the poor results, we addressed this by purchasing a new MR system. In order to give other centres an opportunity to make use of our conclusions, we have reported about the project at different conferences and in medical journals.

The follow-up has so far mainly concentrated on the justification of CT of the lumbar spine and the results are striking. In the near future, we plan to follow up indications for CT examinations. We expect that better awareness of justification also in other areas of imaging will be reached by both the personnel working in the area of radiology and the referring practitioners. We also hope that the project will have an impact on other hospitals and health care centres in Northern Finland, other units in Finland, and other countries, too.

In conclusion, justification of CT examinations in young patients seemed to be inadequate. However, justification could be improved by interventions - education, use of referral guidelines and increased MRI capacity. The main goal of the whole project has been radiation protection of the patients, and the results have been promising.

Screening or selective imaging in paediatric dentistry: from panoramic to CBCT

Horner, Keith
School of Dentistry, University of Manchester, UNITED KINGDOM

Abstract
Dental radiography is one of the most frequent forms of medical X-ray imaging. A large proportion of examinations are performed in the paediatric age group, principally for the detection of dental decay (caries) and developmental anomalies. While most dental X-ray examinations have a very low radiation dose, the introduction of Cone Beam CT (CBCT) brings a higher dose range to dental imaging. Clinical screening of children is good practice, but radiographic screening cannot be justified. Referral (selection) criteria for imaging have been developed by various authorities and organisations, but these have a variable basis upon scientific evidence and uncertain acceptance amongst dentists. Provisional evidence-based referral criteria for CBCT are available through the European SEDENTEXCT project. Considerable research is needed to refine the existing referral criteria for dental radiology and to monitor their adoption in primary dental care.

Introduction
In developed countries, it has been estimated that 20% of X-ray examinations are performed by dentists (UNSCEAR, 2000). This figure conceals considerable national variation, ranging from the highest (839 per 1000 population) in Japan to below 100 per 1000 for many countries. In the United Kingdom it was estimated in 2002 that over 9 million intraoral and over 3 million panoramic radiographs were taken annually (Hart and Wall, 2002). Although some dental practice is conducted in hospitals and community (public health service) clinics, most takes place in dental offices. It is notable, therefore, that the usual practice of dental radiography is one of self-referral, in which the dentist decides radiography is necessary, selects a particular type of X-ray examination, performs the justification process and, often, also performs the examination. In most instances, an external influence on prescription of radiographic examinations is financial, through national or private health insurance schemes.

Another important aspect of dental practice is that a large proportion of radiographic examinations are performed on younger age groups (UNSCEAR, 2000), including children, reflecting two clinical needs. First, dental caries (decay) is a particular risk soon after the eruption of teeth, both for the deciduous and permanent dentitions. Secondly, dental development in childhood is frequently complicated by eruption problems (impaction of teeth), abnormal number of teeth (hypodontia or hyperdontia), discrepancy in size between the teeth and the available space in the mouth (crowding or spacing) and aesthetic problems. These developmental disturbances may necessitate orthodontic treatment. The prevalence of these clinical problems is such that "screening" or routine X-ray examinations have been adopted by some dentists.

Traditional dental radiographic techniques are limited in scope, being intraoral, panoramic and cephalometric techniques. Relative to most medical X-ray examinations, each of these is associated with a low radiation dose (European Commission, 2004; Ludlow et al 2008). Recently, however, Cone Beam CT (CBCT) has become available to dentists, at an equipment cost that makes it affordable. CBCT is associated with a higher radiation dose than is seen with traditional radiographic techniques, raising important challenges in justification and optimisation (SEDENTEXCT, 2009).

Radiographic screening in paediatric dentistry

Screening can be defined as "the testing of a symptomless population in order to detect cases of a disease at an early stage" (Bandolier, 2004). The basic principles of screening are:

- The condition is common and disabling, the natural history is known and that there is a recognisable latent or pre-symptomatic phase.
- The screening test is reliable, valid and repeatable, is acceptable and easy to perform, is sensitive and specific and low cost.
- Treatment should be effective and available, and that there is an agreed policy on who to treat.

How do these criteria fit with paediatric dentistry? As detailed above, there are two broad categories of "common or disabling" conditions for which a dentist (or public health dental service) might choose to screen: dental caries and its sequelae and anomalies of growth and development of the dentition requiring orthodontic management

Dental caries is a common disease in some populations, being associated with low socio-economic status, inadequate fluoride exposure, poor oral hygiene, poor diet and numerous other less frequent risk factors (Faculty of General Dental Practitioners UK, 1998; Pendlebury et al, 2004). In low caries risk populations, however, caries has become a rare condition in children. Nonetheless, the natural history of dental caries is well understood and the disease has a long pre-symptomatic phase and therefore might be seen to comply with the first criterion of a screening programme. Similarly, treatments and care pathways for dental caries are readily available and have well established efficacies, whether these relate to remineralisation of early, non-cavitated, lesions or restoration of carious cavities in teeth.

A significant proportion of children in developed countries may seek orthodontic treatment (Pendlebury et al, 2004; Isaacson et al, 2008). Because of this, clinical screening of children at around 8-10 years has become accepted practice. The addition of radiographic examinations to the clinical screening procedure has, however, become common. The aim of the dentist or orthodontist is to ensure the development of a functional and aesthetic dentition. It is important to remember that an impacted or missing tooth does not necessarily prevent this. The subjectivity of dental aesthetics means that some patients may find entirely acceptable anomalies for which others may demand treatment. On the other hand, the natural history of anomalous dental development and the pre-symptomatic phase are compatible with the first screening criterion. Treatments are effective and available and criteria for treatment have been developed based on clinical findings, notably the DAI (Dental Aesthetic Index; Cons et al, 1986) and IOTN (Index of Orthodontic Treatment Need; Brook & Shaw, 1989). Such indices typically identify that up to about half of children are in need of orthodontic treatment (Chestnutt et al, 2006; Manzanera et al, 2010).

From the above, therefore, it can be seen that a reasonable person might argue that radiographic screening of children is justifiable because the conditions and diseases of greatest prevalence in this age group are of significance and amenable to effective treatment. The question that remains relates to the screening methods that are used. In dental practice, the primary method of diagnosis is always clinical, after which special tests can be selected. The most widely used special test in dentistry remains imaging using X-rays.

Diagnostic tests for dental caries

While clinical examination of clean dry teeth, with good lighting, can reveal dental caries lesions, several high quality reviews indicate that posterior bitewing radiographs are an essential adjunct (Hanlon PM, 1985; Kidd & Pitts, 1990; Henderson & Crawford 1995; Weerheijm 1997; Pitts 1996). Bitewing radiographs (Fig. 1) reveal significantly greater proportions of caries lesions than clinical examination alone in both high and moderate caries risk populations (Faculty of General Dental Practitioners UK, 1998; Pendlebury et al, 2004). The diagnostic accuracy of bitewing radiographs for caries diagnosis has been subject to a systematic review by Bader et al (2001). They reported mean sensitivities ranging from 30-66% (depending on lesion size and site) and specificities of 76-95%. For low caries risk populations the evidence for screening using bitewing radiographs is less convincing (Hintze & Wenzel, 1994).

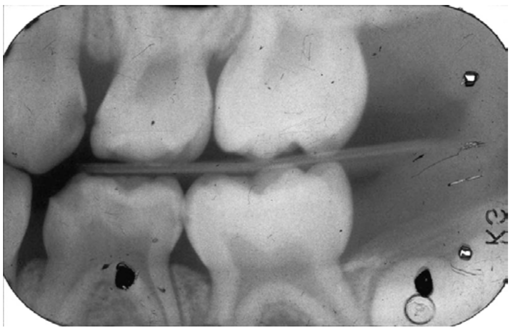

Fig. 1. A bitewing radiograph from a 6 year-old patient in the deciduous dentition.

While there is a well understood body of evidence surrounding the use of bitewing radiographs for dental caries diagnosis, there is less evidence for the role of panoramic radiographs in this respect. The reason for the limited volume of research in this field is, in part, because of the inferior imaging characteristics of panoramic radiography for detection of the small demineralisations of tooth enamel that represent caries lesions. As such, there is not a great pressure to perform research comparing an inferior (panoramic) with a superior (bitewing) technique. Panoramic radiographs have lower resolution and often show overlap between teeth that obscure lesions. Thus, caries diagnosis accuracy is lower than for bitewing radiographs (Scarfe et al, 1994; Rushton & Horner, 1996; Akkaya et al, 2006). Overlying this, image quality is often compromised by poor technique in primary dental care facilities (Rushton et al, 1999). Nonetheless, while emphasising the need for individualised prescription of radiographs, US guidelines still recommend "posterior bitewings with panoramic exam" as appropriate at all paediatric ages subsequent to the eruption of the first permanent molar at around 6 years of age (American Academy on Pediatric Dentistry, 2008).

The advent of CBCT to dentistry raises the potential of its use for the full range of diagnostic applications, including caries diagnosis. The current evidence suggests that limited (small field-of-view) CBCT has a similar diagnostic accuracy to conventional radiography for the detection of caries in posterior teeth *in vitro*, but that the representation of caries depth may be superior (Akdeniz et al, 2006; Haiter-Neto et al 2008; Tsuchida et al 2007; Qu et al, 2010). It should be emphasised, however, that the CBCT systems available to dentists vary enormously in their imaging characteristics, including resolution and field-of-view. In clinical practice, an important additional problem of using CBCT is the presence of artefacts from high atomic number dental restorations that will substantially reduce specificity. Because of these findings, the only currently available evidence-based guidelines on dental CBCT state that "CBCT should not be used as a routine method of caries detection and diagnosis" (SEDENTEXCT, 2009).

Diagnostic tests for anomalies of dental development

The usual radiographic examination performed for the assessment of the developing dentition is the panoramic radiograph (Fig.2). It is an effective method of identifying most dental developmental anomalies, as demonstrated by several surveys of unselected populations (Bergstrom, 1977; Locht, 1980; Ignelzi at al, 1989). The panoramic radiograph may be supplemented by selected intraoral radiographs and, where orthodontic treatment is planned, by a lateral cephalogram. Beyond initial diagnosis, patients who go on to orthodontic treatment may receive repeated X-ray exposures (Hujoel et al, 2006).

The evidence that panoramic radiography can identify dental anomalies should not be seen as a justification for imaging. Many anomalies are of purely documentary interest and the important aspect is whether the radiological findings influence management. Research suggests that in a large proportion of cases the radiographic evidence makes no contribution to diagnostic thinking (Atchinson et al 1991; Han et al 1991). While understandable emphasis has been placed here on the use of screening panoramic radiographs, the role of cephalometric radiographs in management of orthodontic patients has also recently been questioned (Nijkamp et al, 2008). Research performed 20 years ago provided compelling evidence that panoramic radiographic screening for the purpose of assessing malocclusion and timing of treatment was ineffective. In their key paper, Hintze et al (1990) demonstrated that a 2-3 minute clinical examination of an unselected 11-12 year old population, followed by selected panoramic radiographic examination, could identify all children except one in need of immediate orthodontic treatment (a nosological sensitivity of 97%) while excluding 94% of "healthy" children. In a further study in a larger population, Hintze & Wenzel

(1990) reported that screening panoramic radiography resulted in 67% of children being exposed for no benefit.

Fig. 2. A panoramic radiograph from a 9 year-old patient in the mixed (deciduous and permanent) dentition.

It is clear that, for some years, the research evidence has been against the concept of screening panoramic radiography of children for development of the dentition and orthodontic assessment, but in favour of *clinical* screening supplemented by radiographs when indicated. Nonetheless, the practice of radiographic screening and "routine" radiography persists amongst some dentists, particularly in the United States, possibly driven by fears of litigation if "something is missed".

Orthodontics involves the bodily movement of teeth through bone, using appliances that exert a steady force upon the former. This is therefore "three-dimensional" treatment. As such, the arrival of CBCT into dental practice has been greeted enthusiastically by orthodontists as offering an opportunity to have accurate three-dimensional knowledge of tooth position before, during and after orthodontic treatment. For assessment of facial bone shape, position and inter-relationships, there must be a high accuracy of measurements made with CBCT. Several studies have addressed this, reviewed by the SEDENTEXCT Guideline Development Panel (SEDENTEXCT, 2009), usually using direct calliper measurement of dried skulls as a reference standard. Differences between CBCT-derived measurements and the reference standard appear to be small and are unlikely to be clinically significant. Studies are not, however, available for all CBCT machines on the market. In considering the use of CBCT in orthodontics, a clear distinction must be made between localised CBCT (using a restricted field-of-view for a specific purpose) and large volume CBCT in which the facial bones are viewed in their entirety.

For localisation of unerupted teeth, CBCT can be reasonably assumed to have high accuracy. Teeth are relatively large objects, having good contrast with the surrounding bone. It is obvious that a three-dimensional imaging technique with acceptable measurement accuracy and little distortion will identify position of teeth with high diagnostic accuracy. As such, it is not surprising that no formal study has been performed that compares diagnosis of unerupted tooth position using CBCT and conventional radiographs. As conventional ("medical") CT is used in some centres for localisation of unerupted maxillary canine teeth (Alqerban et al, 2009), the dose advantage seen with CBCT means that CBCT may be preferred (SEDENTEXCT, 2009). Fig. 3 shows an image from a localised CBCT examination. A similar argument can be made in favour of CBCT in the assessment of cleft palate, for which conventional CT is the usual examination.

Fig. 3. Images from a localised CBCT examination for the localisation of an unerupted permanent canine tooth in the maxilla (upper jaw).

In contrast to this positive assessment of CBCT, the use of large volume (craniofacial) CBCT as a routine means of assessing growth and development of the dentition and the face in orthodontics causes concern. Compared with a "conventional" examination, using a panoramic and a lateral cephalometric examination, large volume CBCT gives a higher radiation dose, sometimes considerably so. The SEDENTEXCT Guideline document, based on systematic review, described the literature on this subject as "strong on hyperbole and short on evidence of significant clinical impact" (SEDENTEXCT, 2009), with case reports and non-systematic reviews claiming improvements in diagnosis and treatment in orthodontics for CBCT without any objective justification (e.g. Kau et al, 2005; Cattaneo & Melsen, 2008) . The concerns over the spreading use of CBCT as a treatment standard in orthodontics is compounded by anecdotal evidence of large volume CBCT datasets being used solely for the purposes of reformatting into panoramic and cephalometric images, a practice condemned in a recent Health Protection Agency Guideline document in the United Kingdom (Holroyd & Gulson, 2009).

Referral criteria instead of screening

Probably the first set of guidelines dealing with justification of radiology in dentistry, including paediatric uses, were those produced in the United States in 1987 (Dental Radiographic Patient Selection Criteria Panel & Joseph, 1987). These "expert panel" guidelines emphasised that individualized radiographic examinations should be prescribed based upon the patient's signs, symptoms, and history using selection [referral] criteria that increase the likelihood that the patient will benefit from the radiographic examination.

In Europe, most recommendations relating to Justification seem to be general guidance that imaging should be selected on an individual patient basis after a history and examination have been performed, relying on individual dentists' judgements rather than a set of specific referral criteria (European Commission, 2004; Martínez-Beneyto et al, 2007; Peltola et al, 2009). More detailed guidelines have appeared sporadically from European and national dental organisations, notably in the UK (Faculty of General Dental Practitioners UK, 1998) and France (Haute Autorité de Santé, 2006). Apart from national initiatives, guidelines on imaging have also appeared from national (American Academy on Pediatric Dentistry, 2008; Isaacson et al, 2008) and international (Espelid et al, 2003) specialist organisations. On close examination, however, many of these sets of referral criteria are expert panel based, rather than developed using a structured method of literature review. This no doubt explains why different sets of referral criteria may disagree.

In the UK, the Faculty of General Dental Practice (UK) produced evidence-based referral criteria for dental radiography in 1998 (Faculty of General Dental Practitioners UK, 1998.), revised them in 2004 (Pendlebury et al, 2004) and is now working on its 3rd edition. Unlike the US and previous European guidelines, these were very clearly "evidence-based", following a specific methodology which, at best, included systematic review. These guidelines acted as the model for the development of the European Guidelines on Radiation Protection in Dental Radiology (European Commission, 2004). Unfortunately, such is the rapidity with which CBCT has developed and proliferated in dentistry that those guidelines did not address it in any way. This provided the reason for the initiation of the SEDENTEXCT project under the European Atomic Energy Community's Seventh Framework Programme, which has recently developed evidence-based guidelines on CBCT use in dentistry, including referral criteria (SEDENTEXCT, 2009).

Conclusions

The nature of clinical dentistry, based largely in independent practice, increases the chances of inappropriate use of X-ray-based imaging. Conventional radiography has a low dose when appropriately optimised, although the increasingly available CBCT has significantly higher radiation doses. While clinical screening of children for the most common dental disease (caries) and developmental conditions requiring orthodontic intervention is appropriate, radiographic screening of children is unjustifiable on the basis of the research evidence. Instead, referral (selection) criteria have been developed by various organisations to encourage rational prescription of imaging that promotes improved treatment outcomes. Many of these guidelines have a low evidence base, however, and considerable research is needed to refine the existing guidance and to monitor their adoption in primary dental care.

The IAEA OSART programme and radiation safety related findings during recent OSART missions

Lipar, Miroslav
IAEA, AUSTRIA

Abstract

The IAEA operational safety review team OSART for nuclear power plants in Member States have been reformed responding to the changes of the environment of both the industry and Member States needs. The IAEA safety standards for Operations are being applied when conducting the Agency's safety services. Our goal is to ensure that the issues and trends resulting from industry operating experience and the Agency safety services can be effectively communicated to Member States and be used to further reform our safety standards and services. Radiation Protection is an important area of OSART review. The relevant Safety Guide serving as a basis for this area is "Radiation Protection and Radioactive Waste Management in the Operation of Nuclear Power Plants", IAEA Safety Standards Series No. NS-G-2.7. The objective of this presentation is, by referring to the above Safety Guide, to discuss the various findings, recommendations, suggestions and good practices from recent OSART missions in different countries that should to be considered in order to improve Radiation Protection in the Operation of NPPs. The following RP areas are assessed during OSART mission: Organization and function, Radiation work control, Control of occupational exposure, Radiation protection instrumentation, protective clothing and facilities, Radioactive waste management and discharges and Radiation protection support during emergencies.

Radiation safety in new build

Alm-Lytz, Kirsi; Vilkamo, Olli
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract

STUK reviewed the utility Teollisuuden Voima Oyj's (TVO) application for the Construction Licence of the Olkiluoto 3 nuclear power plant unit in 2004-2005. Based on this review STUK prepared its statement on safety together with a safety assessment report of the new plant to the Government. STUK has continued reviewing the detailed design during the construction of the new plant unit. By virtue of the Nuclear Energy Act (990/87) and the Government Decree on the Safety of Nuclear Power Plants (733/2008), Radiation and Nuclear Safety Authority (STUK) issues detailed regulations, YVL Guides, concerning the safety of nuclear power plants. Several YVL Guides deal with radiation safety (site, abatement of releases, worker radiation protection, emergency arrangements, etc). The paper will discuss some radiation safety related requirements in the design of a new Finnish NPP and their implementation in the licensing documentation.

Introduction

The licensing process of a new nuclear power plant in Finland is shown in Figure 1. The project of the fifth Finnish nuclear power reactor was formally started in May 1998 with Environmental Impact Assessment (EIA) process. Then the utility TVO submitted the application for a Decision in Principle in November 2000. The Finnish Government made the decision in January 2002, which Parliament ratified in May 2002.

Late 2003, TVO proposed the plant site to be Olkiluoto and made a contract with a consortium of AREVA (former Framatome ANP) and Siemens AG to build an EPR (European Pressurised Water Reactor). TVO submitted the application for Construction Licence in the beginning of 2004 and the licence was granted by the Government in February 2005. The commercial operation of the new plant unit is expected to take place in 2012 instead of spring 2009 as originally planned. Longer construction schedule is due to the delays in detailed civil work and system design and problems met in the construction and manufacturing of main components. The Operating Licence evaluation process takes approximately one year.

There are also several new nuclear power plant projects ongoing in Finland. Finnish Government and the Parliament are making decisions during 2010 on three applications for a Decision in Principle.

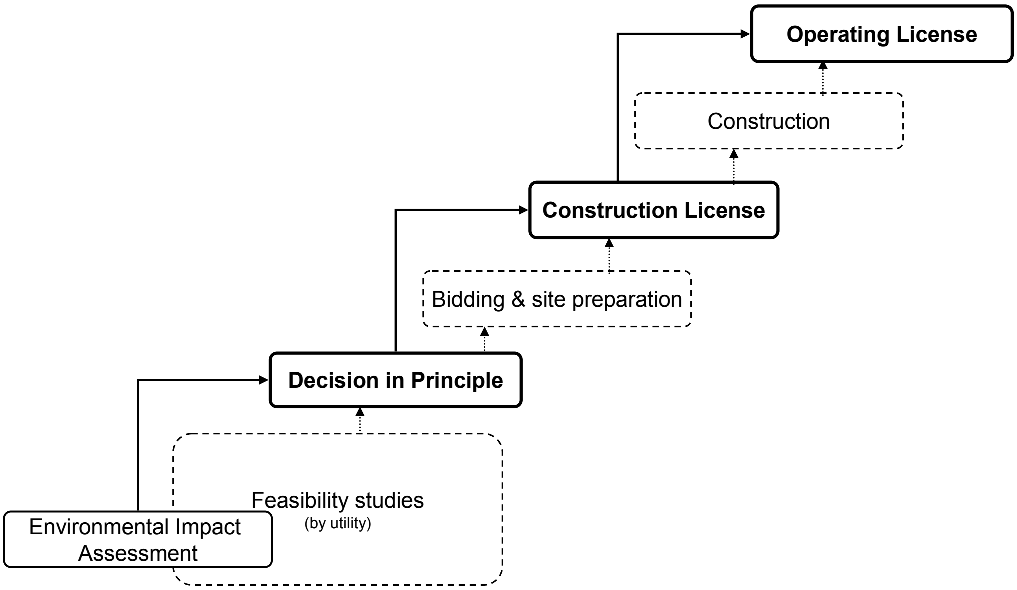

Figure 1. The licensing process of a new nuclear power plant in Finland.

Construction Licence application review at STUK

At the same time as the application for Construction Licence was sent to the Ministry Employment and the Economy (former of Ministry of Trade and Industry), TVO submitted the required licensing documentation to the Radiation and Nuclear Safety Authority (STUK). According to the Finnish Nuclear Energy Decree Section 35, these documents include:

- Preliminary safety analysis report (PSAR)
- Probabilistic risk assessment of the design stage
- Proposal for a Classification Document
- Description of quality management during construction
- Preliminary plans for physical protection, emergency preparedness, and safeguards
- Arrangements for the regulatory control
- Other reports that STUK considers necessary.

Based on the review of these documents, STUK prepared its statement on safety and a safety assessment report, which were submitted to the Ministry in January 2005. STUK's positive statement on safety was a prerequisite for the Government to grant the Construction Licence. In the statement, STUK indicated specific observations on and some further demands for the plant safety.

Radiation safety in YVL Guides

The Guide YVL 7.18, "Radiation safety aspects in the design of NPPs", was updated in 2003 and is now again under revision. This Guide includes radiation safety requirements to be taken into account in the nuclear power plant layout and system design. The Guide covers plant's normal operation, accident situations including severe accidents and aspects of decommissioning. Other relevant radiation guides during the construction licence review were:

- YVL 1.10, "Safety criteria for siting a NPP"
- YVL 7.1, "Limitation of public exposure in the environment of and limitation of radioactive releases from NPPs"
- YVL 7.2, "Assessment of radiation doses to the population in the environment of a NPP"
- YVL 7.3, "Calculation of the dispersion of radioactive releases from a NPP"
- YVL 7.5, "Meteorological measurements at NPPs"
- YVL 7.6, "Monitoring of discharges of radioactive substances from NPPs"
- YVL 7.11, "Radiation monitoring systems and equipment in NPPs".

Further relevant guides for the operating licence review are:

- YVL 7.4, "NPP emergency preparedness"
- YVL 7.7, "Radiation monitoring in the environment of NPPs"
- YVL 7.8, "Environmental radiation safety reporting of NPPs"
- YVL 7.9, "Radiation protection of NPP workers"
- YVL 7.10, "Monitoring of occupational exposure at NPPs".

All of these guides are currently under revision as the whole structure of the STUK's YVL guides will be changed. However, most of these guides were just recently updated, so not major modifications are expected in the revision. The target date for the updated guides is the end of year 2011.

Radiation safety of NPP workers (ALARA)

In the regulatory guide YVL 7.18, a design upper limit for an annual personnel collective dose of 0.5 manSv per 1 GW of net electric power averaged over the plant life is set forth for new reactors. In the European Utility Requirements (EUR) document, the target for annual collective effective dose averaged over the plant life is set as 0.5 manSv per reactor unit.

There are two operating nuclear power plants in Finland; two boiling water reactor (BWR) units at Olkiluoto site and two pressurised water reactor (PWR) units at Loviisa site. They were commissioned between 1977 and 1981. Average personnel collective radiation doses per reactor for existing Finnish NPPs and average values for BWRs and PWRs for the years 1998-2008 are shown in Figure 2. The collective dose at the Olkiluoto NPP has been clearly under the international reference values of the BWR reactors. On the other hand, the comparison of the collective dose at the Loviisa NPP to the PWR reactors does not give such an excellent result. Average collective doses per reactor of the German Konvoi generation NPPs (Emsland 1, Isar 2 and Neckarwestheim 2) and French N4 generation NPPs (Chooz B1 and B2, statistics only from the year 2001) are also shown in Figure 2. The statistics would indicate that the collective dose in the EPR could be low.

The PSAR review of STUK experts on plant radiation sources, shielding, lay-out and radiation protection arrangements, as well as STUK's topical inspection made to the vendor (designer) pointed out some aspects where the applicant and the vendor shall enhance efficient communication between different expert and designer groups. STUK's review on the plant radiation monitoring systems description indicated that the system design covered well the main requirements of YVL 7.11. The detailed design of the systems is now reviewed during the construction phase.

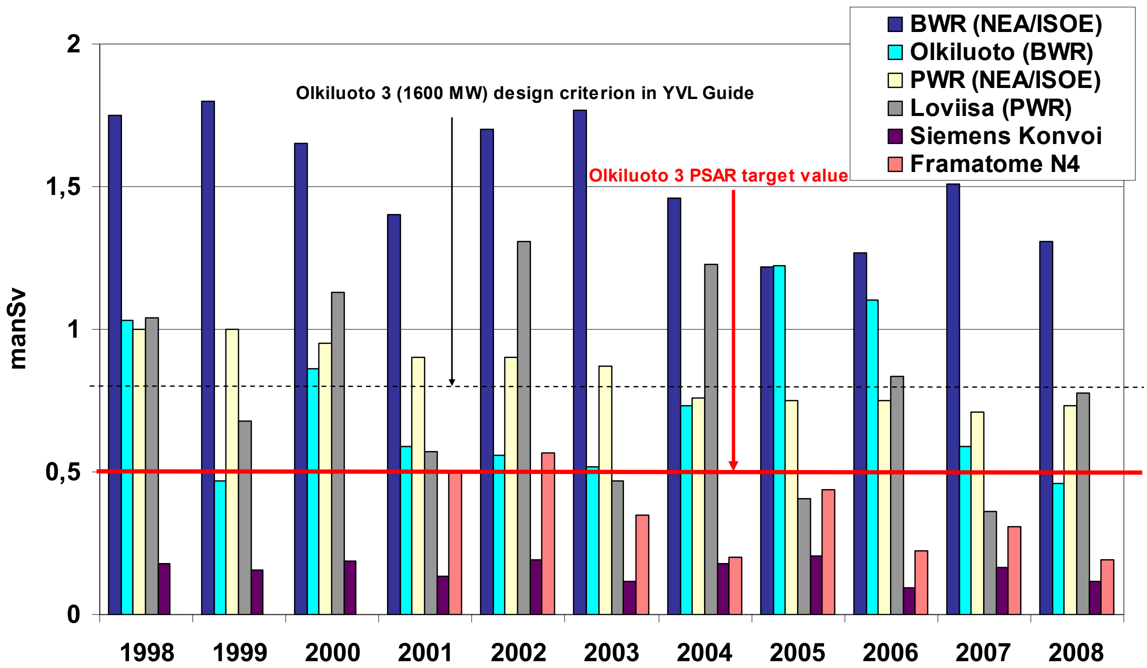

Figure 2. Average personnel collective radiation doses per reactor.

Minimising discharges of radioactive materials during normal operation

The reactor, systems and components containing radioactive substances shall be designed in such a way that releases of radioactive substances and the radiation exposure of the population living in the vicinity of the plant can be kept low. Systems which are capable of cleaning fluids and gases containing radioactive substances shall effectively limit radioactive releases and shall be designed according the principle of Best Available Techniques (BAT). Radioactive releases from a nuclear power plant during normal operation are, to a great extent, determined by leakage from the nuclear reactor fuel rods, reactor coolant and its fission and corrosion products, maintenance operations and waste management (including purification and retention of exhaust gases and liquids).

Based on STUK's review on PSAR and detailed design of the systems, due consideration has been given to the minimisation of discharges of Olkiluoto unit 3. Over the past years fuel leaks at the German and French reference plants have been minor. The same is expected to apply to Olkiluoto 3's reactor fuel. The materials for the reactor cooling circuit have been selected and the water chemistry designed with a view to minimising the creation of radioactive corrosion products. The reactor coolant purification system, the processing system for gaseous wastes, the storage and processing system for liquid wastes and the processing system for radioactive concentrates are based on technology used at the German reference plants, with improvements based on operating experience. The purpose of these systems is to limit the releases of radioactive materials into the environment. These systems are designed with due regard to the Best Available Techniques. Adequate exhaust air filters have been designed for installation in the ventilation systems.

Accident analyses, severe accident management and on-site radiation safety

Analyses of radiological consequences of postulated accidents, design basis accidents, design extension conditions and severe accidents were presented in PSAR and reviewed by STUK. The results from the analyses were well below the dose limits defined in the Government Decree 733/2008 the Safety of Nuclear Power Plants.

At Olkiluoto unit 3, severe accident management is based on reliable depressurisation of the primary circuit and proper containment functions with a unique core catcher. These measures will prevent any major release of radioactive materials (Cs-137 release in excess of 100 TBq shall have a probability less than $5 \cdot 10^{-7}$/a). With regard to protection against external threats, Olkiluoto unit 3 is constructed according to the design features which provide safety and prevent significant releases even in the case of a crash of a big passenger aircraft.

In a nuclear power plant, on-site habitability during accident situations has also to be taken into account in the design. The regulatory guide YVL 7.18 requires analyses of the magnitude and location of the possible radiation sources and evaluation of doses in different accident management and emergency preparedness measures. It shall be shown during the design process, that these doses do not exceed the normal dose limits of a radiation worker, i.e. 50 mSv. STUK's assessment on Olkiluoto 3's PSAR showed that adequate shielding and lay-out arrangement existed in the design. A more detailed review was done during the construction phase based on the detailed design of the systems and structures. It showed that the analysed doses of workers were well below the radiation worker's dose limit.

Regulatory oversight during construction

Regulatory oversight during Olkiluoto 3 construction ascertains that the plant is built according to the design and quality criteria approved in the construction licence phase, and that the prerequisites for high quality end result exist and the licensee is getting prepared for the commissioning and operation of the plant. STUK is currently finalising the review of the detailed design of the systems, structures and components and that includes also verifying that radiation safety requirements are fulfilled.

STUK has also established a construction inspection program to inspect TVO's project progress and implementation. One of the inspections focuses on the consideration of radiation safety issues, i.e., fulfilment of radiation safety criteria in the design and plans for radiation protection programme during plant commissioning and operation. In addition, STUK has performed inspections on the plant vendor and two of them concerned also radiation safety aspects.

Conclusions

Several STUK's YVL Guides deal with radiation safety. STUK has reviewed the application for the Construction Licence of the Olkiluoto 3 nuclear power plant unit in 2004-2005 and is currently finalising the review of the detailed design of the systems, structures and components. This review work includes also verifying that radiation safety requirements are fulfilled. The experience gained in the Olkiluoto 3 regulatory oversight project is taken into account in the revision of the STUK's YVL Guides and in the planning of the next possible oversight projects.

The new IAEA Basic Safety Standards (BSS) and their implementation for the operation of nuclear installations

Lorenz, Bernd[1]; Schwarz, Wolfgang[2]; Holl, Matthias[3]

[2] E.ON Kernkraft GmbH, Kernkraftwerk Isar, GERMANY
[3] RWE Power AG , GERMANY

Abstract

After the issue of ICRP 103 /1/ the process of revising the IAEA Basic Safety Standards (BSS) /2/ started. It follows the policy to adopt all the new ICRP considerations as far as possible. This should not be a problem as the ICRP itself stated "stability and continuity" as the headline for its new recommendations.

Indeed, there are few changes in ICRP: the risk factors are nearly the same and became even smaller, the dose quantities remain and, what is essential, the three basic principles justification, optimization and limitation endure. But there are changes. The process based approach is no longer used, there is new terminology and dose constraints were seen as central part of radiation protection not corresponding to the long lasting practice.

The revision of the BSS triggered a lively discussion in which the operators of nuclear installations participated. The large number of comments on the drafts shows that some remains to be done. Clarifications were already possible during the joint meeting of RASSC and WASSC in November 2008. It was e.g. made clear that not an optimized state has to be assured but the process of optimization. Unfortunately this decision was later cancelled, a situation which is not acceptable. It was also revealed that sometimes it was not yet clear who is responsible and what is a requirement and what a guideline. This could be approved in the following drafts, but the reformatted drafts failed to concentrate on "real" requirements.

For operators of nuclear facilities it is essential that changes in the BSS lead to higher safety and not to higher bureaucracy only. The demand for dose constraints for all sources that could be drawn from the text formally would be an example for that.

The drafting of the new BSS is in the hands of the IAEA and its co-sponsors. The operators need to focus on the discussions in the Safety Standards Committees and on comments. This is an important part of the process and we noticed that experience from practice is welcomed.

Material and methods

The basis for the analysis of the possible changes in radiation protection and their implications to the daily practise has been and still is the drafts of the revised BSS. The last is now Draft 3.0, posted for comments by the IAEA Member States until the end of May 2010. The plan is to finish the work at the end of the year, so the discussion here and during the Meetings of the 4 Safety Standards Committees of the IAEA are the last opportunity to correct things which might be misleading, not adequate or imprecise.

Results

The European nuclear industry has taken the opportunity to participate in the discussions about the revised BSS by a rather new organisation, the European Nuclear Installations Safety Standards Initiative (ENISS). ENISS was given an observer status in 3 Safety Standards Committees (NUSSC, RASSC, WASSC). From the very beginning ENISS commented the drafts of the revised BSS. The ENISS comments focused on 2 major issues: the provisions in the BSS about optimization and the prominent role of the Dose Constraints (DC). All other remarks have been of less importance, sometimes editorial or were accepted by the drafters.

Discussion

In addition to justification and the setting of dose limit, optimisation has been one of the basic principles in radiation protection for a long time now. This has not changed, even with the publication of ICRP 103. The main message of ICRP 103 is "continuity and stability". Persons active in radiation protection will be happy about this message, since it confirms the practical experience in radiation protection so far and calls for its continuation. However, it is in the nature of optimisation not to lead to a standstill. Optimisation means asking yourself constantly if you did everything to keep the risk of radiation exposure as low as reasonably achievable "taking into account all prevailing circumstances".

The implementation of these radiation protection principles has led to a constant decrease of actual exposures for workers. This is clearly indicated by statistics published by the Federal Office for Radiation Protection, BfS, /3/. They are on such a low level that occasionally the issue is raised if any further decrease could still be possible while maintaining the optimisation principle or if minimisation starts or has already started to dominate as a new principle.

> *"From 2003 to 2007, the mean annual dose of all persons exposed decreased by an average of 3% per year. Simultaneously, the number of persons exposed increased by an average of 4% per year. The collective dose remained almost constant. Measured in the increase of persons exposed, this presents a relative decrease in the dose. However, this is considerably less than from 1999 to 2003, when as a result of the new Radiation Protection Ordinance entering into force an absolute decrease in the dose could be observed in spite of a considerable increase in the number of the persons exposed.* ***This may indicate that for the majority of the employees the average annual exposure is becoming as low as reasonably achievable by optimisation measures."***

Fig. 1. Quotation from the BfS Report /3/, bold letters by the authors.

Nevertheless, we state: Radiation protection is on an excellent level implementing the principle of a continuous improvement in the form of optimisation, and a necessity to change the radiation protection concept is therefore not recognisable.

Dealing more intensely with the new basic recommendation of the ICRP of 2007 (ICRP 103), you will find that the ICRP has changed the system in spite of the expectations mentioned above. With the new and specific emphasis on "dose constraints" already introduced in the ICRP 60, these are now seen as one of the most important means of radiation protection optimisation, if not the most important one. This, however, may create a difference between the radiation protection optimisation and the ALARA principle. The reasons for this are difficult to understand.

If you ask around in practical operation, and try to find out where dose constraints are being used, you will learn that they can hardly be found. However, often operational dose restrictions are found that serve to control compliance with dose limits, such as maximum daily doses, maximum monthly doses, permitted dose fractions for external and internal exposure. Furthermore, there are action levels for individual doses that trigger measures when reached, for instance, monitoring. Finally, also collective dose restrictions are defined as standard, in part even as goals for the operation related radiation protection or as decision gates for the planning of radiation protection measures. So one can find a host of dose-oriented criteria of which none complies fully with the "dose constraints" introduced by the ICRP.

It is of interest that Article 7 of the Council Directive 96/29/EURATOM /4/ points moderately to dose constraints: "Dose constraints should be used, where appropriate, within the context of optimisation of radiological protection”. The implementation of this Council Directive 96/29/EURATOM into the German Radiation Protection Ordinance does not even include dose constraints. Now, the question is, what does the ICRP aim at by emphasising the dose constraints and will this lead to an improvement of the radiation protection in practical operation?

According to the ICRP, dose constraints are to be determined relative to sources. By definition, they are lower than dose limits. Contrary to the non-compliance with limits a non-compliance with dose constraints should not be a legal offence but needs to be excluded by adequate planning. If the dose constraint is a solely prospective planning measure or is to be used as well for retrospective evaluation of practical operation is controversial and not clearly indicated by ICRP statements.

The definition of "dose constraints relative to a source" creates a problem: Which source is meant? According to the ICRP, a radiation source is everything leading to radiation exposure. This may be an enclosed radiation source, with several kBq or TBq, a nuclear power plant in its entirety or even individual activities within the plant, such as the replacement of a valve, or an X-ray machine in a dental practice. Also the invasive X-ray diagnostics and even the radon exposure in a residential building qualify a "source" according to the ICRP. Already a first glance at the variety of possible radiation exposures shows you there are just as many options to define radiation sources. Does this mean several thousand dose constraints should be determined? For this, the ICRP does not provide selection criteria. So far, for the Council Directive 96/29/EURATOM the magic word "where appropriate" - even connected with the word "should" - was helpful. Such a restriction seems to be indispensable in the future as well; otherwise, a questionable bureaucracy is to be feared with regard to dose constraints. Indeed the BSS contains a lot of phrases such as “as appropriate”, “where appropriate”, “if appropriate”, otherwise DC’s could not be accepted at all.

For the application, it is imperative to take the dose levels into account. The significance of constraints for very small doses, for example in the range µSv, must be considered low from the outset.

Ionisation smoke detectors are a typical example, for which a dose constraint would not make sense. Here, other radiation protection measures apply based on the optimisation principle, e.g. only use as much activity as necessary, make the design robust and subject of design approval. As the example shows, it is worthwhile to develop criteria, when and where dose constraints are even "appropriate". In the discussion of new BSS, these considerations have not been included yet. Probably, the definition of dose constraints is only reasonable when there are actual design options regarding radiation protection, for example with complex projects or within the design phase of a source.

Which reasons are given by the ICRP for this particularly emphasised position of the dose constraints?

Dose constraints should limit inequity thus avoiding unacceptable high individual exposures as a result of the radiation protection optimisation.

So far, this objective was attributed to the dose limits, i.e. any exposure below these limits was basically acceptable. It is practise that exposures close to the limit values will be avoided. This is also a preventive action to avoid l exceeding the limits. It is customary as well to assign a higher priority to the reduction of exposures close to dose limits, and also a higher alpha value for quantitative considerations. These two procedures have proven to be efficient in reducing exposures at the upper level. To differentiate the acceptance even below the dose limits, maybe even quantitatively supported by DC’s, is very questionable.

Occupationally exposed persons know about possible hazards caused by exposure. They also know how to influence the level of exposure by one's own behaviour. Apart from that, the development of the exposures has been showing a decreasing tendency for many years, as already specified above, and is now on a level clearly below the limits /5/. Higher exposures have also decreased continuously. In radiation applications in the medical field approx. 1%, in the industrial field approx. 2% of the exposed persons are exposed "to a higher degree", i.e. they receive doses of more than 1 mSv. For the few exposure groups with higher exposures, in the first place this affects flight attendants and pilots (approx. 9% of the persons monitored are in the dose range between 1 and 6 mSv), it may be reasonable to consider specific measures to reduce these exposures. However, this reasoning should not justify a change of the entire protection philosophy, as would be provided by a global introduction of dose constraints.

Dose constraints should prevent exceeding dose limits in case of exposures to multiple sources.

This goal has always existed. Its achievement is simple. The personal dosimetry applies to professionally exposed persons. For severely changing exposure situations, the official personal dosimetry performed at longer intervals is supplemented by an operation related dosimetry, which can be evaluated immediately. Thus, intervention to prevent exceeding limits even under consideration of several sources is always possible.

Public exposures are caused by discharges of radioactive material and direct radiation. In Germany, these exposures are controlled by considering the already existing radiological burden within the licensing procedure specified by the Radiation Protection Ordinance. Other countries may have similar regulations. In extreme cases, this regulates new discharges or new direct radiation fractures stricter than the ones already approved for a site. This must be accepted by someone arriving later. There is absolutely no problem for public exposure in the vicinity of such plants. So, even control of multiple exposures does not require the introduction of dose constraints

Apart from that, and this is even stipulated by the ICRP in publication 103, there is usually only an exposure to one source (meaning here one plant, one application technology) both for occupational and public exposure.

Dose constraints are to exclude solutions, which are not considered optimal.

In connection with the principle of optimisation, this presents a problem: How should one know, which is the optimised solution prior to the implementation of the optimisation itself? A way out could be considered the so-called "best practices" for certain applications of ionising radiation, from which preferred solutions could be derived. Strictly speaking, however, general specifications contradict the ALARA principle according to which the circumstances of the individual case must be taken into account. Missing criteria and methodical references for a derivation of dose constraints are another relevant problem. Unfortunately, ICRP 103 is of no help here.

Dose constraints could be understood as being results derived from the optimisation process. Here it is also easy to envision that for comparable technologies or activities dose constraints defined by reference numbers could be useful. This, however, contradicts the ICRP statement that optimisation is required below the dose constraints. Thus, certain arbitrariness exists in the definition of dose constraints, and this is definitely misfortunate.

Another problem is that the ICRP does not provide clear information as to who is to be responsible for finding and setting the dose constraints. ICRP considers the plant operator responsible for optimisation, but recognises a certain necessity to co-ordinate dose constraints with the authorities. Here, there is a lot of room for discussion with regard to the future integration into European and national regulations, and in particular with regard to the subsequent practical operation, which is not of much help to radiation protection.

Ensure that protection and safety are optimized.

The second item of importance for the discussion of the revised BSS is the inadequate formulation of the optimization principle in the BSS, stating that “operators/licensees have to ensure that protection and safety are optimized”. We still believe that this is a crucial item for the implementation of radiation protection in practice. The principle of optimization based on ICRP 103 is correctly described in the introductory chapter 1 of the BSS as a process. In the main text of the BSS optimization has several times been reduced to the misleading phrase "to ensure that protection is optimized". This could create difficulties in practice as there are no clear criteria for the "optimized solution". As we believe, there is no principal difference among the radiation protection experts about the optimization principle, we suggested to change the corresponding formulations. In the RASSC/WASSC Meeting in November 2008 this change was accepted unanimously. However, during the next meetings of the drafting group a backchange was decided. Unfortunately in the following meetings of the Safety Standards Committees a deep going discussion of this issue did not take place.

To explain the concerns with the too short wording of the BSS regarding optimization some questions may enlighten the situation:

- What is optimization in legal terms?
- What are the criteria of being optimized?
- When and how often do operators have to demonstrate that protection and safety is optimized?

Optimization in legal terms

As described in chapter 1 of the BSS according to ICRP optimization is one of the principles of radiation protection and it is definitely a process.

"The optimization of protection and safety, when applied to the exposure of workers, members of the public and comforters and carers of patients undergoing radiological procedures, is a process for ensuring that the magnitudes and likelihood of exposures and the numbers of individuals exposed are as low as reasonably achievable, taking social and economic factors into account. This means that the level of protection should be the best under the prevailing circumstances, maximizing the margin of benefit over harm, and will thus not necessarily be the option with the lowest risk or dose. Optimization is a forward-looking iterative process requiring both qualitative and quantitative judgements, and may be used, if appropriate, in conjunction with individual source-related values of dose or risk that serve as boundaries in defining the range of options in optimization."(BSS Draft 3.0 para 1.14)

ICRP has issued so-called foundation documents in connection with ICRP 103 and the one dealing with optimization is the ICRP Publication 101 /6/. It is clearly stated there that optimization is a process and not dedicated to a specific result. The outcome of the optimization process will always be specific under the prevailing circumstances. From the legal point of view a legal requirement can therefore only be directed towards the process or the principle. The nuclear industry has made time and again a proposal for changing the text into "have to ensure that protection and safety are subject to an optimization process". As said this was already accepted in November 2008.

A counterargument was since then that having a process only is too soft and does not guarantee that results of the process will be implemented. Although this argument is not very convincing one could in addition demand in the BSS that results of the optimization process have to be implemented. From the standpoint of radiation protection practice this is logical anyway.

The current situation in many radiation protection legislations is that only the principle of optimization is fixed legally. A prominent example is the Council Directive 96/29/EURATOM, where Article 6 says, that ”each Member State shall ensure that in the context of optimization all exposures shall be kept as low as reasonably achievable, economic and social factors being taken into account.” The German Radiation Protection Ordinance e.g. indeed contains only this principle. Note that the provision is directed to the Member States only. The BSS addresses not only the regulator and competent authorities but also operators.

Criteria for being optimized

Optimization in the textversion of the ALARA Principle may be interpreted differently: one may stress the word ”low”, asking for exposures in the µSv-range or even Zero-dose, one may stress the ”reasonably” as operators are often said to do so, or one may stress the ”achievable”, as engineers might willing to do. Social factors may be seen differently from a workers point of view and a stakeholders point of view. These examples easily show the great variety of interpretation of being optimized. There are no clear criteria. Getting a licence may be an indicator for being optimized, otherwise an authority would probably not have issued the licence. Getting a type approval is also an indicator. The question than remains what to do during operation. The BSS do not answer this questions and give no indication for the fulfillment of its strict requirement to ensure being optimized. But such a situation is dangerous for any development of protection. Operators might be forced not to change their operational mode as the fear not to get a renewed licence.

When and how demonstrate ”being optimized”?

The optimized solution today may be obsolete tomorrow. The circumstances change permanently. For any radiation protection expert in the field it is clear that one cannot change the rules everyday. Operation needs stability. The BSS do not contain details of how to ensure the optimized solution. In the planning of the framework of IAEA standards a guide about optimization is not to see. Without guidance on optimization it will be difficult to implement the requirement. The experience so far goes along the line of having a process of optimization. With the new formulation of the optimization requirement in the BSS the proven system will be questioned and the outcome is unclear. A situation which is not suited to foster protection and safety.

Conclusions

In summary, it becomes clear that dose constraints according to the ICRP version are needed neither in Germany nor in the EU or elsewhere to achieve excellent radiation protection. Care should rather be taken to avoid new bureaucracy from developing that would do more harm than good.

Dose constraints, defined and applied flexibly and with a sense of proportion make sense when used by the operators of nuclear plants as management tools for a proven practical operation and as a result of optimisation considerations. It may be reasonable to determine a few operation related values. Optimisation, however, is by far more than the determination of such dose constraints.

The shortening of the optimization principle to the requirement "to ensure that protection and safety are optimized" is inadequate, not in line with the ICRP philosophy and the guidance given in ICRP 102. The drafters of the BSS need to come back to the decision from 2008 and reinstall the formulation " ensure that protection and safety are subject to an optimization process".

Occupational radiation exposure – an overview on the exposure of the workers in facilities of the nuclear fuel cycle

Kaulard, Joerg; Schmidt, Claudia; Strub, Erik
Gesellschaft fuer Anlagen- und Reaktorsicherheit (GRS), mbH, GERMANY

Abstract

Workers are subject to radiation exposure in several industries. This contribution will provide an overview of the exposure of workers in facilities of the nuclear fuel cycle. Following a first overview, details on the exposure in nuclear power plants in operation as well as under decommissioning are addressed. Based on recent data, trends in the exposure of workers will be discussed and some examples will be given on how experiences contribute to improvements concerning the exposure of workers.

The data available show, that with time in general the exposure of the individual worker decreases. This is a result of a manifold effort by all parties involved in the radiation protection in nuclear facilities, which is mainly based on a consequent experience feedback from past operation to improve design and operation and regulations relevant for the nuclear sector.

Introduction

In its 2008 report to the United Nations General Assembly, the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) estimates, that today more than 22.8 million workers are exposed to ionizing radiation (UNSCEAR 2008). About 13 million workers are subject to ionizing radiation from natural sources. The remaining 9.8 million workers belong to all sectors of artificial sources, 75 % of them related to the medical sector. Among the 25 % of the 9.8 million workers are those working in facilities of the nuclear fuel cycle (nuclear sector).

This contribution to the Third European IRPA Congress addresses worldwide trends in the occupational exposure in facilities of the nuclear sector. For that, a first overview on the situation worldwide is given, followed by a focus on the situation in nuclear power plants as – in general – one of the main sources for exposure. The factors which influence the occupational exposure and its decrease at nuclear power plants are manifold. As an example for more details and influencing factors, some German trends in occupational exposure in nuclear power plants are explained.

Trends in the occupational exposure in the nuclear sector worldwide

In its 2000 report UNSCEAR has published data on the occupational exposure related to work in different types of facilities related to the nuclear sector (UNSCEAR 2000). The data published cover the years 1975 until 1994 (Note: Currently, an update of this report is under preparation which will be published early 2010 but was not available at the time of preparation of this contribution). The nuclear sector comprises facilities for uranium mining and milling, for uranium enrichment and conversion, for fuel fabrication, for operation of nuclear power plants (NPP), for reprocessing and for research within the nuclear fuel cycle. Although waste management is another branch in the nuclear sector within the UNSCEAR survey only little data become available separately as they are mainly covered in the other branches mentioned.

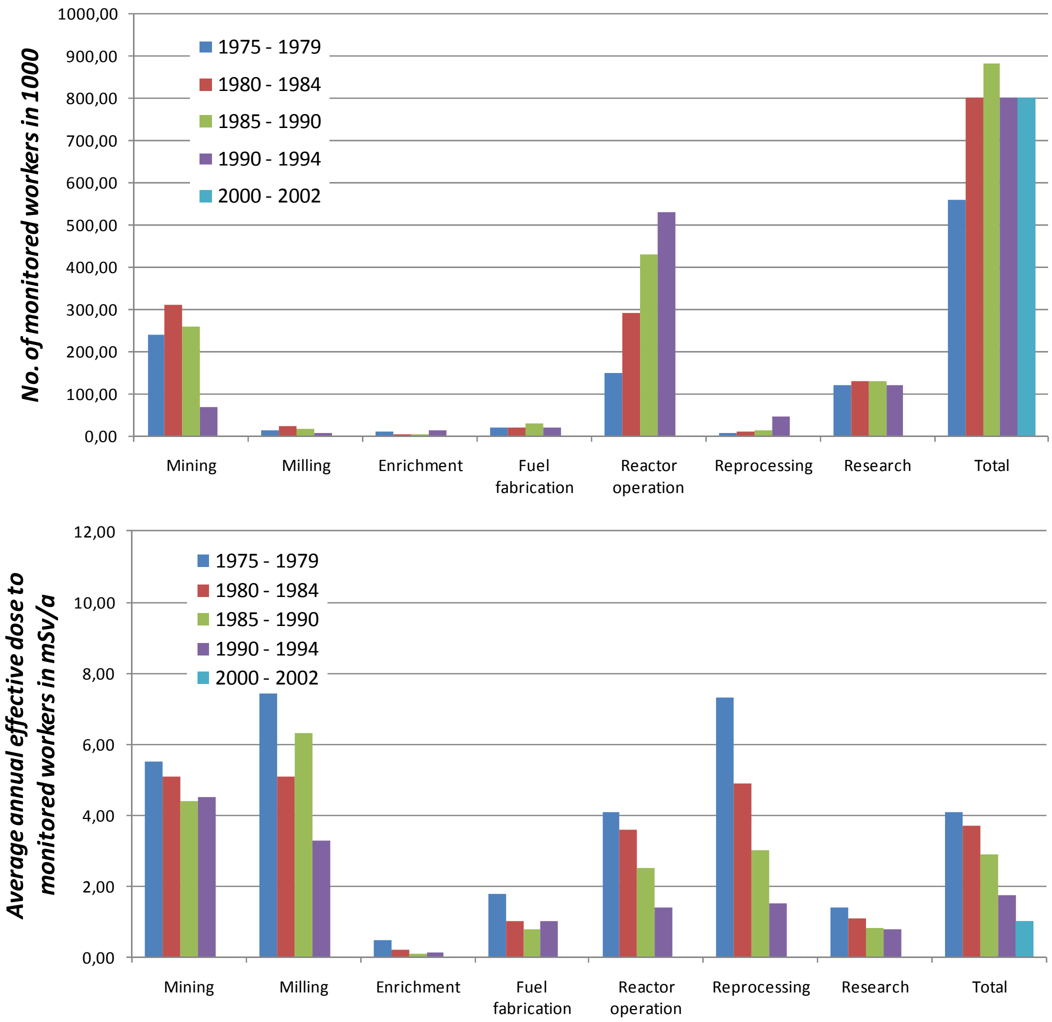

Fig. 1. Number of monitored workers in thousands and average annual collective doses for the different branches in the nuclear sector.

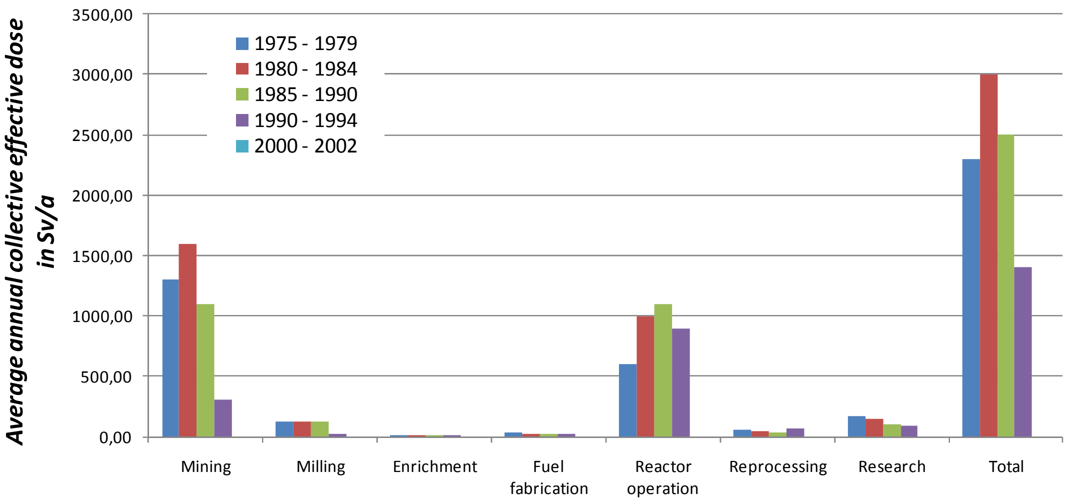
Fig. 1 and Fig. 2 present the trends of estimated numbers of monitored workers, estimated average annual collective doses, the resulting average annual effective doses of monitored workers and the fraction of monitored workers with an annual effective dose of more than 15 mSv for the different branches within the nuclear sector. The data

1975 – 1994 are taken from the 2000 report of UNSCEAR (UNSCEAR 2000), the data 2000 – 2002 are taken from the 2008 report (UNSCEAR 2008), but not for all items 2000 – 2002 numbers were available.

The UNSCEAR data were obtained by surveys of occupational radiation exposure, requesting information from various national authorities and institutions and by collecting supplementary data, e.g. from the Information System on Occupational Exposure (ISOE) of the OECD Nuclear Energy Agency (NEA). As a matter of fact the data reported differ due to national differences e.g. in the statutory dosimetry systems, on reporting of exposed or monitored workers, on the national reporting levels. In addition, not for each period and for all nuclear branches data for all facilities have been supplied. Especially in case of the mining branch, some estimates became necessary to achieve a more complete view on the worldwide situation for the data of the period 1990 – 1994, resulting in some larger uncertainties in the number of monitored workers and the related average annual collective effective dose. Nevertheless, the data prepared allow important insights in the occupational exposure of workers in the nuclear sector.



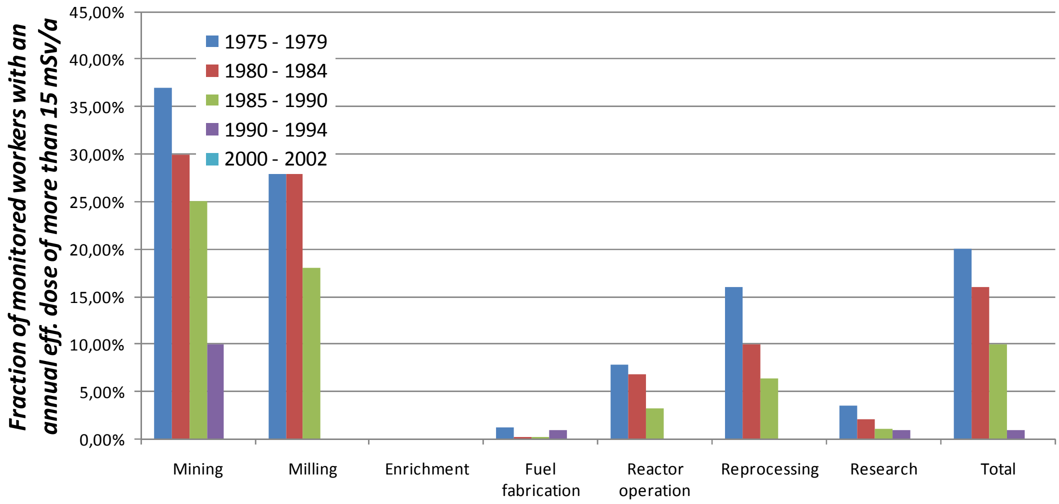


Fig. 2. Average annual effective doses of monitored workers and fraction of monitored workers with an annual effective dose of more than 15 mSv/a for the different branches in the nuclear sector.
(Note: for several branches the fraction for doses of more than 15 mSv is close to 0 in 1990-1994)

Independent from the uncertainties mentioned, the figures and numbers show, that

(a) NPP operation (reactors) is the branch with the highest number of monitored workers in the last period but not with the highest average annual effective dose to monitored workers,
(b) for all branches a decrease in the annual collective effective dose to monitored workers can be observed in the last periods,
(c) the fraction of monitored workers with an annual effective dose of more than 15 mSv decreases over time, but for the mining and milling branches the fraction is still the highest.

As such the data show a general worldwide trend of decreasing occupational exposure by ionizing radiation in the nuclear sector. The average annual effective doses of monitored workers in the nuclear sector decreased from 1975 to 1994 from 4.1 mSv to 1.75 mSv; the recent data of the 2008 report indicate a further decrease to about 1 mSv.

Details on the occupational exposure in nuclear power plants worldwide

While UNSCEAR collects and analyses data on all aspects on the effects of ionizing radiation, the Information System on Occupational Exposure (ISOE) of the OECD Nuclear Energy Agency (NEA) focuses on the occupational exposure of workers in NPPs. Established in 1992 by the OECD-NEA, the overall goal of the ISOE is to facilitate the optimisation of worker radiological protection in NPPs through collection and assessment of relevant data and the exchange of experiences on radiation protection in NPPs. As of January 2010, 63 operators of NPPs in 27 countries are official participants of the ISOE, representing 311 NPPs in operation and 40 NPPs under decommissioning. The central database of ISOE contains data for many more NPPs in operation (401 NPPs) and under decommissioning (about 80). As such the ISOE database represents the largest database on data on the occupational exposure in NPPs under operation.

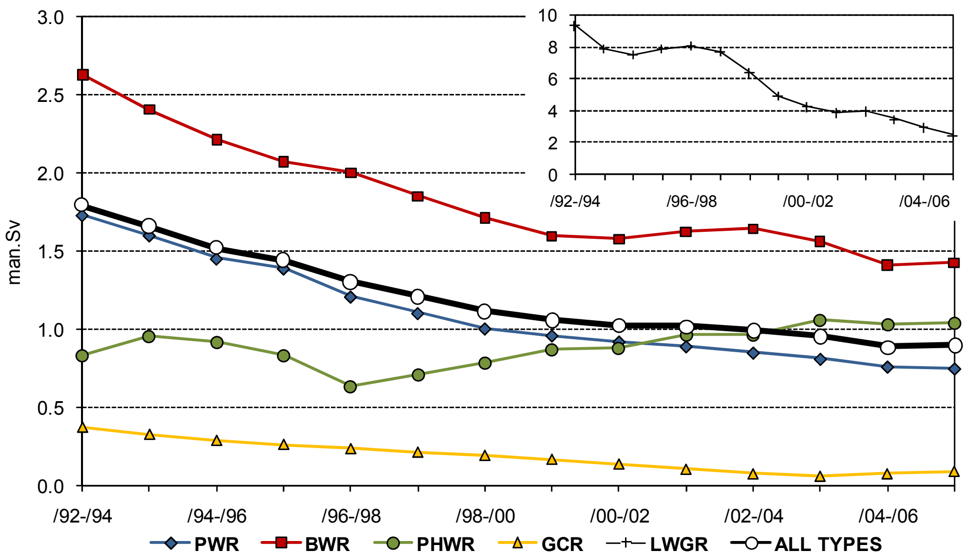

Fig. 3. Three years rolling average annual collective effective dose per nuclear power plant for different reactor types (Ahier 2008, ISOE 2009).

Fig. 3 shows the three years rolling average annual collective effective dose for all NPPs participating in ISOE and for different reactor types. The data show a decreasing trend in the exposure, which supports the conclusions drawn by the UNSCEAR. Nevertheless, it should be taken into account, that the data of the different reactor groups are based on the data of different numbers of NPPs. E.g. for the year 2007 for PWR group (including VVER) about 230 nuclear power plants provided data, while for BWR about 70 nuclear power plants, for PHWR about 30 and for LWGR only 1 NPP provided data (ISOE 2008). Accordingly extraordinary work during outage or refurbishment in an individual NPP has different impact on the averaged dose depending on the reactor group. Such an influence can be recognized in the data of the PHWR, which is representing the CANDU reactor type. Since 1999 (ISOE 2001) an additional NPP provides its data which are significant higher than the average at that time. In combination with major work in other NPPs this resulted in an increase of the average dose overlaying any decreasing trend due to improvements made.

The database data contains also data on the occupational exposure at NPPs under decommissioning. Fig. 4 shows the average annual collective effective dose and the number of the related reporting NPPs under decommissioning (ISOE 2009). The evolution of the average dose with time may be interpreted as a decreasing trend. In fact, such an interpretation is not correct, as – different to the operation of a NPP – the exposure strongly depends on kind and amount of decommissioning work of a year which change during progress of a decommissioning project dramatically. The increase of the reporting NPPs is related to the fact, that ISOE promotes the collection of decommissioning related data within the last years and that new decommissioning projects were started.

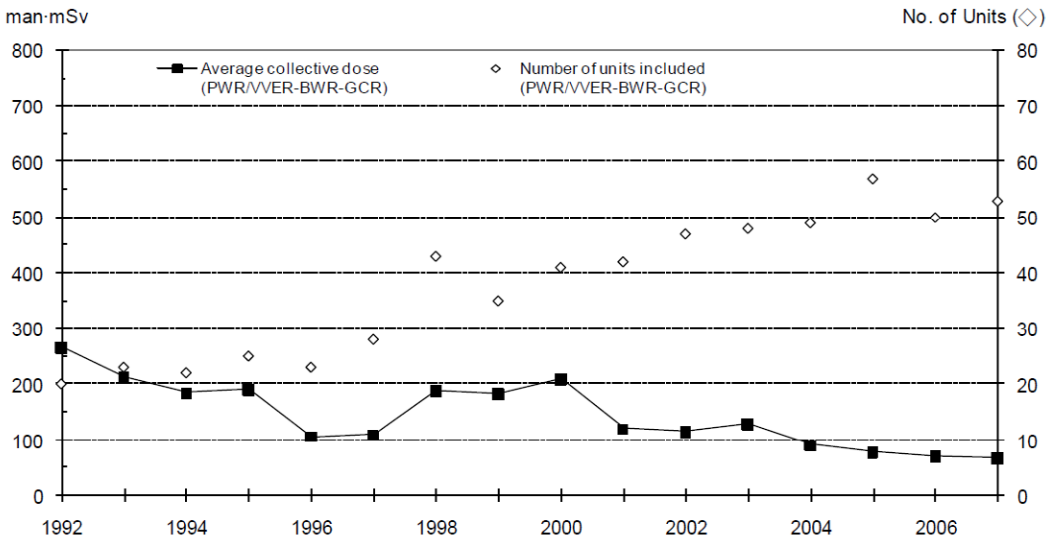

Fig. 3. Three years rolling average annual collective effective dose per nuclear power plant for different reactor types (ISOE 2009).

However, the data available for NPPs under decommissioning show that the average annual collective effective dose is much lower than in case of NPPs in operation. The ratio varies strongly from year to year at least due to the changing decommissioning work.

A spotlight to a national situation – examples from Germany

As already discussed in the context of the UNSCEAR data, main branches for occupational exposure in the nuclear sector are mining and milling and nuclear power plants. Today, in Germany no mining and milling facilities of the nuclear fuel cycle are in operation anymore. 17 nuclear power plants at 12 sites are in operation and 17 nuclear power plants (at 13 sites) are under decommissioning while 2 nuclear power plants were completely dismantled meanwhile.

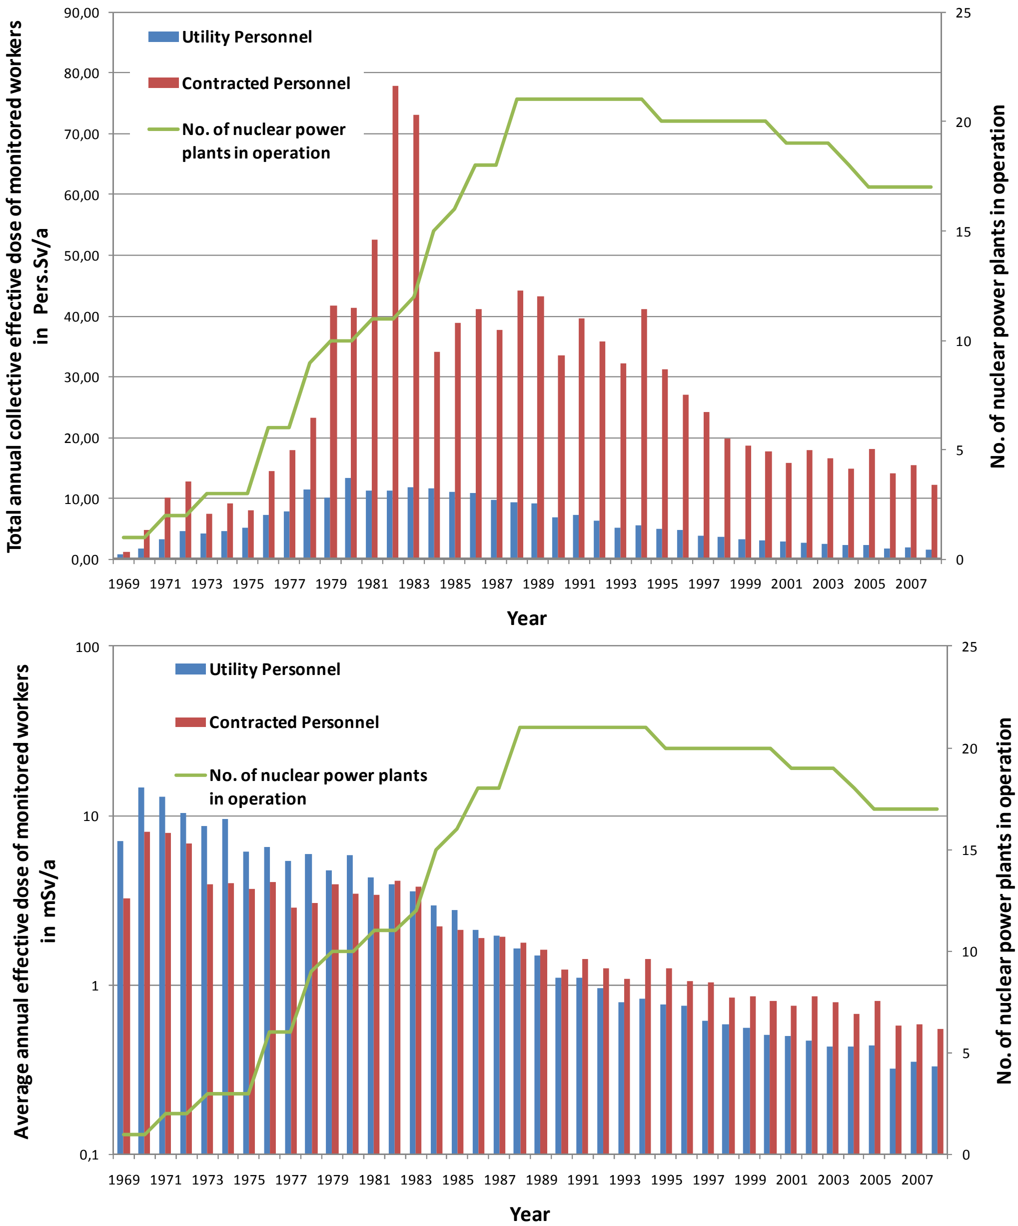

Fig. 5. Total annual collective dose and average annual effective dose of monitored workers for German nuclear power plants in operation.

Fig. 5 and Fig. 6 show the total annual collective dose and the average annual effective dose to monitored workers for all German NPPs in operation and under decommissioning. Both figures are based on data from the occupational dosimetry systems operated by the operators of the NPPs. Thus contracted workers are attributed to each single NPP even, if they entered two or more NPPs during the year. Accordingly, the number of contracted workers in the figures is higher than the number of real persons or the related number of workers registered in the German statutory dosimetry. As a consequence, the average annual effective dose for monitored workers is lower than in case of using the official data of the statutory dosimetry.

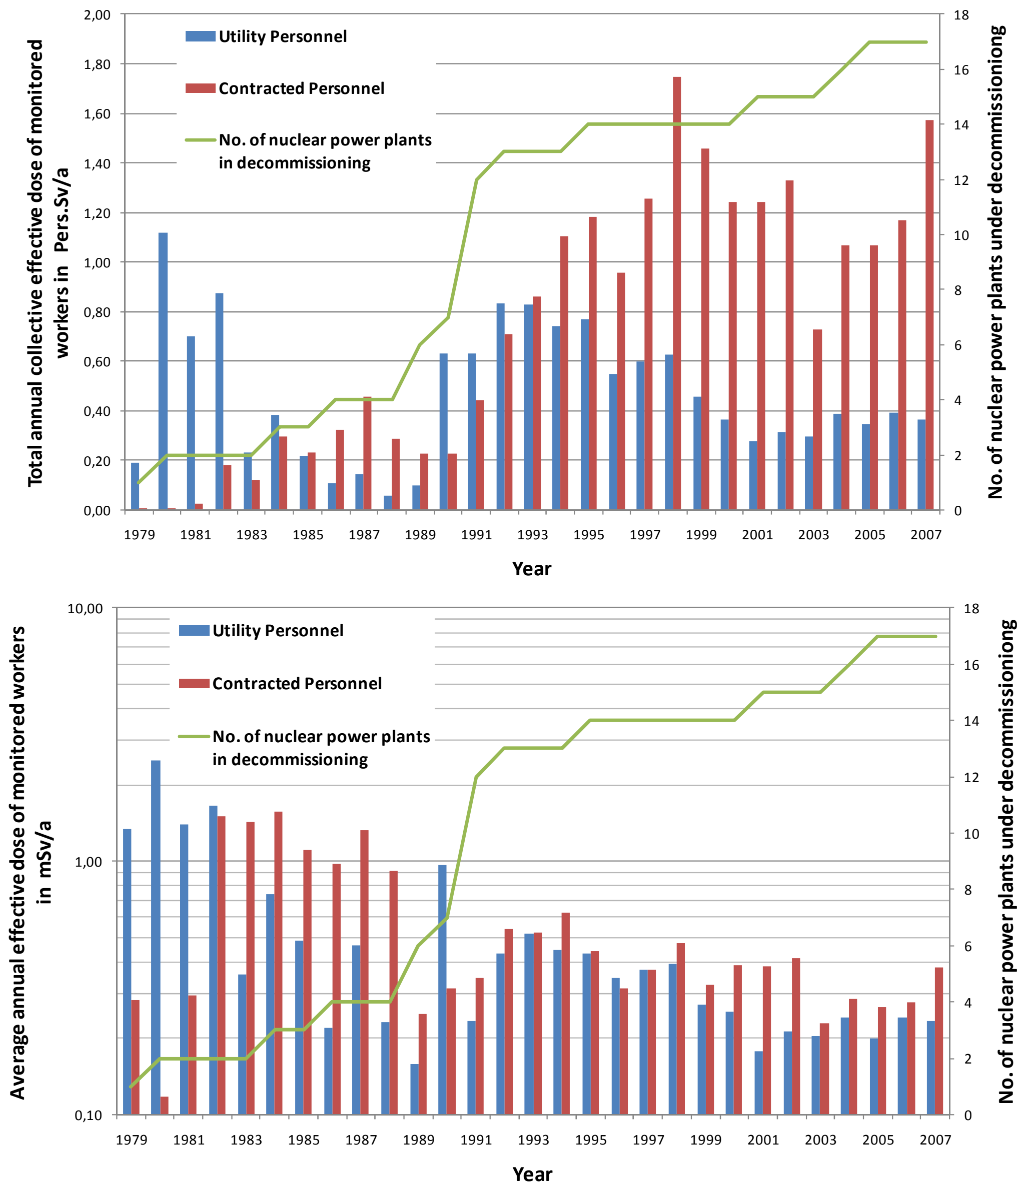

Fig. 6. Total annual collective dose and average annual effective dose of monitored workers for German nuclear power plants under decommissioning.

Fig. 5 shows a clear long term trend of lower total annual collective doses and average annual effective dose of monitored workers. In general terms, this trend is due to a consequent experience feed back and radiation protection work planning process (so called IWRS radiation protection planning) during operation and due to improvements in the design of newer NPPs. For some NPPs, back fitting activities were performed during operation improving also the radiological work conditions. Especially the long term trend for the average annual effective dose of monitored workers indicates that in general the working conditions for workers changed and improved. A further analysis of the distribution of the individual annual effective dose of the monitored workers in German NPPs confirms that the fraction of workers with a higher dose decreases (e.g. Fig. 7 on the distribution of the fraction of monitored utility workers). Since 2001 exposures above the German dose limit above 20 mSv/a, did not occur.

Fig. 6 shows the numbers for nuclear power plants under decommissioning. A trend similar to that of Fig. 5 can not be recognized as was already mentioned during discussion of data from the ISOE. This is due to the fact that the annual effective dose for each nuclear power plant strongly depends on the decommissioning work and the related radiological conditions and which change form year to year, following the overall work planning and decommissioning strategy for the NPP. Obviously, the type, inventory and operational history of the NPP influence the radiological conditions. As such no trends can be expected. But, improvements e.g. due to experience feedback take place and can be identified on the level of an individual NPP. Comparing the data of German NPPs under decommissioning it turns out as a rule of thumb that the decommissioning related average annual effective dose of monitored workers is about 10% to 20% of that for operating, but this ratio depends on the NPP and – as mentioned – the work to be performed.

The influence of the design of the German NPP on the occupational exposure during operation can be easily recognized in Fig. 8 in which the average annual collective effective dose of the works in German NPPs, belonging to a specific design generation, is presented. While the figure considers all commercial NPPs in operation in former West Germany the six NPPs of the former East Germany are not considered, as they belong to another design generations of Russian design. The NPPs of PWR type are divided into 4 generations; during design of the PWRs of the fourth generation (so called Konvoi reactor) all previously made experiences, esp. from operation of PWRs of the first generation, were considered (e.g. on the use of material with low neutron activation, design of compartments to separate components with high dose rates from those with low dose rates to reduce exposure during later maintenance work, design requirements for low dose rates at frequently accessed locations). As such, the Konvoi reactors offer well improved radiological conditions due to design.

Fig. 8 illustrates also the different contributions from the German NPPs to the total annual collective effective dose of the German NPPs in operation and the related annual effective dose of monitored workers. As an example on the different situation in the individual NPPs, for 2008 the average annual effective dose for monitored utility workers varied between 0.04 mSv/a and 0.78 mSv/a. As already mentioned, the individual contributions may change significantly, typically more for the earlier generations, as they are due to the height of their dose contribution more sensible to changes in workload than the Konvoi reactors.

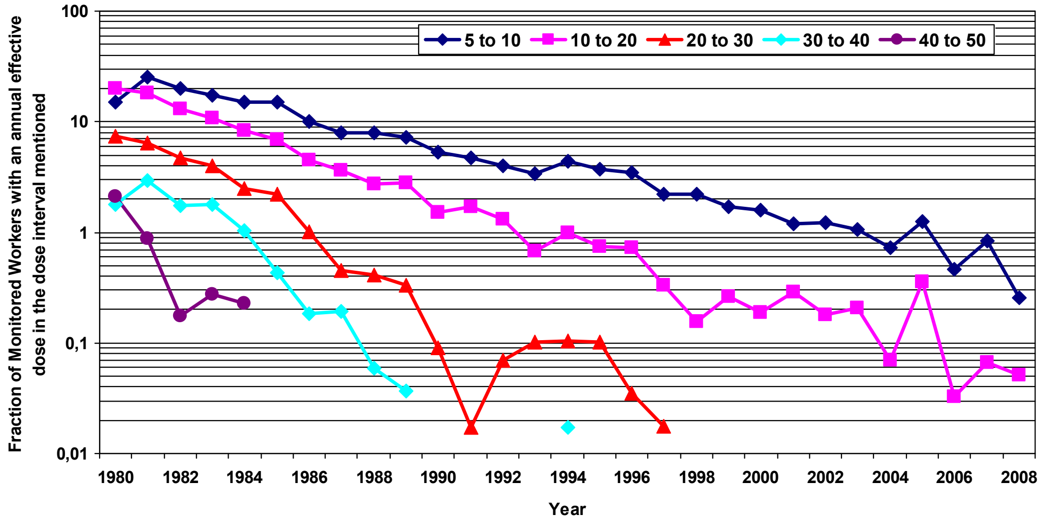

Fig. 7. Distribution of the fraction of monitored utility workers with a specified annual effective dose for German nuclear power plants in operation (in %).

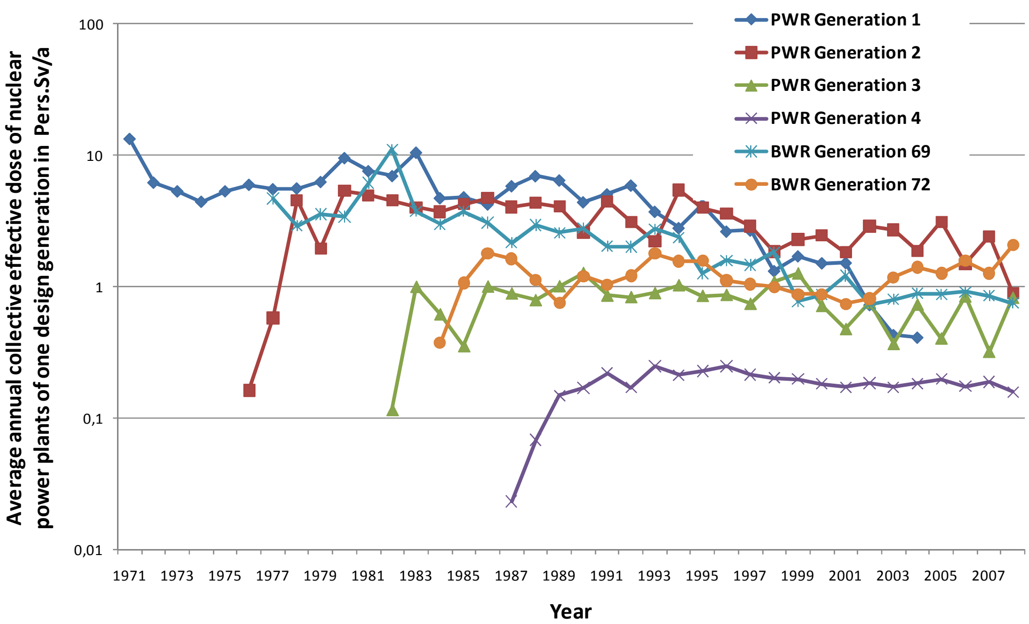

Fig. 8. Average annual collective dose of workers, averaged for German nuclear power plants of similar design generation.

Conclusions

Recent international data of UNSCEAR show, that the occupational exposure for workers in the nuclear sector has decreased during the last three decades. Although these data, especially those related to the mining and milling branch within the nuclear sector, are connected with some uncertainties, but the trend shown can be regarded as realistic.

When focussing on the situation within NPPs, the international data of the ISOE publicly available allow a more specific analysis of the situation including a separation between NPPs in operation and under decommissioning. For the common reactor types

PWR (including VVER) and BWR, a decreasing trend on the average annual collective effective dose for nuclear power plants in operation can be observed; the data for the group of NPPs of reactor type PHWR show an increasing trend, which is due to the increasing number of reporting NPPs in ISOE and the contributions of single NPP with high doses on the average value.

Finally, best insight can be obtained by analysis of national data allowing a high degree of differentiation. As such an example, the data on the occupational exposure in German NPPs show again a decreasing trend for the total annual collective effective dose of German NPPs in operation and for the average annual effective dose of the monitored workers. Depending on the type and generation of the NPP, the improvements during operation are different due to the resulting radiological conditions. Improvements can be observed for all NPPs but the extent of improvement, e.g. expressed in terms of dose savings, depends on the radiological conditions – typically savings are higher in NPPs of the first generations. The national example shows also that an adequate design will ensure best improvements in radiation protection.

Concerning the occupational exposure in NPPs under decommissioning, the available data and their trend are dominated by the specific situation during decommissioning; different to operation, the annual work for a NPP under decommissioning changes dramatically with completely different radiological conditions. As such, the annual collective effective dose of a NPP under decommissioning changes significantly due to the nature of work from year to year. As a consequence, no trends in the annual data can be expected which allow an easy conclusion on radiation protection improvements. But, experiences show, that such improvements take place, resulting e.g. in a much lower real exposure of monitored workers than was expected during planning of the decommissioning.

Floating nuclear power reactors – Fiction or future?

Reistad, Ole[1]; Hansell, Cristina[2]

[1] Norwegian Radiation Protection Authority, NORWAY

[2] James Martin Center for Nonproliferation Studies, UNITED STATES

Abstract

Russia's current floating nuclear power plant (FNPP) plans were initiated nearly 20 years ago, with a competition to develop small-scale power plants for the Russian Arctic. While the locations where the first plants will be sited have been altered several times, the basic design of the prototype plant remains the one that won the competition in 1994: a variant of the Russian icebreaker reactor. This paper describes the development in the Russian plans for building floating nuclear power plants (FNPP), and the status for the ongoing construction project. There have been two major changes since 1994: Russia has promised to fuel the reactors with low enriched uranium (LEU) fuel – whereas icebreakers use 36–90% enriched uranium fuel – and exporting FNPPs has become a key goal for its developers. The project now under realization has also been redesigned to increase safety. Attention to proliferation-resistance has also been highlighted in many Russian presentations on the FNPPs, making a switch back to HEU less likely. Redesigns to increase safety have also been widely touted. While there are many detailed reports about the fuel design, though, there is no data on performance – indeed, it is not clear that performance has indeed been sufficiently demonstrated. There are reports (without data) that testing of the fuel has occurred in other Russian reactor types, however, and Russian designers appear satisfied with the current fuel design. Russian has also approached the IAEA in order to have the Agency involved in assessing the safety of the plant design. Despite these developments, though, there are still several major questions about Russia's FNPP plans that raise concern. Much of the FNPP project remains shrouded in secrecy. Economic calculations, which will surely effect expenditures on safety, security, etc., are unknown – the total cost estimates given vary widely, and do not appear to include security, transport, or back end costs

Assessment of potential consequences of possible radiological accidents in the seas of the Northwest Region of the Russian Federation

Krylov, Alexey; Pavlovski, Oleg
Nuclear Safety Institute of the Russian Academy of Sciences, RUSSIA

Abstract

There are the sites for the storage and decommissioning of the retired nuclear submarines, their nuclear reactors, spent nuclear fuel and radioactive waste, located in Northwest Russia. Many of those sites are not isolated and protected. There are also nuclear shipbuilding facilities, naval objects and nuclear powered vessels (submarines, icebreakers) in the seas. All these sites present potential threat of radiological releases. This was the reason for implementation of the International Project "Enhancement of Radiation Monitoring and Emergency Response System in the Murmansk Region" (Project), managed by the European Bank for Reconstruction and Development. The Nuclear Safety Institute (NSI) of the Russian Academy of Sciences was the main executor of the Project. Possible scenarios and consequences of accidental radioactive contamination of coastal waters of Northwest Russia are discussed in this work. The scenarios assume the location of the potential accidents in the White Sea and in one of the Bays of the Barents Sea. The modelling of possible consequences of radiological accidents was implemented for water objects that strongly differ in size (from 5 to 300 kilometres), tides, currents and characteristic times of water exchange with the Arctic Ocean. The modelling of migration of the radioactive substances was carried out with the use of computer model developed by the NSI specialists. This model is based on the well-known three-dimensional Princeton Ocean Model.

Introduction

There are a lot of seas, gulfs and bays in the world that have been contaminated by radioactivity or are in danger of such contamination. The nuclear Navy facilities and especially nuclear submarines are the main sources of the danger.

The Soviet Union built about 250 nuclear submarines, more than 30 nuclear maintenance service vessels and coastal maintenance bases. The lifetime of most of the submarines and ships is over. The infrastructure proved to be unprepared for the necessary rate of decommissioning. It has resulted in the fast accumulation of the storage facilities for the retired nuclear submarines with spent nuclear fuel on board. The condition of the hulls of the submarines is worsening, presenting a threat of radioactive contamination of the environment. In Russia the sites for the storage and decommissioning of retired nuclear submarines, their nuclear reactors, spent nuclear fuel and radioactive waste are located at the coasts of the Barents Sea, White Sea, Kamchatka peninsula and at the Russian Far East (Takano et al., 2001; Nikitin et al., 1996; Compton et al., 2003; Vysotsky, 2008).

It is necessary to mention that the hazards are not hypothetical. For example, in 1985 the reloading of nuclear fuel at the nuclear submarine in the Chazhma Bay in the Russian Far East resulted in the accident with discharge of the large amount of radioactivity (Sivintsev, 2000).

Four Russian and two American nuclear submarines sank during combat duty. They lay on the ocean bed throughout the world. One Russian decommissioned submarine sank in the Barents Sea during transportation. Moreover several reactor units of the nuclear submarines were dumped with nuclear fuel on board (Reistad, 2006; IASA, 2003).

There are also regions of ocean that are radioactively pure nowadays, but with intense traffic of nuclear submarines. Underwater collisions of submarines represent another potential threat (IASA, 2003).

Thus, the geography of potential radioactive contamination of the World Ocean is broad enough. Integration of a radioactivity transport model into the Princeton Ocean Model (POM) could give the necessary tool to nuclear safety specialists.

At present in Northwest Russia, especially at the coast of the Barents Sea in the Murmansk Region, there are a lot of sites for the storage and decommissioning of the retired nuclear submarines, their nuclear reactors, spent nuclear fuel and radioactive waste. The highest radiation potential (~45% of total in the region) have nuclear submarines, located at the naval bases in the Murmansk region. The radiation potential of the storage sites in this part of Russia is higher than activity of long-lived radionuclides, released during the Chernobyl accident (Sarkisov, 2009). Some of those sites are not isolated and protected. This was the reason of implementing of the international Project "Enhancement of Radiation Monitoring and Emergency Response System in the Murmansk Region" (Project), managed by the European Bank for Reconstruction and Development (Amozova, 2007). Under this Project two crisis centres were established and equipped by the software necessary for nuclear safety specialists. Within the frame of the Project specialists of Nuclear Safety Institute of the Russian Academy of Sciences implemented initial improvements of the POM code.

Description of the regions of modelling

The Sayda Bay is situated in the Murmansk Region of the Russian Federation. The size of the Bay is about 5.6 km from east to west and 5.1 km from south to north (see Figure 1). The Sayda Bay is a restricted territory and is not used economically by local population. The bay is connected by narrow neck with Kola Bay of Barents Sea, There is no major rivers flow into the Sayda Bay. The tides in this bay are considerable. There is hydro-meteorological station at the Yekaterininskaya Harbor in the Kola Bay near the mouth of the Sayda Bay. The recorded tides are up to the 4 meters.

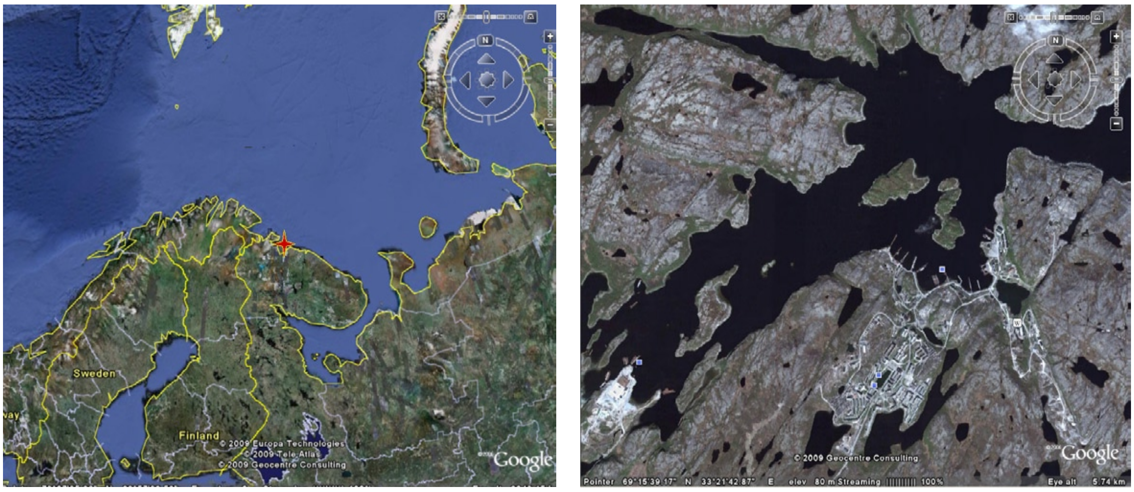

Fig 1. Location (left) and satellite photograph (right) of the Sayda Bay.

White Sea belongs to the internal seas of the Arctic Ocean. In the north it connects to the Barents Sea through the Gorlo and Voronka straits. The area of the sea is $8.7*10^{10}$ m^2, the volume of water - about $6*10^{12}$ m^3, the average water depth - 67m, and the greatest - 350m. (Figure 2, left). Annual runoff averages $2.2*10^{11}$ m^3.

The horizontal circulation of waters of the White Sea is formed under the combined effect of wind, river runoff, tides, compensation flows, so it is diverse and complex in detail. The resulting motion forms counterclockwise movement of waters under the influence of the Coriolis forces, peculiar to the seas of the Northern Hemisphere (Figure 2, right) - (Dobrovolskiy 1982).

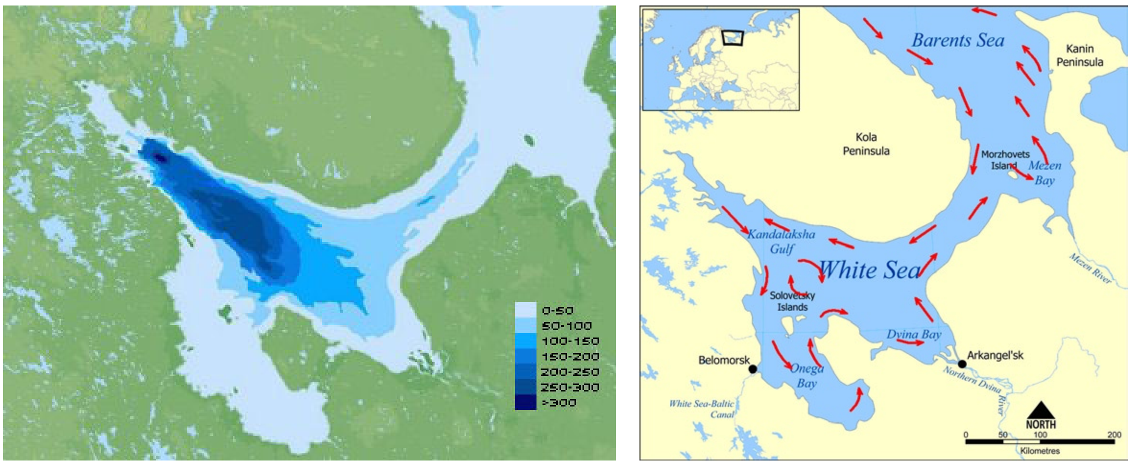

Fig 2. Depths (left) and a constant surface currents (right) in the White Sea.

The velocities of the constant currents are small and usually equal to 0.1 – 0.15 m/s in narrow waters and reach 0.3 – 0.4 m/s around capes. In some areas tidal currents have much higher speeds. In Gorlo strait and Mezenski Bay they reach 2.5 m/s, in Kandalaksha bay - 0.30 – 0.35 m/s, in Onega Bay - 0.8 – 1.0 m/s. In the sea basin velocity of the tidal currents is approximately equal to velocity of the constant currents (Dobrovolskiy 1982).

Improvements of the POM necessary to enable modelling of the radioactivity transport

Radioactive substances in the marine environment are transported in solute and sorbed on particles, first of all, on the finest fractions of the suspended matter. Modelling of radioactivity migration in the solute can be done by analogy with salinity. It is necessary to mention that calculation of salinity as a function of time and space is included into the POM.

In order to model radioactivity sources it is necessary to apply appropriate boundary conditions. The most probable types of radioactive contamination sources of the marine environment are as follows:

- A permanent point source on the seabed. It can include leakage of radioactivity from a sunken submarine, a piece of nuclear fuel or another radioactive fraction of a ship as it was in the Chazhma Bay accident.
- A permanent point source on the coast. It can include leakage from a coastal radioactively dangerous object or the mouth of a contaminated river.
- A short-term or instantaneous point source. It can include accidental radioactivity discharge from a nuclear vessel, submarine or from a coastal facility. It might even be deliberate discharge of liquid radioactive waste into the sea.
- A spatial surface source. Such sources can occur in case of an accident with a radioactivity discharge to the atmosphere and subsequent fallout on the sea surface. The area of fallout can be vast, its duration can be prolonged and the intensity can be extremely variable.

There are no significant difficulties in modelling of permanent sources. Boundary conditions should add the necessary amount of radioactivity each time step to the appropriate cells of the grid. Modelling of instantaneous point sources is also easy. But for this type of sources it is very important to spin up the model before adding the radioactivity. The spatial sources of radioactivity are most difficult for modelling as source characteristics require close interaction of models of contaminant dispersion in the marine environment and atmosphere.

It should be mentioned that POM computer code has no special module for the calculation of radioactive contaminant dispersion. Therefore authors of the paper have decided to use for this purpose seawater salinity forecast approaches used in POM code (Krylov 2009). It should be taken into account that unlike the salinity, the radioactive contaminants can be not always considered conservative. In most cases it is not necessary to take into account radioactive decay for long-lived radioactive substances, like ^{137}Cs or ^{90}Sr, as their half-life time is 30 years. And if the time of simulation is much less the decay can be neglected. But for accidents with a discharge into marine environment radionuclides with the half-life time of several days, like ^{131}I, it is very important to take into account their radioactive decay. For this purpose it is necessary to add the exponential decrease of the amount of radioactivity throughout the calculation grid.

Taking into account daughter radionuclides is much more difficult task. Daughter radionuclide can be much more dangerous than the maternal one. For example ^{241}Pu decays to ^{241}Am which is much more dangerous to the humans and the environment. In most cases daughter radionuclides are taken into account implicitly - dose coefficients of maternal radionuclide include effects of daughter ones. But if migratory characteristics of mother and daughter radionuclides differ significantly it may be necessary to model daughter radionuclides explicitly.

There is the mode splitting mechanism in the POM to use appropriate time steps for fast external gravity waves and slow internal gravity waves (internal and external modes). As the variability of radionuclides concentration fields can differ significantly from variability of fields of currents, salinity, temperature it is reasonable to develop further the mode splitting and to develop the «radioactivity mode» (the analogue of the «internal mode») enabling calculation of transport of radioactivity with a different time step.

To take into account the transport of sorbed radioactive substances it is necessary to take into consideration the processes of particle sedimentation, resuspension and transport of suspended particles and of course processes of sorption and desorption of radioactivity on suspended matter. The coupling of sediment transport model with the POM model was done by Dr. Wang (Wang, 2002; Wang et al., 2005).

Let us assume that transport of radioactivity sorbed on different fractions of suspended matter can be described with the use of one effective fraction of suspended matter with the effective sorption and physical characteristics. The models taking into account several fractions of suspended matter are similar. They are more detailed but more vulnerable to inaccuracies due to uncertainty in the values of characteristics of all of the fractions.

Explicit dynamic modelling of sorption and desorption is the difficult problem because even in case of first-order approximation of the processes there are three parameters (the rates of reversible sorption, irreversible sorption and the rate of desorption) that are unknown functions of the chemical composition of the water and suspended particles. Accurate assessment of the sorption and desorption rates is a complex problem.

Fortunately, in many cases explicit modelling of the sorption and desorption processes can be avoided. Equilibrium between radionuclides sorbed on suspended particles and in solution is reached relatively quickly (from hours to tens of hours) (Ferronski 1977; Venicianov, 1983). The assumption of the equilibrium enables one to model migration of sorbed radioactive substances with the use of distribution factors. Values of the factors can be measured or if it is impossible they can be estimated on the base of recommendations of the International Atomic Energy Agency (IAEA, 2001).

In this case following expressions can be used:

$$C_{sorbed} = K_d C_{dissolved} \quad (1)$$

$$C = S_{eff} C_{sorbed} + C_{dissolved} \quad (2)$$

$$Q = K_d S_{eff} Q_{suspended\_matter} + Q_{dissolved} \quad (3)$$

Where: C – total specific activity of a radionuclide in the water, Bq/m^3; $C_{dissolved}$ – specific activity of the dissolved phase, Bq/m^3; C_{sorbed} – specific activity of the sorbed phase, Bq/kg; Q – total flux of a radionuclide, Bq/s; $Q_{dissolved}$ – flux of a radionuclide in the dissolved state, Bq/s; $Q_{suspended\_matter}$ – effective flux of suspended matter, kg/s; K_d – distribution coefficient, m^3/kg; S_{eff} – effective concentration of the suspended matter, kg/m^3.

Interaction between the radioactivity in the boundary layer and in the seabed can be taken into consideration by the boundary conditions. The principal processes on this border are particle sedimentation and resuspension. Diffusive mass-transfer between seabed and water is usually less significant.

And at last but not least, it is necessary to take into account that many-hour simulation can be unacceptable in case of real accident when decisions are to be made very promptly. Prompt modelling of radioactivity transport in some cases can be achieved by separating calculation of radioactivity transport from calculation of currents and transport of particles. I.e. it is reasonable to develop capability of calculation of radioactivity transport with the use of calculated beforehand varying in time current fields.

The improved computational code was used to model consequences of the hypothetical radioactivity discharge into the Sayda Bay and White Sea. To model tides we have developed the subroutine taking into account 21 fundamental harmonics (Rotter, 2000). It can be used for other sites if parameters for the harmonics are known. The tide model was successfully validated against the data of water levels at the Yekateriniskaya Harbor (69.2000° N, 33.4667° E) and Port Kem (64.9833° N, 34.7833° E), using data provided at http://www.mobilegeographics.com/.

Calculations for the Sayda Bay

Wind and tidal forcing was taken into account. As it was mentioned above, the main objective of modelling the Sayda Bay was to find out possibility of quick transport by sea of significant quantity of radioactivity out from the Sayda Bay in case of an accident at the temporary storage facility of reactor units. Thus the modelling period of several days is most important because this time is necessary to establish full-scale radiation control in the Sayda Bay and taking appropriate population and environmental protecting measures.

The uniform computational grid with 89 steps (63m each) from East to West and 77 steps (66 m each) from South to North was used. In vertical direction non-uniform sigma coordinate computational grid with 7 steps from water surface to bottom was used. Outline of the modelling area is shown at the Figure 3. Southwest part of the area was chosen for more detailed analysis.

The velocity fields and spatial distribution of radioactivity were calculated for a 120 hours period after the accident. The source of radioactivity was considered instantaneous, located near the sea surface and comparable in order of magnitude with the radioactive inventory of a reactor unit of a nuclear submarine.

The sorption and radioactive decay were not taken into account. Neglecting sorption approach will be accurate for radionuclides tending to migrate in solute (strontium, technetium, uranium, iodine, tritium, etc). For radionuclides tending to be sorbed on particles (plutonium, cesium, cobalt, etc) it can lead to somewhat over-dispersion of the radioactivity.

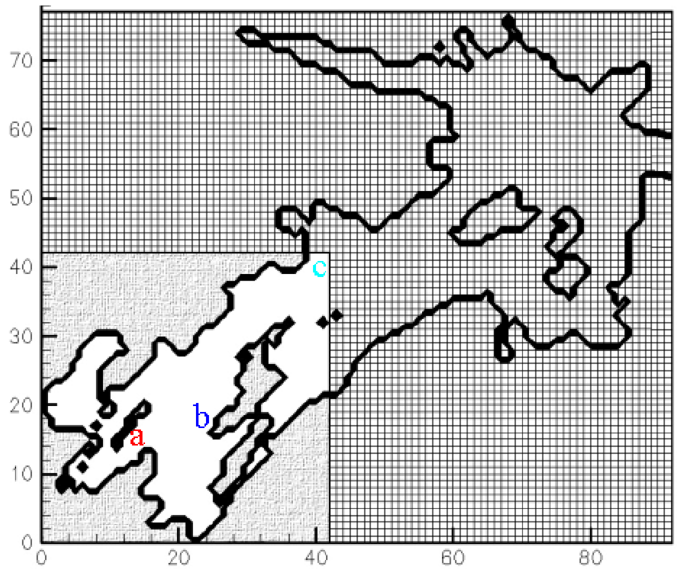

Fig 3. Outline of the modelling area. The red ("a") point indicates the place of the hypothetical accident. The blue ("b") and the pale blue ("c") indicate reference points at the distance of 570 and 2300 meters from the point of accident accordingly.

As it was mentioned above, for instantaneous sources it is important to spin up the model before adding the radioactivity. Concentration of the radioactive substance was calculated for the Southwest part of the Sayda Bay in one and in five days after the hypothetical accident. The calculation results have shown that two and five days of the preliminary spin up gave almost identical results. Therefore two days of spin up are enough for the scale of the Sayda Bay and all subsequent modelling was conducted with two days of preliminary spin-up.

The modelling was conducted for different weather conditions and tide phases in the period of the hypothetical accident. Figure 4 shows that the accident, taking place in the time of low-tide results in much wider dispersion of radioactivity than the one, taking place in the time of high-tide. The influence of wind direction and speed on the processes of radioactivity dispersion in the bay has been estimated. Calculations showed that these factors have significantly less influence than tidal effects.

In addition, we calculated the area of radioactive contamination of the bay with the values of the concentration of radioactive substances exceeding certain prescribed standard. As one of the options of such calculations it was assumed that the total activity of ^{137}Cs in water revenues in the accident was 37 TBq (1 kCi). Further, based on the allowable concentration of this nuclide in foods intended for international trade (1 kBq / kg) (IAEA, 2003) and the factor of accumulation of ^{137}Cs in marine fish in comparison with its content in sea water (100 times) (IAEA, 2001), it was found that within 5 days after the accident, the area of the bay with a water contaminated above allowable level will not exceed 2-5% of its total land area (depending on the time of the accident with regard to tidal currents and surface wind velocity). In addition, this area of contamination would be far from the bay mouth and radioactivity will not be discharged into the open part of the Barents Sea.

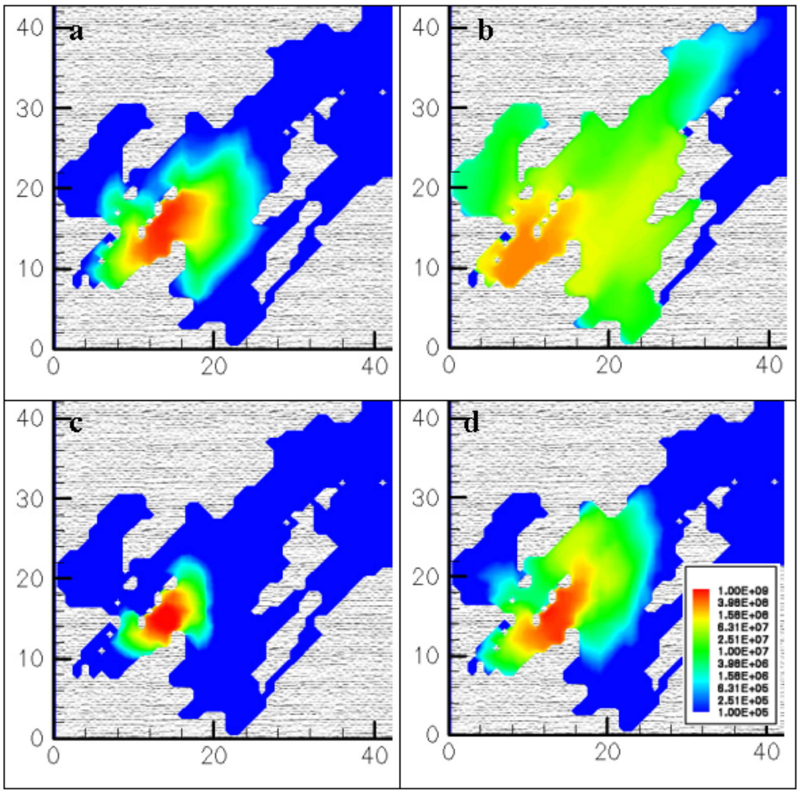

Fig 4. Predicted radioactive pollution of the surface layer depending on the phase of tide at the moment of accident, rel. units. No wind. "a" and "b" – low-tide (0,67 m). "c" and "d" - high-tide (3,56 m). "a" and "c" – 24 hours after the accident. "b" and "d" – 120 hours after the accident.

Calculations for the White Sea

Testing of the calculation module was implemented also for the White Sea. Calculations were performed on two versions of a computational grid with the number of cells 91*93 and 182*186, with the size of cells varied from 3.5 – 5.0 to 1.7 – 2.5 km. With the increase in cell size and the large area of the calculated zone, it was decided to increase also the duration of the pre-calculations, which amounted to 10 days. One of the variants of the calculations is shown in Figure 5. The calculations assumed that the intake of radioactive material occurs in August during the peak of the tidal wave and wind speed above the sea surface amounting to10 m. The wind direction - from the Gorlo strait into the sea. As it is clear from the Figure for this variant of calculation the contamination spot moves along the south-eastern part of Kola Peninsula due to the continuous surface current in this sea area and wind-induced recession. Calculations on the size of contamination zone, with the values of ^{137}Cs concentration in sea water above allowable levels, similar to those described above for the Sayda Bay, showed that within a few days the size of such zone is practically reduced to zero, which is connected with a significantly large scale of actual mixing zone of sea water.

Analysis of simulation of contaminants dispersion in the marine environment by the example of the small sized Sayda Bay showed that tides appear to be the main factor affecting the speed of dispersion processes, especially in the first few days after the accident.

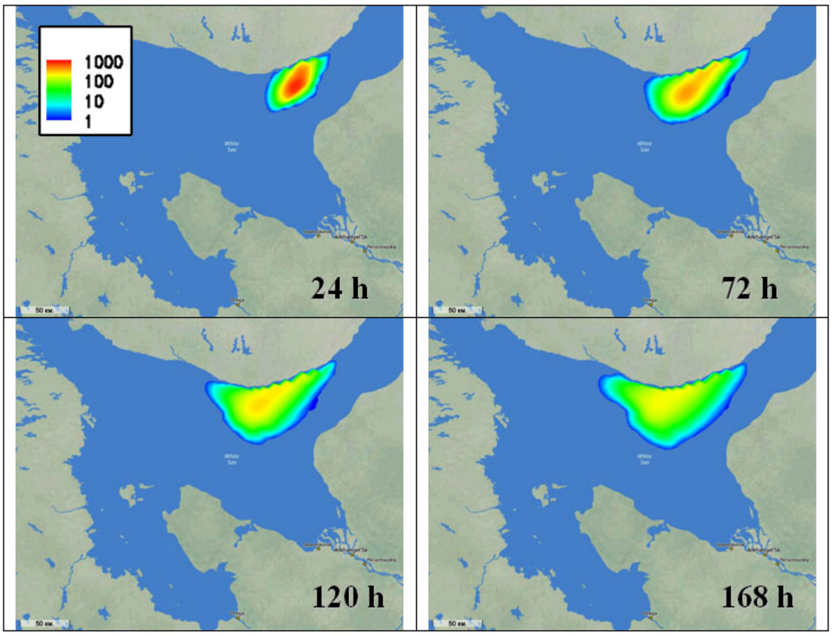

Fig 5. Calculated values of radionuclide concentrations in the surface layer of the White Sea, depending on the time after the emergency discharge, rel. units.

As far as modelling of the hydrological processes in the White Sea are concerned, besides the tide currents the significant factors are the gradients of the temperature and salinity as well as stable currents.

Conclusions

Modelling of the contaminant dispersion processes in the Sayda Bay and water area of the White Sea has shown that the improved computational code gives reasonable results on radioactivity transport in the marine environment. In the present state the model is applicable for periods up to several days for radioactive substances that tend to be sorbed by particles and for longer periods for substances that tend to migrate in the solute.

From the author's point of view the most important tasks for the future are:

- to study the influence of air and water temperatures at various sea depths on the change of rates of contaminant dispersion;
- to implement validation of the hydrodynamic model based on measurements of the sea surface elevation, fields of the currents velocities and salinity in different parts of the White Sea;
- to make possible modelling of radioactive decay and separate migration of maternal and daughter radionuclides if their sorption characteristics differ significantly;
- to enable modelling of radioactivity transport on suspended particles and to enable the use of fields of currents calculated beforehand.

Clement, Christopher
International Commission on Radiological Protection (ICRP)

Abstract
This paper focuses on ICRP *Publication 103*, the 2007 Recommendations of the International Commission on Radiological Protection, which lays out the system of radiological protection for all exposure situations and exposure types. In addition, subsequent ICRP publications which delve more deeply into specific aspects of this system are reviewed to some extent, including: ICRP *Publication 104* Scope of Radiological Protection Control Measures; ICRP *Publication 105*, Radiological Protection in Medicine; ICRP *Publication 108*, Environmental Protection — the Concept and Use of Reference Animals and Plants; ICRP *Publication 109*, Application of the Commission's Recommendations for the Protection of People in Emergency Exposure Situations; and an ICRP publication in press titled Application of the Commission's Recommendations to the Protection of People Living in Long Term Contaminated Areas After a Nuclear Accident or a Radiation Emergency.

Introduction
The International Commission on Radiological Protection (ICRP) is an independent, international organization that advances for the public benefit the science of radiological protection, in particular by providing recommendations and guidance on all aspects of protection against ionizing radiation.

ICRP was established in 1928 by the International Society of Radiology (ISR) to respond to growing concerns about the effects of ionizing radiation being observed in the medical community.

In preparing its recommendations, ICRP considers the fundamental principles and quantitative bases upon which appropriate radiation protection measures can be established, while leaving to the various national protection bodies the responsibility of formulating the specific advice, codes of practice, or regulations that are best suited to the needs of their individual countries.

ICRP offers its recommendations to regulatory and advisory agencies and provides advice the intended to be of help to management and professional staff with responsibilities for radiological protection. Although ICRP itself has no formal power to impose its recommendations, in fact legislation in most countries adheres closely to ICRP recommendations. In addition, the International Atomic Energy Agency (IAEA) International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources (commonly referred to as "the BSS") is based heavily on ICRP recommendations, and the International Labour Organisation (ILO) Convention 115, Radiation Protection Convention, General Observation 1992, refers specifically to the recommendations of ICRP. Effectively, ICRP recommendations form the basis of radiological protection practice, programmes, regulations, and international standards and guidance worldwide.

ICRP has published well over one hundred publications on all aspects of radiological protection. Most address a particular area within radiological protection, but a handful of publications, the so-called fundamental recommendations, each describe the overall system of radiological protection. The system of radiological protection has been developed by ICRP based on (i) the current understanding of the science of radiation exposures and effects and (ii) value judgements. These value judgements take into account societal expectations, ethics, and experience gained in application of the system.

The 1990 Recommendations of ICRP (ICRP *Publication 60*) form the basis of the current IAEA BSS, and are also the foundation of most radiological protection practices, programmes and regulations worldwide. The 2007 Recommendations of ICRP (ICRP *Publication 103*) recently replaced the 1990 Recommendations. They are the result of nearly a decade of development and several major worldwide public consultations.

The 2007 Recommendations replace the 1990 Recommendations and update, consolidate, and develop additional guidance on the control of exposure from radiation sources issued since 1990. They reflect a more up-to-date understanding of the science behind radiological protection and evolving societal expectations.

The System of Radiological Protection

The system of radiological protection described in the 2007 Recommendations is an evolutionary change from that described in the 1990 Recommendations. This evolution is necessary in order for the system to remain current with our evolving understanding of the relevant scientific findings, and also to continue to reflect current societal norms. For example, the revised radiation and tissue weighting factors reflect updated scientific knowledge, while a greater emphasis on environmental protection reflects a heightened social awareness of the importance of this area. As well, practical application of the system can point out areas for improvement.

What follows is a brief review of the system of radiological protection as described in the 2007 Recommendations and subsequent publications. Much of this is, necessarily, taken almost directly from ICRP *Publication 103*.

Scope

The system of radiological protection applies to all exposures to ionising radiation from any source, regardless of its size and origin. However, the system can apply in its entirety only to situations in which either the source of exposure or the pathways leading to the doses received by individuals can be controlled by some reasonable means. Some exposure situations are excluded from radiological protection legislation, usually on the basis that they are unamenable to control with regulatory instruments, and some exposure situations are exempted from some or all regulatory requirements where such controls are regarded as unwarranted. ICRP *Publication 104* elaborates on the scope of radiological protection control measures.

Health effects of ionising radiation

An understanding of the health effects of ionising radiation is central to the system of radiological protection. Following a review of the biological and epidemiological information on the health risks attributable to ionising radiation ICRP concluded that the distribution of risks to different organs/tissues has changed somewhat since 1990. However, assuming a linear response at low doses, the combined detriment due to excess cancer and heritable effects remains essentially unchanged at around 5% per Sv (see Table 1). Embodied in this current estimate is the use of a dose and dose-rate effectiveness factor for solid cancers which is unchanged at a value of 2. In addition, following prenatal exposure, the cancer risk will be similar to that following irradiation in early childhood, and a threshold dose exists for the induction of malformations and for the expression of severe mental retardation.

The assumption of a linear dose–response relationship for the induction of cancer and heritable effects, according to which an increment in dose induces a proportional increment in risk even at low doses, continues to provide the basis for the summation of doses.

Table 1. Detriment-adjusted nominal risk coefficients (10^{-2} Sv^{-1}) for stochastic effects after exposure to radiation at low dose rate.

Exposed population	Cancer	Heritable effects	Total
Whole	5.5	0.2	5.7
Adult	4.1	0.1	4.2

From ICRP *Publication 103*, Table 1.

Dose limits

The dose limits (see Table 2) remain unchanged from those recommended in 1990. However, it is recognized that further information is needed and revised judgements may be required particularly in respect of the lens of the eye. In addition, emerging data on possible excess risk in non-cancer diseases (e.g., cardiovascular disorders) are being watched closely.

Table 2. Dose limits in planned exposure situations.

Type of Dose Limit	Occupational	Public
Effective dose	20 mSv per year, averaged over defined periods of 5 years, and 50 mSv in any single year[a]	1 mSv in a year
Annual eququivalent dose in: Lens of the eye Skin Hands and feet	 150 mSv 500 mSv 500 mSv	 15 mSv 50 mSv –

[a] Additional restrictions apply to the occupational exposure of pregnant women.
From ICRP *Publication 103*, Table 6.

The use and calculation of equivalent and effective dose

Effective dose is intended for use as a protection quantity. The main uses of effective dose are the prospective dose assessment for planning and optimisation in radiological protection, and demonstration of compliance with dose limits for regulatory purposes.

Although the use of equivalent and effective dose remains unchanged, a number of revisions have been made to the methods used in their calculation. Reviews of the range of available data on the relative biological effectiveness of different radiations, together with biophysical considerations, have led to changes to some of the values of radiation weighting factors (see Table 3 and Figure 1). In addition, the distribution of risks to different organs/tissues has changed somewhat since 1990, particularly in respect of the risks of breast cancer and heritable disease, resulting in revised tissue weighting factors (see Table 4) intended to apply as rounded values to a population of both sexes and all ages.

Another change is that doses from external and internal sources will be calculated using reference computational phantoms of the human body based on CT images (the first appearing in ICRP *Publication 110*), replacing the use of various mathematical models. For adults, equivalent doses will be calculated by sex-averaging of values obtained using male and female phantoms.

Note that calculation of equivalent and effective dose use models and parameters selected from a range of experimental investigations and human studies through judgements, and meant to apply to a population rather than individuals. For individual retrospective dose and risk assessments, individual parameters and uncertainties have to be taken into account.

Collective effective dose is used for optimisation, predominantly in the context of occupational exposure. It is not intended as a tool for epidemiological risk assessment, and it is inappropriate to use it in risk projections. The aggregation of very low individual doses over extended time periods is inappropriate, and in particular, the calculation of the number of cancer deaths based on collective effective doses from trivial individual doses should be avoided.

Table 3. Radiation weighting factors.

Radiation type	Radiation Weighting Factor, w_R
Photons	1
Electrons and muons	1
Protons and charged pions	2
Alpha particles, fission fragments, heavy ions	20
Neutrons	A continuous function of neutron energy (See Figure 1)

From ICRP *Publication 103*, Table 2.

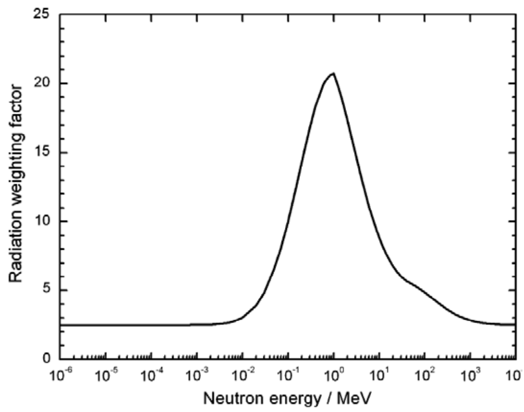

Fig. 1. Radiation weighting factor, w_R, for neutrons versus neutron energy (from ICRP *Publication 103*, Fig.1).

Table 4. Tissue weighting factors.

Tissue	Tissue weigting factor, w_T	$\sum w_T$
Bone-marrow (red), Colon, Lung, Stomach, Breast, Remainder tissues*	0.12	0.72
Gonads	0.08	0.08
Bladder, Oesophagus, Liver, Thyroid	0.04	0.16
Bone surface, Brain, Salivary glands, Skin	0.01	0.04
TOTAL		1.00

* Remainder tissues: Adrenals, Extrathoracic (ET) region, Gall bladder, Heart, Kidneys, Lymphatic nodes, Muscle, Oral mucosa, Pancreas, Prostate (male), Small intestine, Spleen, Thymus, Uterus/cervix (female). From ICRP *Publication 103*, Table 3.

Planned, existing and emergency exposure situations

The system of radiological protection described in the 2007 Recommendations recognises planned, existing and emergency exposure situations. These are intended to cover the entire range of exposure situations, and replace the previous categorisation into practices and interventions.

Planned exposure situations (which include situations previously categorised as practices) encompass sources and situations that have been appropriately managed within the system of radiological protection. Protection during medical uses of radiation is also included in this type of exposure situation. Recommendations for planned exposure situations are substantially unchanged from these provided previously.

Existing exposure situations include naturally occurring exposures as well as exposures from past events and accidents, and practices conducted outside the system of radiological protection. In this type of situation, protection strategies will often be implemented in an interactive, progressive manner over a number of years.

Indoor radon in dwellings and workplaces is an important existing exposure situation, and is the subject of current high-priority work for ICRP. In November 2009 ICRP issued a Statement on Radon. The intention is to publish this Statement in the Annals of the ICRP with an accompanying report on assessment of lung cancer risk from radon, after undertaking a public consultation on the two documents together.

The statement reaffirms that, for planned exposure situations, any workers' exposure to radon incurred as a result of their work, however small, shall be considered as occupational exposure. However, because of the ubiquity of radiation, the direct application of this definition to radiation would mean that all workers should be subject to a regime of radiological protection. Therefore the use of 'occupational exposures' is limited to radiation exposures incurred at work as a result of situations that can reasonably be regarded as being the responsibility of the operating management.

Emergency exposure situations include consideration of emergency preparedness and emergency response. Emergency preparedness should include planning for the implementation of optimised protection strategies which have the purpose of reducing exposures, should the emergency occur, to below the selected value of the reference level. During emergency response, the reference level would act as a benchmark for evaluating the effectiveness of protective actions and as one input into the need for establishing further actions.

Occupational, public and medical exposures

The system of radiological protection continues to distinguish among three categories of exposure: occupational, public, and medical. Table 5 shows these three categories of exposure, the three exposure situations, and the dose constraints and reference levels applicable in each circumstance.

Table 5. Dose constraints and reference levels used in the system of radiological protection.

Type of situation	Occupational exposure	Public Exposure	Medical Exposure
Planned exposure	Dose limit Dose constraint	Dose limit Dose constraint	Diagnostic reference level (Dose constraint[b])
Emergency exposure	Refrerence level	Reference level	n/a
Existing exposure	n/a[a]	Reference level	n/a

[a] Exposures resulting from long-term remediation operations or from protracted employment in affected areas should be treated as part of planned occupational exposure, even though the source of radiation is 'existing'.
[b] Comforters, carers, and volunteers in research only.
From ICRP *Publication 103*, Table 4.

Fundamental principles of radiological protection

The three key principles of radiological protection have remained unchanged in the 2007 Recommendations. The principles of justification and optimisation apply in all exposure situations. The principle of application of dose limits applies only for doses expected to be incurred with certainty as a result of planned exposure situations. These principles are defined as follows:

- The Principle of Justification: Any decision that alters the radiation exposure situation should do more good than harm.
- The Principle of Optimisation of Protection: The likelihood of incurring exposure the number of people exposed, and the magnitude of their individual doses should all be kept as low as reasonably achievable, taking into account economic and societal factors.
- The Principle of Application of Dose Limits: The total dose to any individual from regulated sources in planned exposure situations other than medical exposure of patients should not exceed the appropriate limits specified by the Commission.

Emphasis on optimisation

The 2007 Recommendations emphasise the key role of the principle of optimisation. This principle should be applied in the same manner in all exposure situations. Restrictions are applied to doses to a nominal individual (the Reference Person), namely dose constraints for planned exposure situations and reference levels for emergency and existing exposure situations. Options resulting in doses greater in magnitude than such restrictions should be rejected at the planning stage. Importantly, these restrictions on doses are applied prospectively, as with optimisation as a whole. If, following the implementation of an optimised protection strategy, it is subsequently shown that the value of the constraint or reference level is exceeded, the reasons should be investigated but this fact alone should not necessarily prompt regulatory action. This emphasis on a common approach to radiological protection in all exposure situations should aid application of the system of radiological protection in the various circumstances of radiation exposure.

Table 6. Framework for source-related dose constraints and reference levels with examples of constraints for workers and the public from single dominant sources for all exposure situations that can be controlled.

Bands of constraints and reference levels[a] (mSv)	Characteristics of the exposure situation	Radiological protection requirements	Examples
Greater than 20 to 100	Individuals exposed by sources that are not controllable, or where actions to reduce doses would be disproportionately disruptive. Exposures are usually controlled by action on the exposure pathways.	Consideration should be given to reducing doses. Increasing efforts should be made to reduce doses as they approach 100 mSv. Individuals should receive information on radiation risk and on the actions to reduce doses. Assessment of individual doses should be undertaken.	Reference level set for the highest planned residual dose from a radiological emergency.
Greater than 1 to 20	Individuals will usually receive benefit from the exposure situation but not necessarily from the exposure itself. Exposures may be controlled at source or, alternatively, by action in the exposure pathways.	Where possible, general information should be made available to enable individuals to reduce their doses. For planned situations, individual assessment of exposure and training should take place.	Constraints set for occupational exposure in planned situations. Constraints set for comforters and carers of patients treated with radiopharmaceuticals. Reference level for the Highest planned residual dose from radon in dwellings.
1 or less	Individuals are exposed to a source that gives them little or no individual benefit but benefits to society in general. Exposures are usually controlled by action taken directly on the source for which radiological protection requirements can be planned in advance.	General information on the level of exposure should be made available. Periodic checks should be made on the exposure pathways as to the level of exposure.	Constraints set for public exposure in planned situations.

[a] Acute or annual dose.
From ICRP *Publication 103*, Table 5.

The relevant national authorities will often play a major role in selecting values for dose constraints and reference levels. Guidance on the selection process is provided by recommending bands of constraints and reference levels (see Table 6).

Emphasis on optimisation using reference levels in emergency and existing exposure situations focuses attention on the residual level of dose remaining after implementation of protection strategies. This residual dose should be below the reference level, which represents the total residual dose as a result of an emergency, or in an existing situation, that the regulator would plan not to exceed. These exposure situations often involve multiple exposure pathways so protection strategies involving a number of different protective actions will have to be considered. However, the process of optimisation will continue to use the dose averted by specific countermeasures as an important input into the development of optimised strategies.

Radiological protection of the environment

In the past, ICRP concerned itself with the environment primarily with regard to the transfer of radionuclides through it because this directly affects the radiological protection of human beings. In the 1990 Recommendations ICRP stated that "the standard of environmental control needed to protect man ... will ensure that other species are not put at risk. Occasionally, individual members of non-human species might be harmed, but not to the extent of endangering whole species or creating imbalance between species."

However, in its 2007 Recommendations, ICRP acknowledges that that it is now necessary to demonstrate, directly and explicitly, that the environment is being protected. Therefore, it is necessary to develop a clearer framework to assess the relationships between exposure and dose, and between dose and effect, and the consequences of such effects, for non-human species, on a common scientific basis. This is further developed in ICRP *Publication 108*.

Recent ICRP Publications which Further Elaborate the System of Radiological Protection

ICRP *Publication 104*: Scope of Radiological Protection Control Measures

In principle the system of radiological protection applies to all exposures to ionizing radiation. However, in practice the measures undertaken to control these exposures must be limited based on practical considerations. ICRP *Publication 104* discusses the scope of radiological protection control measures, and describes certain tools (e.g. exemption, exclusion and clearance) that can be used to manage the scope.

ICRP *Publication 108*: Environmental Protection – the Concept and Use of Reference Animals and Plants

The 2007 Recommendations acknowledge that that it is now necessary to demonstrate, directly and explicitly, that the environment is being protected, rather than simply assume that adequate protection of humans is sufficient to protect the environment. Therefore, it is necessary to develop a clearer framework to assess the relationships between exposure and dose, and between dose and effect, and the consequences of such effects, for non-human species, on a common scientific basis.

To this end, ICRP *Publication 108* sets out some high-level ambitions with regard to environmental protection. To aid in demonstrating whether these ambitions are being achieved, and help optimise the level of effort that might be expended on environmental protection, and ICRP has developed a set of Reference Animals and Plants (RAPs) and derived consideration reference levels (DCRLs). ICRP does not propose the application of dose limits to Reference Animals and Plants.

Recent ICRP Publications Elaborating on Specific Exposure Categories and Situations

One of the first publications following the 2007 Recommendations was ICRP *Publication 105* on Radiological Protection in Medicine. This publication describes the application of the system of radiological protection for medical exposures, an exposure category quite different from occupational and public exposures by virtue of the fact that most of the time, most of the benefit and the detriment apply to a single individual: the patient. In the other two exposure categories, typically one group receives most of the detriment (e.g. the workers in a facility), while another group receives most of the benefit (e.g. the public at large receiving electrical power).

Two publications each examine one of the three exposure situations: ICRP *Publication 109* examines emergency exposure situations, and the ICRP publication in press titled Application of the Commission's Recommendations to the Protection of People Living in Long Term Contaminated Areas after a Nuclear Accident or a Radiation Emergency examines the system of radiological protection as applied to existing exposure situations.

Other Current Initiatives and Future Work

For more information on current and future work of ICRP the reader is referred to another paper prepared for this congress by the same author titled “International Commission on Radiological Protection – recent publications, current initiatives and future work”.

Acknowledgements

Preparation of this paper drew extensively on the hard work of ICRP members through several ICRP publications shown in the references section. The author would like to acknowledge the dedication of those ICRP members who contributed to these publications, and thus recognize their important contribution to this paper.

Abstract
Quantitative assessments of external and internal exposure need reasonable state-of-the-art physical / biological / ecological models and reliable quantities and measurement methods and instruments. Fundamental basis for dose and activity measurements are solid instruments and adequate measurement methods.

In this paper, the appropriate quantities and units as far as necessary measurement chains to assure traceability from international primary standards to end-user measurement facilities are given. The basic concepts and practical implementation of uncertainty assessments in activity and dose measurements methods are presented. Finally main aspects of quality assurance in the field of radiation protection measurements are discussed.

The target group for this information are newcomers as far as experienced radiation protection experts, radionuclide and dosimetry metrologists and end-user of measurement instruments in radiation protection.

Introduction
Accurate and high-quality measurements of ionizing radiation and radionuclide activities are required in a wide range of industrial, scientific and medical applications where they are critical relating to human health and safety. Dose and activity measurements for radiation protection are stringent in its accuracy and reliability requirements. Generally this means that the uncertainty of measurements for radiation protection around the internationally agreed dose limits should not exceed a few percent.

To provide an international metrological basis for measurements in radiation protection and other sectors (e.g. medical diagnostics and therapy), the 11th *General Conference of the Meter Convention* decided to establish the Ionizing Radiation section at the *Bureau International des Poids et Mesures*, BIPM, in 1960.

The main activities of the BIPM in the field of ionizing radiation are to maintain the international reference standards for dose and activity measurements [1]. These standards are used in the BIPM key comparisons and their development and improvement is a major part of the international metrological research and development programme. The ionising radiation section of the BIPM also undertakes calibrations for national laboratories, and participates in international comparisons.

At the European level *European Association of National Metrology Institutes* EURAMET is acting as the regional metrolo¬gical organisation. It is coordinating the metrological activities of the European National Metrology Institutes (NMI's) and Designated Institutes (DI's) of the European Union including the Joint Research Centres of the European Commission, EFTA and EU Accession States. The objective of EURAMET is to promote the coordination and development of metrological activities and services and support the European Metrology Research Programme EMRP. EURAMET is working in Technical Committees; on of them is the TC Ionising Radiation. This TC is divided the Sub-Fields photon dosimetry, radioactivity, and neutron measurements. The basic activities are jointly done by co-operative scientific and technical projects e.g. joint research projects and comparisons.

In Fig. 1 the international, European and national (for example the Austrian) organisations supporting the quality of measurements for radiation protection are schematically shown. In addition to the metrological infrastructure there is a support in legal metrology (International Organization of Legal Metrology OIML; European Cooperation in Legal Metrology WELMEC; national/Austria: Federal Office for Metrology and Surveying BEV) and for accreditation (International Laboratory Accreditation Cooperation ILAC; European co-operation for Accreditation EA; National/Austria: Federal Ministry of Economy, Family and Youth, BMWFJ) established.

Fig. 1. International, European and national metrological infrastructure.

Fig. 2 shows the international organisations and network between society's and economics' needs together with science and technological support for the provision of quality in measurements. Additional to ILAC the *International Accreditation Forum, Inc. (IAF)* acts as the world association of Conformity Assessment Accreditation Bodies and other bodies interested in conformity. In the field of technological standardisation the *International Electrotechnical Commission* IEC (Technical Committee 45 *Nuclear* *instrumentation*, Sub Committee 45B *Radiation protection instrumentation*), the *International Organisation for Standardisation* ISO (Technical Committee 85 *Nuclear Energy*, Sub Committee 2 *Radiation Protection*) and the *Telecommunication Standardization Sector of the International Telecommunication Union* ITU-T (for non-ionising radiation) support the development and implementation of measurement radiation protection instruments and methods.

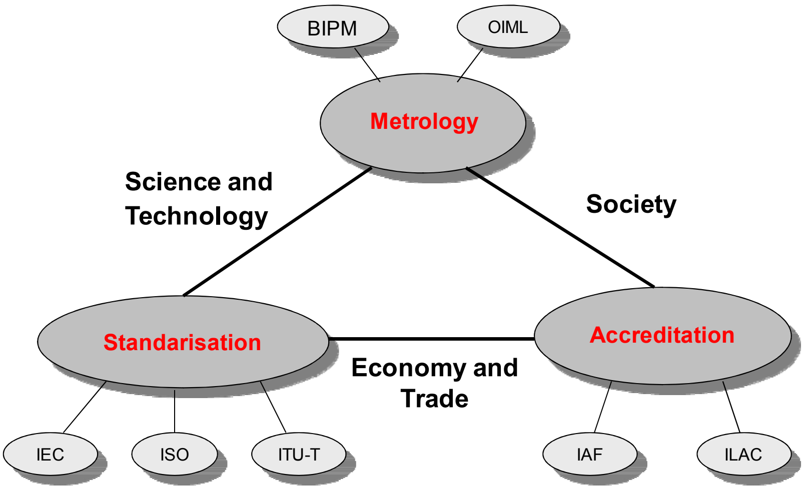

Fig. 2. International organisations and network to ensure quality in measurements.

Basic metrological items and its definitions

In this section the most significant basic definitions of items for metrology and measurement are given. The items / definitions are largely compatible to them given in the International Vocabulary in Metrology (ISO/IEC, 2007; VIM, 2008).

Quantity

… Property of a phenomenon, body, or substance, where the property has a magnitude that can be expressed as a number and a reference.

A reference can be a measurement unit, a measurement procedure, a reference material, or a combination of such. Symbols for quantities are given in ISO 80000 and IEC 80000 series Quantities and Units.

Measurement unit; unit

… Real scalar quantity, defined and adopted by convention, with which any other quantity of the same kind can be compared to express the ratio of the two quantities as a number.

Measurement units are designated by conventionally assigned names and symbols. In some cases special measurement unit names are restricted to be used with quantities of a specific kind only. For example, the measurement unit ‘second to the power minus one’ (1/s) is called hertz (Hz) when used for frequencies and becquerel (Bq) when used for activities of radionuclides.

Metrological traceability; traceability

… Property of a measurement result whereby the result can be related to a reference through a documented unbroken chain of calibrations, each contributing to the measurement uncertainty.

For this definition, a 'reference' can be a definition of a measurement unit through its practical realization, or a measurement procedure including the measurement unit for a non-ordinal quantity, or a measurement standard. The abbreviated term "traceability" is sometimes used to mean 'metrological traceability'. The full term of "metrological traceability" is preferred if there is any risk of confusion.

Metrological traceability chain; traceability chain

… Sequence of measurement standards and calibrations that is used to relate a measurement result to a reference.

A metrological traceability chain is defined through a calibration hierarchy.

Metrological traceability to a measurement unit; metrological traceability to a unit

… Metrological traceability where the reference is the definition of a measurement unit through its practical realization.

The expression "traceability to the SI" means 'metrological traceability to a measurement unit of the International System of Units'.

Calibration

… Operation that, under specified conditions, in a first step, establishes a relation between the quantity values with measurement uncertainties provided by measurement standards and corresponding indications with associated measurement uncertainties and, in a second step, uses this information to establish a relation for obtaining a measurement result from an indication.

A calibration may be expressed by a statement, calibration function, calibration diagram, calibration curve, or calibration table. In some cases, it may consist of an additive or multiplicative correction of the indication with associated measurement uncertainty. Calibration should not be confused with adjustment of a measuring system, often mistakenly called "self-calibration", nor with verification of calibration. Often, the first step alone in the above definition is perceived as being calibration.

Calibration hierarchy

… Sequence of calibrations from a reference to the final measuring system, where the outcome of each calibration depends on the outcome of the previous calibration.

Measurement uncertainty necessarily increases along the sequence of calibrations. The elements of a calibration hierarchy are one or more measurement standards and measuring systems operated according to measurement procedures. For this definition, the 'reference' can be a definition of a measurement unit through its practical realization, or a measurement procedure, or a measurement standard.

Measurement standard; etalon

… Realization of the definition of a given quantity, with stated quantity value and associated measurement uncertainty, used as a reference

A "realization of the definition of a given quantity" can be provided by a measuring system, a material measure, or a reference material. A measurement standard is frequently used as a reference in establishing measured quantity values and associated measurement uncertainties for other quantities of the same kind, thereby establishing metrological traceability through calibration of other measurement standards, measuring instruments, or measuring systems.

A primary measurement standard is a measurement standard established using a primary reference measurement procedure, or created as an artifact, chosen by convention (eg. Kilogramm artefact) than again a secondary measurement standard is established through calibration with respect to a primary measurement standard for a quantity of the same kind.

Measurement uncertainty; uncertainty

… Non-negative parameter characterizing the dispersion of the quantity values being attributed to a measurand, based on the information used.

Notes:

Measurement uncertainty includes components arising from systematic effects, such as components associated with corrections and the assigned quantity values of measurement standards, as well as the definitional uncertainty. Sometimes estimated systematic effects are not corrected for but, instead, associated measurement uncertainty components are incorporated. The parameter may be, for example, a standard deviation called standard measurement uncertainty (or a specified multiple of it), or the half-width of an interval, having a stated coverage probability.

Measurement uncertainty comprises, in general, many components. Some of these may be evaluated by Type A evaluation of measurement uncertainty from the statistical distribution of the quantity values from series of measurements and can be characterized by standard deviations. The other components, which may be evaluated by Type B evaluation of measurement uncertainty, can also be characterized by standard deviations, evaluated from probability density functions based on experience or other information (ISO/IEC Guide 98-3:2008).

Does quantities and their units

In this section the most significant quantities and units used for radiation protection purposes are assembled. The given items and their definitions are compiled from current international standards and documents (ICRU, 1985; 1998; IEC 60050-393, 2003; IAEA, 2007; ICRP 103, 2007; ISO 12749-1, 2010).

Absorbed dose, *D*

… Quotient of $\mathrm{d}\bar{\varepsilon}$ by d*m*, where $\mathrm{d}\bar{\varepsilon}$ is the mean energy imparted to matter of mass d*m* thus

$$D = \frac{\mathrm{d}\bar{\varepsilon}}{\mathrm{d}m} \tag{1}$$

The unit of absorbed dose is J·kg^{-1}. The special name for the unit of absorbed dose is gray (Gy). The mean energy imparted $d\bar{\varepsilon}$ is the expectation value of the energy imparted by ionizing radiation to the matter in a given volume. The unit of the mean energy imparted is J.

dose equivalent, *H*

… Product of *D* and *Q* at a point in tissue, where *D* is the absorbed dose and *Q* is the quality factor for the specific radiation at this point, thus

$$H = D \cdot Q \tag{2}$$

The unit of dose equivalent is joule per kilogram (J kg^{-1}), and its special name is sievert (Sv).

Ambient dose equivalent, *H**(*d*)

… Dose equivalent that would be produced by the corresponding aligned and expanded field in the ICRU sphere at a depth *d* on the radius opposing the direction of the aligned field.

This quantity is defined at a point in a radiation field and is used as directly measurable proxy (i.e. substitute) for effective dose for use in monitoring of external exposure. The recommended value of d for strongly penetrating radiation is 10 mm.

The ICRU sphere is a sphere with 30 cm diameter consists of ICRU tissue. This is a material with a density of 1 g cm^{-3} and a mass composition of 76,2 % oxygen, 10,1 % hydrogen, 11,1 % carbon, and 2,6 % nitrogen (ICRU 39, 1985)

Directional dose equivalent, $H'(d, \vec{\Omega})$

… Dose equivalent that would be produced by the corresponding expanded field in the ICRU sphere at a depth *d* on a radius in a specified direction $\vec{\Omega}$.

This quantity is defined at a point in a radiation field and is used as directly measurable proxy (i.e. substitute) for equivalent dose in the skin for use in monitoring of external exposure. The recommended value of d for weakly penetrating radiation is 0,07 mm. In practice $\vec{\Omega}$ is chosen in direction of maximum *H*', indicated as *H*'(*d*).

Personal dose equivalent, H_p (*d*)

… Dose equivalent in the 'ICRU sphere' at an appropriate depth, d, below a specified point on the human body.

The unit of personal dose equivalent is joule per kilogram (J·kg^{-1}) and its special name is sievert (Sv). The specified point is usually given by the position where the individual's dosimeter is worn. In most cases of penetrating radiation d = 10 mm is chosen: $H_p(10)$. For weakly penetrating radiation d = 0,07 mm is chosen: $H_p(0{,}07)$. In a unidirectional field, the direction can be specified in terms of the angle, α, between the direction opposing the incident field and a specified normal on the phantom surface.

Effective dose

… Sum of the weighted equivalent doses in all tissues and organs of the body.

The effective dose is expressed in units of joules per kilogram (J·kg^{-1}) with the special name sievert (Sv). The effective dose is not directly measurable. It can be approximated by operational dose equivalent quantities for external exposure and by dose conversion models (dose conversion factors) in the case of intake (inhalation, ingestion) of radionuclides. The effective dose is used in dose limitation / restriction concepts in radiation protection. Effective dose is a measure of dose designed to reflect the amount of radiation detriment likely to result from the dose. Values of effective dose from any type(s) of radiation and mode(s) of exposure can be compared directly.

Activity quantities and their units

In this section the most significant quantities and units used for radiation protection purposes are assembled. The given items and their definitions are compiled from current international standards and documents.

Activity

… Quotient, for an amount of radionuclide in a particular energy state at a given time, of $\langle \mathrm{d}N \rangle$ by d*t*, where $\langle \mathrm{d}N \rangle$ is the expectation value of the number of spontaneous nuclear transitions from this energy state in the time interval of duration d*t*:

$$A = -\frac{\langle \mathrm{d}N \rangle}{\mathrm{d}t} \tag{3}$$

The unit of activity is s^{-1} with the special name *becquerel* (Bq).

Activity concentration;

… Quotient of activity by either the total mass or the total volume of the sample.

This quantity is expressed either in becquerels per kilogram (Bq/kg) or in becquerels per cubic-meter (Bq/m³). For a gas, in some cases it is necessary to indicate the temperature and pressure conditions for which the activity concentration, expressed in becquerel per cubic metre, is measured, for example standard temperature and pressure (STP). For solid material, sometimes it is necessary to indicate the sample moisture or dryness conditions for which the activity concentration, expressed in becquerel per kilogram, is measured, for example Bq/kg material dried at 105 °C.

Specific activity; massic activity

… Quotient of activity by the total mass of the sample.

This quantity is expressed either in becquerels per kilogram (Bq/kg).

The distinction in usage between specific activity and activity concentration is controversial. A common distinction is that specific activity is used with reference to a pure radionuclide (e.g. 1 g ^{226}Ra has the specific activity of 37·10^{9} Bq). Activity concentration (which may be activity per unit mass or per unit volume) is used for any other situation (e.g. when the activity is in the form of contamination in or on a material).

Volumic activity; volumetric activity

… Quotient of the activity by the total volume of the sample.

This quantity is expressed in becquerels per cubic metre (Bq/m^3).

Surface activity

… Quotient of the activity by the total area of surface of the sample.

This quantity is expressed in becquerels per square metre (Bq/m^2).

Measurement uncertainties in radiation protection

In most cases, a measurand Y is not measured directly, but is determined from N other quantities $X_1, X_2, ..., X_N$ through a functional relationship f:

$$Y = f\left(X_1, X_2, ..., X_N\right) \tag{4}$$

An estimate of the measurand Y, denoted by $\bar{y}$, is obtained from Y using input estimates $\bar{x}_1, \bar{x}_2, ..., \bar{x}_N$ for the values of the N quantities $X_1, X_2, ..., X_N$. Thus the output estimate $\bar{y}$, which is the result of the measurement, is given by

$$\bar{y} = f\left(\bar{x}_1, \bar{x}_2, ..., \bar{x}_N\right) \tag{5}$$

When the input quantities are not correlated, the combined standard uncertainty $u_c(\bar{y})$ is the positive square root of the combined variance $u_c^2(\bar{y})$, which is given by

$$u_C(\bar{y}) = \sqrt{\sum_i \left(\frac{\partial f\left(\bar{x}_1, \bar{x}_2, ...\bar{x}_N\right)}{\partial X_i}\right)^2 \cdot u^2\left(\bar{x}_i\right)} \tag{6}$$

When the input quantities are correlated, the appropriate expression for the combined variance $u_c^2(\bar{y})$ associated with the result of a measurement is

$$u_c^2(\bar{y}) = \sum_i \sum_j \frac{\partial f}{\partial X_i} \frac{\partial f}{\partial X_j} \cdot u\left(\bar{x}_i, \bar{x}_j\right) = \sum_i \left(\frac{\partial f}{\partial X_i}\right)^2 u\left(\bar{x}_i\right) + 2\sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \frac{\partial f}{\partial X_i} \frac{\partial f}{\partial X_j} \cdot u\left(\bar{x}_i, \bar{x}_j\right) \tag{7}$$

where $u\left(\bar{x}_i, \bar{x}_j\right) = u\left(\bar{x}_j, \bar{x}_i\right)$ is the estimated covariance associated with $\bar{x}_i$ and $\bar{x}_j$. The degree of correlation between $\bar{x}_i$ and $\bar{x}_j$ is characterized by the estimated correlation coefficient

$$r\left(\bar{x}_i, \bar{x}_j\right) = \frac{u\left(\bar{x}_i, \bar{x}_j\right)}{u\left(\bar{x}_i\right) u\left(\bar{x}_j\right)}$$

where $r\left(\bar{x}_i, \bar{x}_j\right) = r\left(\bar{x}_j, \bar{x}_i\right)$, and $-1 \leq r\left(\bar{x}_i, \bar{x}_j\right) \leq +1$. If the estimates $\bar{x}_i$ and $\bar{x}_j$ are independent, $r\left(\bar{x}_i, \bar{x}_j\right) = 0$, and a change in one does not imply an expected change in the other.

Equation (6) and its counterpart for correlated input quantities, Equation (7), both of which are based on a first-order Taylor series approximation of the measurand Y, express what is termed the law of propagation of uncertainty.

In most cases, the best available estimate of the expectation value $\langle X_i \rangle$ of an input quantity X_i that varies randomly, and for which independent observations have been obtained under the same conditions of measurement, is the arithmetic mean or average $\langle x_i \rangle$ of the observations. Thus, for an input quantity X_i determined from independent repeated observations, the standard uncertainty $u(\bar{x}_i)$ of its best estimate $\langle x_i \rangle$ is $u(\bar{x}_i) = s(\bar{x}_i)$, with $s^2\langle \bar{x}_i \rangle$ is the experimental variance or the estimate of the variance $\sigma^2\langle X_i \rangle$. For convenience, $u^2(\bar{x}_i) = s^2\langle \bar{x}_i \rangle$ and $u(\bar{x}_i) = s\langle \bar{x}_i \rangle$ are sometimes called a Type A variance and a Type A standard uncertainty, respectively.

In Tab. 1 a worksheet for the practical implementation of the measurand's uncertainty estimation from uncorrelated (independent) input quantities based on formula (4) to (6) is given.

Table 1. Worksheet for the estimation of the expanded uncertainty *U* of the output quantity (measurand) *Y* from estimates of independent uncorrelated input quantities X_i.

input quantity	estimate of input quantity	evaluation type	sensitivity coefficient c_i	standard uncertainty	square products
X_i	$\bar{x}_i$	A or B	$\dfrac{\partial f(\bar{x}_1, \bar{x}_2, \bar{x}_3, \ldots)}{\partial X_i}$	$u(\bar{x}_i)$	$\left(\dfrac{\partial f(\bar{x}_1, \bar{x}_2, \bar{x}_3, \ldots)}{\partial X_i}\right)^2 \cdot u^2(\bar{x}_i)$

			expanded uncertainty: $U(\bar{y}) = k \cdot u_\mathrm{C}(\bar{y})$		

Quality management of radiation protection measurements

The state-of-the-art main source for laboratory quality management is the European standard EN ISO/IEC 17025:2005. In this standard the main conformity requirements of an appropriate QM system for testing and calibration laboratories are given:

- **Management requirements:** organisation, management system, document control, review of requests, tenders and contracts, subcontracting of tests and calibrations, purchasing services and suppliers, services to the customer, complaints, control of nonconforming testing and/or calibration work, improvements, corrective action, preventive action, control of records, internal audits, and management reviews.

- **Technical requirements:** general, personnel, accommodation and environmental conditions, test and calibration method validation, equipment, measurement traceability, sampling, handling of tests and calibration items, assuring the quality of tests and calibration results, reporting the results.

Especially for measurements in radiation protection and radiation safety the required measurement traceability is explained in IAEA (2008):

"7.28. To be sure that the measurement results will comply with international standards, each measurement device that has an influence on the results should be calibrated before being put into service and at defined intervals afterwards. The standards used for these calibrations should be traceable to the International System of Units (SI). In some cases — e.g. in connection with ^{222}Rn — the only means of providing confidence in measurements is through participation in suitable international intercomparison exercises.

7.29. Calibration services have to trace their standards and measuring instruments to the SI System by means of an unbroken chain of calibrations or comparisons linking them to relevant primary standards for the SI units of measurement. For measurement services, this traceability can be achieved by using a calibration service."

This metrological requirement must be strictly implemented in the QM system and assured in the day-to-day laboratory practice and documentation.

Conclusions

Measurements in radiation protection and radiation safety for the assessment of external and internal exposure need reliable measurement instruments and methods. To ensure high-quality measurements, an appropriate quality management system has to be implemented and followed in the day-to-day practice. Careful attention has to be paid to the use of appropriate quantities, the reasonable estimation of measurement uncertainties and the metrological traceability of the measurement instruments.

External dosimetry and individual monitoring

Stadtmann, Hannes
Dosimetry, Seibersdorf Labor GmbH, AUSTRIA

Abstract
Individual monitoring is required by international regulations to demonstrate the compliance of dose limits. This paper gives an introduction which types of personal dosemeters are in use and how these dosemeters are calibrated in the operational dose quantities $H_p(10)$ and $H_p(0.07)$. In addition type test requirements for different dosemeters stated in recent international standards (IEC) are summarised and compared.

General principles and requirements
The main principles for the radiation protection system are the following three issues:

- **principle of justification**
- **principle of optimization of protection**
- **principle of application of dose limits**

Based on the last principle monitoring of the individual exposure of persons constitutes an integral part of any radiation protection programme. Especially the principle of dose limitation requires reliable assessment of individual doses.

Legal requirements and international recommendations
The fundamental principles for the operational protection of occupationally exposed persons, apprentices and students are laid down in EU Council Directive 96/29/Euratom Basic Safety Standards (BSS) [(2)]. The requirements for dose assessments and the corresponding dose limits are mandatory specified in these BSS based on international recommendations by the International Commission on Radiological Protection (ICRP) and reports of the International Commission on Radiation Units and Measurements (ICRU).

Dose limits and dose quantities
In these regulations dose limits, dose constraints, and reference levels for different situations are stated. In the BSS, the requirements for dose assessment and for dose limits are given in terms of the protection dose quantities, effective dose, equivalent dose to the lens of the eye, equivalent dose to the extremities and equivalent dose to local skin. These protection quantities are difficult to assess and impossible to measure directly. The BSS state that operational dose quantities for external radiation, personal

dose equivalent for personal monitoring, and ambient dose equivalent and directional dose equivalent for area monitoring, are to be used for monitoring for operational protection purposes. All these measurements are required to be traceable to international recognise metrological institutions maintaining primary standards for the relevant basic dose quantities. This traceability is normally ensured by proper calibration of the dosemeter by an accredited calibration laboratory.

The relationship between the different quantities is implicitly given by the exact definition of those (Table 3). For practical reasons conversion factors are published (in most cases determined by MC calculation) for special well defined conditions or procedures (e.g. for the purpose of calibration in a well-defined set up).

One important difference between all these quantities is the fact that the definition considers different concepts: the basic physical quantities are defined in any point of the radiation field. The operational quantities are defined in a point in a special phantom (ICRU sphere or the human body of a person wearing a personal dosemeter) in an aligned and expanded radiation field (Figure 1). The protection quantities are doses averaged over an organ/tissue or weighted over the whole body of a person.

Table 1. Annual dose limits given in the BSS [(2)].

Limiting quantity (protection dose quantity)	**Exposed workers** (aged over 18)	**Apprentices and students** (aged between16 and 18)	**Public**
Effective dose	100 mSv / 5a and 50 mSv on a single year;	6 mSv	1 mSv
Equivalent dose for the lens of the eye	150 mSv	50 mSv	15 mSv
Equivalent dose for the skin and extremities	500 mSv	150 mSv	50 mSv

Table 2. Summary of the system of different types of dose quantities.

Dose quantities		
basic physical quantities	**operational quantities**	**protection quantities**
Fluence (m^{-2}) Kerma (Gy) Absorbed dose (Gy)	Ambient dose equivalent (Sv) Directional dose equivalent (Sv) Personal dose equivalent (Sv)	Equivalent dose for organs and tissues (Sv) Effective dose for the whole body (Sv)
Realised by primary standards	Measured with a calibrated routine dosemeter	Quantity for which dose limits are stated
Defined by ICRU		Defined by ICRP

The detailed definitions and explanations of the system of basic quantities, protection quantities and operational quantities are summarised in Table 3.

Table 3. Definition and SI units of dose quantities (definitions of ICRU and ICRP).

Definition	Equation	SI unit
The **fluence, Φ** is the quotient of dN by da, where dN is the number of particles incident on a sphere of cross-sectional area da	$\Phi = \frac{\mathrm{d}N}{\mathrm{d}a}$	m^{-1}
The **Kerma, *K*** is the quotient dE_{tr} by dm, where dE_{tr} is the sum of the initial kinetic energies of all charged ionizing particles liberated by uncharged ionizing particles in a volume element of mass dm	$K = \frac{\mathrm{d}\,E_{\mathrm{tr}}}{\mathrm{d}\,m}$	$J.kg^{-1}$ special name: gray (Gy)
The **absorbed dose, D** is the quotient of $\mathrm{d}\bar{\varepsilon}$ by dm, where $\mathrm{d}\bar{\varepsilon}$ is the mean energy imparted by ionizing radiation to matter of mass dm	$D = \frac{\mathrm{d}\bar{\varepsilon}}{\mathrm{d}m}$	$J.kg^{-1}$ special name: gray (Gy)
The **equivalent dose, $H_{T,R}$** , is the absorbed dose in an organ or tissue multiplied by the relevant radiation weighting factor, where $D_{T,R}$ is the absorbed dose averaged over the tissue or organ T, due to radiation R and w_R is the radiation weighting factor for radiation type R	$H_{\mathrm{T,R}} = w_{\mathrm{R}} \cdot D_{\mathrm{T,R}}$	$J.kg^{-1}$ special name: sievert (Sy)
The **effective dose, E,** is a summation of the equivalent doses in tissue, each multiplied by the appropriate tissue weighting factor, where H_T is the equivalent dose in tissue T and w_T is the tissue weighting factor for tissue T.	$E = \sum_{\mathrm{T}} w_{\mathrm{T}} \cdot H_{\mathrm{T}}$	$J.kg^{-1}$ special name: sievert (Sy)
The **dose equivalent, *H*** is the product of Q and D at a point in tissue, where D is the absorbed dose and Q is the quality factor at that point,	$H = Q \cdot D$	$J.kg^{-1}$ special name: sievert (Sy)
The **ambient dose equivalent, *H**(*d*)** at a point in a radiation field is the dose equivalent that would be produced by the corresponding expanded and aligned field in the ICRU sphere at a depth, *d*, on a radius opposing the direction of the aligned field	$H^*(d)$	$J.kg^{-1}$ special name: sievert (Sy)
The **directional dose equivalent, *H′*(*d*, *Ω*)** at a point in a radiation field is the dose equivalent that would be produced by the corresponding expanded field in the ICRU sphere at a depth, d on a radius in a specific direction, Ω.	$H'(d,\Omega)$	$J.kg^{-1}$ special name: sievert (Sy)
The **personal dose equivalent, $H_p(d)$** at a point in a radiation field is the dose equivalent in soft tissue at an appropriate depth d, below a specified point on the body.	$H_p(d)$	$J.kg^{-1}$ special name: sievert (Sy)

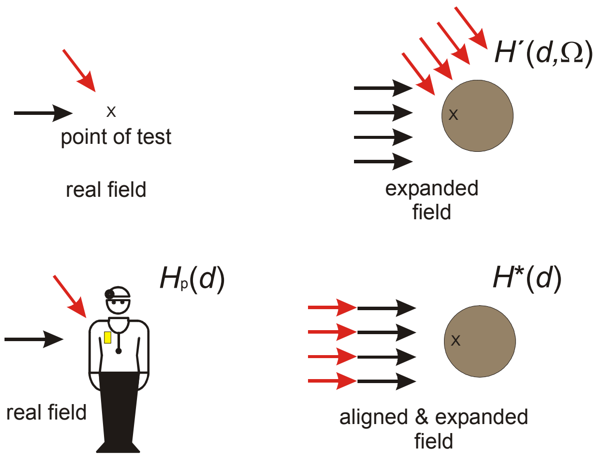

Figure 1. Schematic example of expanded and aligned radiation fields used in the definition of the operational quantities H*(d) and H‘(d,Ω), defined in the ICRU-sphere. The quantity H_p(d) is defined in the real field in a point in the human body wearing a dosemeter.

Quality factor Q and Radiation weighting factors w_R

The radiation weighting factor is defined as a factor w_R by which the tissue or organ absorbed dose $D_{T,R}$ is multiplied to reflect the higher biological effects of neutron, proton and alpha radiation compared to low LET-radiation. Considerable changes of the previous values were recently introduced by ICRP 103 [(11)]. Especially the weighting factor for neutrons was decreased by a factor of two for neutron energies below 1 MeV.

In the early 1960s, radiation weighting in the definition of radiological protection quantities was related to the radiation quality factor Q, as a function of LET. In ICRP 60 [(8)] the method of radiation weighting was changed in the definition of the protection quantities equivalent dose and effective dose. ICRP selected a general set of radiation weighting factors (w_R) that were considered to be appropriate for application in radiological protection. Today the quality factor Q however is still used for defining the operational quantities H*, H’ and H_p.

Tissue weighting factors

The tissue weighting factor w_T is defined as a factor by which the equivalent dose to a tissue or organ H_T is multiplied in order to account for the relative stochastic detriment resulting from the exposure of different tissues or organs. Recent ICRP publication 103 [(10)] recommended in 2007 new tissue weighting factors for 14 organs and tissues and for a remainder (Figure 1).

New factors in ICRP 103

ICRP 110 [(9)] compares conversion coefficients for effective dose to air kerma for ICRP 60 and ICRP 103 values. For photons no significant differences especially in the lower energy region were stated. For neutrons mainly the change of the quality factor influences the conversion coefficient for energies below one MeV by a factor of 2.

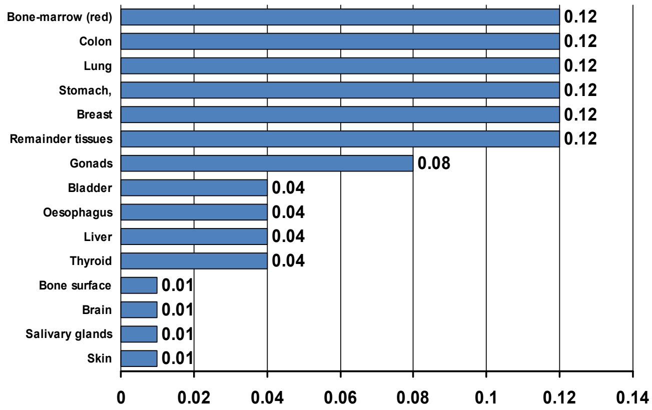

Figure 2. Tissue weighting factors (ICRP-103).

Assessment of the limiting quantities by the corresponding operational quantities

The *protection dose quantities* - defined by the ICRP - form the basis for dose limitation. These quantities are not directly measurable. The exposure can only be assessed by calculations when both the irradiation geometry and the radiation field parameters (type of radiation, intensity, spectral energy distribution etc.) are known. For routine monitoring, measurements with personal dosemeters calibrated in the operational quantities are performed. The suitability of this procedure to give a reasonable estimation of the appropriate limiting quantity was investigated by a joint task group of the ICRP and the ICRU. The results are published both as ICRP publication 74 [(10)] and ICRU report 57 [(7)]: in these publications the dose measured by the operational quantities were compared with the dose of the corresponding protection quantities (effective dose, equivalent dose, all weighting factors from ICRP 60). Some results are given in Figure 3. The influence of the changed neutron radiation weighting factor from ICRP 103 is added in addition. These diagrams show that the operational quantities for photons for irradiations from the front side (AP) always give a conservative estimate of the effective dose. This is valid for neutrons below 10 MeV too, when the new neutron radiation weighting factors from ICRP 103 are applied.

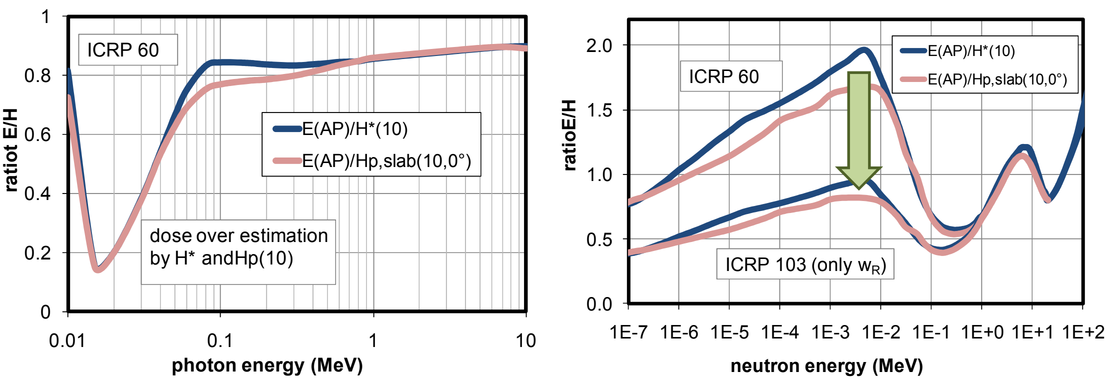

Figure 3. Ratio of the effective dose E and ambient dose equivalent H*(10) and personal dose equivalent $H_{p,slab}(10,0°)$ for photons and neutrons in AP irradiation geometry (ICRP60 weighting factors, except right figure where the new ICPR radiation factors for neutrons are used for the two lower lines) from [(10)] and [(7)].

Detection techniques

For routine individual monitoring active and passive dosimetry systems are used. Active systems give the worker an instant indication of both accumulated dose and sometiomes dose rate. If an alarm function is available these devices can be used simultaneously as an integrating dosemeter and as an alarm dosemeter. Active dosemeters are suitable also for short monitoring periods and low dose values. Recent investigations show that some active dosemeters are not capable to measure reliably doses in pulsed radiation fields. Significant under responses were reported [(4)]. These systems are therefore not recommended/allowed for specific tasks. Passive integrating systems are used normally for longer monitoring periods (weeks and months). These dosemeters are commonly issued by individual monitoring services (IMS). Implementation of a quality management system and sometimes formal accreditation are often national requirements for these services. Pulsed radiation fields generally do not cause problems for the applied measuring techniques. Table 4 shows an overview of the different dosimetry systems.

Table 4. Summary of different types of personal dosemeters

System type	External photon/beta radiation	Neutron radiation
Passive integrating systems	Photographic film Thermoluminescence (TLD) Optically Stimulated Luminescence (OSL) Radio-Photo-Luminescence (RPL) Direct Ion Storage (DIS)	TLD albedo dosimeters Track etch techniques Direct Ion Storage (DIS) bubble detectors
Active systems	APD (different detectors) (3) (Direct Ion Storage - DIS)	APD (different detectors)
Wearing position	trunk (whole body), extremity	trunk (whole body),
Dose quantity	$H_p(10)$, $H_p(0,07)$, (in future $H_p(3)$?)	$H_p(10)$,

Several international standards exists for area and personal dosemeters. A summary of most recent IEC standards and a comparison of the main requirements for these dosemeters are given in Table 5 and in [(1)]. Fulfilling these requirements limits the measuring uncertainties for the measured dose. Uncertainty estimations result in typical expanded uncertainty (k=2) of ±25% for photon doses at higher dose levels (some mSv) [(10)].

Table 5. recent international IEC standards for area and personal dosemeters.

IEC Standards	Radiation protection dosemeters		
	Personal dosemeter		Area dosemeter
	active	passive	active
Standard ID	IEC-61526 (2005)	IEC-62387-1 (2007)	IEC-60846 (2002)
Dose quantity	$H_p(10)$, $H_p(0,07)$		$H^*(10)$, $H'(0,07)$, $[K_a]$
Minimum. dose range	100 µSv to 1 Sv		4 orders of magnitude
Minimum. dose rate range	0,5 µSv h^{-1} to 1 Sv/h	-	4 orders of magnitude
Energy- and angular response	-29%, +67% (photons) -35%, +300% (neutrons) (±60°)	-29%, +67% (±60°)	±40% (±45°)
Linearity	±15%	-9%, +11%	±20%
Coefficient of variation	15% to 5% (11 µSv) (photons) 25% to 5% (5,1 mSv) (neutrons)	15% to 5% (1,1 mSv)	15% to 5% (11 µSv)
Temperature dependence	±15%	-17%, +25%	±10% (inside) ±20% bis 30%
Intrinsic error	No requirements		±20%

Calibration in terms of the operational quantities

Calibration in general is the procedure to establish a relationship between the indicated value of a measuring instrument and the conventional true value of the quantity to be measured under well-defined conditions.

Radiation protection instruments for external radiation are calibrated in well-defined reference radiation fields. Recommended fields for calibration as well as the calibration methods are defined in different documents of the International Organization for Standardization (ISO) for photon [16, 17, 18], neutron [13, 14, 15] and electron radiations [19, 20, 21]. These reference radiation fields are generally defined in terms of the basic physical quantities since only these are directly traceable to primary standards.

Conversion coefficients

For the calibration in terms of the operational quantities, conversion coefficients are necessary relating the basic physical quantities to the operational quantities. Based on the results of radiation transport codes and appropriate mathematical models both ICRU [7] and ICRP [10] recommend a set of conversion coefficients for photons, neutrons and electrons. These published values are however restricted to monoenergetic radiation fields. When fields with spectral distributions are used a spectrum weighted conversion coefficients must be applied.

According to the definition of the operational quantities the conversion coefficients for $H^*(10)$, $H'(10, \Omega)$ and $H'(0.07, \Omega)$ are derived from calculated dose distributions in the ICRU sphere.

Since the personal dose equivalent is defined in the individual body of the person wearing the dosemeter, individual conversion coefficients would be required. Since this is not practical, conversion coefficients for $H_p(10)$ and $H_p(0.07)$ are calculated only for three standard phantoms representing typical wearing positions (trunk, wrist and ankle, finger) of common used dosemeter types. All these phantoms are composed of ICRU-tissue with a density: 1 g/cm³ and a mass composition of: 76.2% oxygen, 11.1% carbon, 10.1% hydrogen and 2.6% nitrogen. For the calibration of personal dosemeters similar shaped calibration phantoms are used – due to practical reasons the material of these phantoms however is different (see Table 6)

Calibration method

The calibration method and the application of the conversion factor are carried out in principal in the following way:

- Selection of the dosemeter to be calibrated and the calibration conditions (calibration quantity, radiation quality, direction of incidence etc.)
- Selection of a suitable reference radiation field and a point of test (parameters like radiation quality, intensity, field size and homogeneity etc. needs to be considered)
- Determination (measurement) of the value of the appropriate basic physical quantity in the point of test (without the dosemeter and any calibration phantom)
- Calculation of the value of the required operational quantity by application (multiplication) of the corresponding conversion factor. This result is considered to be the conventional true value.
- Positioning of the dosemeter (and a phantom if required) with its reference point at the point of test, irradiating the dosemeter and reading the indicated value.
- Calculation of the calibration factor of the dosemeter defined as the ratio of the conventional true value (step 4) to the indicated value (step 5).

Table 6. Phantoms for the calibration of personal dosemeters

Calibration phantoms				
Name	**Shape and dimension**	**Material**	**Calibration quantity**	**Wearing position of dosemeter**
Water slab phantom	Slab: 30 cm x 30 cm x 15 cm	PMMA walls (100 mm, on front side 2,5 mm thick) filled with water	$H_p(10)$; $H_p(0,07)$	trunk
Pillar phantom	Cylinder: Diameter 7,3 cm Length 30 cm	PMMA walls (2,5 mm on circum-ference, 10 mm on faces sides thick) filled with water	$H_p(0,07)$	wrist, ankle
Rod phantom	Cylinder: Diameter 1,9 cm Length 30 cm	PMMA	$H_p(0,07)$	finger

Calibration phantoms

Depending on which dosemeter type is calibrated, special calibration phantoms must be used. The calibration of area monitoring instruments in terms of $H^*(d)$ or $H'(d, \Omega)$ is carried out free in air. No calibration phantoms are needed.

The calibration of personal dosemeters in terms of $H_p(d)$ is carried out always on an appropriate calibration phantom. The function of these phantoms is the production of backscattered radiation. Three different calibration phantoms are recommended depending on the wearing position of the personal dosemeter. Details for the water slab, pillar and rod phantom are given in Table 6. When using calibration phantoms the corresponding conversion factor must be applied.

Summary

Individual monitoring is required by international regulations to demonstrate the compliance of dose limits. Whole-body and extremity dosemeters are calibrated in the operational dose quantities $H_p(10)$ and $H_p(0{,}07)$. The question if $H_p(3)$ should be used in addition is still under discussion. In most cases it is assumed that these operational quantities are a conservative estimate for the limiting quantities effective dose and equivalent dose. Recent changes of the radiation weighting factor for neutrons by a factor of two improved the applicability of $H_p(10)$ for the estimation of effective dose for neutrons. International standards for personal dosemeters state minimum requirements for these dosemeters. Fulfilling these requirements limits the measuring uncertainties for the measured dose and guarantees reliable dose measurements.

Radiobiology – Evaluation of health risks after ionising radiation

Streffer, Christian
University Clinics Essen Auf dem Sutan 12, D-45239 Essen, GERMANY
streffer.essen@t-online.de

Abstract
For radiological protection two classes of effects are grouped: deterministic and stochastic effects. Deterministic effects with threshold doses are mainly tissue effects, dose response is well-known from clinical experience and animal experiments. For stochastic effects (cancer and hereditary effects) no threshold dose is assumed. The knowledge of mechanisms is necessary for solving these open questions. DNA damage and its repair, apoptosis, adaptive response, bystander effects, genomic instability are important in this connection and will be discussed. Radiations with different LET as well as biological systems with different sensitivities like prenatal development and genetic diseases will be of high interest.

Clinical auditing and quality assurance

Järvinen, Hannu
STUK – Radiation and Nuclear Safety Authorit , FINLAND

Abstract
In the jungle of the concepts of quality management, with a diversity of approaches and procedures in order to improve and maintain high quality, the meaning of concepts can easily be confused with each other and this has been particularly true for clinical audit. Clinical audit is a systematic review of the procedures in order to improve the quality and the outcome of patient care, whereby the procedures are examined against agreed standards of good practices.

While it certainly is an important part of the overall quality assurance activities, it should not be confused with either overall quality assurance or quality control programmes. It should neither be confused with external quality assessments such as accreditations or certification of quality systems, or with regulatory inspections.

In Europe, the Council Directive 97/43/EURATOM introduced the concept of clinical audit to medical RADIOLOGICAL (diagnostic radiology, nuclear medicine and radiotherapy)[1] procedures. Recently, the European Commission has published further guidelines on clinical audits (Report Radiation Protection 159). In this refresher course, the purpose, scope and methods of clinical auditing are presented in accordance with the EC guidelines. The role of clinical audit as a part of overall quality assurance is explained and its relation to the concepts of quality management clarified.

Introduction
It has been estimated [UNSCEAR, 2000] that worldwide there are about 2000 million x-ray studies, 32 million nuclear-medicine studies and over 6 million radiation therapy patients treated annually, and the numbers are constantly increasing. The use of radiation for medical diagnostic examinations contributes over 95 % of the man-made radiation exposure and is only exceeded by natural background as a source of exposure [UNSCEAR, 2000]. Furthermore, the dose to patients for the same type of examination differs widely between centres, suggesting that there is considerable scope for management of patient dose. About 40 to 60 % of all cancer patients are treated at least once during their disease with radiotherapy and more than half of these with curative intent. The difference between the dose that is required to achieve local control and the dose that can cause serious side effects is often quite small.

[1] "RADIOLOGICAL", written in capital letters, is used throughout this paper to denote all three fields of application: diagnostic radiology, nuclear medicine and radiotherapy. When only diagnostic radiology is concerned, the term is written in small letters ("radiological"). .

The above facts have stressed the importance of proper justification, optimization and quality assurance procedures in order to ensure the high quality and safety of RADIOLOGICAL procedures. A lot of attention has been paid to the quality management in the medical use of radiation, and worldwide there has been a tendency to establish quality systems and introduce appropriate quality audits. Among the regulatory efforts, the Council Directive 97/43/EURATOM (the MED directive; Article 2 and Article 6(4)) [European Commission, 1997] introduced the concept of *clinical audit* for medical RADIOLOGICAL procedures. According to the MED directive, clinical audits shall be implemented in accordance with national procedures.

In the jungle of the concepts of quality management, with a diversity of approaches and procedures in order to improve and maintain high quality, the meaning of concepts can easily be confused with each other and this has been particularly true for *clinical audit*. While it certainly is an important part of the overall quality assurance activities, it should not be confused with either quality assurance or quality control programmes. It should neither be confused with external quality assessments such as accreditations or certification of quality systems, or with regulatory inspections.

In this refresher course, the purpose, scope and methods of clinical auditing are presented in accordance with the EC guidelines. The role of clinical audit as a part of overall quality assurance is explained and its relation to the concepts of quality management clarified.

EC Guidelines on clinical audit

The concept of clinical audit is not a new one but has long been applied in many health care practices. In the European Commission (EC) directive 97/43/EURATOM (MED) [European Commission, 1997], this concept has been introduced for the assessment of medical RADIOLOGICAL practices. The MED-directive defined clinical audit as

> "a systematic examination or review of medical radiological procedures which seeks to improve the quality and the outcome of patient care, through structured review whereby radiological practices, procedures, and results are examined against agreed standards for good medical radiological procedures, with modifications of the practices where indicated and the application of new standards if necessary".

EU Member States are required to implement clinical audits "in accordance with national procedures" (Article 6.4 of the MED). Due to the high variation between the approaches of the Member States in its implementation, in 2007-2008, the EC conducted a special project to provide guidance on clinical auditing for an improved implementation of Article 6.4 of the MED.

The EC guidelines [European Commission 2009] provide a general framework for the Member States in order to establish sustainable national systems of clinical auditing of RADIOLOGICAL practices (diagnostic radiology, nuclear medicine and radiotherapy). The guidelines are sufficiently flexible and will enable the Member States to adopt the model of clinical audit with respect to their national legislation and administrative provisions.

The EC guidelines document introduces the basic principles of clinical audit (objectives, coverage, standards of good practice etc) aiming at clarifying its profound meaning and recommended application. It defines the topics which should be covered while the criteria of good practice are discussed only on generic levels. It discusses the interrelation of clinical audit with other audit systems such as certification of quality systems, accreditation, peer review and quality award, and also its interrelation with regulatory control. Finally, it gives general advice for the practical implementation of audits, including organization of audits, recommendations for auditors, models of financing, national coordination and the role of scientific and/or professional societies and regulatory authorities.

It is important to recognize that the EC guidelines are not a legal requirement. The guidelines will only give recommendations and highlight some possible "national procedures" as expected by the MED.

Simultaneously with the European development, the IAEA has developed comprehensive audit programmes under the term of clinical audit [IAEA 2007; 2010]. Further, several dosimetry or quality audit programmes traditionally applied in the field of radiotherapy (e.g. by the IAEA [Izewska et al. 2004] or the ESTRO [Ferreira et al. 2000]) have been recognized to form an important part of clinical audit. There are also several national efforts of clinical auditing providing examples of potential approaches, e.g. the AuditLive system in the UK [The Royal College of Radiologists 2009] and the Finnish nationwide organization [Soimakallio 2003]. The general framework published in the EC guideline is well supported by these other international and national developments.

Essentials of clinical audit

The general purpose of any clinical audit is to

- improve the quality of patients' care
- improve the effective use of resources
- enhance the provision and organization of clinical services
- further professional education and training

With these objectives, clinical audit is an integral part of the overall quality improvement process and should be considered as an integral part of quality management and clinical governance. In the conceptual frame of quality concepts, clinical audit is a type of quality audit, which is one of the methods to implement overall quality assurance, which itself is one of the tools of quality management as shown in Fig. 1.

Clinical audit should cover the whole clinical pathway, and address the three main elements of the RADIOLOGICAL practices: structure, process, and outcome For RADIOLOGICAL procedures, the priorities should be as shown in Table 1. Clinical audits should address both the critical issues of the radiation protection for the patient and key components of the overall quality system.

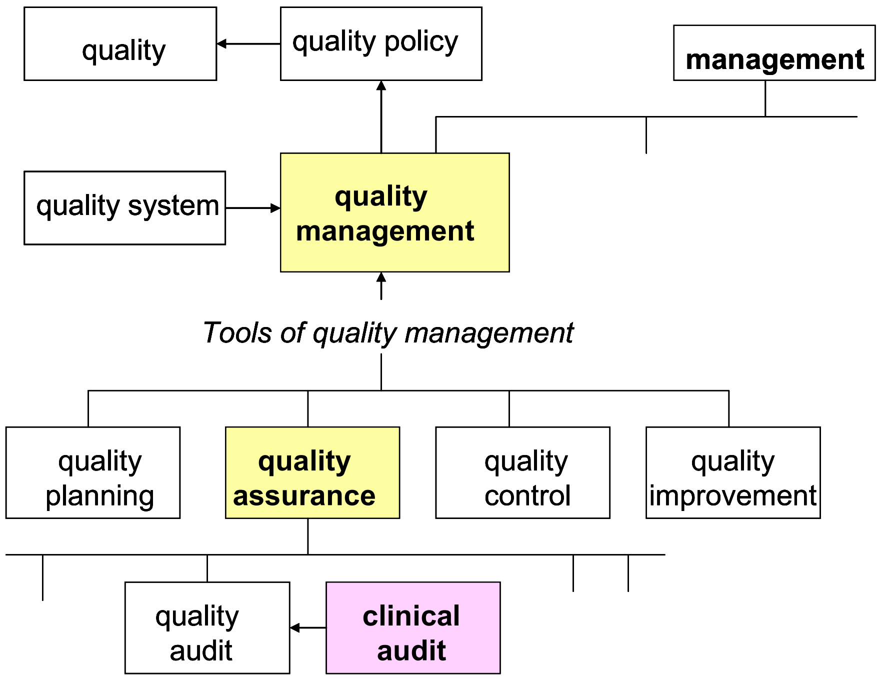

Fig. 1. Clinical audit in the "jungle" of quality management concepts; quality management scheme based on EN ISO 8402 [ISO 1995].

Table 1. The priorities of clinical audit of RADIOLOGICAL practices.

Structure	The mission of the unit for RADIOLOGICAL practices Lines of authorities and radiation safety responsibilities Staffing levels, competence and continuous professional development of staff, in particular for radiation protection Adequacy and quality of premises and equipment
Process	Justification and referral practices, including referral criteria Availability and quality of examination and treatment guidelines (protocols, procedures) Optimization procedures Patient dose and image quality in diagnostic radiology and nuclear medicine procedures, and comparison of patient dose with nationally accepted reference levels Procedures for dose delivery to the patient in radiotherapy (beam calibrations, accuracy of dosimetry and treatment planning) Quality assurance and quality control programmes Emergency procedures for incidents in use of radiation Reliability of information transfer systems
Outcome	Methods for the follow-up of outcome of examinations and treatment (short term and long term)

Clinical audit aims at continuous improvement of the medical practices. Therefore, it should be carried out regularly and it should be ensured that the audit cycle is completed (Fig.2). The general audit cycle consists of selecting a standard of good practice, assessing and comparing local practice with accepted standards, implementing change when necessary, and re-auditing after a certain time. Regular re-audits will improve the quality or give reassurance that a good quality is maintained.

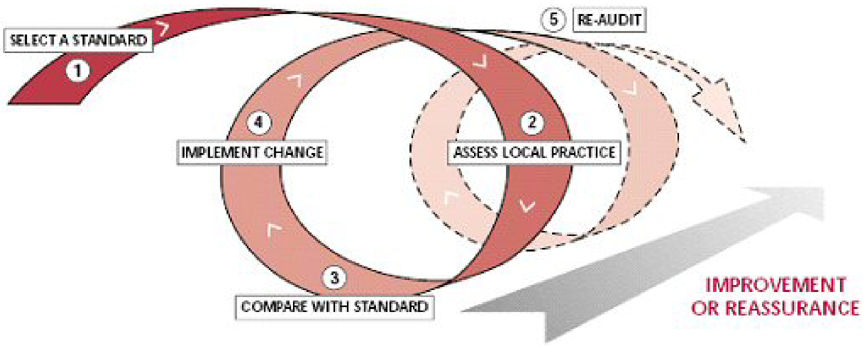

Fig.2 The audit cycle. Reprinted from Goodwin R, de Lacey G, Manhire A (eds). Clinical Audit in Radiology: 100+ Recipes, 1996 by permission of The Royal College of Radiologists.

It is evident from the definition that clinical audit is a truly multi-disciplinary, multi-professional activity. It must be carried out by auditors with extensive knowledge and experience of the radiological practices to be audited, i.e., they must generally be professionals involved in clinical work within these practices. Further, the general understanding of the concept "audit" implies that the review or assessment is carried out by auditors independent of the organizational unit or practice to be audited.

Both internal audits and external audits should be implemented. These should be of equal importance and supplement each other. *Internal* audits are undertaken within a given health care setting by staff from the same institution, while the audit findings can be also externally reviewed. In small health care units, internal audits would rather be self-assessments. *External* audits involve the use of auditors who are independent of the radiology department/institution. External audits may help identify other, unrecognised areas for improvement. They are needed to remove possible “blindness” of internal experts to recognize weaknesses of own unit and to give more universal and broader perspectives. External auditors should also possess better benchmarking skills in relation to the assessment.

The *standards of good practice* should be derived from evidence based data, long term experience and knowledge gained. In practice, these can be adopted from legal requirements, results of research, consensus statements, recommendations by learned societies or local agreements (if there is no other more universal reference). International medical/scientific/professional societies could play an important role in developing such standards. In a case where a consensus of the good practice is not easily achieved, the criteria of good practice adopted should be regarded as giving only preliminary orientation, and the results of audit should then be used like a benchmarking tool to achieve improved evidence and possible adjustment of the chosen criteria.

Clinical audits can be of various types and levels, either reviewing specific critical parts of the RADIOLOGICAL process (partial audit) or assessing the whole process (comprehensive audit). Dosimetry audit is an important example of partial audits and should be within the scope of a comprehensive clinical audit, as assured dosimetry is a vital component of accurate clinical practice. The comprehensive clinical audit must include the full patient pathway from referral to follow up.

Audits can address various “depths” of the procedure, from generic features to details of a given examination or treatment. Auditing the detailed practice for a given examination or treatment can usually mean only a few selected processes per audit run. Full details of the procedures should be assessed at least for the items of the procedure where a reasonable consensus on a good practice can be achieved.

Before starting the clinical audit the critical areas should be identified and the objectives agreed. For internal audits, the objectives are set by the management of the health care unit to be audited. For external audits, the detailed objectives should be agreed between the auditing organization and the unit to be audited, and should be based on any legal requirements on audit programmes, as well as on any recommendations by national coordinating organizations or by health professional and/or scientific societies when available.

The practical organizing of *external* clinical audits can be through site visits of an audit team or, for a limited part of practices with relevant documented or measurable data, by the collection of data via mail or internet, with central assessment of the data. Examples of the latter technique are the assessment of the quality of CT referrals by mailed questionnaire [Almen et al., 2009] and a national audit of provision of MRI services [Barter et al., 2008]. For comprehensive audits, a site visit is needed and should comprise a series of interviews, observations, document and data reviews, measurements, collection of data samples and analysis. Due to the multidisciplinary nature of the audit, a team of auditors is usually needed, comprising different professionals - radiologist, medical physicist, radiographer etc - depending on the scope of the audit. Besides the basic clinical competence, the auditors should receive specific training on the general audit procedure and techniques, as well as the agreed audit programme and the criteria of good practices to be applied.

Once the clinical audit has been completed and the auditor’s report with recommendations is available to all staff, the unit should respond to the recommendations with an agreed timeline for improvement. This is important not only to achieve maximum benefit from the audit but also to retain the respect and motivation of the staff for subsequent re-audits.

In summary, clinical audit is an important tool of quality improvement and can have a major impact on developing the medical RADIOLOGICAL practices in compliance with the most recent data on good practices. The audits will yield multiple benefits to the health care system such as:

- improvement of practice
- recognition for quality and awareness of good practices
- recognition of outdated practice
- motivation of staff to increase quality
- improvement of local standards and adherence to national standards
- prevention against litigation

- improvement of communication within the institution,
- revealing weak points and
- promoting development of quality systems.

Relationship with other audits

While it is obvious that clinical audit has some similarities with other activities for the development and control of RADIOLOGICAL practices, it is imperative not to confuse it with such activities as

- research
- quality control program for equipment
- regulatory inspection nor any other regulatory activity.

Further, clinical audit should not be confused with other external quality assessments systems, broadly categorized as [European Commission 2009]:

- certification by International Standards Organization (ISO)
- accreditation
- professional peer review –based schemes
- award seeking such as European Quality Award and their national variants (i.e. European Foundation for Quality Management (EFQM) Excellence Model).

Alhough the methodology and terminology of these external review systems differ, a constant movement towards collaboration and convergence of those models has been observed [European Commission 2009]. The purpose of these other activities should be properly understood, and conversely to duplicating any efforts, clinical audits should be developed to supplement the other activities.

Research is a systematic investigation to increase the sum of our knowledge. For clinical audit, the aim of research is to determine what a good practice is, while audit itself should ask the question: "Are we actually following good practice?"

The *quality control* of RADIOLOGICAL equipment aims at ensuring adequate performance characteristics and safe operation throughout the lifetime of the unit, and the responsibility for the checking lies solely on the health care organization, the user of the equipment or the practitioner. Any audit or external control does not remove or release this responsibility while, however, can give desirable confidence on the results of the quality control.

A legislative and statutory framework is needed in each country to regulate the safety of facilities and activities, including medical use of radiation. The *regulatory requirements* will generally depend on the level of risk or complexity associated with the medical use, as determined by the regulatory body. In radiotherapy, for example, the high risk profile justifies maximum regulatory efforts, including regulatory inspections. The purpose of such an inspection is to verify that various detailed requirements for radiation protection are being met. The methods of verification can include both documentary assessments and verification measurements. While the verification procedures can be partly similar to some clinical audit procedures, the basis of the review and the use of the results are quite different (Table 2) and clinical audits should not be confused with *regulatory inspections*.

Table 2. Main differences between clinical audit and regulatory inspection.

	Clinical audit	Regulatory inspection
Focus of review	"Agreed standards for good medical RADIOLOGICAL procedures". These are often not requirements but recommendations to the users. There may be more than just one agreed standard.	Legislative and statutory framework (laws, statutes and other regulations). These are unambiguous and usually binding requirements to the users.
Use of the results	Auditor's report, with the findings and recommendations, is given to the user. *The auditor cannot enforce any actions*, but the actions are solely decided by the user.	The non-compliance with specified conditions and requirements leads to *enforcement actions* by the regulatory body. The regulatory inspector may impose on the spot corrective requirements to the user.

A quality system in conformance with international quality standards such as the ISO 9001 [ISO, 2000] is generally considered a good basis for the overall quality management in a RADIOLOGICAL unit. To ensure that the local quality system conforms to the specifications of the quality standard, *certification* by a certification body can be acquired by special quality (system) audits carried out regularly by quality system experts. These experts are usually not clinical experts and the assessment does not address the quality of the clinical practice but solely its conformance with the general quality rules. Conversely, in clinical audits, clinical experts concentrate on the evaluation of the conformance of the clinical practice to the agreed good practice. The difference between quality system audits and clinical audits is demonstrated further in Fig. 3.

While clinical audit is not a systematic assessment of the quality system, the quality system documentation is a prerequisite for meaningful evaluation of the practices against standards of good practices. Therefore, an important supplementary benefit of clinical audits has been noted to be that their implementation has speeded up the development of appropriate quality systems in health care units.

The system of *accreditation* deals with the competence of the unit to perform certain practices, in accordance with given standards. This can become very close to the aims of clinical auditing, while usually the scope is narrower and limited to the definite standards. In RADIOLOGICAL practices, such standards are either very general or not very common and limit the applicability of accreditation in the sense of replacing the clinical audits.

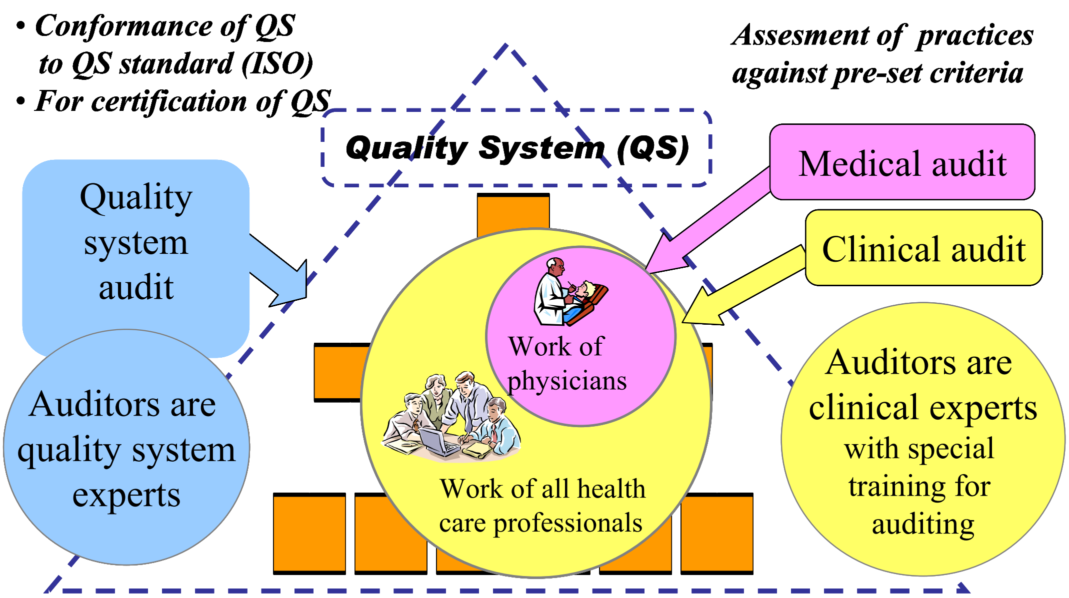

Fig. 3. Quality audits for a health care organization: Clinical audit versus quality system audit.

Conclusions

Clinical audit is a systematic review of the procedures in order to improve the quality and the outcome of patient care, whereby the procedures are examined against agreed standards of good practices. It is an important tool of quality improvement and can have a major impact on developing the medical RADIOLOGICAL practices in compliance with the most recent data on good practices. While it is an important part of the overall quality assurance activities, it should not be confused with either quality assurance or quality control programmes. It should neither be confused with external quality assessments such as accreditations or certification of quality systems, or with regulatory inspections.

Natural radiation environment and NORM

Markkanen, Mika
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract
We are exposed to natural radiation all the time and everywhere. However, the types and levels of exposure vary considerably from "insignificant background" to situations where workers or members of the public receive doses which would not be accepted in any planned uses of radiation sources. In some cases, human activities have modified or even caused new pathways of exposure to natural radiation sources.

The refresher course will introduce the most common sources of natural radiation, as well as, types and levels of exposures delivered to workers and the members of the public. It will also highlight key aspects and challenges in reducing exposures and in introducing regulatory requirements for e.g. radon in workplaces, natural radioactivity in building materials and industries involving NORM (Naturally Occurring Radioactive Material).

The aim of the refresher course is to provide a general overview on natural radiation environment and NORM and to highlight practical aspects in managing related exposures.

Introduction
This refresher course introduces the most common sources of natural radiation, as well as, types and levels of exposures delivered to workers and the members of the public. The aim is also to highlight practical aspects in managing related exposures by means of regulation and regulatory control.

The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) has provided a comprehensive overview on sources and levels of exposures to natural radiation. The following chapters are mostly summaries condensed from the UNSCEAR 2000 report (UNSCEAR, 2000). Because condensing always imply personal preferences it is recommended to refer to the full report for complete information.

The current EU Basic Safety Standards Directive (BSS, 1996) covers work activities which involve the presence of natural radiation sources. The EU Member States are required to identify by means of surveys or by any other appropriate means work activities which lead to significant exposure of workers or members of the public. Corrective measures to reduce exposures and a system of radiological protection shall be applied to occupational and public exposures, where appropriate.

In this refresher course, the also Finnish experiences in implementing the above mentioned EU provision are discussed (separate Power-Point slides) as examples of imposing regulatory requirements and controls on exposures to natural radiation.

Cosmic radiation

Cosmic rays

The earth is continually bombarded by high-energy particles that originate in outer space. These cosmic rays interact with the nuclei of atmospheric constituents, producing a cascade of interactions and secondary reaction products that contribute to cosmic ray exposures. The cosmic ray interactions also produce a number of radioactive nuclei known as cosmogenic radionuclides.

Galactic cosmic rays consist of a nucleonic component, which in aggregate accounts for 98% of the total, and electrons, which account for the remaining 2%. The nucleonic component is primarily protons (88%) and alpha particles (11%), with the remainder heavier nuclei. These primary cosmic particles have an energy spectrum that extends from 10^8 eV to over 10^{20} eV.

Another component of cosmic rays is generated near the surface of the sun by magnetic disturbances. These solar particle events are comprised mostly of protons of energies generally below 100 MeV and only rarely above 10 GeV. These particles can produce significant dose rates at high altitudes, but only the most energetic affect dose rates at ground level.

The most significant long-term solar effect is the 11-year cycle in solar activity, which generates a corresponding cycle in total cosmic radiation intensity. At times of maximum solar activity the field is at its highest and the galactic cosmic radiation intensity is at its lowest.

The high-energy particles incident on the atmosphere interact with atoms and molecules in the air and generate a complex set of secondary charged and uncharged particles, including protons, neutrons, pions and lower-Z nuclei. The secondary nucleons in turn generate more nucleons, producing a nucleonic cascade in the atmosphere.

The pions generated in nuclear interactions are the main source of the other components of the cosmic radiation field in the atmosphere. The neutral pions decay into high-energy photons, which produce high-energy electrons, which in turn produce photons etc., thus producing the electromagnetic, or photon/electron, cascade.

Exposure at ground level

The world average effective dose from cosmic radiation is 380 μSv/a. Dose is influenced by geomagnetic latitude, altitude, solar activity and shielding effect of buildings.

At high altitude areas doses may be significantly higher than at sea level. For example, in La Paz, Bolivia, which is located at the altitude of 3,9 km, the effective dose is about 2 mSv/a.

The effective dose rate at the equator is about 34 nSv/h and at polar regions about 43 nSv/h. Variation during the 11-year solar activity period is about 10%. At high altitudes the variation is more significant than at sea level. The shielding factor for buildings vary between 0.4 - 1, the average being about 0.8. Values like 0.4 may apply to some lower storeys of substantial concrete buildings. For houses with minimum vertical shielding (e.g. small wooden houses) the shielding factor is close to 1.

Exposures at aircraft altitudes

Aircraft passengers and crew are subject to cosmic radiation exposure rates much higher than the rates at ground level. Total exposure on a given flight depends on the particular path taken through the atmosphere and flight time; that is, it depends on the duration of exposure at various altitudes and latitudes. Complicating the situation is the fact that the exposure associated with any flight path may vary with time.

There are two possible approaches to dose assessment under these circumstances: area and/or individual monitoring for each flight, and determining the radiation fields as a function of time and space and calculating the effective dose for any flight path.

Commercial subsonic aircraft generally have cruising altitudes of 7 to 12 km. The annual number of hours flown by crew members varies. The range is 300 - 900 hours per year, with an average of about 500.

For altitudes of 9 - 12 km at temperate latitudes, the effective dose rates are in the range 5 - 8 µSv/h, such that for a transatlantic flight from Europe to North America, the route dose would be 30 - 45 µSv. At equatorial latitudes, the dose rates are lower and in the range of 2 - 4 µSv/h.

Cosmogenic radionuclidies

The interactions of cosmic-ray particles in the atmosphere produce a number of radionuclides, including ^{3}H, ^{7}Be, ^{14}C, and ^{22}Na. Production is greatest in the upper stratosphere, but some energetic cosmic-ray neutrons and protons survive in the lower atmosphere, producing cosmogenic radionuclides there as well.

Except for ^{3}H, ^{14}C, and ^{22}Na, which are elements with metabolic roles in the human body, the cosmogenic radionuclides contribute little to radiation doses and are mainly of relevance as tracers in the atmosphere and in hydrological systems after deposition. The annual effective doses from cosmogenic radionuclides are about 12 µSv from ^{14}C, 0.15 µSv from ^{22}Na, 0.01 µSv from ^{3}H, and 0.03 µSv from ^{7}Be.

Terrestrial radiation

Naturally occurring radionuclides of terrestrial origin (also called primordial radionuclides) are present in various degrees in all media in the environment, including the human body itself. Only those radionuclides with half-lives comparable to the age of the earth, and their decay products, exist in significant quantities in these materials.

Irradiation of the human body from external sources is mainly by gamma radiation from radionuclides in the ^{238}U and ^{232}Th series and from ^{40}K. Some other terrestrial radionuclides, including those of the ^{235}U series, ^{87}Rb, ^{138}La, ^{147}Sm, and ^{176}Lu, exist in nature but at such low levels that their contributions to the dose in humans are small.

External exposures outdoors

The levels of external exposures from terrestrial radionuclides are related to the types of rock from which soil originate. Higher radiation levels are associated with igneous rocks, such as granite, and lower levels with sedimentary rocks. There are exceptions, however, as some shales and phosphate rocks have relatively high content of radionuclides.

Three components of the external radiation field, namely from the gamma-emitting radionuclides in the ^{238}U and ^{232}Th series and ^{40}K, make approximately equal contributions to the externally incident gamma radiation dose to individuals in typical situations both outdoors and indoors.

The activity concentration of ^{40}K in soil is an order of magnitude higher than that of ^{238}U or ^{232}Th. The worldwide median values are 400, 35, and 30 Bq/kg, and the population weighted values are 420, 33, and 45 Bq/kg for ^{40}K, ^{238}U, and ^{232}Th, respectively. The population-weighted average absorbed dose rate in air outdoors from terrestrial gamma radiation is 59 nGy/h and typical variation at different locations is from 10 to 200 nGy/h. Some areas with much higher levels exist, for example Guarapari in Brazil and Kerala in India (thorium baring monazite sand deposits).

In addition to variations from place to place, the ambient background gamma dose rate in air at any specific location is not constant in time. It is subject to fluctuation, in particular from the removal of radon progeny in air by rainfall, soil moisture and snow cover. Washout and rainout of radon progeny from air may result in the short-term enhancement, by 50% - 100%, of the gamma ray dose rate in air. The extent of the elevation depends on rain interval, as well as, the rainfall amount. Snow cover depresses the background level by about 1% for each centimetre of snow.

External exposures indoors

Indoor exposure to gamma rays, mainly determined by construction materials, is inherently greater than outdoor exposure if earth materials have been used; the source geometry changes from half-space to a more surrounding configuration indoors. When the duration of occupancy is taken into account, indoor exposure becomes even more significant. Buildings constructed of wood add little to indoor exposures, which may then be comparable to outdoor exposures.

The world-wide population-weighted average is 84 nGy/h with national averages ranging from 20 to 200 nGy/h. The indoor to outdoor ratios range from 0.6 to 2.3, with a population-weighted value of 1.4. Thus indoor exposures (absorbed dose rate in air from terrestrial gamma radiation) are, in general, 40% greater than outdoor exposures.

Effective dose

To estimate annual effective doses, account must be taken of (a) the conversion coefficient from absorbed dose in air to effective dose and (b) the indoor occupancy factor. The average numerical values of those parameters vary with the age of the population and the climate at the location considered. Assuming 0.7 Sv/Gy for the conversion coefficient from absorbed dose in air to effective dose received by adults and 0.8 for the indoor occupancy factor, i.e. the fraction of time spent indoors and outdoors is 0.8 and 0.2, respectively, the components of the annual effective dose are determined as follows:

Indoors: 84 nGy/h × 8,760 h × 0.8 × 0.7 Sv/Gy = 0.41 mSv
Outdoors: 59 nGy/h × 8,760 h × 0.2 × 0.7 Sv/Gy = 0.07 mSv

The resulting worldwide average of the annual effective dose is 0.48 mSv, with the results for individual countries being generally within the 0.3 - 0.6 mSv range. For children and infants, the values are about 10% and 30% higher, in direct proportion to an increase in the value of the conversion coefficient from absorbed dose in air to effective dose.

Internal exposures other than radon

Internal exposures arise from the intake of terrestrial radionuclides by inhalation and ingestion. Doses by inhalation result from the presence in air of dust particles containing radionuclides of the ^{238}U and ^{232}Th decay chains. The dominant component of inhalation exposure is the short-lived decay products of radon, which because of their significance are considered separately under section “Radon and decay products”.

Doses by ingestion are mainly due to ^{40}K and to the ^{238}U and ^{232}Th series radionuclides present in foods and drinking water. It should be noticed that potassium concentration in the body is under homeostatic control and, therefore, the dose due to ^{40}K remains essentially constant, irrespectively of the amount of intake.

Inhalation intake of radionuclides of the ^{238}U and ^{232}Th decay chains (other than radon and its decay products) makes only a minor contribution to internal exposure. These radionuclides are present in air because of resuspended soil particles. Typical concentrations in air are 1 - 2 µBq/m^3 corresponding to a dust loading of 50 µg/m^3 and ^{238}U and ^{232}Th concentrations in the dust in the range 25 - 50 Bq/kg. The age-weighted annual effective dose is about 6 µSv from inhalation of uranium- and thorium-series radionuclides in air.

Ingestion intake of natural radionuclides depends on the consumption rates of food and water and on the radionuclide concentrations. Concentrations of naturally occurring radionuclides in foods vary widely because of the differing background levels, climate, and agricultural conditions that prevail. There are also differences in the types of local foods that may be included in the categories such as vegetables, fruits, or fish.

The total effective dose from inhalation and ingestion of terrestrial radionuclides is 310 µSv, of which 170 µSv is from ^{40}K and 140 µSv is from the long-lived radionuclides in the uranium and thorium series. It should be noted, however, that variations may be very significant. Some ground waters and waters from bed rock (drilled wells) may contain very significant levels of natural radionuclides including radon. Levels leading to doses up to several tens of mSv have been observed.

Radon and decay products

Radon (^{222}Rn) and thoron (^{220}Rn) are the gaseous radioactive products of the decay of the radium isotopes ^{226}Ra and ^{224}Ra, which are present in all terrestrial materials. Radon and its short-lived decay products in the atmosphere are the most important contributors to human exposure from natural sources.

The half-life of ^{222}Rn is 3.824 d. It has four short-lived decay products: ^{218}Po (3.05min), ^{214}Pb (26.8min), ^{214}Bi (19.9 min), and ^{214}Po (164 µs). Both polonium isotopes are alpha-emitters. The relatively short half-life of thoron (55.6 s) means that it does not have much time to travel from its production site to the immediate environment of human beings.

The evaluation of exposure to radon and thoron and their decay products must take account of the actual activity concentrations of the various alpha-emitting radionuclides in the decay series. An equilibrium factor F is defined that permits the exposure to be estimated in terms of the potential alpha energy concentration (PAEC) from the measurements of radon gas concentration. This equilibrium factor is defined as the ratio of the actual PAEC to the PAEC that would prevail if all the decay products in each series were in equilibrium with the parent radon. However, it is simpler to evaluate this factor in terms of an equilibrium equivalent radon concentration, C_{eq}, in the following manner:

$$F = C_{eq}/C_{rn}$$

$$C_{eq} = 0.105\ C_1 + 0.515\ C_2 + 0.380\ C_3\ (^{222}\text{Rn series})$$
$$C_{eq} = 0.913\ C_1 + 0.087\ C_2\ (^{220}\text{Rn series})$$

where the symbols C_1, C_2, and C_3 are the activity concentrations of the decay progeny, namely ^{218}Po, ^{214}Pb, and ^{214}Bi, respectively, for the ^{222}Rn series and ^{212}Pb and ^{212}Bi (C_1 and C_2) for the thoron series. The constants are the fractional contributions of each decay product to the total potential alpha energy from the decay of unit activity of the gas.

In this way, a measured radon concentration can be converted to an equilibrium equivalent concentration (EEC) directly proportional to PAEC. This provides a measure of exposure in terms of the product of concentration and time. The EEC can be converted to the PAEC, when desired, by the relationships 1 Bq/m^3 = 5.56 ·10^{-6} mJ/m^3 = 0.27 mWL (222Rn) and 1 Bq/m^3 = 7.6·10^{-5} mJ/m^3 = 3.64 mWL (thoron).

The value of the equilibrium factor may vary considerably depending on the prevailing circumstances, even from as low as 0.1 up to 0.9. However, typical value of the equilibrium factor in indoors is 0.4 and outdoors 0.6. If equilibrium factor is not determined with measurements, these values can usually be assumed.

Radon as source of indoor radon and exposure is discussed in a separate refresher course "Indoor radon sources, remediation and prevention in new construction". Therefore, characteristics of radon, its behaviour and exposures caused are not further discussed here.

Industrial activities

There are a number of circumstances in which materials containing natural radionuclides are recovered, processed, used, or brought into position such that radiation exposures result. This human intervention causes extra or enhanced exposures.

Industry uses many different raw materials that contain naturally occurring radioactive materials, sometime abbreviated NORM. These raw materials are mined, transported, and processed for further use. The consequent emissions of radionuclides to air and water lead to the eventual exposure of humans. Industries and materials for which NORM-issues have been of interest are, for example:

- Phosphate processing
- Metal ore processing
- Zircon sands

- Titanium pigment production
- Fossil fuels
- Oil and gas extraction
- Building materials
- Thorium compounds
- Scrap metal industry

The natural radionuclides present in the raw materials or wastes of these industries are those of the ^{238}U and ^{232}Th series. Releases are mainly to air or water, although landfills after dredging or wastes disposed on land may also provide pathways of exposure.

Both external and internal exposures may result from naturally occurring radionuclides released by industrial activities. In general, installations are located away from residential areas, and because external radiation levels decrease with distance from the plant, local residents are not significantly exposed. The workers, however, may receive low doses in connection with ore stock piles or waste deposits. Estimated and measured doses are in the range 0.1 - 300 µSv/a from direct exposures.

Inhalation contributes to exposure only in the vicinity of the plant, particularly with mineral sands-processing plants. Doses depend on distance and could be up to 50 µSv/a for office workers in a building just outside the plant site. In most other industries the contributions to total dose appear to be negligible.

Because most food products consumed by individuals are produced in large agricultural regions, possible dose from ingestion of radionuclides are small. For a typical situation, a small population in the vicinity of an elementary phosphorus plant, the calculated dose would be of the order 100 µSv/a. More generally, the estimated doses would be 1 - 10 µSv/a. Ingestion doses that could result from discharges of wastes to water are negligible compared to those by the other pathways.

Internal dosimetry and individual monitoring

Etherington, George
Centre for Radiation Chemical and Environmental Hazards, Health Protection Agency, Chilton, Didcot, Oxon. OX11 0RQ, UNITED KINGDOM

Abstract
A description is given of the main principles and methods of internal dosimetry. Factors that are unique to internal dosimetry (e.g. protraction of doses over time) are discussed, and the implications for the dose quantities used in internal dosimetry are explained. The principles underlying the use of biokinetic models are discussed, and ICRP's models of the respiratory tract and human alimentary tract described. As an example of the current approach to systemic modelling of the elements, the biokinetic model for plutonium is described. Lastly, the use of individual monitoring for the retrospective assessment of internal doses is discussed.

Introduction
Internal dosimetry addresses the determination of radiation doses resulting from the intake of radioactive materials into the body by inhalation, ingestion, absorption through the skin or *via* wounds. Internal doses may be determined for particular organs or tissues in the body, or for the whole body. It is not possible to measure internal doses directly, although the activity of a radionuclide in the body can be measured. *Individual monitoring* for internal contamination is the direct or indirect measurement of the amount of a radionuclide in the body, and the retrospective assessment of internal doses using the results of such measurements.

In this paper, the main steps in the calculation of internal dose are first summarised. Subsequent sections describe the dose quantities used in internal dosimetry, the method used to calculate internal doses, and the biokinetic models used to describe the movement of radionuclides through the respiratory and gastro-intestinal tracts. As an example of the current approach to modelling the biokinetics of radionuclides after uptake from blood, the biokinetic model used to predict the systemic behaviour of plutonium is described. Finally, individual monitoring for internal contamination is discussed.

This paper aims to provide a summary of the basics of internal dosimetry and individual monitoring for internal contamination, and to give an account of recent developments in the field. It is aimed at radiation protection professionals who may have limited experience of internal dosimetry, or who wish to learn about recent advances.

Assessment of Internal Doses

The risk or severity of any adverse effects on health resulting from an intake of a radionuclide is in almost all cases determined by making an assessment of the internal radiation dose. Risks to health are then evaluated making use of information on the relationship between risk and dose such as that provided by epidemiology studies, notably the follow up of Japanese A-bomb survivors.

Since internal doses cannot be measured directly, they have to be calculated using mathematical models describing the behaviour of radionuclides in the body. The main steps in a calculation of internal dose resulting from a specified intake (i.e. a prospective assessment of dose) are as follows:

- Modelling of the **intake** process to determine the location(s) at which the radionuclide is initially deposited or through which it transits (e.g. regions of the respiratory tract; organs in the gastro-intestinal tract), and the amounts deposited in those locations
- Modelling of the **clearance** of the radionuclide from the initial site of deposition, to determine the amount cleared and rates of clearance
- Modelling of the **uptake** of the radionuclide from the initial deposition site to the blood and then to the rest of the body
- Determination of the amounts then **deposited** in the various organs and tissues of the body, and the rates at which the radionuclide is removed from these organs and tissues
- Calculation of the amounts of **energy deposited** in each target organ as a result of the decay of the radionuclide in each source organ
- Calculation of the **absorbed dose** received by each organ over time, from the amount of energy deposited per unit mass of the organ
- Calculation of the **equivalent dose** received by each organ over time, determined by applying the appropriate radiation weighting factors to the absorbed dose for each radiation type, so allowing for the different effectiveness of each radiation type in causing stochastic effects
- Calculation of the **committed equivalent dose** for each organ, by summing the equivalent dose received from the intake over a fixed time period (e.g. 50 years for occupational exposure)
- Calculation of the committed **effective dose**, determined by applying the appropriate tissue weighting factors to the committed equivalent dose for each organ and then summing, so allowing for the different radio-sensitivities of the organs for stochastic effects

Dose Quantities

The calculation of doses from radionuclides within the body (internal emitters) is less straightforward than with external radiation. A number of factors that are specific to internal dosimetry influence the dose quantities that are used, as described below.

Internal doses are protracted over time

Individuals cease to receive doses from external radiation when they leave the radiation field. In contrast, radionuclides within the body continue to deliver dose until they are removed from the body by normal biological processes or until the amount remaining is reduced to a negligible level because of radioactive decay. Thus, ICRP recommends that the quantity to be controlled should be the *committed dose*, defined as the dose incurred in the fifty years following intake for an adult, and from intake to age 70 years for children (equation 1).

$$D(70-t_0)=\int_{t0}^{70}\dot{D}(t)dt \qquad (1)$$

where "*D_dot*" is the absorbed dose rate at time t, and t_0 is the age at intake

Organs are the sources of irradiation

A particular organ may receive a dose either as a result of radionuclide decay within the same organ, or in other organs. For the purposes of a dose calculation, an organ in which radionuclide decay is taking place is called a *source organ* (denoted S), while an organ that receives a dose is called a *target organ* (denoted T). All organs in which radionuclides are present are in principle source organs, and all source organs are also target organs. Other organs may or may not be target organs, depending on how penetrating the radiation type (e.g. α, β, γ) is.

Radiosensitivity of organs is variable

Some radiation types are more effective than others in causing stochastic effects such as cancer. For radiation protection purposes, the absorbed dose associated with each radiation type is multiplied by a *radiation weighting factor*, w_R, which reflects these differences. In general, the decay of any radionuclide gives rise to the emission of more than one type of radiation, and so the absorbed dose from each radiation type must be weighted separately and then summed. The result is the *equivalent dose*, defined in equation (2) for a particular target organ T, and denoted H_T.

$$H_T=\sum_R w_R\overline{D}_{T,R} \qquad (2)$$

where D is the absorbed dose, which is averaged over the organ T, and the summation extends over all radiations R. The unit of equivalent dose is the sievert (Sv).

The radiation weighting factors, w_R, represent judgments regarding the potential relative biological damage of radiation R, taking into account all of the possible target organs or tissues (e.g. the lung) and all the possible health outcomes (e.g. lung cancer). In part, they reflect the density of ionization within the target organ, which is associated with the linear energy transfer (LET) of the radiation. Clearly, the use of radiation weighting factors represents a very simplified view of the health effects of different types of radiation. Their use is justified provided it is clear that the resulting assessed doses are only to be used for radiation protection purposes (for example, to confirm that doses are well below dose limits). The values of w_R on which current legislation is based are given in ICRP Publication 60 (ICRP, 1991), while ICRP's current recommended values are given in ICRP Publication 103 (ICRP, 2008).

Dose distributions in the body may be very inhomogeneous

It is not unusual for doses to target organs to differ by several orders of magnitude. Nevertheless, for radiation protection purposes, it is useful to derive a single dose quantity that broadly reflects the overall risk of stochastic effects on health. If all the organs and tissues of the body had the same sensitivity to ionising radiation, then a "mean dose" could be determined simply by taking a weighted average of the organ/tissue doses, with the weight factors equal to the ratio of the organ/tissue mass to the total body mass. However, there are significant differences between the radio-sensitivities of the organs/tissues, and these are reflected in the set of *tissue weighting factors* specified by ICRP. The sum of the weighted organ doses is the *effective dose*, E, which is defined as:

$$E = \sum_T w_T H_T \qquad (3)$$

where the summation extends over the organs/tissues assigned tissue weighting factors w_T. The values of w_T on which current legislation is based are given in ICRP Publication 60, while ICRP's current recommended values are given in ICRP Publication 103.

Calculation of internal dose

The committed equivalent dose rate at time t in target tissue T can be expressed as:

$$\dot{H}_T(t) = c \sum_S \sum_j q_{S,j}(t) \cdot SEE(T \leftarrow S;t)_j$$

where $q_{S,j}(t)$ is the activity of decay chain member j present in the source region S at age t; $SEE(T\leftarrow S;t)_j$ is the equivalent dose in the target tissue T per nuclear transformation in region S at age t for radionuclide j ; and c is any numerical constant required by the units of q and *SEE* (the Specific Effective Energy).

The committed equivalent dose in the target tissue T accumulated by age 70 y due to a single intake of a radionuclide j at age t_0, $H_T(70-t_0)$ is:

$$H_T(70-t_0) = \int_{t_0}^{70} \dot{H}_T(t)dt = c \cdot \int_{t_o}^{70} \sum_S \sum_j q_{S,j}(t) \cdot SEE(T \leftarrow S;t)_j \, dt$$

For each radionuclide, the *SEE* at age t takes into account the contributions of each radiation emitted by the radionuclide weighted by the appropriate radiation weighting factor. The *SEE* is :

$$SEE(T \leftarrow S\,;\,t) = \frac{1}{M_T(t)} \left[\sum_i E_i \, Y_i \, w_{R,i} \, AF(T \leftarrow S\,; E_i\,, t) + w_{R,\beta} \int_0^\infty Y(E) \, E \, AF(T \leftarrow S\,; E, t) \, dE \right]$$

where E_i is the energy of the ith discrete radiation emitted by the radionuclide with intensity Y_i per nuclear transformation, $M_T(t)$ is the mass of the target tissue T at age t, $w_{R,i}$ is the radiation weighting factor applicable to the ith radiation, $AF(T\leftarrow S;\, E_{i,\,t})$ is the absorbed fraction, which is the fraction of the energy E_i emitted in S that is absorbed in T for an individual of age t, and $Y(E)\,dE$ denotes the number of electrons in the beta or positron spectrum, with energy between E and $E+dE$.

In most cases for non-penetrating radiations (alphas, betas, positrons, electrons), energy is assumed to be deposited only in the region where the radionuclide resides, and so *AF* is equal to 1 when S and T are identical and zero otherwise. However, in some dosimetric models where the location of target cells is given special consideration (e.g. bone, the alimentary tract and the respiratory tract), the calculation of *AF* is more complicated, generally being undertaken using Monte Carlo methods in radiation transport models.

For penetrating radiations (gammas and X-rays), *AF* generally has to be calculated for all possible combinations of source and target organs. Calculations are performed using a computer model of the body often termed a "phantom" which describes the geometric relationship between the different tissues and organs of the body. Two types of phantom are currently in use: mathematical phantoms made up of arrangements of geometric shapes (e.g. the MIRD phantom); and voxel phantoms, derived from computed tomography (CT) or magnetic resonance images (MRI) obtained from high resolution continuous scans of a single individual. The MIRD phantom was used for dosimetry calculations for many years, but voxel phantoms are now coming into general use.

Biokinetic Models

The mathematical models describing the movement of radionuclides in the body are called biokinetic models. All of the models currently in use are compartment models which use first order kinetics to describe the transfer of material between compartments. Models contain a number of compartments, each representing a particular organ, part of an organ or tissue. A compartment is assigned a deposition or uptake fraction that determines its initial content (if any), and each path out of a compartment is assigned a rate constant which determines the removal rate *via* that pathway. The sum of the rate constants of the pathways leaving a compartment determines the retention half-time (also known as the biological half-time) for that compartment. A simple model may contain only two or three compartments linked by a single pathway in a linear chain. In more complex models, there may be networks of interconnected compartments in which recirculation between compartments may occur.

Biokinetic models describe the distribution of activity within the body as a function of time. Radioactive decay can be included, and the model can then be used to calculate the number of decays that take place in each compartment as a function of time. For single intakes of radionuclides with short physical half-lives or biological half-times, such as ^{131}I, almost all the dose is delivered over a period of days or weeks, whereas for radionuclides such as ^{239}Pu, with long radioactive decay half-lives and biological half-times, dose is delivered over the lifetime of the individual.

Ideally, model parameter values are determined from human studies, but for many elements, animal data must be used, and for some elements where no data is available, parameter values must be determined from data on chemically similar elements.

Biokinetic models can be used to describe the processed of intake, distribution, retention and excretion. Radionuclides entering the body by inhalation or ingestion cause the respiratory tract and gastro-intestinal tract to be irradiated. (Other organs will also be irradiated if the radiation is penetrating). Entry through contaminated wounds will also result in local irradiation of tissues. The subsequent behaviour of the radionuclide depends on the element concerned and its chemical form, which determine the solubility of the radionuclide and the extent to which it dissolves and is absorbed into blood. The chemical nature of the element determines the distribution between the organs of the body, and the retention times in each organ. If a radionuclide is an isotope of an element that is normally present (e.g. Na, K, Cl) then it behaves like the stable element. If it has similar chemical properties to an element normally present, then it tends to follow the metabolic pathways of that element, although its rate of movement between the various compartments in the body may be different (e.g. ^{90}Sr and ^{226}Ra behave similarly to Ca, ^{137}Cs and ^{86}Rb similarly to K). The behaviour of other radionuclides depends upon their affinity for biological ligands and other transport systems in the body. Radionuclides entering the blood may distribute throughout the body (e.g. ^{3}H, ^{40}K, ^{137}Cs); they may selectively deposit in a particular tissue (e.g. ^{131}I in the thyroid; ^{90}Sr in bone); or they may deposit in significant quantities in a number of tissues (e.g. ^{144}Ce, ^{210}Po, ^{239}Pu, ^{241}Am).

In addition to the direct entry of radionuclides by absorption to blood, insoluble materials may be moved slowly through the lymphatic system in the form of small particles. Movement along lymphatic vessels can lead to accumulation of radionuclides in regional lymph nodes, e.g. the tracheo-bronchial lymph nodes following movement from the lungs or the axillary lymph nodes following movement from a wound in the hand. Particles may slowly reach the bloodstream and are then rapidly removed from the circulation by phagocytic cells of the reticulo-endothelial system in the liver, spleen and bone marrow.

This paper describes some of the biokinetic and dosimetric models developed by the International Commission on Radiological Protection (ICRP). Dose coefficients for intakes of radionuclides (that is, dose per unit intake values) derived using these models and published by ICRP (ICRP, 1989, 1993, 1994b, 1995a, 1995b), are incorporated into legislation in the European Union and others parts of the world.

The ICRP Human Respiratory Tract Model

The ICRP model of the Human Respiratory Tract, HRTM (ICRP, 1994a), applies explicitly to all members of the population, utilising reference parameter values for 3 month-old infants, 1, 5, 10 and 15 year old children and adults. The model can be used both for dosimetry and for the interpretation of individual monitoring data (such as measurements of activity in the lungs).

Physiology

The respiratory tract (Figure 1) is represented by five regions. The extrathoracic (ET) airways are divided into the ET_1 region, the anterior nasal passages, and the ET_2 region, which comprises the posterior nasal and oral passages, the pharynx and larynx. The other regions are within the lungs. They are the bronchial region (BB: trachea, generation 0 and bronchi, airway generations 1-8), the bronchiolar region (bb: airway generations 9-15), and the alveolar-interstitial region (AI: the gaseous exchange region). Lymphatic tissue is associated with both the extrathoracic and thoracic airways (LN_{ET} and LN_{TH} respectively).

Intakes and deposition

The HRTM can be used to calculate doses per unit exposure to radionuclides in air as well as doses per unit intake. Intake depends on ventilation, i.e. the product of the breathing frequency and tidal volume of the lungs. This is the main aspect of the model that depends on age and level of exercise. The model can determine doses per unit exposure for four levels of exercise: sleep, sitting, light exercise, and heavy exercise.

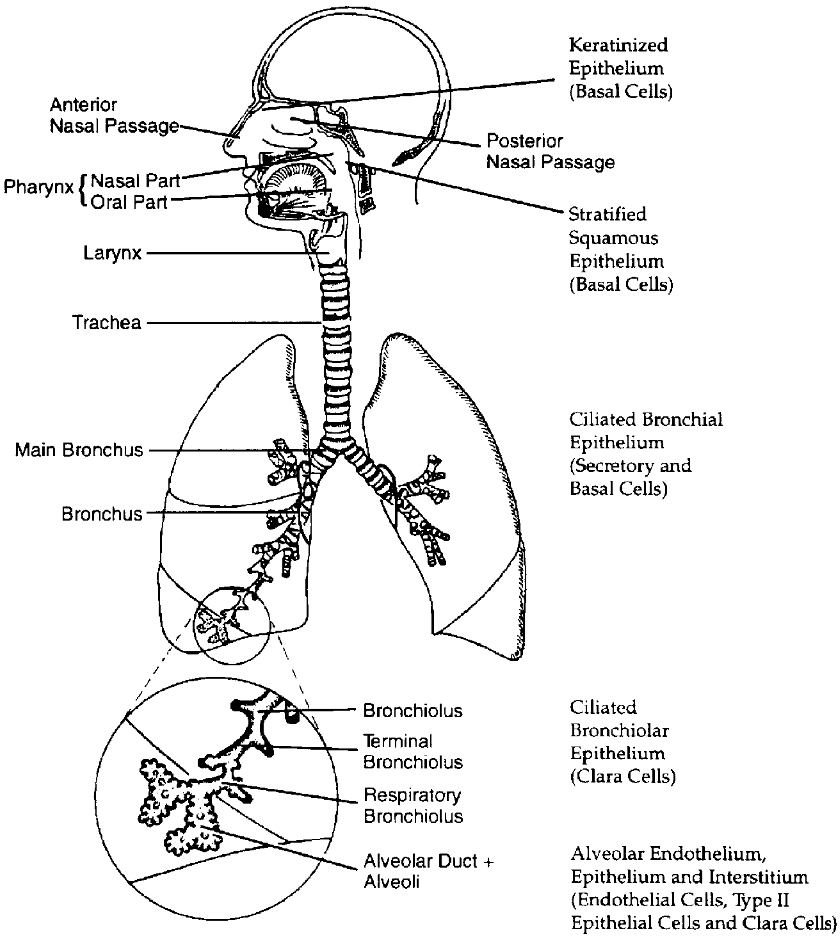

Fig. 1. Respiratory tract regions.

Deposition is calculated for each region of the respiratory tract taking account of both inhalation and exhalation. This is done as a function of particle size, breathing parameter values and/or work load, according to the age and sex of the subject. Deposition parameter values are specified for a particle size range of 0.006 µm AMTD[1] to 100 µm AMAD[2]. Default deposition parameter values for individuals are based on average daily patterns of activity. In general, deposition in the extrathoracic airways is greater for a 5 µm AMAD aerosol (the default value for occupational exposure), and conversely penetration to the alveoli is greater for a 1 µm AMAD aerosol (the default value for environmental exposure).

[1] Activity Median Thermodynamic Diameter (AMTD) is used for particle sizes < 0.5 µm, where thermodynamic processes dominate. AMAD (defined below) is used for larger particles sizes where aerodynamic processes (gravitational sedimentation, inertial impaction) dominate.
[2] Activity Median Aerodynamic Diameter (AMAD), defined such that 50% of the activity of an aerosol is associated with particles with aerodynamic diameters greater than the AMAD.

The model can be used for intakes of gases and vapours as well as particulate material. Three classes are defined: SR-0 for insoluble and non-reactive materials for which uptake/retention is negligible; SR-2 for very soluble and reactive materials for which absorption to blood is assumed to be complete; and SR-1, an intermediate category.

Clearance

The HRTM describes three clearance pathways. Material deposited in ET_1 (the front of the nose) is removed by extrinsic means such as nose-blowing. In other regions, clearance is competitive between (a) particle transport to the gastrointestinal (GI) tract and the lymphatic system, and (b) absorption into blood. Particle transport to the GI tract occurs by mucociliary clearance. It is assumed that particle transport rates are the same for all materials. Absorption into blood is material-specific and is assumed to occur at the same rate in all regions except ET_1, where none occurs.
Figure 2 shows the compartment model for particle transport. It is assumed that the AI deposit is divided between AI_1, AI_2 and AI_3 in the ratio 0.3:0.6:0.1 (half-times of about 30d, 700d and 7000d). The fraction of the deposit in bb and BB which moves slowly (bb_2 and BB_2) is particle size dependent (up to 50% for <2.5 μm) with 0.7% retained in the walls (bb_{seq} and BB_{seq}). A small fraction is retained in the wall in the ET_2 region (ET_{seq}) and the rest is cleared rapidly to the GI tract. Simultaneous absorption to blood occurs as a competing process in all compartments except ET_1.

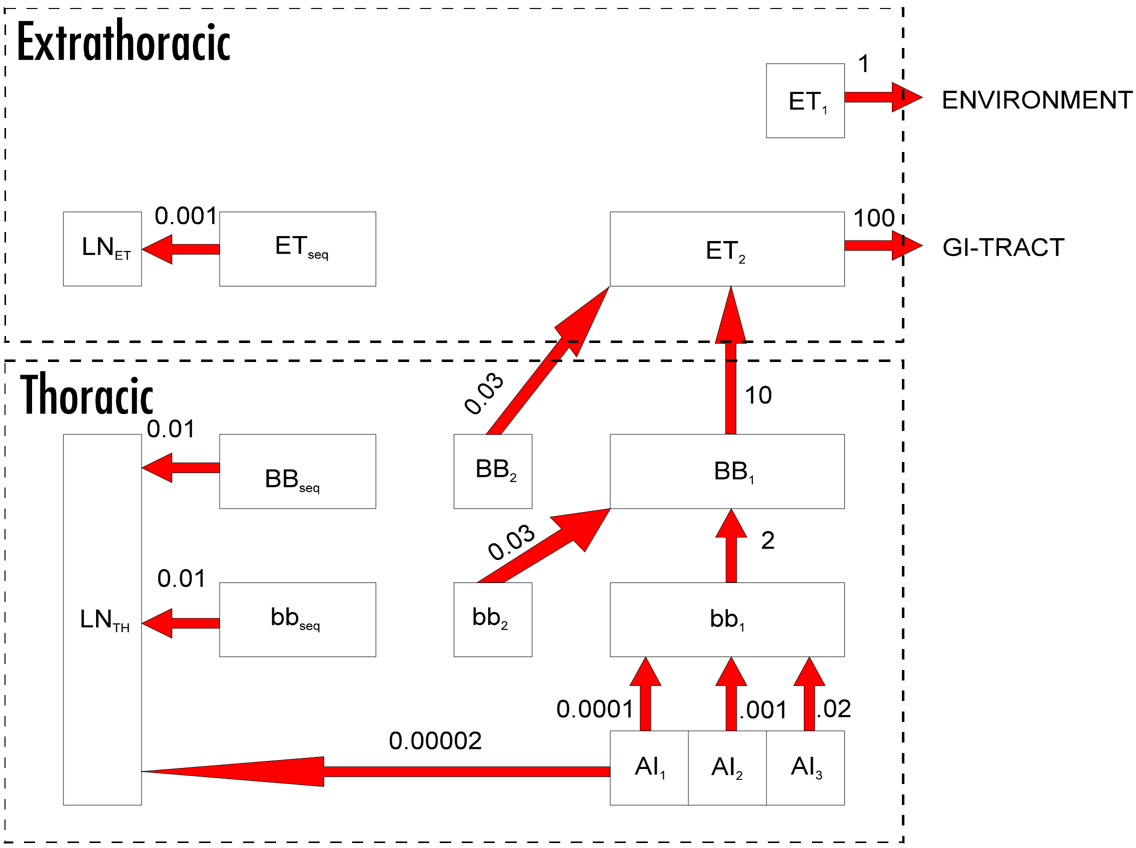

Fig. 2. Particle transport in the HRTM (ICRP Publication 66). Transfer rates are in units of d^{-1}.

Absorption

Absorption to blood depends on the chemical nature of the element and the chemical form deposited but is assumed to be independent of deposition site (with the exception of ET_1). The model allows for changes in dissolution and absorption to blood with time. The use of material-specific dissolution rates is encouraged but defaults are given; i.e. Types F (fast), M (medium) and S (slow). Type F has a single clearance component, whereas Types M and S have two components. Expressed as approximate half-times, these absorption rates are: Type F - 10 min (100%); Type M - 10 min (10%), 140d (90%); Type S - 10 min (0.1%), 7000d (99.9%).

For the example of a 1 µm AMAD aerosol, the total amounts reaching blood from the respiratory tract as predicted by the HRTM are 24% (F), 9% (M) and 1% (S) of the total inhaled. In each case, a further fraction of the inhaled material reaches blood by absorption from the gut after mechanical clearance and swallowing; this fraction will be greatest for Type F materials (most soluble) and least for Type S materials.

Dosimetry of the respiratory tract

In the respiratory tract model (as well as in models for the bone and gastro-intestinal tract), special attention is given to the locations of both source tissues (where radionuclides reside) and targets (tissues whose cells are thought to be at risk of cancer). Radionuclides are known to be deposited in the fluids lining the airways or alveoli, from where they can be absorbed to blood, perhaps residing in the airway wall for some time, or cleared to other regions of the lung by the action of mucus and cilia. There is good evidence that the target cells for cancer induction are the basal and secretory cells in the epithelia of the conducting airways, and certain cells of the alveolar region such as the Clara cells. To calculate doses to the sensitive tissues, cylindrical models of the airways are used, with the various cells modelled as concentric layers. Calculations are performed using Monte Carlo simulations of radiation transport. To calculate the dose to the lungs as a whole, a weighted average of the doses to the tissues is determined, independently of their relative masses. In the current model, the tissues are given equal weighting. For calculations of effective dose, the tissue weighting factor for the lungs (w_T = 0.12) is apportioned equally to the AI, BB and bb regions (i.e. 0.04 each).

Table 1. Committed doses from inhalation of radionuclides (1 µm AMAD aerosol) by adults (Sv Bq^{-1} intake).

Nuclide	Principal emissions	Half-life	Absorption Type	Equiv. Dose to lungs	Effective dose	% lung dose [1]
^{131}I	β,γ	8d	F	6.0×10^{-11}	7.4×10^{-9}	<1
^{137}Cs	β	30y	F	4.3×10^{-9}	4.6×10^{-9}	11
^{210}Po	α	138d	M	2.6×10^{-5}	3.3×10^{-6}	95
^{238}U	α	4.5×10^{9}y	M	2.2×10^{-5}	2.9×10^{-6}	91
^{239}Pu	α	2.4×10^{4}y	M	3.3×10^{-5}	5.0×10^{-5}	8
^{239}Pu	α	2.4×10^{4}y	S	8.7×10^{-5}	1.6×10^{-5}	65

1. % of effective dose contributed by equivalent dose to lungs

Table 1 gives examples of committed equivalent doses to the lungs and committed effective dose. The lung dose varies from 9 x 10^{-5} Sv Bq^{-1} for insoluble compounds of ^{239}Pu (i.e. Type S) to 6 x 10^{-11} Sv Bq^{-1} for ^{131}I, i.e. by over five orders of magnitude, reflecting the different retention times in the lung and the energy and type of radiation emitted.

Similarly, the contribution of lung dose to the effective dose varies from high values of about 90% (^{210}Po, ^{238}U) to a value of <1% for ^{131}I. The rapid absorption of Type F materials from the lungs to blood makes lung dose less important compared to doses to other tissues - the thyroid in the case of ^{131}I. For insoluble ^{239}Pu the lung dose dominates the effective dose (65%) due to its long retention in lung, whereas this is not true for more soluble Type M forms (8%) since in this case doses to systemic tissues are higher.

ICRP Human Alimentary Tract Model

Until 2007, the model of the gastrointestinal tract used by ICRP was that described in Publication 30 (ICRP, 1979). This is a simple model, containing four compartments in a linear chain representing the stomach, small intestine and upper & lower large intestines. In 2007, the Publication 30 model was superseded by ICRP's Human Alimentary Tract Model, HATM (ICRP, 2007), and future ICRP publications will use this model. However, current EU legislation contains dose coefficients generated using the Publication 30 model. This section describes the main features of the HATM, shown in Figure 3.

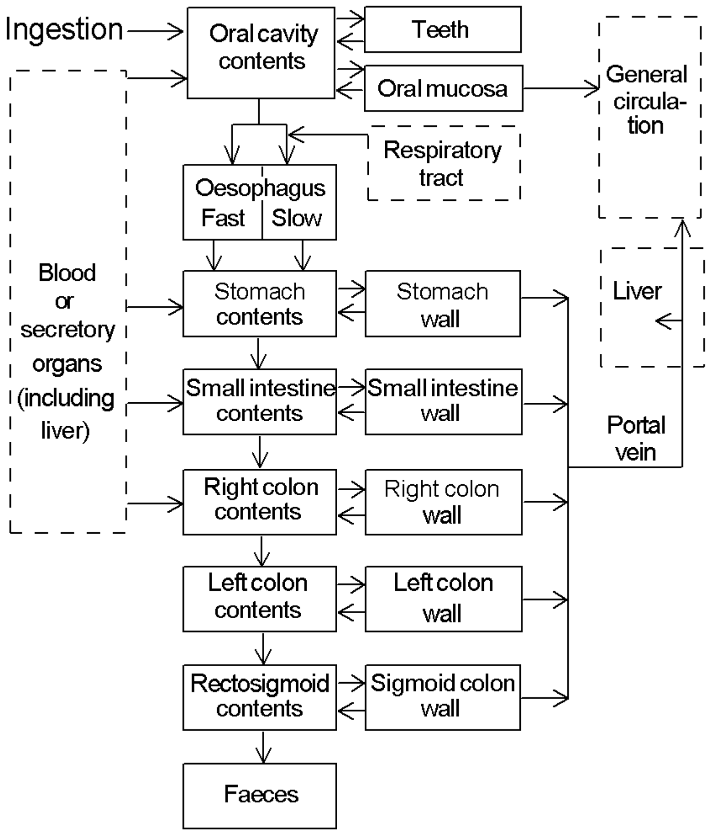

Fig. 3. Structure of the HATM. The dashed boxes are included to show connections with the respiratory tract model and systemic models.

The increased complexity reflects the wider scope and greater degree of realism of the HATM as compared to the Publication 30 model. The main features of the HATM are:

- Age-dependent parameter values are specified for the dimensions of alimentary tract regions and associated transit times of contents through the regions, as are gender-dependent parameter values of dimensions and transit times for adults.
- Retention of radionuclides in the mucosal tissues of the walls of alimentary tract regions is included. For some radionuclides, such as isotopes of iron and related elements, there may be significant retention in the intestinal wall.
- Explicit calculations are made of dose to target regions for cancer induction within each alimentary tract region. The sensitive cells for cancer induction are thought to be the stem cells in the base of the crypts which are likely to receive negligible doses from α-emitting nuclides in the gut lumen and lower doses for most beta emitters.
- All alimentary tract regions are included. Doses are calculated for the oral cavity, oesophagus, stomach, small intestine, right colon, left colon and recto-sigmoid (including the rectum). Colon doses are combined as a mass-weighted mean.
- Transit times are specified for food and liquids, as well as for total diet, for the mouth, oesophagus and stomach.

Table 2. Comparison [1] of ingestion dose coefficients derived using the HATM and ICRP Publication 30 models for adult males.

Nuclide	Equivalent doses [1]			Effective dose [1]
	Stomach	Right colon [2]	Left colon [3]	
^{90}Sr	1.0	0.2	0.1	-6%
^{106}Ru	1.2	0.2	0.1	-60%
^{239}Pu	0.8	0.4	0.2	0%

1. Equivalent doses compared as a ratio (HATM : Pub 30), effective doses as a fractional change (%).
2. Compared with the upper large intestine of the Publication 30 model.
3. Compared with the lower large intestine of the Publication 30 model.

Table 2 compares doses calculated using the HATM and Publication 30 models for three examples. For the beta-emitting nuclides ^{90}Sr and ^{106}Ru, the substantial reduction in colon doses in the HATM reflects reduced Specific Absorbed Fractions (SAF). For ^{239}Pu, there is no direct dose to alimentary tract regions using the HATM; all of the dose is due to absorbed ^{239}Pu deposited in soft tissues. The extent to which differences in equivalent doses to the tissues of the alimentary tract affect the effective dose depends on the relative contribution of these tissues to the effective dose. For ^{90}Sr, effective dose is dominated by skeletal doses (bone surfaces and red bone marrow) and there is little difference in the effective dose calculated using the HATM and Publication 30 models. For ^{106}Ru, doses to alimentary tract regions contribute significantly to effective dose with the result that the value obtained using the HATM is about half of that using the Publication 30 model. For ^{239}Pu, as for ^{90}Sr, doses to alimentary tract regions make only a small contribution to effective dose, the dominant contributors being liver and skeletal tissues.

Biokinetics and dosimetry for plutonium

The absorption of Pu and other actinide elements from the GI tract is very low; default fractional absorption (f_1 values) recommended by ICRP for adults are 10^{-5} for Pu oxide, 10^{-4} for Pu nitrate and similar compounds and 5 x 10^{-4} for other chemical forms and environmental forms of Pu. For inhalation, the default absorption assumption is Type M for Pu (Type S for Pu oxide).

After absorption to blood, the principal sites of deposition of Pu and related elements are the skeleton and liver. In Publications 56 and 67 (ICRP 1989, 1993) a physiologically-based age-dependent model was developed and applied to Pu, Am and Np and subsequently to Th and Cm (ICRP 1995a,b). The model is shown in Figure 4.

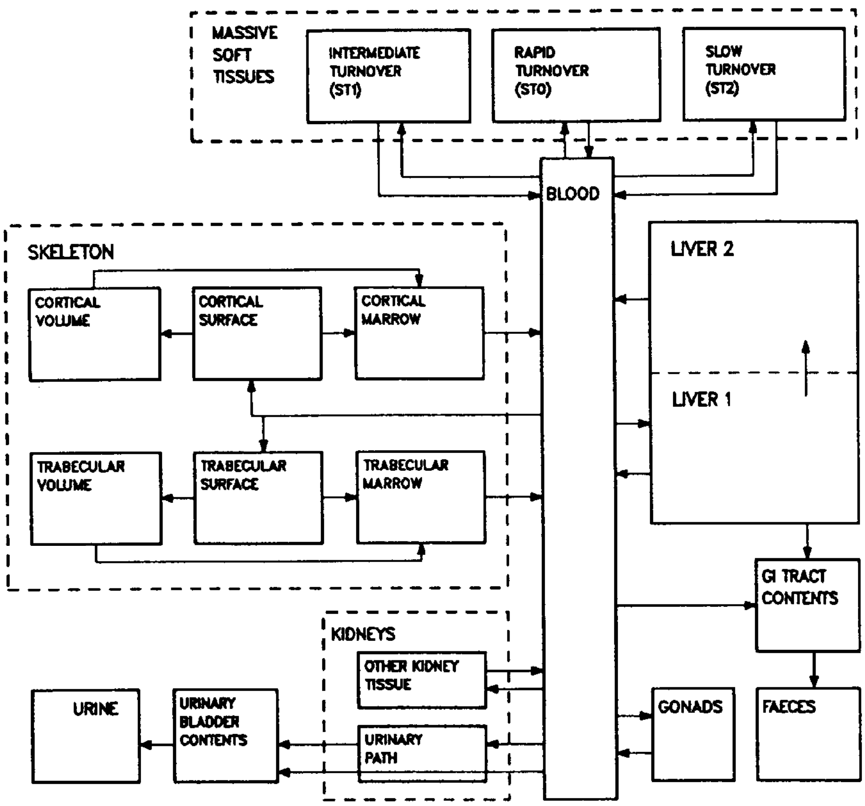

Fig. 4. Biokinetic model for the actinide elements: Pu, Am, Cm, Th, Np.

The radiation-sensitive parts of the skeleton are the red bone marrow, for leukaemia induction, and a layer of cells (the endosteal cells) on the inner bone surface, for induction of bone cancer. In adults, red bone marrow is contained in the trabecular or “spongy” bone which constitutes, for example, the vertebrae and the ends of the long bones. Cortical or compact bone, which constitutes the shafts of the long bones, contains only inactive fatty marrow in the adult. The model treats cortical and trabecular regions of the skeleton separately, with initial deposition on bone surfaces. A specific aspect of the biokinetics of Pu and related elements is that incorporation into bone volume results from burial surface deposits of new bone.

Pu removed from the bone surfaces may be retained in bone marrow. Accordingly, the model includes transfer to bone volume and to bone marrow. It also includes transfer from bone volume to bone marrow due to resorption. Activity is eventually released from bone marrow to blood and becomes available for recycling to all tissues including the skeleton. For simplicity, rates of bone growth and resorption are all taken to be the same and show the same age-dependence.

The liver has two compartments for all elements except Am and Cm, for which one compartment is used. Activity taken up by Liver 1 is transferred to Liver 2 except for a small proportion excreted in bile to the GI tract. Activity is lost to blood from Liver 2. Figures 5 and 6 illustrate the retention of Pu in the skeleton and liver predicted by the model for different ages at intake.

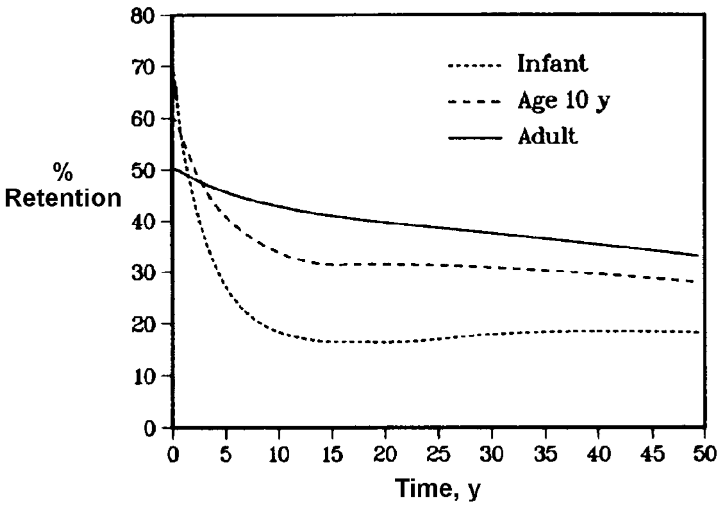

Fig. 5. Model predictions for the retention of Pu in the skeleton as a function of time after entry to blood (% total entering blood).

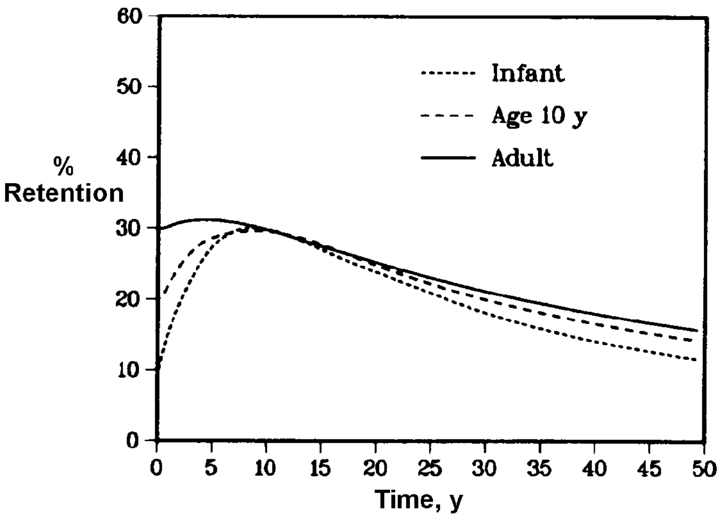

Fig. 6. Model predictions for the retention of Pu in the liver as a function of time after entry to blood (% total entering blood).

Table 3 shows dose coefficients for the ingestion or inhalation of ^{239}Pu. Committed effective doses after ingestion are due very largely to contributions from doses to skeletal tissues and liver with smaller contributions from doses to the gonads (testes or ovaries).

Table 3. Committed effective doses from the ingestion or inhalation of ^{239}Pu, 10^{-6} Sv Bq^{-1}.

Age	Ingestion *	Inhalation (1 µm AMAD)†	
		Type M	Type S
3 months	4	80	43
1 year	0.4	77	39
5 years	0.3	60	27
10 years	0.3	48	19
15 years	0.3	47	17
Adult	0.3	50	16

*Environmental forms; $f_1 = 5 \times 10^{-4}$, 5×10^{-3} for infants

‡Type M is default; Type S = e.g. Pu oxide

After inhalation, doses to the lungs are also important, particularly for Type S materials. Doses are lower after ingestion than inhalation because of the small amount absorbed to blood (most activity passes unabsorbed through the GI tract; >99%). Doses per unit intake are greatest at younger ages because of the smaller tissue masses, greater relative uptake in the skeleton (and greater f_1 value in infants).

Monitoring for ^{239}Pu is usually based on urine monitoring followed by mass- or alpha-spectrometry. Modern laboratories can detect levels less than a few mBq per litre. Faecal monitoring can also be used with some advantage, but there are often acceptability problems with workforces. Plutonium-239 emits 17 keV X-rays during alpha decay and these emissions can be detected by whole-body counting.

In general ^{239}Pu, like other alpha-emitters, presents problems for monitoring since intakes of a relatively small mass can lead to dose limits being exceeded. Excretion levels resulting from a small mass are low, and the non-penetrating nature of alpha emissions make detection difficult. In some cases the presence of other Pu isotopes, ^{241}Am, and fission products can make detection easier because of higher energy emissions but, of course, the composition of the mixture needs to be established.

Individual monitoring for internal contamination

The previous sections have described methods for calculating doses from a known intake received by a reference person using standard phantoms and biokinetic models. This is a prospective assessment of dose, because it answers the question “What would the dose be if a person receives an intake of x Bq?”. Usually a unit intake (1 Bq) is assumed and the results are known as dose coefficients (Sv Bq^{-1}) and are published in standard compendia (e.g. ICRP, 1994b). To obtain estimates of doses to individuals the dose coefficients must be multiplied by the known intake (Bq). For environmental intakes this can be derived from measurements of concentrations in foodstuffs (e.g. Bq kg^{-1}) and habit data giving the typical consumption of the foodstuff in a set time period.

In occupational settings however, workers are monitored on a regular basis and the results of measurements on their bodies or excreta can be used to estimate intake. This is a retrospective assessment of dose, because it answers the question "What is our best estimate of the dose, give that x Bq (or y Bd d^{-1}) has been measured in the lungs (or in urine, etc)?". This section gives general information on the design and use of these methods; it is taken largely from ICRP Publication 78 (ICRP, 1997).

Methods of Individual Monitoring

The purpose of this section is to describe briefly the main measurement techniques, their advantages and their limitations. In most cases, individual monitoring for intakes of radionuclides may be achieved by body activity measurements, excreta monitoring, air sampling with personal air samplers, or a combination of these techniques. The choice of measurement technique will be determined by several factors: the radiation emitted by the radionuclide; the biokinetic behaviour of the contaminant; its retention in the body taking account of both biological clearance and radioactive decay; the required frequency of measurements; and the sensitivity, availability, and convenience of the appropriate measurement facilities.

Routine monitoring programmes usually involve only one type of measurement if adequate sensitivity can be achieved. For some radionuclides, only one measurement technique is feasible, e.g. urine monitoring for intakes of tritium. For radionuclides such as plutonium isotopes that present difficulties for both measurement and interpretation, a combination of techniques should be employed. If different methods of adequate sensitivity are available, the general order of preference in terms of accuracy of interpretation is: body activity measurements; excreta analysis; personal air sampling. Results of monitoring of the working environment (area monitoring) may provide information that assists in interpreting the results of individual monitoring, e.g. information on particle size, chemical form and solubility, time of intake.

The results of workplace monitoring for air contamination may sometimes be used to estimate individual intakes. However the interpretation of the results of measurements from air sampling in terms of intake is not simple and may be misleading. The most common form of representative sampling is by using fixed samplers at a number of selected locations intended to be reasonably representative of the breathing zone of the worker.

Monitoring in relation to a particular task or event may often involve a combination of techniques so as to make the best possible evaluation of an unusual situation, for example, a programme of both body activity and excreta measurements.

In some cases of suspected incidents, screening techniques (such as measuring nose blow samples or nasal smears) may be employed to give a preliminary estimate of the seriousness of the incident.

In vivo measurements

The IAEA (IAEA, 1996) has given guidance on the direct measurement of body content of radionuclides. Direct measurement of body or organ content provides a quick and convenient estimate of activity in the body. It is feasible only for those radionuclides emitting radiation that can escape from the body. In principle, the technique can be used for radionuclides that emit: X or γ radiation; positrons, since they can be detected by measurement of annihilation radiation; energetic β particles that can be detected by measurement of bremsstrahlung; and some α-emitters that can be detected by measurement of the characteristic X rays.

Many facilities for the measurement of radionuclides in the whole body or in regions of the body consist of one or a number of high efficiency detectors housed in well-shielded, low-background environments (IAEA, 1996). The geometrical configuration of the detectors is arranged to suit the purpose of the measurement, e.g. the determination of whole-body activity or of activity in a region of the body such as the thorax or the thyroid. The skull or knees may be used as a suitable site for measurement of radionuclides in skeleton.

Care must be taken to remove surface contamination before body activity is measured. For routine measurements, determination of whole-body content is often adequate for radiological protection purposes.

Commonly encountered fission and activation products, such as ^{131}I, ^{137}Cs and ^{60}Co, can be detected with comparatively simple equipment at levels that are adequate for radiation protection purposes. Such simple equipment may consist of a single detector, viewing the whole body or a portion of the body, or, for iodine isotopes, a small detector placed close to the thyroid. The advantage of simple equipment is that it may be operated at the place of work, thereby avoiding the time required to visit a remote whole-body monitoring facility. Measurements may then be made more frequently so that any unusually large intake would be recognised soon after it had occurred.

In contrast, high sensitivity techniques are needed for monitoring a few radionuclides at the levels that are required for protection purposes. Examples are the α-emitting radionuclides such as plutonium isotopes.

The activity present in a wound can be easily detected with conventional β-γ detectors if the contaminant emits energetic γ-rays. In the case of contamination with α-emitting radionuclides, detection is more difficult since the low energy X rays that follow the α-decay will be severely attenuated in tissue; this effect is more important the deeper the wound.

Analysis of Excreta and other Biological Materials

In some cases, excreta monitoring may be the only measurement technique for those radionuclides which have no γ-ray emission or which have only low energy photon emissions. Excreta monitoring programmes usually involve analysis of urine, although faecal analysis may be required in some circumstances, for example where an element is preferentially excreted via faeces or to assess clearance of insoluble material from the respiratory tract. Other samples may be analysed for specific investigations. Examples are nose blow or nasal smears as routine screening techniques or blood, in the case of suspected high level contamination.

The collection of urine samples involves three considerations:

- Firstly, care must be taken to avoid adventitious contamination of the sample.
- Secondly, it is usually necessary to assess the total activity excreted in urine per unit time from the sample provided. For most routine analyses, a 24 hour collection is preferred but, if this is not feasible, it must be recognised that smaller samples may not be representative. (Tritium is a particular case for which it is

usual to take only a small sample and to relate the measured activity concentration to the concentration in body water.)

- Thirdly, the volume required for analysis depends upon the sensitivity of the analytical technique. For some radionuclides, adequate sensitivity can be achieved only by analysis of several days' excreta.

Radionuclides that emit γ-rays may be determined in biological samples by direct measurement with scintillation or semiconductor detectors. Analysis of α- and β-emitting radionuclides requires chemical separation followed by appropriate measurement techniques. Measurement of so-called total α or β activity may occasionally be useful as a simple screening technique, but there is no method that will determine accurately all the α and β activity in the sample. The technique may be used in routine monitoring situations where intakes are expected to be very low compared with annual limits. The results would not be interpreted quantitatively, but would be used to provide confirmation of satisfactory conditions, an unusual result indicating the need for further investigation which would include radiochemical analysis. Total activity measurements may also be useful following a known contamination event or to identify those samples that merit early attention. Measurements of total α or β activity cannot be used in quantitative evaluations of intake or committed effective dose, unless the radionuclide composition is known.

Measurement of activity in exhaled breath is a useful monitoring technique for some radionuclides. In practice this method may be useful for ^{226}Ra and ^{228}Th since the decay chains of both these radionuclides include gases which may be exhaled. It can also be used to monitor $^{14}CO_2$ formed *in vivo* from the metabolism of ^{14}C-labelled compounds.

Air Sampling

A Personal Air Sampler (PAS) is a portable device specifically designed for the estimation of intake by an individual worker from a measurement of time-integrated concentration of activity in air in the breathing zone of the worker. A sampling head containing a filter is worn on the upper torso close to the breathing zone. Air is drawn through the filter by a calibrated air pump carried by the worker. Ideally, sampling rates would be representative of typical breathing rates for a worker (~1.2 m3 h^{-1}). However, sampling rates of current devices are only about 1/10 of this value. The activity on the filter may be measured at the end of the sampling period to give an indication of any abnormally high exposures. The filters can then be retained, bulked over a longer period, and the activity determined by radiochemical separation and high sensitivity measurement techniques. An estimate of intake during the sampling period can be made by multiplying the measured integrated air concentration by the volume breathed by the worker during the period of intake.

A PAS does not provide information on particle size. Nevertheless, it is important either to determine the particle size distribution of the inspirable material or to make realistic assumptions about it, since it can have a marked effect on deposition fractions in the respiratory tract, and hence on dose estimates. All samplers are size selective to a greater or lesser extent, under- or over-sampling at particular particle sizes, and this can result in errors in intake estimation. The aspiration efficiency of a PAS should therefore be determined to indicate whether corrections are necessary.

Static air samplers (SAS) are commonly used to monitor workplace conditions, but can underestimate concentrations in air in the breathing zone of a worker, typically by a factor of up to about 10. Nevertheless, if SAS devices are sited appropriately, a comparison of PAS and SAS measurements can be used to define a PAS:SAS air concentration ratio which can be used in the interpretation of SAS measurement for dose assessment purposes. It should however be recognised that the use of SAS is a relatively indirect method for assessing doses, and use of the results to estimate individual dose requires a careful assessment of exposure conditions and working practices. Apart from their potential use for dose estimation, SAS devices can also provide useful information on radionuclide composition, and on particle size if used with a size analyser such as a cascade impactor.

Estimation of Intake and Dose

In an investigation of an incident for which the time of intake is known, the intake can be estimated from the measured results using the values of measured quantities predicted by the biokinetic models for a unit intake. If only a single measurement is made, the intake can be determined from the measured quantity, M, by:

$$Intake = \frac{M}{m(t)}$$

where m(t) is the predicted value at the time of intake t. The intake can be multiplied by the dose coefficient to give the committed effective dose; this can then be compared with the dose limit or some investigation level based on dose.

If the measurement indicates that an investigation level has been exceeded, further investigation is required. The nature of the investigation will depend upon the circumstances and the extent to which the investigation level is exceeded. The following should be considered:

- repeated measurements to confirm or refine the initial evaluation, and
- the use of additional monitoring techniques.

The predicted values can then be scaled to obtain the best fit to the measured data points. The best fit is usually taken to be that fit which minimizes the sum of the squares of the residuals, a residual being defined as the number of standard deviations separating a measurement from the fitted curve. The intake is then equal to the value by which the predicted values are scaled. Many laboratories have developed software for fitting the intake in this, and other more mathematically advanced, ways, for example HPA's IMBA program.

When a positive measurement is detected by routine monitoring, say at monthly intervals, certain assumptions have to be made about the time of intake when calculating doses. It is often assumed that intake took place in the middle of the monitoring interval of T days. If the dose is large further measurements would be necessary. It should be noted that an intake in a preceding monitoring interval may influence the actual measurement result obtained.

Optimisation of radiation protection for pediatric and adult patients in radiography and computed tomography

Geleijns, Jacob
Leiden University Medical Center, THE NETHERLANDS

Introduction

The need for optimization of radiation protection of patients in diagnostic medical imaging became clear already some 30 years ago. Scientists that pioneered in radiation protection observed that large variations in radiation exposure of patients existed for one and the same diagnostic examination. This triggered many national and international field studies. The field studies that have been carried out in the United Kingdom are particularly well known, and the observed steady reduction of third quartile adult patient dose values from three reviews of UK national patient dose data for the mid-1980s; the year 1995; and the year 2000 illustrates that improvements in acquisition protocols and imaging equipment resulted in substantial optimization of radiation protection [Wall]. The need for optimization of radiation protection of young patients became evident when the number of clinical indications for CT examination of children grew rapidly mainly due to the enhanced speed of the CT scanners around the year 2000. It was observed in the United States that many CT scans of children were performed with acquisition protocols that were developed for adults, and that used too high exposures for small children [Brenner et al.]. This led to special efforts worldwide in optimization of pediatric CT examinations; the Alliance for Radiation Safety in Pediatric Imaging of the United States of America (USA) encourages on its website [www.pedrad.org] increased awareness of opportunities to lower radiation dose in pediatric CT procedures. A recently published field study in the USA revealed CT that as the major contributor to the population dose [Mettler et al.]. In 2006, Americans were exposed to more than seven times as much ionizing radiation from medical procedures as was the case in the early 1980s. Radiation exposure due to medical examinations in the United States is now assessed at about 3 mSv per year, the USA is the first country were the population exposure is dominated by exposures from diagnostic imaging, whereas in other countries the population exposure is dominated by exposure to natural sources of ionizing radiation (Figure 1). The high levels of radiation exposures from CT as were observed in the USA are not (yet) observed in Europe. Nowadays the manufacturers of CT scanners offer improved opportunities for optimization of radiation protection in CT examinations; the biggest challenge for the future in optimization of CT seems now to be achieving proper (evidence based) justification of the referral for CT examinations. It has to be established which CT examination really contribute to the proper clinical care of patients, and which referrals are mainly based on too defensive diagnostic strategies.

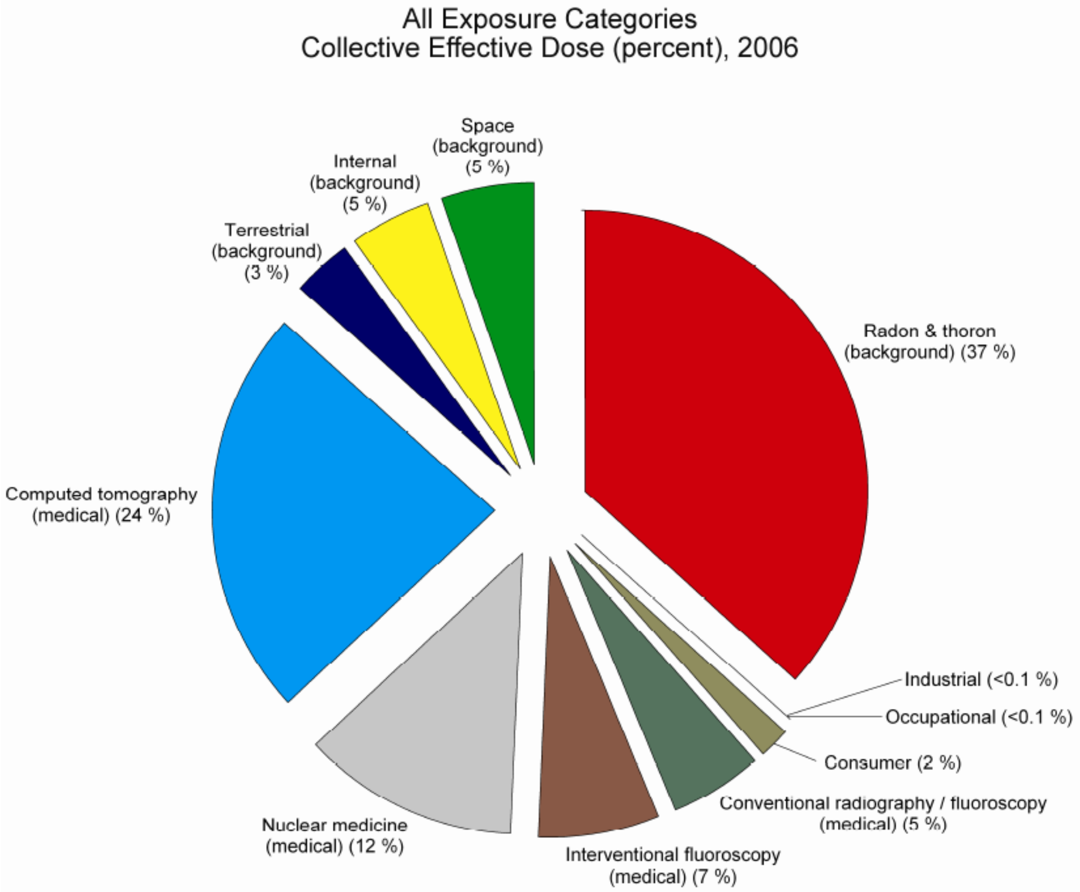

Fig. 1. The distribution of the population dose in the United States. Note that CT is a major contributor to the population dose. In 2006, Americans were exposed to more than seven times as much ionizing radiation from medical procedures as was the case in the early 1980s. Radiation exposure due to medical examinations in the United States is now about 3 mSv per year [Mettler et al.].

Optimization in radiography

X-ray projection radiography is a well known, widely available, and relatively cheap imaging procedure for medical diagnosis; dental X-ray radiography is the most frequently performed examination, next comes chest x-ray radiography. Radiographs of the extremities (legs, arms, hand, feet), of the abdomen, and of the spine are also often made (Figure 2). Radiography of the skull is nowadays rarely performed, the skull is preferably examined with 3D imaging techniques like computed tomography of magnetic resonance imaging.

Radiographs were traditionally recorded on x-ray film. The latent image that is recorded by x-ray film became visible after developing the film. Digital detectors became available about 30 years ago. There were initially high expectations with regard to the improvement of image quality and the reduction of patient dose when the first systems for computed radiography (CR) were introduced. The latent image that is recorded on CR plates is translated into light in readout units by photo-stimulation with a laser. The generated light is then translated into an electrical signal, and the electrical signal into a digital image. Unfortunately in the early years of CR, the high expectations were not fulfilled. Users of CR systems often had to increase dose in order to achieve images with sufficiently good image quality. Advances in detector design made that CR finally evolved into a dose efficient alternative for x-ray radiography on film. Systems for digital radiography (DR) became available somewhat later, these systems use a detector that both records the image, and that translates the image into an electrical signal. DR detectors generally provide the best dose efficiency in radiography, they can be operated at dose levels well below the doses that are used in radiography with film or CR. The opportunity for dose reduction that detectors like CR and DR offer is not the only advantage. It is nowadays generally recognized that, compared to film, CR and DR systems are capable to provide better image quality, and that with these systems less retakes are required. Digital archives and fast networks make it possible to store and distribute digital images much more efficiently compared to film.

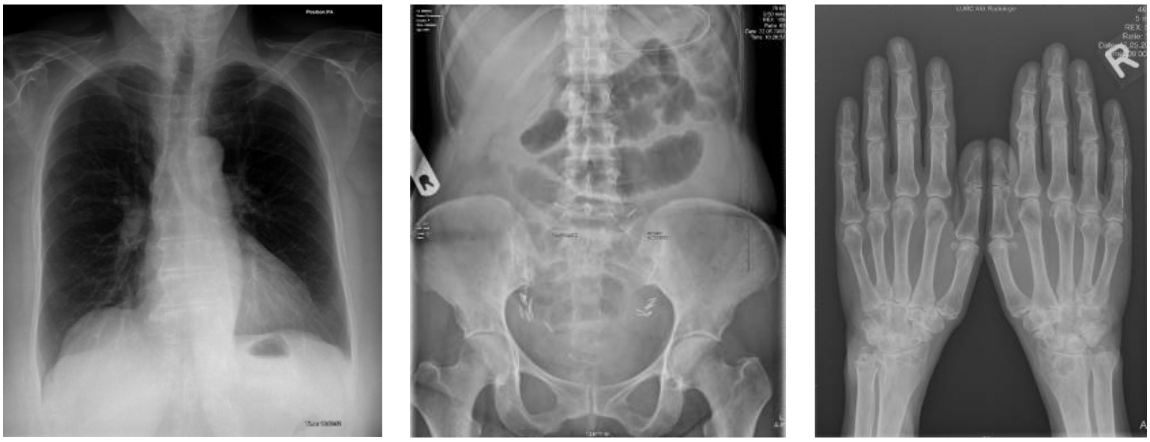

Fig. 2. Three examples of radiography, from the left to the right radiography of the chest (frontal view), radiography of the abdomen (frontal view), and radiography of the hands. Note that radiography yields an superposition in a 2D plane of all tissues within the examined area.

Acquisitions of radiographs have to be optimized; this can be achieved by optimizing the x-ray spectrum. The ‘color’ of the spectrum (or the distribution of photons of different energies in the spectrum) can be optimized by choosing the appropriate tube voltage (kV) and tube filtration (in addition to the inherent filtration by the window of the x-ray tube, additional aluminium and copper filters are being used). Spectra with photons with relative low energies can be used for imaging relatively thin objects (extremities, children), spectra with higher photon energies are used for imaging thicker body parts (abdomen, spine). Very high photon energies are used in chest radiography to reduce the contrast between bone (ribs) and soft tissue (lungs), this is required since the ribs may, at lower photon energies, obscure the lesions in the lung soft tissue. The ‘brightness’ of the spectrum (or the intensity of the spectrum) can be optimized by selecting the most appropriate tube charge (mAs), which is the product of tube current (mA) and exposure time (s). Most x-ray units make use of automatic exposure control, in this case a radiation detector measures the dose that the detector receives, and when the required preset dose level is reached, the system terminates the exposure. It is necessary that the preset dose level is optimized to provide the best balance between the required image quality and at the same time the lowest possible dos for the patient. It is essential that the automatic exposure system of modern CR and DR systems is configured to operate well below the preset dose that would be used for recording images on film. Sometimes it is not possible to use automatic exposure control, for example when radiographs are being made with a mobile x-ray unit at the department of intensive care, in this case a table with appropriate and optimized acquisition techniques that cover all relevant examination should be available for the radiographer. In addition the field size should be optimized, by collimation of the x-ray beam the field size should be just sufficiently large to visualize the body part of interest.

It is also important to realize that for one clinical question; often more that one radiograph is being made. For chest radiography, generally two radiographs are being made; one provides a frontal view, the other a lateral view of the patient. For some clinical referrals, it has been observed that great variety exists in the number of the radiographs that are being taken, and in the views of these radiographs, for example when imaging the cervical spine, the abdomen, or the pelvis. These large variations in clinical practices and acquisition protocols provide a substantial, and until now hardly exploited, opportunity for optimization in x-ray radiography, Figure 3 illustrates that for one and the same clinical question (cervical spine, neck pain), and in only 11 hospitals, eight different views were being used in routine practices, and the numbers of views varied between two and five [Teeuwisse et al.].

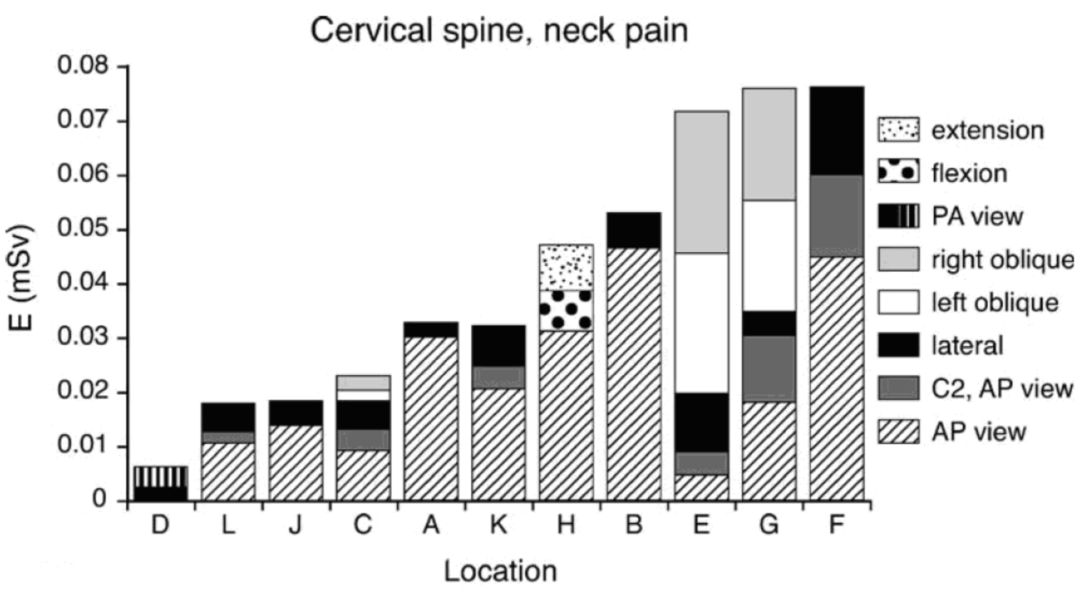

Fig. 3. Cumulative effective dose (mSv) for the clinical radiography indication cervical spine, neck pain illustrates the impact of the clinical protocol (the number and type of views) and the dose for the different views on the spread in integral patient dose [Teeuwisse et al.].

Dosimetry in radiography is usually based on measurement of the dose-area product (DAP, Gy.cm^2), this is a useful quantity, since the DAP incorporates the effect on patient dose of all relevant acquisition parameters like tube voltage, tube charge, and field size. DAP can be converted into effective dose by using appropriate effective dose conversion factors or preferably by dedicated software (PCXMC, Radiation and Nuclear Safety Authority in Finland). The so-called DICOM header that is added as supplementary information to the digital images, generally also stores the dose-area product. Ideally, the dose-area product could be retrieved with a simple query from the digital archive in which the radiographs are being stored; however, unfortunately such a functionality is not always available. European countries defined diagnostic reference levels for selected projections in x-ray radiography of adults; some countries also established diagnostic reference levels for pediatric radiography.

Optimization in computed tomography

Computed tomography (CT) was introduced in 1974. The substantial advances in CT technology for 3D imaging with excellent image quality led to a fast increase of its clinical use. CT is often applied for the diagnosis of tumours, vascular disease, and trauma. CT shows anatomy and pathology in arbitrary planes, or in 3D reconstructions (Figure 4). The excellent image quality of CT comes, compared to radiography, at the price of a substantial higher radiation exposure. CT is nowadays the major source of radiation exposure of patients which makes optimization (and justification) of applications of CT of particular relevance.

CT scanners are equipped with a rotating x-ray tube and detector. During one rotation, of the x-ray tube and detector, the early CT scanners were only capable of scanning one thick axial slice, these scanners were relatively slow, they provided good image quality in the axial plane, but the 3D image quality was poor. Advances in CT technology like multislice CT (CT scanners that were able to scan more than one image in one rotation) and helical CT (CT scanners that combined the rotation of the x-ray tube and the detector with translation of the patient) made CT an excellent imaging modality for fast 3D imaging. With the introduction of volumetric CT (CT scanners that allow for imaging 320 slices during one rotation), entire organs like the brain or the heart can be imaged within a fraction of a second.

Optimisation of CT was mainly enhanced by technical improvements, but can also be achieved by adapting optimal imaging protocols. An important step in the improvement of the dose efficiency of CT scanners was achieved by the transition from air filled CT detectors to solid state CT detectors. Another important step was the introduction of automatic exposure control in CT, this allowed for adapting the tube current for the size of the patient but also for the local attenuation of the patient. To achieve consistent image quality within the scanned range, CT scanners nowadays automatically use higher exposure in thick patients and lower exposure in thin patient. During the CT scan the exposure can also be adapted to the local attenuation, during a CT of the chest for example the tube current is higher when the CT scan passes the shoulder (with its highly attenuating bones) and lower when it scans the lungs. Sophisticated noise reduction algorithms contribute further to the dose efficiency of CT scanners. CT scans can be optimized by carefully selecting the most appropriate preset for the automatic exposure control, which determines the tube charge (mAs) during the scan. Figure 5 shows the differences in image quality within the brain when different presets of the tube current are being used. Experiments to establish the optimal tube current cannot be performed by scanning the patient several times but such experiments have to be performed using low dose simulation algorithms and observer studies

[Joemai et al.]. CT scans can be further optimized by carefully selecting the most appropriate tube voltage, generally a tube voltage of 120 kV is applied in CT, for obese patients a higher tube voltage of for example 140 kV might be more appropriate, but for iodine contrast enhanced vascular studies a lower tube voltage of 100 kV or even 80 kV might be preferred.

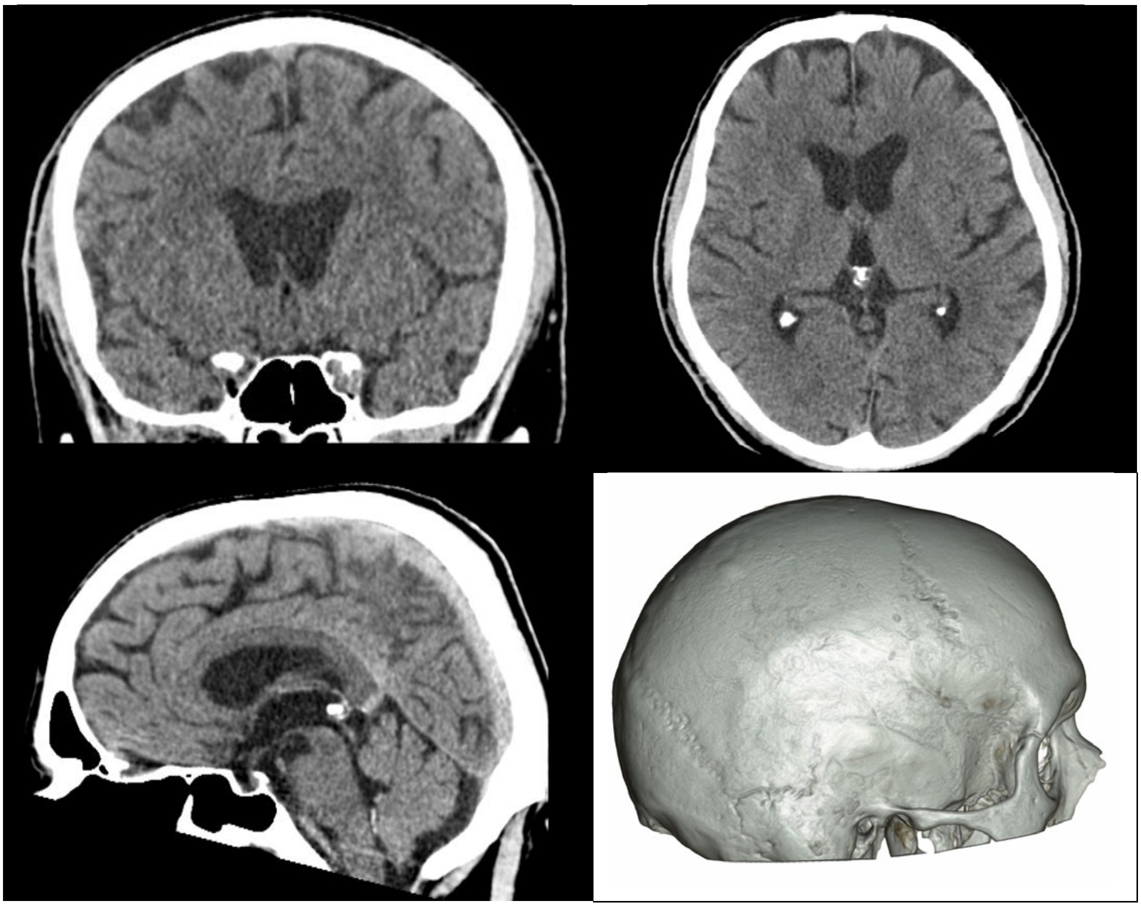

Fig. 4. Computed tomography allows for 3D imaging with superior low contrast resolution compared to radiography. Above respectively reconstructions of a CT head scan in a coronal, axial and sagittal plane; and a 3D surface rendering of the skull.

Dosimetry in CT is based on the concepts of the CT dose index (CTDIvol, mGy) and the dose-length product (DLP, mGy.cm). The CTDIvol represents the average dose that is absorbed during one rotation in the axial plane of either a head phantom or a body phantom (these are cylindrical PMMA phantoms of respectively 16 and 32 cm diameter and 15 cm length). The DLP is the product of the CTDIvol and the actually exposed range. The CTDI takes into account the effects on patient dose of tube voltage, rotation time of the x-ray tube, and tube current, but only represents the local dose within the scanned range. In addition, the DLP takes into account the extent of the exposed range, and therefore DLP represents best the patient dose. DLP can be converted into effective dose by using appropriate effective dose conversion factors or preferably dedicated software like the ImPACT CT dosimetry calculator (Shrimpton et al.).

Like in radiography the DICOM header in CT generally also stores the CTDIvol and DLP. Ideally, these quantities could be retrieved with a simple query from the digital archive in which the CT scans are being stored; however, unfortunately such functionality is not always available. European countries defined diagnostic reference levels for selected acquisitions projections in CT of adults; some countries also established diagnostic reference levels for pediatric CT.

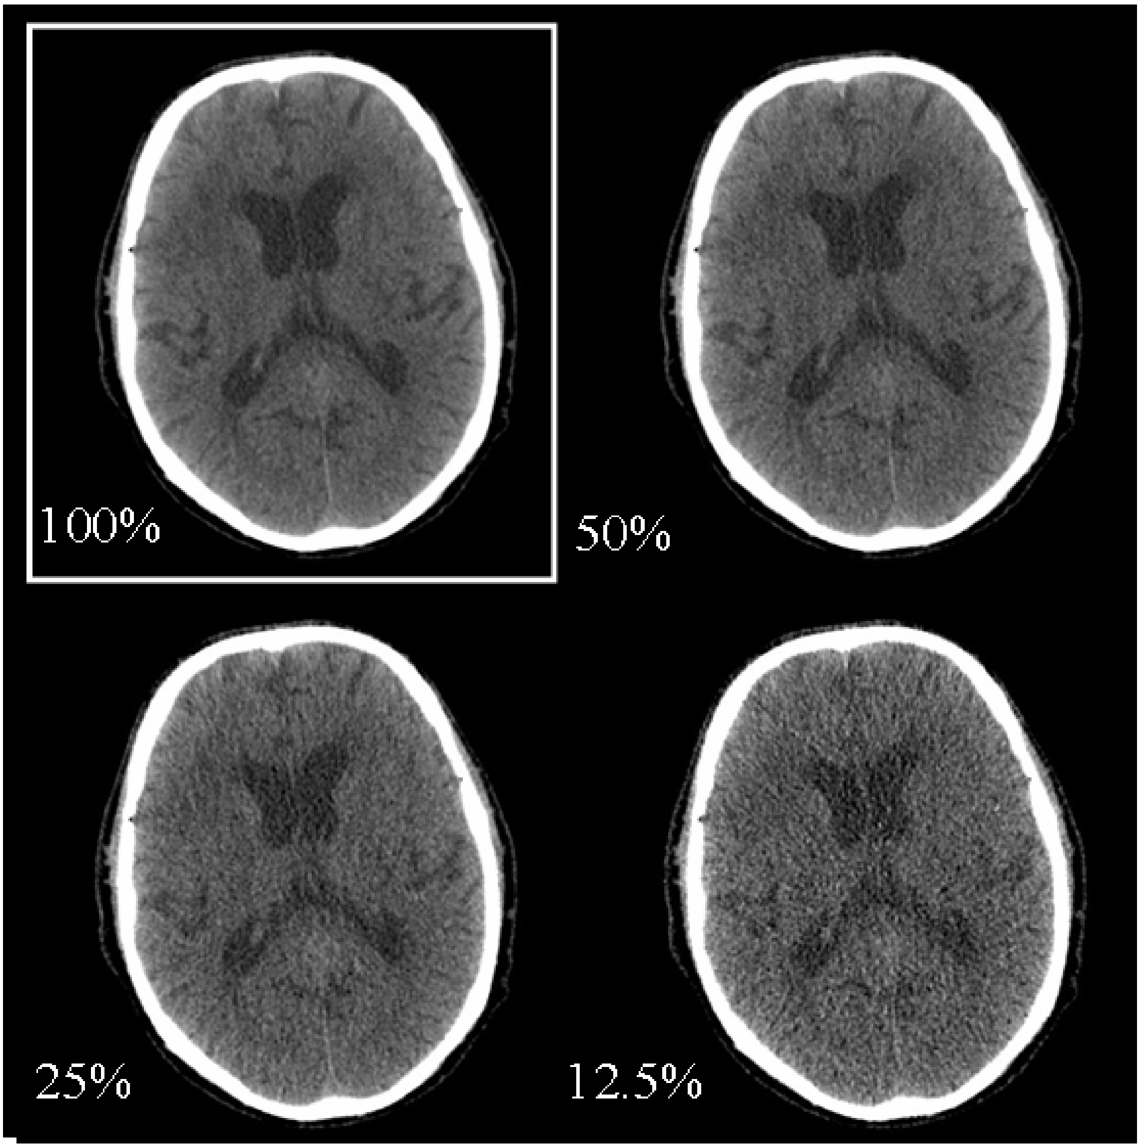

Fig. 5. Four axial images of the brain. The 100% image is acquired as a clinically indicated scan. The other images represent the image quality that would be achieved when a 50%, 25%, and 12.5% lower tube current would have been used. These brain images at reduced dose levels are not scanned images but they are simulated to using a dedicated software algorithm [Joemai et al.]. Note the increased noise in the low dose images. Such low dose simulations allow for studying the image quality of low dose acquisition protocols in observer studies without the need of repeating the CT examination on patients.

Clinical exposures

Table 1 provides an indication of the radiation exposure from natural and medical exposures. The yearly dose limits can be regarded as a frame of reference. For most radiographs of adults, exposures are well below 0.1 mSv; and of the order of magnitude of natural exposures like one week skiing or an intercontinental flight. Exposures from radiographs of extremities are extremely low; radiographs of the abdomen are relatively high and may be several tenths of a millisievert. For CT exposures can be several millisieverts, but remain in general below 10 mSv; this is true for both CT scans of adults and for proper optimized acquisition protocols for pediatric CT.

Table 1. Typical effective doses for exposures to natural and medical sources of ionizing radiation.

Natural exposures and dose limits	
One week skiing	0.015 mSv
Intercontinental flight (London-Los Angeles)	0.08 mSv
Population exposure to natural sources of radiation per year	2.5 mSv/year
Public dose limit per year	1 mSv/year
Occupational dose limit per year	20 mSv/year
Medical exposures radiography, adults	
Dental radiography	< 0.001 mSv
Extremities (e.g. knee, ankle, or elbow)	< 0.001 mSv
Chest, frontal view	0.02 mSv
Chest, lateral view	0.04 mSv
Pelvis, frontal view	0.3 mSv
Abdomen, frontal view	0.5 mSv
Medical exposures CT, adults	
CT head, stroke	1 mSv
CT chest, pulmonary embolism	4 mSv
CT spine, fracture L1	4 mSv
CT abdomen, abscess	8 mSv
Medical exposures, pediatric	
CT head, follow up of hydrocephalus, 4-6 year old child	1 mSv
CT head, battered child or trauma, 1-12 months old child	2 mSv
CT chest, bronchiectasis, 4-6 year old child	3 mSv
CT chest, congenital abnormality, 1-12 months old child	4 mSv

Future developments

Further optimization of diagnostic medical imaging with x-rays can be expected. This will be mainly achieved by technical improvements of current technologies and the development of new technologies. A recent and particular dose efficient technology for detecting x-rays, by photon counting detectors, is already implemented in mammography and may find its way to other imaging modalities. In computed tomography the development of new reconstruction algorithms may allow for lower dose acquisitions for certain, yet to be established, clinical applications. In cardiac CT examinations an enormous reduction of patient dose becomes available for scanners that allow for prospective, ECG triggered, scanning of the heart. Sliding collimators that optimize the beam width at the start and the end of a helical acquisition contribute to the optimization of helical CT acquisitions. Volumetric CT, which allows for scanning entire organs in one single rotation allows for dose reduction for certain acquisition protocols [Kroft et al.]. Tomosynthesis, which is already a clinical application in mammography, overcomes to a certain extend the problem of overprojection in projection mammography, and is expected to be introduced also for chest radiography. Compared to CT tomosynthesis can be performed at relatively low doses, similar to doses in radiography, but does not yield the excellent 3D image quality of CT. However, dedicated ultralow dose acquisitions in CT, combined with dedicated reconstruction and noise reduction algorithms, may provide better performance compared to tomosynthesis. Dedicated low dose CT of the breasts has for example been developed, and it offers the opportunity to scan the breast in real 3D, with superior image quality compared to projection mammography or tomosynthesis of the breast, and at the same dose of projection mammography [Boone et al.]. Low dose cone beam CT scanners that are available for dental applications may also provide opportunities for low dose scanning of other parts of the skull like the inner ear.

Radioecology and environmental exposure pathways

Strand, Per; Dowdall, Mark
Norwegian Radiation Protection Authority, NORWAY

Abstract
Radioecology ("radiation ecology") is the scientific field encompassing the relationships between ionizing radiation or radioactive materials and the environment or subunits thereof. Radioecology and its study constitutes an important component of radiological protection of both humans and environment mainly, although not solely, through its relevance in understanding and describing environmental exposure pathways and quantifying radionuclide transport along them. Such pathways can be described as the route radioactive substances take from their source to their end point and how humans or biota can be exposed to the substance. This lecture introduces the basics of radioecology and discusses the role of radioecology with respect to environmental exposure pathways for radioactive contaminants. It presents the fundamental concepts of radioecology, the tools used by radioecologists with respect to the study of exposure pathways and future directions of research in the field.

Radioecology and environmental exposure pathways
Radioecology is the term used to describe the scientific discipline concerned with the relationship between ionizing radiation and radioactive substances and the environment or its constituents. These constituents may be populations, communities, ecosystems or biomes and include both humans and biota. Radiobiology on the other hand differs from radioecology with respect to its focus on the effects of ionizing and non-ionizing radiation on biological systems – from the molecular to the individual organism. Three main scientific areas are of interest with respect to radioecology, these being:

1. Radionuclide movement and accumulation in environmental components such as soil, water and biota and within ecosystems;
2. The effects of ionizing radiation upon species, populations, communities and ecosystems;
3. The use of radionuclides and ionizing radiation in understanding the structure, form and function of ecosystems and the constituent parts of those ecosystems.

The pursuit of radioecology as a discipline can be traced back to the early 1940's with the formation of the Applied Fisheries Laboratory in the United States, the purpose of which was to elucidate the effects of releases of radioactive substances to the Columbia River as a result of operation of reactors at the Hanford site (see Whicker and Schultz, 1982). Since then radioecology has matured as a science, that maturation having occurred, somewhat sporadically, during periods such as the early years of nuclear power, the decades of nuclear weapons testing and in the aftermath of accidents such as those at Chernobyl in 1986 and Kyshtym and Windscale in 1957.

In recent years radioecology has addressed new challenges such as those afforded by non-nuclear industries, the nuclear legacies of many countries and the increased focus on protection of the environment as well as man. As radioecology has grown as a discipline, the fundamental set of questions that its pursuit seeks to answer has been distilled to perhaps four that serve to adequately describe the scientific challenges facing radioecology:

1. How, at what rate and to what extent do radionuclides move between parts of an ecosystem and what are the mechanisms and pathways by and along which such transfers occur?
2. What are the concentrations and resultant doses from radionuclides in ecosystem components in relation to the overall contamination levels in the environment?
3. What are the long-term effects and behaviour of these contaminants in the environment?
4. What environmental concentration of radionuclides will result in effects at population level?

Intrinsically linked to these four fundamental questions, and therefore to the study of radioecology is the concept of the *environmental exposure pathway*.

Environmental exposure pathways

An environmental exposure pathway can be defined as the path a substance travels from its source to its environmental endpoint and how people or biota can be exposed to that substance. In essence, environmental exposure pathways can be considered as consisting of five common components:

1. the source of the contamination (e.g. point discharge from a power plant, fallout, abandoned source, etc.);
2. an environmental media and transport mechanism (e.g. soil – soil water, physical transport, bioturbation; water – transport as dissolved substance, particulate transport etc.);
3. an exposure point (i.e. a geographic or temporal point at whicgh the exposure actually occurs);
4. a route of exposure (e.g. eating contaminated food or prey, drinking contaminated water, inhalation of contaminated soil or dust)
5. a receptor population (e.g. rabbits living in contaminated soil, people eating contaminated fish, etc.).

Consideration of these five components of environmental exposure pathways indicates that the nature of the pathway is to a large extent governed by the nature of the environment in which the contaminant is present and the receptor population being considered. Consequently there are a large number of potential exposure pathways (see Figure 1) some of which are generally more dominant than others and some of which are relatively specific to certain isotopes, geographic regions, areas or populations. For the purposes of elaboration it is therefore convenient to breakdown the discussion of environmental exposure pathways with respect to environment "types" – terrestrial, marine and freshwater.

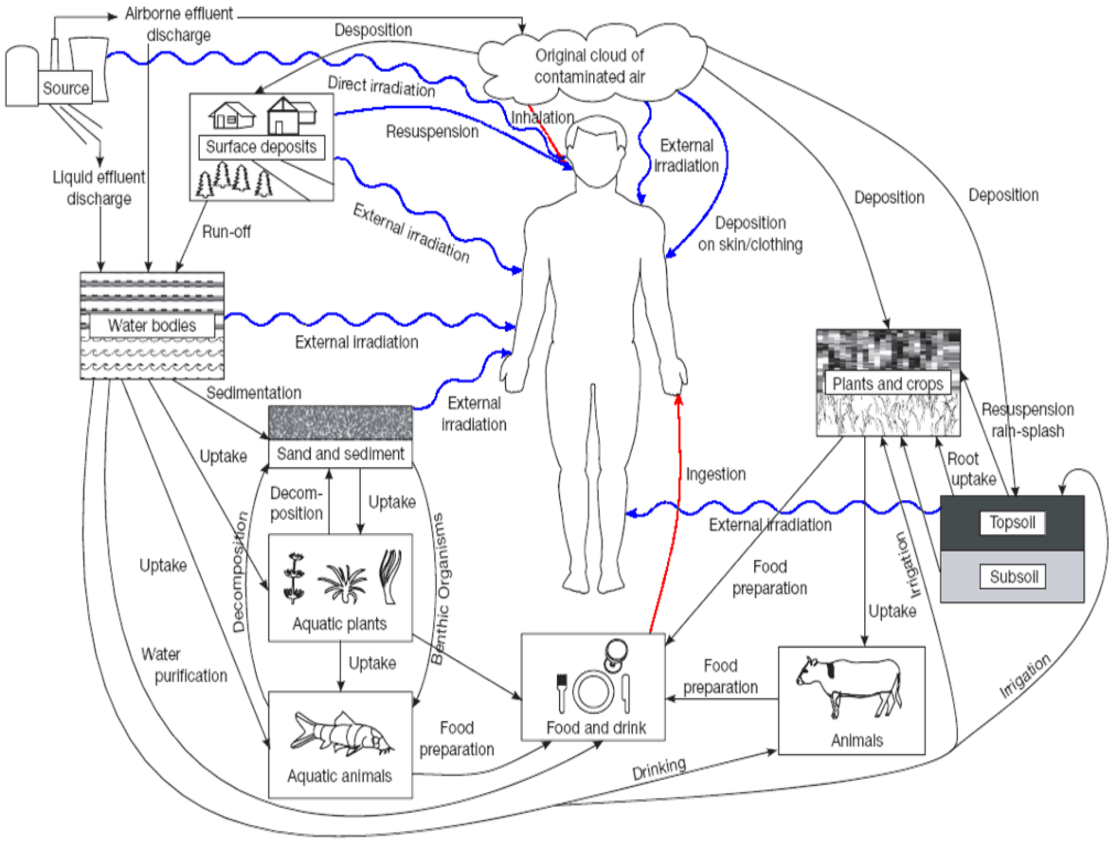

Fig. 1. Potential environmental exposure pathways for radioactive substances.

The isotopes of most interest with respect to radioecology and exposure pathways have varied over time and with respect to which source terms were of most relevance. In general those isotopes produced by fission (controlled or uncontrolled) or nuclear cycle processes and which have a half-life long enough to represent a potential impact on humans or the environment dominate radioecological studies. Typically the suite includes isotopes of plutonium, cesium, strontium, iodine, technetium, uranium, radium, thorium, carbon, hydrogen and cobalt among others.

Terrestrial exposure pathways

Although terrestrial environments can be broken down with respect to climate etc., the main mechanisms and processes involved in governing terrestrial exposure pathways are the same for all although the pathways may differ in their relative importances. As an example, wind resuspension and inhalation of contaminated soils may be an exposure pathway common to both European agricultural ecosystems and tropical deserts but will probably be of greater significance in the latter. Numerous transport processes are of relevance with respect to the terrestrial environment and can include transport by groundwater, particulate transport with soil particles, resuspension of soils and dusts by wind or rain, runoff/snowmelt etc. The most direct exposure pathways for terrestrial environments include direct exposure of the organism to external radiation from deposited radionuclides or ingestion/inhalation of contaminated soils or dusts. Uptake of radionuclides by plant species with subsequent transfer to humans or biota via the food chain is perhaps the exposure pathway that has received most attention over the decades.

Radioecology has played an important role in the study of terrestrial exposure pathways although the years up to the early 1990s were primarily focussed on studies regarding human exposure. This resulted in much information dealing with agricultural systems as the main source of food for large populations with a concomitant neglect of forest, semi-natural and natural and tropical ecosystems. This earlier neglect has been addressed in the last two decades with the radioecology of these ecosystems being studied in greater detail. The heightened vulnerability of Arctic populations to radioactive contaminants such as isotopes of cesium appears to be caused by a short environmental exposure pathway that efficiently transfers cesium to a human endpoint. Deposited cesium is taken up efficiently by Arctic vegetative and lichen species due to the nature of the Arctic climatic regime and adaptations of Arctic biota and is transferred to reindeer which feed almost exclusively on these plants. Arctic populations consuming large amounts of reindeer and foodstuffs such as fungi and berries which also accumulate cesium can be exposed to higher levels of radioactive contaminants that would be expected for a similar amount of environmental contamination in more temperate regions.

Marine and freshwater exposure pathways

Although there can be differences in the radioecological behaviour of radionuclides in freshwater and marine systems, the exposure pathways are generally the same. Direct exposure of humans and biota can occur via external radiation from contaminated water and sediments. Ingestion of contaminated water or sediment or inhalation of spray can also result in exposures although the main exposure pathway is ingestion via the food chain. Benthic biota can be exposed due to living in and on contaminated sediments. The extent to which radionuclides are transferred along aquatic pathways is dependant on a range of factors including organic matter content, suspended sediment content, salinity, isotope type, residence times of waters, nutrient status, species etc. Radioecological studies of freshwater and marine systems have been plentiful although the vast majority of these have been concerned with radiocesium and ^{90}Sr. An important radioecological control in aquatic systems is the salinity of the system – uptake of isotopes such as ^{137}Cs and ^{90}Sr in aquatic fish species has repeatedly shown to be higher in systems with low levels of K^+ and Ca^{2+}.

Marine systems have been the focus of much radioecological study over the years and this work has gone a long way towards a better understanding of exposure pathways in this environment. For marine systems, radionuclides present in the particulate or colloidal form may tend to be accumulated to a greater extent by marine animal species than those present in dissolved form – this being in contrast to freshwater and terrestrial systems where the converse generally tends to be true (hence the predominance of ^{90}Sr and ^{137}Cs in the exposure pathways of the latter two environments). This is primarily due to the chemical nature of the marine environment which features large amounts of chemical analogues for both strontium and cesium and the fact that many marine species on the lower rungs of the food chain (and hence at the early stages of exposure pathways) are filter feeders, a feeding mechanism ensuring high uptake of particulate bound radionuclides.

Quantifying transfer in exposure pathways

An important focus of radioecology regarding environmental exposure pathways has been the means of quantifying radionuclide transfer along these pathways and a number of means of doing so have been developed. The first of these can be encapsulated by three "factors" used within radioecology to describe transfer:

$$\text{Transfer Factor (TF)} = \frac{\text{Nuclide conc. in plant tissue (Bq/kg)}}{\text{Nuclide conc. in soil (Bq/kg)}}$$

$$\text{Concentration Factor (CF)} = \frac{\text{Nuclide conc. in biota tissue (Bq/kg)}}{\text{Nuclide conc. in filtered water (Bq/l)}}$$

$$\text{Aggregated Transfer Coefficient } (T_{ag}) = \frac{\text{Nuclide conc. in plant tissue (Bq/kg)}}{\text{Nuclide deposition on soil (Bq/m}^2\text{)}}$$

Such factors have proved useful in quantifying transfer along exposure pathways for assessment purposes related to regulation, emergency response, rehabilitatory efforts etc. Large scale efforts in the evaluation and collation of empirical data sets regarding radionuclide transfer as expressed by factors such as those above have resulted in compendia published by bodies such as the IAEA (IAEA, 2004; IAEA, 2010). An important and significant common characteristic of such compendia is the high degree of variability in the data sets (often orders of magnitude) for individual isotopes reflecting the complexity of the processes involved in the transfer of radionuclides to plants and animals (see Figure 2). Addressing and accounting for this variability has proven to be a significant driver in radioecological research over the years.

It should also be considered that the transfer of radionuclides to animals or plants is largely a dynamic process and that quantification of transfer by expressions such as those above only represents a temporal "snapshot" and one that is likely to vary considerably depending on the time it was taken if equilibrium had not been achieved.

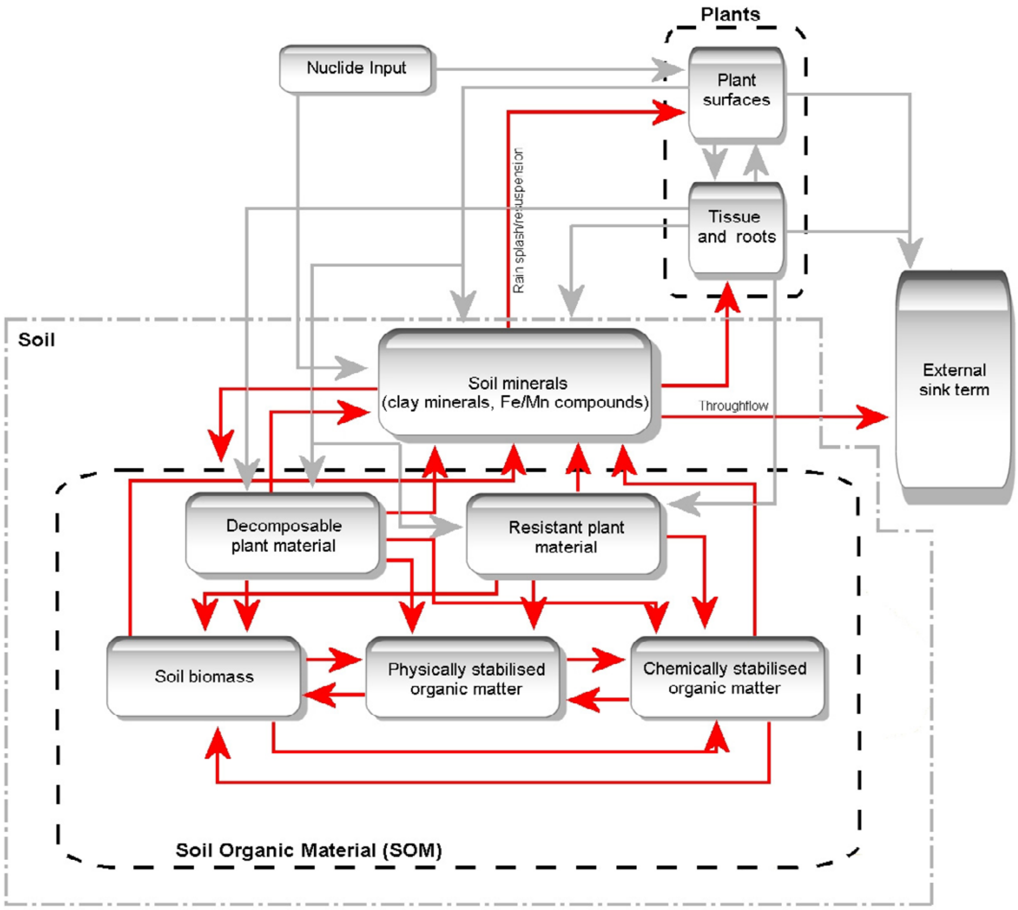

Fig. 2. Schematic of soil processes governing transfer of radionuclides from soil to plant.

For the many situations or radionuclides where data is lacking or the inherent weaknesses of the CF/TF approach are unacceptable (see Green et al., 1997), alternative methods for estimating transfer have been developed. Mechanistic kinetic approaches have been available since the 1980s (see Whicker and Schulz, 1982) and such methods include the advantage that the transfer at any time can be estimated as opposed to the equilibrium assumption inherent in CF/TF approaches. Despite this, mechanistic kinetic approaches have still not fully fulfilled their potential. Allometry, which relates radionuclide uptake to body size, has proved a potentially useful avenue of research in describing transfer (see Higley et al, 2003) as has phylogenetic approaches to extrapolate information on transfer of radionuclides from information derived for one species to another (see Willey and Fawcett, 2006).

Bioavailability

A key concept in the study of environmental exposure pathways is that of bioavailability - bioavailability generally refers to the extent to which humans and ecological receptors are exposed to contaminants in soil or sediment (see Desmet et al, 1991) and with respect to radioecology can be understood as the quantity of a radionuclide available for biological uptake. It is accepted that bioavailability is the factor that ultimately controls the exposure of both humans and biota and therefore the impact of contaminant radionuclides. In studying bioavailability within radioecology, much emphasis has been upon the transfer of radionuclides from soil to plant and an extensive corpus exists in this field although much work remains to be done. Factors such as climate, soil properties and radionuclide speciation have been focussed upon as controllers of terrestrial bioavailability and have been the subject of radioecology research over six decades. As ^{137}Cs came to be recognised as a radionuclide of importance during the period of atmospheric weapons testing and in the aftermath of the Chernobyl accident, significant effort was expended on understanding the bioavailability of this isotope. Cs-137 and study of its behaviour in the environment highlighted the complexity of the problem and although important advances were made in understanding, for example, the role of organic soil materials and potassium in its environmental transfer, much work remains to be done in order to develop mechanistic models describing its uptake by plants and further transfer through ecosystems although some models are currently available. In this respect, bioavailability is a significant area of research in radioecology as models and predictions with respect to environmental exposure pathways are reliant on a thorough understanding of the processes and mechanisms involved.

Current and future directions

Perhaps the most significant development of relevance to radioecology in recent years has been the acceptance that one can not always assume that if humans are protected from the effects of radioactive contaminants, then so is the environment. This acceptance has led to consideration of environmental exposure pathways that are not strictly directed towards the human endpoint but which are of relevance to wildlife species. This expansion in the scope of the pathways and species that must be considered has presented new challenges for radioecology and will continue to be a focus in coming years. In addition, radioactive contaminants occur in the environment as part of a large suite of other contaminants. Radioecology has begun to recognise this and view radioactive contaminants and exposure pathways as part of the wider spectrum of contaminants.

Malicious events: scenarios, consequences and response

Prosser, Lesley
Health Protection Agency, UNITED KINGDOM

Abstract

The potential use of radioactive materials by individuals with malicious intent has become an area of increasing international concern in recent years. This refresher course session will cover a number of key areas:

– Consideration of a range of potential scenarios and consequences both in the short and longer term;
– Examination of how lessons identified from past accidents can be used to develop preparedness in this area;
– Discussion of the key elements of planning arrangements required to respond effectively to a scenario of this nature; and
– Reviewing the key international planning guidance that is available to assist in the preparation for such scenarios.

Indoor radon sources, remediation and prevention in new construction

Arvela, Hannu
STUK – Radiation and Nuclear Safety Authority, FINLAND

Abstract
Radon is the second leading cause of lung cancer in the general population, after smoking. Strategies for both radon prevention in new dwellings and mitigation in existing dwellings are needed to achieve an overall risk reduction. The inflow of radon laden soil air into living spaces is the main source of elevated radon concentrations.

The methods of indoor radon remediation are normally based on depressurization of soil under floor construction and decreasing soil air radon concentration. Sealing of entry routes, improvement of air exchange rate and decreasing underpressure level in living spaces has also been used. Sub-slab depressurization (SSD) and radon well have been found the most efficient methods. Typical reduction factors are 70-90%. Ventilation based methods and sealing of entry routes result normally in a clearly lower radon reduction. A SSD system comprises a cavity in the ground immediately under the floor slab. This suction cavity is linked by pipe work to the outside. A radon well sucks air from a well pit constructed outside the building. This air flow reduces the soil air concentration in a wide area round the well. A radon well can be applied on coarse soil types.

Most prevention strategies address steps to limit soil gas infiltration due to air pressure differences between the soil and the indoor occupied space. Both sealing based and sub-slab depressurization based measures have been recommended. The available research results show an average efficiency of 50 % for passive prevention measures. Fan activated sub-slab depressurization reduces radon concentration by up to over 95%. Widespread use of radon resistant construction has resulted in Finland in an average reduction of 30% in radon concentrations of new low rise residential buildings.

1 Introduction
Radon is the second leading cause of lung cancer in the general population, after smoking. Strategies for both radon prevention in new dwellings and mitigation in existing dwellings are needed to achieve an overall risk reduction. In EU countries the typical proportion of low rise residential houses exceeding the national reference value of 400 Bq/m^3 is 0.1% - 5%. Presently the reference value for design and new construction is typically 200 Bq/m^3. In the case of this lower reference value the proportion is typically 0.5% - 15%. New international recommendations have resulted also in a reference value of 100 Bq/m^3 (WHO 2009). The proportion of houses above

100 Bq/m^3 may be 5% - 50%. Respectively the country specific number of houses needing remedial measures can be as high as 400 000 - 2 000 000.

The inflow of radon-bearing soil air into living spaces is the main source of elevated radon concentrations. Radon prevention strategies are therefore based on limitation of soil gas infiltration through reduction of the air pressure difference between soil and indoor spaces and on decreasing the radon concentration in soil air. Prevention goals and strategies are especially important because neglecting the strategy leads to increase of the total number of dwellings with elevated indoor radon.

In this presentation the new WHO radon handbook, several national guides and website material of remedial measures and prevention in new construction has been utilized. Special emphasis has been given also to Finnish experience, especially regarding radon wells and new sample survey results of radon prevention in new construction.

2 Radon sources

Inflow of radon laden soil air is the main entry mechanism increasing radon concentrations in indoor spaces. This inflow is forced by underpressure in rooms above the floor construction compared with soil or spaces beneath the floor. The underpressure is created by indoor-outdoor temperature difference, wind and when in use also by mechanical ventilation. Table 1 shows typical underpressure levels in Finnish low rise residential houses when outdoor temperature is 0 deg C. Mechanical exhaust ventilation creates a high underpressure, depending on the air tightness of the building shell. In the case of a mechanical supply and exhaust ventilation the underpressure can be controlled through adjustment of air flows.

In living spaces building materials are normally only in special cases the reason to elevated indoor radon concentration above 200 Bq/m^3. If the air exchange rate is well below the recommended values (ACH 0,5 1/h), even normal radon emissions can cause elevated indoor radon concentrations.

Figure 1 presents typical entry routes in UK. Figure 2 presents a typical Finnish slab-on-grade foundation. Permeable light-weight concrete blocks promote flow of soil air into living spaces.

3. National radon prevention and remediation programmes

In the recent WHO Radon Handbook (WHO 2009) the following key elements for successful radon prevention and mitigation actions within the framework of a national radon programme have been given.

1. Radon control actions should consider a combination of building types:
   - new and existing homes, since the greatest amount of radon exposure is generally in homes;
   - buildings where public is likely to be exposed for long periods, such as schools, preschool facilities, state-owned or leased buildings, and lodging facilities.

2. Research on buildings should be used to identify the most cost-effective radon control strategies for prevention and mitigation. Structural, foundation, and ventilation systems as well as construction practices vary from region to region. Specifically, this research should be used to develop:
   - radon prevention standards and regulations such as building codes for new dwelling construction;
   - radon mitigation standards and requirements for remediation of existing dwellings.

3. The contribution of different radon sources varies between countries and even regions. The following mechanisms may be considered:
   - pressure driven soil gas infiltration;
   - emanation of radon from building materials;
   - water transport of radon.

4. Appropriate training and certification of building professionals should be implemented to ensure the efficiency of prevention and mitigation actions.

WHO Radon Handbook gives the following design criteria for the radon control systems for prevention as well as mitigation (WHO 2009):

- able to reduce radon concentrations considerable below the reference level
- safe and not creating back-drafting
- durable and functional for the expected life of the building;
- easy monitoring of the performance
- quiet and unobtrusive
- low cost for installation, operation and maintenance
- easy to install an additional fan when passive soil depression systems (PSD) are used.

4 Remediation in existing dwellings

4.1 Overview on the efficiency of remediation methods

The methods of indoor radon remediation are normally based on the following principles.

1. Depressurization of soil under floor construction and decreasing of soil air radon concentration
2. Sealing of entry routes
3. Improvement of air exchange rate and/or decreasing underpressure level in living spaces
4. Combination of these methods

Table 2 shows the efficiency of different methods in UK and the influence of house characteristics (Naismith et al. 1998). Reduction factors of 1,5 -3 are typical for the methods based on sealing and ventilation corresponding to a percentage reduction of 30-70 %. Figure 3 shows radon reduction factors achieved using various mitigation methods in Finland (STUK 2008). The Finnish results are based on a questionnaire study in 400 houses. Well designed and implemented mitigations result often in reductions which are better than the typical reduction (middle 50 % of results) in figure 3.

Table 2. The influence of house characteristics on radon reduction factors. Reduction factors has been defined as the ratio of radon concentration before and after the remedial measure. A reduction of 50 % corresponds in the table to the reduction factor of 2.0 (Naismith et al. 1998).

Remedial measure	Grouping of data	Number of homes	GM of initial radon level	GM reduction factor	Percentage of homes reduced below the action level
Sump	Installed by major contractor, post-war house	166	540	17	95
	Installed by major contractor, pre-war house	102	630	9	77
	Installed by local builder, post-war house	65	430	11	82
	Installed by local builder, pre-war house	43	530	6	70
	Installed by householder, post-war house	31	550	7	77
	Installed by householder, pre-war house	22	560	4	64
Positive ventilation	Living room and bedroom on different floors	43	500	1.9	42
	Living room and bedroom both on ground floor	51	580	3.7	63
Additional permanent ventilation of the house	Without additional sealing of cracks or service entry points	59	370	1.5	49
	With additional sealing of cracks or service entry points	56	430	2.4	60
Mechanical ventilation of the underfloor space	All data	63	540	2.8	54
Natural ventilation of the underfloor space	All data	171	390	1.9	53
Sealing of cracks or service entry points	All data	71	470	1.7	41

Sub-slab depressurization (SSD) and has been found the most efficient method. Typical reduction factors are 70-90%. Ventilation based methods and sealing of entry routes result normally in clearly lower radon reduction. In the Irish guide to likely effectiveness of remediation techniques (RPI, 2009, Fig. 4) the fan-assisted sump is the only technique with a high likelihood of success above 800 Bq/m^3. The target concentration in Ireland is 200 Bq/m^3 or below. The radon concentration range for good success for other methods is typically 200 - 700 Bq/m^3, for sealing and improving ventilation 200 - 400 Bq/m^3. This guidance is agreement with the Finnish results in figure 3. Radon well technique (chapter 4.3) has been used in Finland and Sweden. The results are on average as good as those for SSD, figure 3.

4.2 Sub-slab depressurization (SSD)

Sub-slab-depressurization is the most common and also most efficient methods in radon remediation. Following names have been used for this system:

- Sub-slab depressurization (SSD)
- Sub-floor depressurization
- Active or passive sub-slab depressurization (ASD, PSD)
- Radon sump (UK, Ireland)
- Sub-slab suction system
- Fan-assisted sump

SSD is based on two processes, first on depressurization of soil beneath the leaking floor structures and second on decreasing the radon concentration of the soil air flowing through the floor. This depressure reverses the pressure differential between soil under floor and the room above. A radon sump comprises a cavity (suction pit) about the size of a bucket (10 - 30 litres) in the ground immediately under the floor slab that is open to the surrounding under-floor hardcore. The sump is linked by pipe work to the outside. A suction pit is needed in order to minimize the flow losses in soil round the sump. The pipe penetrations and possible gaps and cracks in floor construction close to the suction pit should be sealed. Leakage through such gaps can decrease the efficiency remarkably.

Using a sump with an electrical fan is called as an active system. A reduced efficiency can be achieved through a passive sub-slab depressurization. In this case the system works without a fan. Typical radon reduction for an active SSD is 70-90%. In difficult cases additional sealing work is needed in order to achieve a low enough radon concentration.

The best location of the suction pit is in the central area of the floor slab or in a part of floor area which is divided by load bearing foundation walls into separate blocks. In the case this kind of foundation walls prevent the extension to other parts of foundation, two or more suction pits may be needed. In the case of one undivided floor block, one suction pit is normally sufficient for a floor area of 250 m^2 (BRE 2003) or 120 m^2 (STUK 2008), depending on the soil and foundation constructions.

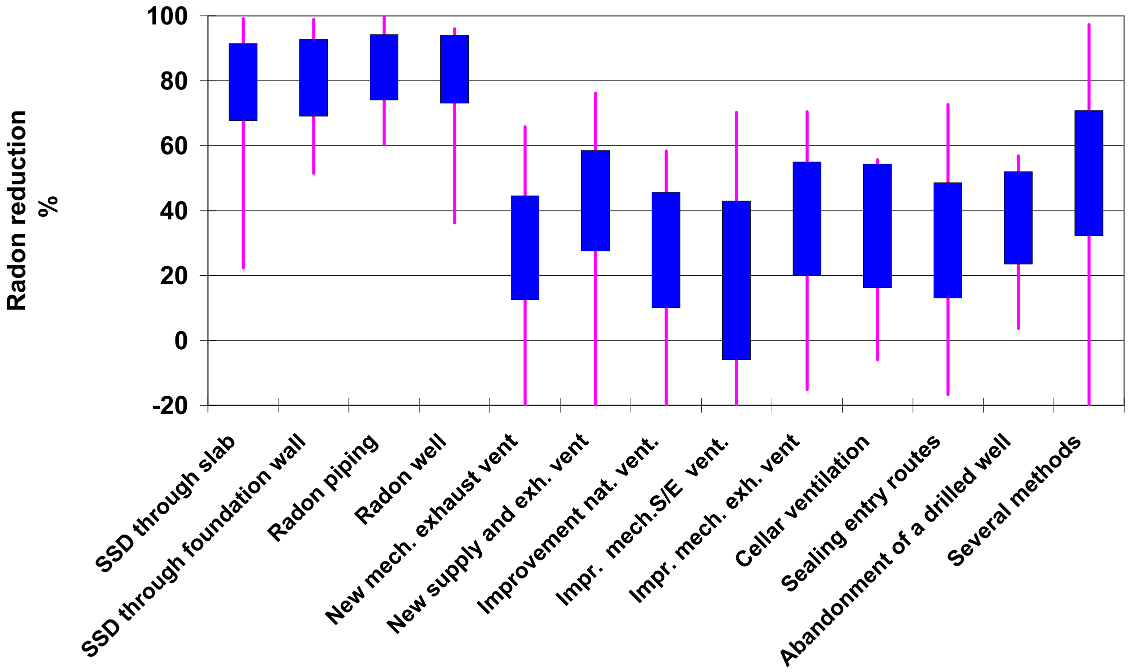

Fig. 3. Radon reduction factors achieved using various mitigation methods, minimum, 25% percentile, 75% percentile and maximum. The results are based on a questionnaire study in 400 Finnish houses. SSD: Sub-Slab Depressurization (STUK 2008).

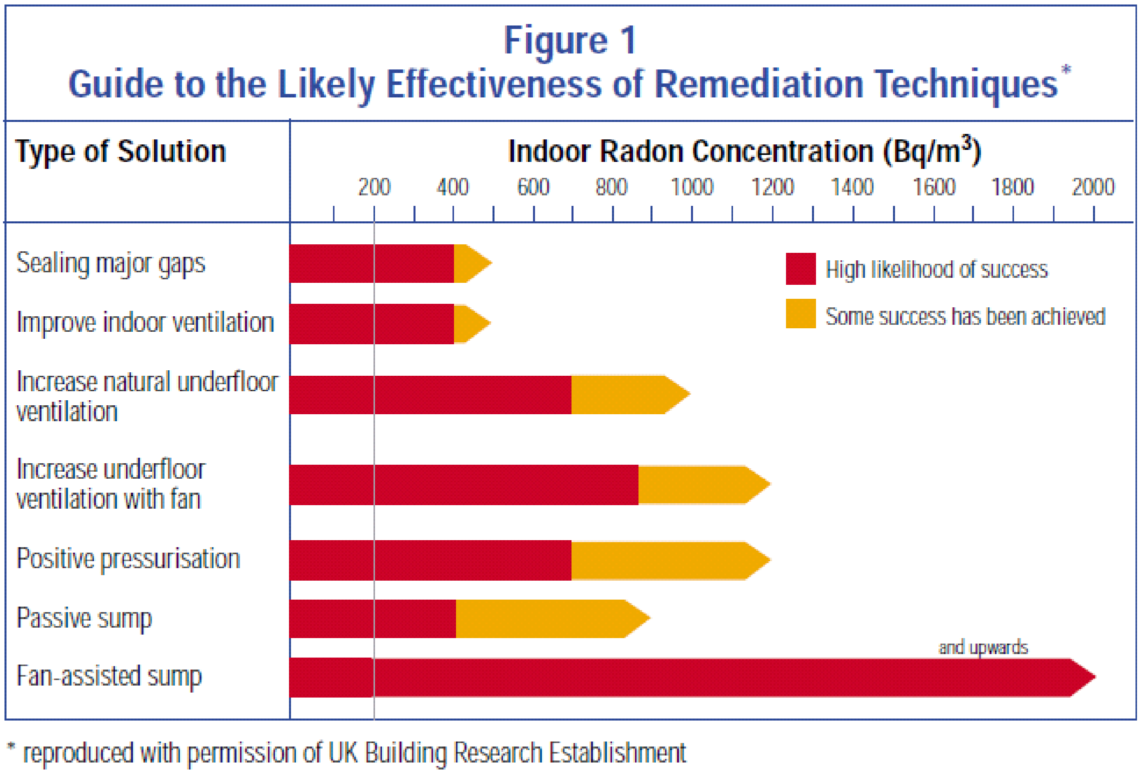

Fig. 4. Guide to likely effectiveness of solutions in Ireland (RPI 2009).

In the basic UK-guide (BRE 2003) **the standard sump** should be located close to the centre of the dwelling. It can be constructed using a paving slab 600*600 mm and a few rows of bricks with air gaps left between them or by using a prefabricated sump (Figure 5A). Typical fan power is approx. 70 watts.

A simple **mini sump** (Figure 5B) can be constructed by breaking out or core drilling a 120 mm diameter hole in the floor slab and excavating about a bucketful (10 -30 litres) of material from below (clearing out a space approximately 200mm in radius). A good volume in the suction pit decreases air flow resistance and increases thus the extension of the air flow.

A SSD can be constructed also from outside the building, According to the BRE guide, an **externally excavated mini sump**, figure 5C can be constructed by breaking out or core drilling a 120mm diameter hole through the external wall just below the floor slab and excavating about a bucketful of material (clearing out a space approximately 200 mm in radius).

Passive sump systems

Experience has shown that in cases where the indoor radon level is relatively low, i.e. just above the action level, it is possible, in the right circumstances, to operate a sump system *passively* – without the need for an electric fan (BRE 2003). If it works, a passive sump system is always preferable to a fan driven one as it is easier and cheaper to install, run and maintain, and will be quieter. However they are not as effective as systems fitted with fans. On average passive sump systems produce a 50% reduction in radon levels, whereas fan powered systems achieve relatively larger reductions – often more than 90%. The important point is that it is a simple task to add an electric fan later if the passive system does not adequately reduce the radon level.

Multiple suction points

Example in figure 6 shows a Czech application (Jiranek 2003) of multiple suction point system in a typical Czech cellar house. The effectiveness of such systems varies between 70 and 98 %, which means that indoor radon concentration decreases to 30 % up to 2 % of the initial values. The effectiveness is mainly influenced by the vertical profile of soil permeability and by the air tightness of the building substructure.

Depressurized hollow floor

Figure 7 shows an application of depressurized hollow floor (Swiss Radon Handbook). The system is appropriate when radon bearing soil air is coming mainly through the floor. In this example a reduction from 1400 Bq/m^3 to 50 Bq/m^3 was achieved.

Installation of radon piping and a SSD system

In cases where floors in old houses have been opened and renewed, it is practical to install a radon piping below the new floor. Figure 8 shows a French example of piping installation (CSTB 2008). Piping has been used also for controlling the leakages through the lower parts of the walls. Piping has been installed into a permeable aggregate layer and has been covered with geotextile and plastic membrane. Radon concentrations before the remedy were 1300 - 2800 Bq/m^3. Radon reductions up to 90% were achieved.

Depressurization of drainage system

In houses with existing drainage system depressurization of the drainage piping can be utilized. According to the Swiss Radon Handbook this system is effective only in 10 % of cases. US EPA (USEPA 2003) gives an average reduction factor of 50 %. The efficiency can be enhanced through installation of sealed valves or drain traps at exits of the drainage system. A sufficient quantity of water opens the valves. In Finland the method has been tested with a success in several houses. Creating a good depressure in the piping is the key problems. Further studies are needed for a good guide material for this method.

4.3 Radon well

Principle of radon well

A radon well is constructed outside the house and the well sucks air from the soil from the depth of 3 - 5 meters (STUK 2008). Figure 9 shows the principle of a radon well. Soil ventilation caused by the exhaust fan decreases efficiently the radon concentration of the soil air below the house foundations. Close to the house a radon well can also create underpressure below floor slab. A single radon well can reduce the radon concentration in several dwellings at the distance of up to 20-30 meters.

Building a radon well requires experience and expertise in soil geology. The efficiency of a radon well is affected e.g. by soil permeability, layer structure, depth of the suction pit and the power of the suction fan. Radon well is effective only when built on coarse soils as gravel and coarse sand. If the soil is fine and impermeable, such as clay, silt and moraine, it is not possible to create an air flow field with a good extension. Also fine sands may be problematic. Soil layers with coarse and fine material affect the extension and form of the air flow field.

Figure 10 presents the construction of a radon well. The best depth for the suction pit is normally 4-5 meters, below the footings of the house. The depth of the well promotes the extension of the flow field to a wide area.

The exhaust pipe can be either on the cover of the well ring or at good distance from the well using a horizontal transfer pipe below soil surface. In the case of houses on hillside (split level house), the best location of a radon well is on the upper side of the house.

Radon well in Hollola

Figures 11 and 12 present a radon well installation of a row house company with four buildings and 20 dwellings (STUK 2008). The aim was to achieve good results using two radon wells. Fig 11A presents the exhaust fan of 300 W installed in a well ring. A transfer pipe is leaving the well ring towards the gable of the house. Fig. 11B presents the cover of the radon well and the discharge pipe installed above the eave height of the building. The thermally insulated pipe ensures that the pipe does not freeze in the winter. This high exhaust pipe releases the radon bearing exhaust air away from the yard area (including a playground). The depths of the wells are 3.5 - 4 m. The air flows measures were 68 l/s (250 m^3/h, well no 1) and 58 l/s (210 Bq/m^3, well no 2). The average reduction of indoor radon concentration, in 17 dwellings originally above 400 Bq/m^3, was 88% (Fig. 12). The best reduction rate was 99%.

Fig 11. Exhaust fan in a well ring (A) and cover of the well ring as well as the exhaust pipe installed above the eave height of the building (STUK 2008).

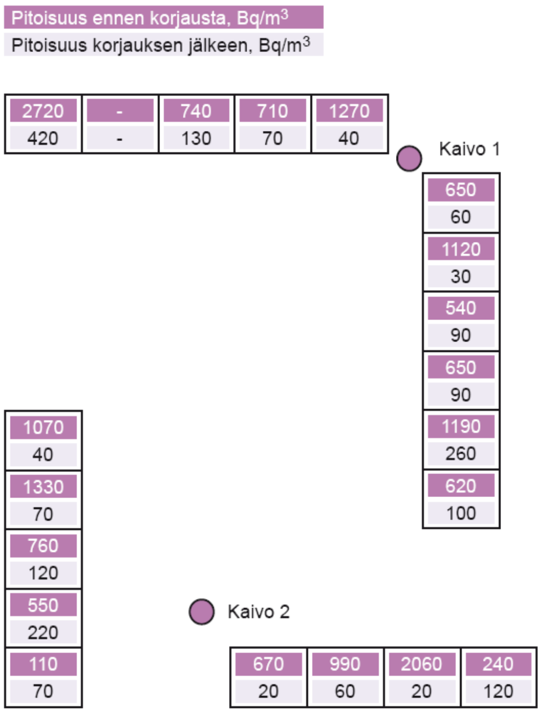

Fig. 12. Reduction of indoor radon concentration in 20 dwellings of a row house company after starting of two radon wells. Radon concentrations before and after the mitigation (STUK 2008).

4.4 Improving ventilation and sealing

Improving ventilation of occupied spaces

The British guide recommends the measures presented in figure 13. The guide emphasizes that it is important to recognise that in most cases the reduction in radon level that can be achieved by changing the way in which you ventilate your home will be small. Generally ventilation approaches are more common in mechanically ventilated schools and other large buildings than in small houses. The systems may be especially useful in the following cases.

- Building materials are the major entry route.
- There are other indoor air quality problems, for example very low air exchange rate.
- In the case of mechanical exhaust ventilation and tight building shell, reduction of underpressure level may be effective.

Radon reduction measures based on ventilation reduce radon concentration either through increased ventilation or decreased underpressure level. Reduction factors above 50% have been achieved only in cases where the original air exchange rate has been defective or when the underpressure level has been high. The typical reduction factors in Finland have been 10-40% (Fig. 3). Increasing the operation time or the power of mechanical ventilation, opening the existing or installing new fresh air vents are typical mitigation measures. Installation of new fresh air vents does not normally result in reduction factors above 50%.

In the Finnish experience the best results have been achieved through installation of a new supply and exhaust ventilation system. The underpressure created can be minimized and controlled in this strategy, which is important in radon control.

Temperature and moisture aspect should always be taken into account when changing the ventilation or depressure conditions.

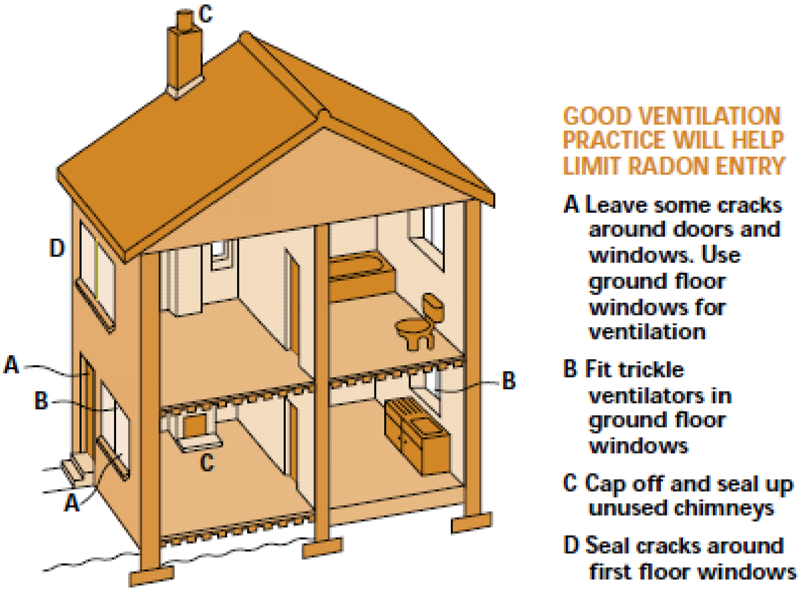

Fig. 13. Good ventilation practices in the UK guidance (BRE 2003).

Sealing entry routes

Sealing entry routes aims at reduction of leakage flows of radon bearing soil air into the living spaces. Sealing may be very demanding. In many cases the results of sealing are sufficient only when the entry routes have been sealed almost completely.

Floor joints with foundation walls of porous light-weight concrete cannot be sealed with normal sealing methods. Porous elements provide new leakage routes although the wall-floor gap has been sealed. Hollow block wall elements need similarly special consideration. Best results in Finland, when sealing the joint of floor and wall have been achieved in houses where the foundation wall is of casting concrete.

5 Radon prevention strategies

Most prevention strategies address steps to limit soil gas infiltration due to air pressure differences between the soil and the indoor occupied space. Radon prevention strategies should consider the specific mix of construction practices, radon sources, and transport mechanisms in the region or country, in order to be cost-effective. Under certain conditions a combination of strategies may be necessary such as in buildings with multiple types of foundations.

Preconstruction site assessment

The WHO Radon handbook (WHO 2009) presents following aspects on preconstruction site assessments. A number of approaches are used to assess the potential for elevated indoor radon concentrations across geographic areas. The most common approach involves mapping of indoor radon concentration in existing houses. This approach can be complemented through utilization of geological information. Areas of permeable sand and gravel e.g. can be classified to the high radon category. Another approach used in some countries, such as the Czech Republic, involves testing individual building sites prior to construction using soil gas measurements to establish a radon index for the site. The index is then used to define the degree of radon protection needed for building on that site. However, in countries including Finland, Ireland, Norway, Sweden, Switzerland, the United Kingdom, and the United States of America, the most cost-effective approach appears to be the use of radon control options in all new homes or in homes in specified areas.

Requirements in Ireland and UK

As an example the requirements in UK and Ireland are considered (BRE 2007, Ireland 2007). The basis for the requirements is the following: It is not possible to accurately predict the concentration of indoor radon likely to occur in a proposed building on the basis of a pre-construction site investigation. Both UK and Ireland have published the results of a national survey of radon levels in existing houses. Based on the results of the survey the countries have identified **High Radon Areas**. In Irish high radon areas, it is predicted that more than 10% of dwellings in the area will have radon gas concentrations above 200Bq/m^3. However, houses with high concentrations of radon gas are not confined to these areas and can occur in individual dwellings in any part of the country. In UK the Health Protection Agency defines Radon Affected Areas as those with 1% chance or more of a house having a radon concentration at or above the Action Level of 200 Bq/m^3.

In Irish high radon areas **full protection** is required. In this case a fully sealed membrane and a radon sump should be provided. In other than high radon areas buildings should be provided with potential means of extracting radon for example a radon sump or sumps with connecting network.

In the radon affected areas of UK sufficient protection will be provided by a well installed damp-proof membrane. This is called the **basic radon protection**. In areas of higher potential **full protection** is required. This means supplementary provisions for radon sump or sub-floor ventilation.

Prevention strategies

Radon prevention practices include both passive and active methods. The passive systems include providing barriers to soil gas entry. Membranes and sealing of openings can be used. Active systems are based on sub-floor depressurization and/or ventilation. Passive systems are to be preferred. However the systems should include provisions for active systems.

Sub-slab depressurization provisions in new construction may be similar with those used in remediation. However in new construction well designed and efficient piping arrangements can be used.

A basic UK approach for a radon-proof membrane and sub-floor depressurization is presented in Figure 14. Figure 15 shows an active soil depressurization approach in USA (USEPA 1993).

In the Finnish guidance (Building Information Ltd 2003) membranes covering the whole floor area are not recommended. Instead the joint of foundation wall and floor slab should be sealed using a strip of reinforced bitumen felt, figure 16. A preparatory radon piping should always be installed, figure17.

The Austrian guide for citizens gives the following general instructions (Lebensministerium, Austria 2005).

- Do not build earth floors.
- Avoid cracks in floor slab.
- Seal the joint of foundation, basement wall in contact with soil and floor slab.
- Seal pipe penetrations.
- Seal pipes if these can serve as routes for soil air.

Radon prevention in new construction, Finnish survey 2009

The building code for radon prevention and the associated practical guidelines were revised in Finland in 2003 to 2004. Thereafter, preventive measures have become more common and prevention practices more effective. Consequently, indoor radon concentrations in new construction have been markedly reduced. In the 2009 study, the indoor radon concentration was measured in 1 500 new low-rise residential houses (Arvela et al. 2010). The houses were randomly selected and represented 7% of houses that received building permission in 2006.

The average radon concentration of all houses measured, which were completed in 2006 to 2008, was 95 Bq/m^3, the median being 58 Bq/m^3. The average was 30% lower than in houses completed in 2000 to 2005. The decrease was 50% in provinces with the highest indoor radon concentration and 20% elsewhere in the country. In houses with a slab-on-ground foundation that had both passive radon piping (discharge pipe uncapped) and sealing measures carried out using a strip of bitumen felt in the joint between the foundation wall and floor slab (Fig. 16), the radon concentration was on average reduced by 55% compared to houses with no preventive measures.

Preventive measures were taken in 50% of single family houses, and in provinces with the highest radon concentration in 90% of houses. Active prevention in areas with high indoor radon concentrations has reduced the regional differences in the radon concentration. Slab on ground is the prevalent type of foundation and necessitates careful radon prevention measures throughout the country. The most serious defects were observed in prevention practices in houses with walls made of lightweight concrete blocks that were in contact with soil. The foundation types with the lowest radon concentrations were those with a crawl space and a reinforced uniform floor slab.

Effectiveness of protective measures

Research results of the effectiveness of protective measures are much more uncommon than results of remedial measures. In order to estimate the effectiveness of protective measures one needs also relevant reference values for houses without preventive measures. For example previous local values can be utilized. In the case of active methods as activation of sub-slab-depressurization, radon concentration measured for the passive system can be used as reference values.

In UK the use of membranes resulted in a reduction of approx. 50 % for both block and beam (under floor ventilation) and in-situ concrete floor (Figure 14) types (Woolliscroft 1994). The results are based on field studies involving over 400 dwellings.

Studies in 44 US homes showed a reduction of 50 % for passive sub-slab depressurization (Dewey and Novak 1994). Two-week tests were conducted in each home with the discharge pipe capped and uncapped.

Results from Czech republic show a reduction of 40% - 80% for membrane and sub-slab depressurization (Jiranek 2003).

Finnish new construction study 2009 in 160 houses (above) gives a reduction of 55% for houses with passive radon piping and sealing using bitumen felt (Arvela et al. 2010).

Activation of radon piping in SSD houses in Finland has resulted in typical reductions of 70 - 90% (STUK 2008).

Radiation exposure of space and aircrew

Hajek, Michael
Institute of Atomic and Subatomic Physics, Vienna University of Technology, AUSTRIA

Abstract

Cosmic radiation and its secondaries created in interactions with planetary atmospheres, shielding structures and the human body constitute one of the most important hazards associated with space and air travel. Crew members are facing exposures to radiation levels that may easily exceed those routinely received by terrestrial radiation workers. To assess the significance of potential biological implications on the health of space and aircrew, it is necessary to discuss the characteristics of the cosmic-ray environment and its dependencies on altitude and geomagnetic latitude. Exposure of space and aircrew to cosmic radiation will be reviewed, and recommended dose limits for astronauts working in low-Earth orbit will be dealt with in comparison with radiation protection guidelines of aircrew personnel.

Introduction

Accomplishments in engineering over the past century have provided unprecedented opportunities for people to become mobile and travel rapidly on or near the surface of the Earth (White and Averner, 2001). Now that new technologies are at our hands to enable us to travel away from our home planet, we are about to become citizens of the universe. For this to happen requires the development of both a new understanding of the risks imposed by the potentially dangerous levels of cosmic radiation, extended weightlessness and psychological stressors, and a more effective means of coping with these hazards to the human organism. Ions of high charge and energy encountered in cosmic radiation have been shown to produce distinct biological damage compared with radiation on ground, leading to large uncertainties in the projection of cancer and other health risks, and obscuring evaluation of the effectiveness of possible countermeasures (Cucinotta and Durante, 2006). On a microscopic scale, it becomes apparent that these particles are likely to deposit their energy in a rather heterogeneous way. Although absorbed doses—averaged over a sufficiently large macroscopic mass element—might be small, there will be microscopic regions of extremely high local doses in close vicinity to the ion path.

Cosmic radiation environment

The radiation environment in space is characterized by a high degree of complexity and dynamics. It is mainly fed by solar and galactic sources (Fig. 1), with additional particles created in interactions with planetary atmospheres, shielding structures and the human body. Among these secondary radiations, neutrons are of foremost importance.

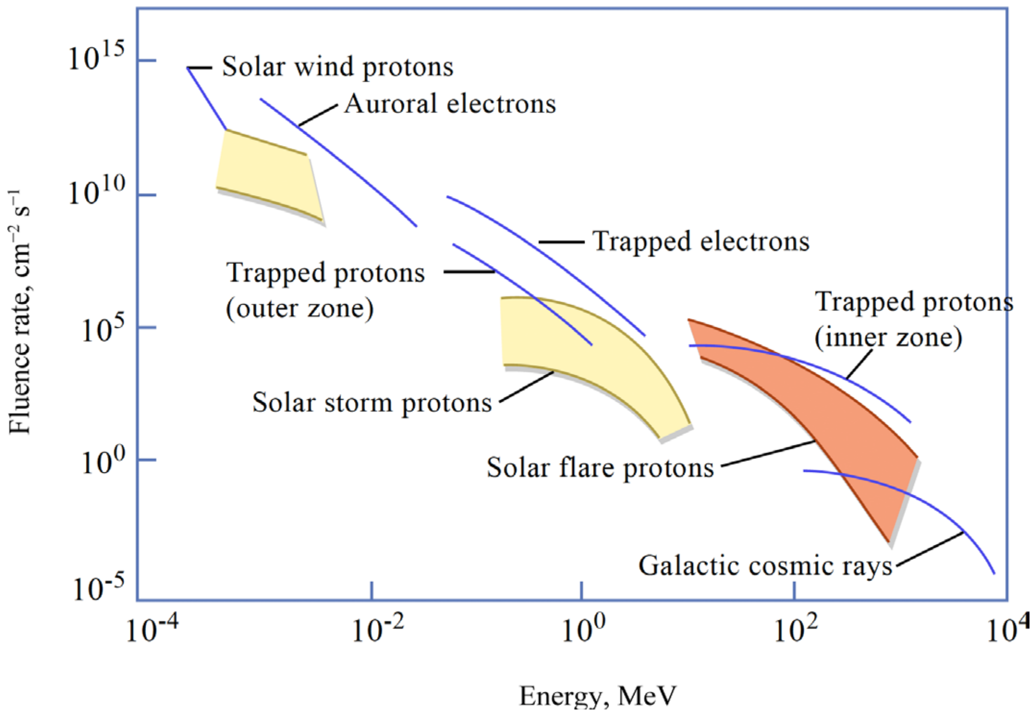

Fig. 1. Energy spectra of cosmic-ray contributors: energetic particles encountered in free space and low-Earth orbit cover a very broad range of energy and fluence rate (MIT OpenCourseWare).

Galactic cosmic radiation (GCR) originates from outside our solar system and is isotropic in distribution, *i.e.*, it arrives at any point in deep space with equal intensity from all directions. The GCR spectrum consists of all naturally occurring chemical elements with energies beyond 10^{20} eV (Lodders, 2003; Mewalt, 1988). Stellar flares, supernova explosions, pulsar spin-offs, or explosions of nascent galactic nuclei were believed to be the sources of GCR acceleration. However, there seems to be no credible mechanism, either inside or outside the galaxy, for accelerating particles to energies above 10^{20} eV (Schwarzschild, 1997). Astrophysicists developed plausible models for how ultra-high-energy cosmic rays might be produced, perhaps even involving new particle-physics phenomena or topological space-time defects left over from the Big Bang, but they still have no definite answers (Cronin *et al.*, 1997). The fluence rate of primary cosmic rays in the galaxy is ~1 cm^{-2} s^{-1}. Low-energy GCR particles consist of 92% protons and 6% helium nuclei, with the remainder being heavier ions with charges of $Z \leq 92$ (^{238}U). The incident fluence rate of cosmic rays with energies above 1 GeV is of the order of 10^{-2} cm^{-2} s^{-1} at the edge of the exosphere.

Solar cosmic radiation (SCR) comprises the flood of low-energy electrons and protons called the solar wind, which increases by factors of the order of 10^{6} during an active sun period to build into a torrential storm. This plasma, streaming out from the Sun's corona at velocities as high as 120 km s^{-1}, creates the interplanetary magnetic field (IMF), which varies according to the 11-year cycle of solar activity. GCR particles entering the heliosphere are scattered by IMF irregularities and undergo convection and adiabatic deceleration in the expanding solar wind (Heber *et al.*, 2009). The GCR intensity is thus anti-correlated with solar activity, which is usually determined from the number of sunspots (Lantos, 1993). Sporadically occurring solar particle events (SPEs) originate from impulsive solar flares, coronal mass ejections or shocks in the interplanetary medium. The emitted protons have energies up to several hundred MeV and, during strong flares, their flux at the Earth's orbit can increase for some hundred percent during hours or days. It is these events, which are of particular concern for the possible manifestation of acute radiation syndrome effects such as nausea, emesis, haemorrhaging or, possibly, even death, since SPEs are still impossible to forecast and might be accompanied by significant dose enhancement (Townsend, 2005).

Energetic particles trapped in the geomagnetic field are confined via magnetic mirroring in two radiation belts, which surround the Earth. The inner belt, which extends from ~1–3 Earth radii in the equatorial plane, was discovered by J. A. Van Allen and co-workers[1] using data taken from Geiger-Müller counters flown on early U.S. satellites. It is mostly populated by protons with energies exceeding 10 MeV. The origin of these protons is thought to be the decay of albedo neutrons from the Earth's atmosphere. The inner belt is fairly quiescent. Particles eventually escape due to collisions with neutral atoms in the upper atmosphere above the Earth's poles. However, such collisions are sufficiently uncommon that the lifetime of particles in the belt range from a few hours to 10 years. Clearly, with such long trapping times only a small input rate of energetic particles is required to produce a region of intense radiation. The outer belt, which extends from ~3–9 Earth radii in the equatorial plane, consists mostly of electrons with energies below 10 MeV. The origin of these electrons is via injection from the outer magnetosphere. Unlike the inner belt, the outer belt is very dynamic, changing on time scales of a few hours in response to perturbations emanating from the outer magnetosphere. In regions not too far distant (*i.e.*, less than 10 Earth radii) from the Earth, the geomagnetic field can be approximated as a dipole field, which is tilted with respect to the Earth's rotational axis by an angle of ~11°. The intersection between the magnetic and rotational axis is located ~500 km more to the North, above the centre of the Earth. Because of this tilt and translation, the radiation belts are closest to the Earth's surface over the South Atlantic Ocean. This region is called the South Atlantic Anomaly (SAA) and is of great significance to space vehicles that orbit the Earth at several hundred kilometres altitude. These orbits take them through the anomaly periodically, each time exposing them for several minutes to increased radiation levels. The high SAA proton fluxes were explained to give rise to light flash phenomena in the eyes of astronauts (Casolino *et al.*, 2003).

Galactic cosmic rays and energetic particles generated in large solar flares finally interact with the Earth's atmosphere to produce in cascade-like reactions hadron, lepton and photon fields at aircraft altitude. The energy spectra of these secondary particles extend from the lowest possible energy to more than 10^{18} eV (O'Brien *et al.*, 1996). The total flux of ionizing particles in the upper atmosphere is fairly constant from 150–50 km altitude. Below 50 km the flux increases due to build-up of cascades and reaches the so-called Pfotzer maximum at about 15–20 km above sea level where absorption starts to dominate. The geomagnetic field deflects the incoming cosmic rays, depending on their rigidity, *i.e.*, momentum per unit charge, and angle of incidence. The vertical critical rigidity is zero at the magentic poles and at its maximum near the magnetic

[1] Van Allen was actually trying to measure the GCR flux in deep space, to see if it was similar to that measured on Earth. However, the flux of energetic particles detected by his instruments so greatly exceeded the expected value that it prompted one of his co-workers to exclaim, "My God, space is radioactive!"

equator. As a consequence, the primary (and secondary) cosmic-ray flux shows a distinct latitude effect. With respect to dose equivalent, atmospheric neutrons are the most important particles at aircraft altitude. They are produced as evaporation products of highly excited nuclei to form a peak around 1 MeV, and in peripheral collisions or charge exchange reactions of high-energy protons with a maximum flux around 100 MeV (Hajek *et al.*, 2004a). The dependence of neutron production on solar activity is most pronounced in polar regions, while the variation around the equator is just about 5%, since low-energy primaries are shielded by the Earth's magnetic field and high-energy particles undergo only slight solar modulation. The higher energy of primary cosmic rays entering the atmosphere around the equator causes the created neutrons to be able to penetrate deeper into the atmosphere, compared with pole-near latitudes. The maximum of the neutron flux is thus found at about 120 g cm^{-2} at the equator and at about 75 g cm^{-2} in polar regions. Considerable fluxes of neutrons are also produced when a strong solar flare hits the Earth.

Space crew exposure and radiation protection

Space travellers are facing exposures to radiation levels that may easily exceed those routinely received by terrestrial radiation workers. Missions in low-Earth orbit (LEO) are not exposed to the full intensities of the GCR and SPE spectra because of the protection afforded by the Earth's atmosphere and magnetic field. Hence, particle fluence rates are much lower than will be encountered in interplanetary missions—about a factor of three from the International Space Station (ISS) to deep space, where no protection from the magnetosphere or planetary bulk exists. The degree of protection is a function of spacecraft orbital inclination and altitude. For the 51.6° orbit of the ISS, typical dose equivalent rates are between 0.5 and 1.2 mSv d^{-1} (Berger, 2008; Hajek *et al.*, 2008), with ~75% coming from GCR and 25% coming from protons encountered in passages through the SAA region of the radiation belts (NCRP, 2006). For high-inclination space missions in LEO, only 25–30% of SPE protons are intercepted due to geomagnetic shielding, while the contribution of SPEs to the radiation load of astronauts is mostly negligible for low-inclination orbits (Benton and Benton, 2001). Outside the protection offered by the geomagnetic field, doses received from a major SPE in less shielded modules might reach lethal levels within a couple of hours. Hence, radiation shelters have to be provided to minimize the health risks for astronauts.

Radiation transport codes, which model the atomic and nuclear interactions of the cosmic-ray particles, are usually applied to describing how the external radiation fields are altered by passage through the spacecraft structure (Sihver, 2008). However, the high degree of complexity of both the shielding distribution and the generation of secondary charged and uncharged radiation makes it virtually impossible to simulate in detail the variation of the resulting particle fluence and energy spectra of the radiation field constituents within a space vessel. Unlike the situation for terrestrial exposures, the high costs of launching materials into space place limitations on spacecraft size and mass and preclude the purely engineering solution of providing as much additional shielding as needed to reduce radiation exposure to some desired level. Some model predictions indicate that some types of shielding materials may even give rise to secondary radiation environments that are more damaging than the unattenuated primary fields, which produced them.

Table 1. 10-year career limits for stochastic radiation effects applicable to missions in low-Earth orbit. Limits are expressed in effective dose (*E*). Recommendations by NASA and JAXA are age and gender specific (male/female).

NASA		Roscosmos	JAXA		CSA
Age, yrs	*E*, Sv	*E*, Sv	Age, yrs	*E*, Sv	*E*, Sv
25	0.7 / 0.4	1.0	25−29	0.6 / 0.6	1.0
35	1.0 / 0.6		30−35	0.9 / 0.8	
45	1.5 / 0.9		36−39	1.0 / 0.9	
55	2.9 / 1.6		≥ 40	1.2 / 1.1	

The development of radiation protection recommendations for astronauts reflects the current knowledge about radiation risks, which is based to a large extent on cancer incidence and cancer mortality in the atomic-bomb survivors of Hiroshima and Nagasaki. Since until now only few experimentally verified data on the biological effectiveness of heavy ions and the dose distribution within the human body exist, the concepts of terrestrial radiation protection are of limited applicability to human spaceflight, except for the principles of justification and optimization (ALARA). Radiation protection limits for astronauts are designed to prevent deterministic or non-cancer hazards and reduce the risk of stochastic effects to an acceptable level. Instead of applying the annual dose limits for workers on ground also to astronauts, whose careers are of comparatively short duration, the overall lifetime risk is used as a measure. The selection of dose limits for stochastic effects are related to the risk for fatal cancers (solid tumours and leukaemia) as well as for genetic effects. While radiation protection in the pre-Apollo era was concerned primarily with the avoidance of exposures, which might deteriorate the operational performance of astronauts, the first genuine radiation protection guidelines of the U.S. Space Science Board (NAS/NRC, 1970) allowed doubling of the spontaneous incidence of malignant tumours[2]. In 1989, the National Council on Radiation Protection and Measurements (NCRP) proposed age and gender specific dose limits for a 10-year career on the basis that a lifetime excess risk of cancer mortality of 3% was acceptable (NCRP, 1989). This risk was comparable with the risk in less safe but ordinary occupations, such as agriculture and construction. However, it is lower than the 5% lifetime risk that a radiation worker on ground would incur if the present annual protection limits were exhausted (20 mSv per year over 50 years). The increase of risk factors for fatal cancers per unit dose by UNSCEAR and BEIR V required reappraisal of the effective dose limits (Table 1), which were published in NCRP Report 132 (NCRP, 2000).

The Russian Federal Space Agency Roscosmos allows an annual limit of 500 mSv, and—in agreement with the Canadian Space Agency (CSA)—a career limit of 1 Sv, both independent of age and gender, since Russian studies yielded an increasing probability of non-cancer radiation effects with age that compensates the decreasing cancer risk (Roscosmos, 2004). The Russian career limit corresponds to an excess risk between 4.6% (at 30 years of age) and 2.4% (at 50 years of age). Like their U.S. analogue, the dose limits defined by the Japan Aerospace Exploration Agency

[2] In industrialized countries, the spontaneous cancer incidence is on average 20–25%.

(JAXA) depend on age and gender, but differ in the tolerated dose values and the age structure (Table 1). The associated excess risk is ~3%, but never exceeds 5%. The European Space Agency (ESA) based its radiation protection concept on the recommendations of the International Commission on Radiological Protection (ICRP, 1991) and the European Council Directive 96/29/Euratom (European Commission, 1996), both of which do not explicitly classify astronauts as radiation workers[3]. The limits applied to European astronauts are thus based on thresholds for deterministic radiation effects in dedicated organs and tissues (Straube *et al.*, 2010).

Dose limits for acute deterministic effects in the bone marrow, lens of the eye and the skin (Table 2) are expressed in gray equivalents (Gy-Eq), in which the organ absorbed dose is weighted by multiplication with the appropriate relative biological effectiveness (RBE) for a specific radiation quality and endpoint. The concept of Gy-Eq became necessary, since the radiation weighting factors used for stochastic effects do not apply to deterministic detriments. Considering the significant uncertainties in assessing RBE at low dose and dose rate, the values on which the dose limit recommendations are based have been determined at the threshold doses for the regarded deterministic effect (ICRP, 1989; Urano *et al.*, 1984).

For long-term missions outside Earth's magnetic field, the acceptable level of risk has not yet been defined, since there is not enough information available to estimate the risk of effects to the central nervous system and of potential non-cancer radiation health hazards (cataracts, cardiovascular diseases, etc.). Available data and pending questions have been compiled in NCRP Report 153 (NCRP, 2006), which will form the basis for developing radiation protection guidelines for missions into deep space.

Table 2. Recommended organ dose limits in Gy-Eq applicable to missions in low-Earth orbit. All limits are independent of age and gender.

Organ		NASA	Roscosmos	JAXA	ESA	CSA
Bone marrow, Gy-Eq	Acute	0.25	0.15	–	–	–

[3] A task group appointed by the ICRP in 2006 shall develop recommendations for human space missions in low-Earth orbit and beyond.

Aircrew exposure and radiation protection

Aircraft passengers and crew are subject to elevated levels of secondary cosmic radiation produced in the atmosphere, the aircraft structure and its contents. From the beginning of the first commercial supersonic Concorde operations, measurements on board passenger aircraft became attractive and contributed to the vast pool of data available today. Total exposure on a given flight depends on the particular air route in terms of altitude (pressure rather than radar altitude) and geomagnetic latitude, as well as on solar activity and the duration of the flight. The dose rate increases with altitude and geomagnetic latitude, reaching a maximum at 15–20 km and a constant level above ~55°, respectively. As a rule of thumb, the effective dose from neutrons in polar regions is enhanced by a factor of ~6 compared with the equator, while the dose delivered by the directly ionizing component increases only by a factor of ~2. Commercial subsonic aircraft generally have cruising altitudes of 7–12 km. The effective dose rate at an altitude of 8 km in temperate latitudes is typically up to ~3 μSv h^{-1}, but decreases to only ~1–1.5 μSv h^{-1} near the equator (Fig. 2). At 12 km, the values are greater by about a factor of two. The dose for a return trans-Atlantic flight is typically 60–70 μSv (Hajek *et al.*, 2004b). The annual hours flown by crew members varies from individual to individual and from airline to airline, depending on policy. The average appears to be 300–900 hours per year. The annual effective doses received by aircraft crew usually lie within 2–4 mSv, with only few crew members receiving higher doses. At aircraft altitude and temperate latitudes, representative values of the main components of effective dose are neutrons 55%, electrons and positrons 20%, protons 15%, photons 5% and muons 5% (Bartlett, 2004). At sea level, the dominant component of effective dose is the muon component.

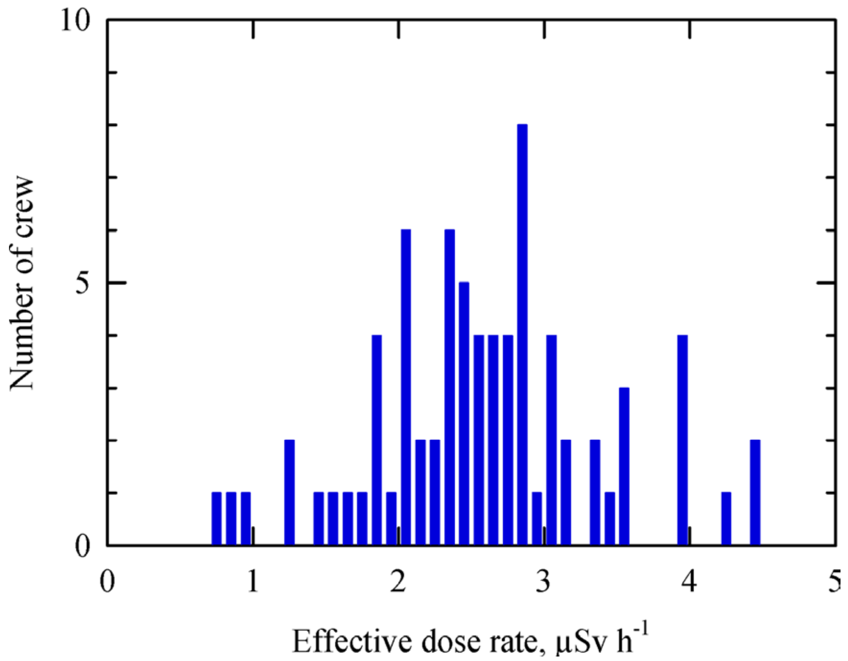

Fig. 2. Histogram of Tyrolean Airways crew radiation exposure on short- and medium-haul flights. The distribution of measured effective dose rates peaks between 2 and 3.5 μSv h^{-1}. For an average of 750 flight hours per year, effective dose can be estimated to result in 1.5–2.6 mSv.

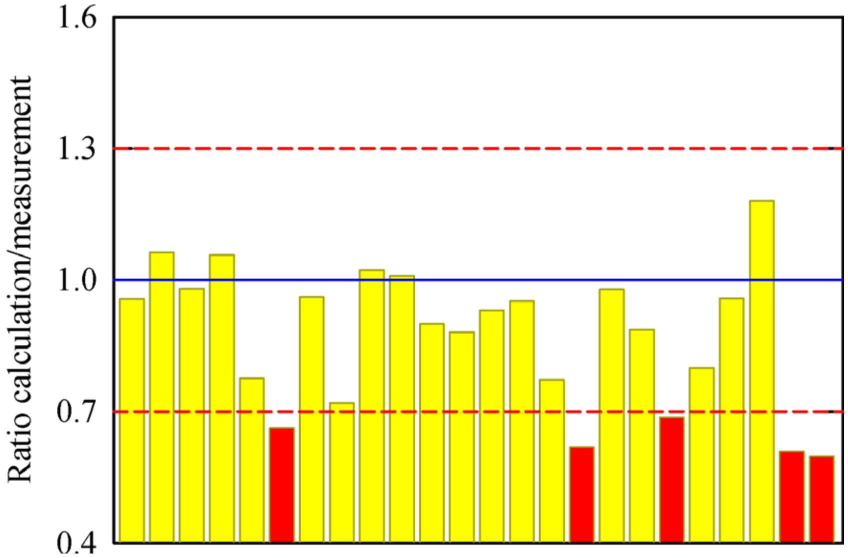

Fig. 3. Comparison of computed and measured route doses for 24 Tyrolean Airways flights. Agreement within ±30% is indicated, as required by Austrian regulations. There is generally good agreement between the results of calculations using CARI-6M and experimental determinations, except for very short-haul flights operated by propellant aircraft at low altitude.

There are a number of radiation transport codes and programmes to calculate dose rates and route doses in current use. The radiation transport codes take as input the cosmic radiation field at the top of the atmosphere and solve, either analytically or by Monte Carlo simulation, the radiation transport equations, which describe the interactions of each particle with the constituents of the atmosphere, in order to calculate the field at a given aircraft altitude and geographic location. The effect on particle trajectories of the Earth's magnetic field is included in approximations using tables of rigidity cut-offs. The programmes take account of the effects of IMF variation by applying an equivalent heliocentric electrostatic field. Generally, there is good agreement (Fig. 3) between the results of calculations and experimental determinations (Lindborg *et al.*, 2004).

Following ICRP recommendations (ICRP, 1991), the European Union (EU) introduced a revised Basic Safety Standards Directive (European Commission, 1996), which, *inter alia*, included the exposure to enhanced levels of cosmic radiation. The Directive requires account to be taken of the exposure of aircrew personnel liable to receive effective doses of more than 1 mSv per year. It further identifies the following protection measures (Bartlett, 2004): (i) to assess the exposure of the crew concerned; (ii) to take into account the assessed exposure when organizing working schedules with a view to reducing the doses of highly exposed crew; (iii) to inform the workers concerned of the health risks their work involves; and (iv) to apply the same special protection during pregnancy to female crew irrespective of the 'child to be born' as to other female workers. The EU Directive has already been incorporated into laws and regulations of the majority of the EU Member States and has been included in the aviation safety standards and procedures of the Joint Aviation Authorities (JAA). The preferred approach, supported by guidance from the European Commission and ICRP Publication 75 (ICRP, 1997), is that where the assessment of the exposure of aircraft crew to cosmic radiation is necessary, doses can be computed from staff roster information, flight profiles and calculations of cosmic radiation dose rates as a function of altitude, geomagnetic latitude and solar modulation. The calculations are to be verified by measurements.

Stakeholder involvement and engagement

Koskelainen, Markku[1, 2]
[1] STUK – Radiation and Nuclear Safety Authority, FINLAND
[2] The University of Manchester, UK

Abstract
One of the greatest challenges facing radiation protection professionals today is, how to include the society in radiation protection decision making. In response to this issue, internationally accepted guiding principles for radiation protection professionals on stakeholder engagement have been published by the International Radiological Protection Association (IRPA). IRPA goal is to ensure that consensus on directions for improvement of stakeholder involvement programmes is reached among radiation protection professionals, and that these guiding principles are taken into account during the development of future stakeholder involvement programmes.

Introduction
This work has been supported by Finnish Radiation and Nuclear Safety Authority, and parts of it have been published previously by International Radiation Protection Association and Nuclear Energy Agency within the Organisation for Economic Co-Operation and Development.

Stakeholder involvement and engagement are often used interchangeably when referring to public participation. In this article stakeholder involvement will refer to the policy and action taken with the stakeholders, whereas stakeholder engagement will refer to the process of how to engage with the stakeholder.

What is Stakeholder Involvement? Stakeholder involvement comprises of effective interaction between private and public companies, regulators and communities to make sure future activities and plans are discussed and understood by all parties. In decision making the stakeholder involvement is not intended to be stand alone process. Rather, it is designed to be an integral part of the decision-making and management processes, and it only has meaning if all parties have this intent from the outset. Whatever the level of involvement is, the distinction has to be maintained between the extent to which participants are responsible for the decision making and the level of interaction with stakeholders. Once this has been achieved the open and transparent approach of stakeholder engagement can help in establishing and maintaining effective relationships between all stakeholders (IRPA 2007).

History of Stakeholder involvement in Radiation Protection

Stakeholder involvement is not a new idea, but we are learning more and more of its application and benefits. Until the 1950s, the so called "managerial model" defined the relationships between the authorities and the public (Beierle and Crayford, 2002). In the "managerial model" the government administrators and experts in government agencies, are committed to pursuing the common good. In addition, they have been deliberate choices as possible so that the public interest and their policy have been used to produce the greatest benefit to most people in the long run. The signing of the Administrative Procedure Act in the United States in 1946, was a definite sign that the "managerial model" was reaching the end of the road. Soon other developed economies followed this trend with similar legislations. As the economies developed further and became more and more industrialised, the governments were faced with difficult decision making on matters related to environmental and health issues in particular (Beierle and Crayford, 2002, OECD/NEA, 2006).

In the 1970s, pluralism began to replace the "managerial model" as the primary approach to administrative decision making (Reich, 1985). According to this pluralist view, government regulators and politicians were not asked to have the impossible role of objective guardians and decision makers in the public interest, but rather be arbiters among different possible interests within the society. It was recognised that everlasting "common good" has no objective meaning, but rather that public interest has to be debated and arrived at by negotiation among different interested parties (Williams, 1995). This attitude was reflected in the 70s and 80s in many decisions where the role of public industrial (including nuclear) agencies was revised, with a clear separation of agencies having regulatory responsibilities and agencies aiming at promoting industrial development and applications (OECD/NEA, 2006). This separation of regulator and operator functions has since that time been a necessary element of any developed regulatory system (IAEA, 1996).

In the 1990s the "pluralist model" came under pressure as even more intense participatory perspective was expected by the stakeholders; with the aim to have consensus outcome rather than unsatisfying compromise, and from a desire to have long term sustainable decisions rather than immediate decisions from a better funded opposition (Beierle and Crayford, 2002, OECD/NEA, 2006). This "democratic model" stresses the importance of the act of public participation, not only in influencing decisions but also in strengthening public capabilities and social capital (Beierle and Crayford, 2002), emphasises interaction among often adversarial interests, but that interaction is viewed less as competitive negotiation than as a way to identify the common good and subsequently act on shared communal goals (Dryzek, 1997). From the public perspective, the act of participation *"makes people more aware of the linkages between public and private interests, helps them develop a sense of justice, and is a critical part of the process of developing a sense of community"* (Laird, 1993).

In today's regulatory environment stakeholder involvement provides the decision-framing, decision-aiding and decision making processes along the lines of the "popular-pragmatistic" model. The goal of radiological protection is, and has always been, to provide an appropriate standard of protection for man and environment. At the same time the justification principle requires, that consideration is given to the benefits arising practices, which give rise to radiation exposure, and that doses are optimised in accordance to the optimisation principle (ICRP, 2007). These principles are the cornerstones of radiological protection, and they can not be sidelined in any radiation protection decision making. The implementation of these principles was first thought to be possible through semi-quantitative analytical methods, such as cost benefit analyses. While these approaches provide a great guideline it has to be complemented with a genuine public participation.

The result of the evolution of the radiological protection system, towards increasing public participation in environmental and health related decision-making, can be fully appreciated in the current ICRP Recommendations (ICRP, 2007), where a paragraph is devoted to the participation of stakeholders.

"This decision making process may often include the participation of relevant stakeholders rather than radiological specialists alone."

Stakeholders

To understand how to involve the stakeholder, it is first necessary to understand what a stakeholder is and what it will be defined as in this paper. In the simplest form "A stakeholder is a person or other actor with special concern and interest in an issue, and may be considered to be concerned either on the basis of self report or on the basis of observed activities", (Sjoberg, 2003). Significantly, stakeholders bring differing perspectives to the process, given the range of backgrounds and disciplines that stakeholders are drawn from. For instance, some internal and external stakeholders may have a reasonable degree of commonality of interest or a legal obligation within the subject under discussion. These are sometimes referred to as 'true stakeholders'. But other stakeholders become involved because they are affected by the decisions taken, or have a strong view on the conduct of companies and government organisations, even if their interests are very different from those of the organisation in question .

For radiation protection issues the following stakeholders can be identified:

- Regulatory Stakeholders ('true stakeholders'). All practitioners, who require a 'licence to operate' from defined stakeholders, such as radiation protection regulators, health and safety regulators or environmental regulators. In some countries, there are also legal requirements to consult statutory stakeholders with a regulatory or quasi-regulatory function in many contexts (especially planning-related).
- Campaign groups often see themselves as having a 'license to operate' or watchdog role, but they are also significant as opinion formers, able to influence other stakeholders particularly through the media.
- The media are sometimes considered to be stakeholders, but are more often considered separately alongside other opinion formers. There is usually no strong commonality of interest between the media and industry. The media has, almost by definition, the potential to exert considerable influence on other stakeholders, including the public.
- The local community is the main target in many stakeholder programmes. However the community cannot be treated as a single entity, relationships between practitioners and the above are contained within it. The people who live around affected by the decisions and the community are complex and

all the different types of stakeholder described community groups and local authorities that speak for them, have a wide range of inter-relationships and perspectives. There is usually no such a thing as 'the community view'.

- Industry and commerce are often neglected in many stakeholder programmes. Similarly local communities, it is impossible to identify industry a joint commerce view, as there a number of interests and opinions represented in industry and commerce.

To engage with the stakeholders and fully realise the benefits of involving stakeholders in the decision-making processes International Radiological Protection Association (IRPA) have developed Guiding Principles for Radiation Protection Professionals on Stakeholder Engagement.

Guiding Principles for Radiation Protection Professionals on Stakeholder Engagement

The need for Guiding Principles on stakeholder engagement were first identified by IRPA in 2004, when it was agreed that stakeholder involvement, should play an important and integral part in decision-making processes related to radiological protection. The aim of the guidance was to help radiation protection professionals to understand the objectives, requirements and demands of stakeholder involvement, encourage participation and provide a framework for establishing a constructive dialogue with other stakeholders.

According to the IRPA guidance radiological protection professionals should endeavour to:

1. Identify opportunities for engagement and ensure the level of engagement is proportionate to the nature of the radiation protection issues and their context.
2. Initiate the process as early as possible, and develop a sustainable implementation plan.
3. Enable an open, inclusive and transparent stakeholder engagement process.
4. Seek out and involve relevant stakeholders and experts.
5. Ensure that the roles and responsibilities of all participants, and the rules for cooperation are clearly defined
6. Collectively develop objectives for the stakeholder engagement process, based on a shared understanding of issues and boundaries.
7. Develop a culture which values a shared language and understanding, and favours collective learning.
8. Respect and value the expression of different perspectives.
9. Ensure a regular feedback mechanism is in place to inform and improve current and future stakeholder engagement processes.
10. Apply the IRPA Code of Ethics in their actions within these processes to the best of their knowledge.

Case Studies

Radiation protection regulators around the world are in a situation where they are regulating activities at NPPs and other facilities with radiation risks, which were constructed in a previous era without true stakeholder involvement in the associated decision making. However, with the recent developments in the nuclear industry, it is anticipated, that a variety of stakeholders will seek participation in decision making as new plants are developed and old ones decommissioned.

IRPA, ICRP, IAEA and OECD/NEA have all concluded that the expectations of stakeholders of a right to participate in decision making, is something that the radiation protection authorities should address, and in some countries already do. Decisions regarding such matters as policy, regulating radiation practices and siting and construction of NPPs, should be voluntarily opened up to all stakeholders from the closed domain of technical experts and government officials (IAEA, 2006, IRPA, 2007). Below are a few case studies demonstrating the application of stakeholder involvement in radiation protection, full details of these case studies can be seen in Appendix 1, case studies are taken from a OECD/NEA Expert Group on Stakeholder Involvement and Organisational Structures.

Stakeholder Involvement in mobile phones and radiation (Sweden, SSI)

The Swedish Statens strålskyddsinstitut (SSI) has responsibility for ionising and non-ionising radiation. This case study concerned debate around new mobile phone masts. A decision was taken at the European level and licenses issued in Sweden by the post and telecommunications authority for construction of a network for a 'third generation' of mobile phones. However, concerns amongst sections of the population over the health impacts of radiation from the masts associated with the network led to opposition to construction of masts. SSI's risk assessment concluded that the risk from the masts was essentially zero. To understand the views of those concerned by the masts, to explain its own view and to allow dialogue with other stakeholders, SSI organised three seminars around the topic. Although the seminars did not result in consensus, stakeholders discussed with each other and were able to improve their own understanding of other stakeholder roles and views.

Stakeholder Involvement in NPP Siting (Finland, STUK)

The Säteilyturvakeskus (STUK) has a role as an expert body and regulator for the new nuclear power plant at Olkiluoto in Finland. STUK's role was essentially one of providing technical expertise in an open fashion, in a context where local and national elected representatives had to explicitly approve construction of the power plant. STUK provided information on the regulatory process and its work in it, responding to address topical, yet potentially sensitive issues such as aircraft impact. It was also willing to interact with questioning stakeholders. The approach used was open but, broadly speaking, more reactive than proactive and seems to have resulted from a general presumption of openness in STUK. STUK's approach appeared to be effective and 'fit-for-purpose'.

Stakeholder Involvement in post-Chernobyl contamination monitoring (Belarus, CORE)

Generally radiological protection is concerned with 'normality' in 'normal' situations i.e. tasks are entrusted to professionals. However, the situation is somewhat different in the contaminated territories where it becomes even more important to balance radiological protection with other aspects of life. Indeed, 'integrate' is probably a better word, since the question is one of co-working with civil society, rather than arriving at a better informed decision or improving credibility. Thus, the question moves from 'regulation' to 'governance'. A lesson to be learned from experiences in Belarus is that for the public in general to share in governance of a topic, it is necessary for people to fully appreciate all the issues and feel like they have created a real partnership in the decision processes affecting their safety and living conditions.

Stakeholder Involvement in UK Nuclear Decommissioning Authority (UK, NDA)

The Nuclear Decommissioning Authority (NDA) is a public body set up to run decommissioning of United Kingdom civil nuclear facilities. The actual decommissioning is carried out by contractors. Drawing on experience in the nuclear industry and on the findings of a government commissioned report, stakeholder involvement was recognised as an important factor and included in the NDA from its inception. By re-invigorating previous site local liaison groups (run by the operators), the NDA set out to involve stakeholders in its work in a local and national framework. Local liaison groups include representatives from civil society, local municipalities, regulators and contractors as well as the NDA. One of the aims of introducing the national tier was to link local concerns to national, strategic considerations. Through founding legislation and its own policies, the NDA retains a firm commitment to stakeholder involvement in its work.

Stakeholder Involvement in Policy Formulation (USA, USNRC)

The United States Nuclear Regulatory Commission (USNRC) is a federal regulator tasked with nuclear regulation. In developing Below Regulatory Concern (BRC) policy USNRC consulted their stakeholders to achieve a sustainable decision.

This process began in earnest in the early 1990's, but it had limited success. USNRCs most recent effort to consult stakeholders on clearance policy was termed NUREG-1640 rulemaking (NRC, 2002). This programme built on the early BRC stakeholder programme, which started with good intentions, but it polarised the views of the stakeholders further it went along. Consequently four of the eight environmental and consumer groups that had been actively involved from the beginning of the BRC policy formulation refused to enter a proposed consensus building process and the programme ended in failure. The new process centred around a series of public meetings, in which the stakeholders were asked to participate. For their detriment USNRC had lost the trust and confidence of some of the important stakeholders during the first BRC policy formulation and had not done enough in the meantime to engage the public in any effective manner to regain the trust of the stakeholders. This scepticism and lack of trust again led to some national environmental and consumer advocacy groups to boycott the public meetings. Due to the stakeholder feedback USNRC decided to postpone the rulemaking and carry on with case by case clearance.

Conclusions

Stakeholder involvement is a key concept in modern approaches to decision making and it has received considerable attention from IRPA, ICRP IAEA and OECD/NEA (IRPA, 2004, 2008, ICRP, 1991, 2007, IAEA 2006, OECD 2003, OECD/NEA, 2001a, 2001b, 2003, 2004). It is worthwhile to mention the role played by IRPA in identifying the need for the Guiding Principles for Radiation Protection Professionals on Stakeholder Engagement. These principles were produced to help radiation protection professionals to understand the objectives, requirements and demands of stakeholder engagement, encourage participation and provide a framework for establishing a constructive dialogue with other stakeholders.

Taking into account the views of different stakeholders is sometimes considered a time-consuming process leading to solutions technically not optimised. As the case studies have shown stakeholder involvement is often essential in obtaining societal acceptance of decisions. It should be noted, however, that in some cases stakeholders will not wish to accept decision, and that for them the perfect solution is the "do nothing" option sustaining the status quo. Under these circumstances, the regulators will have to decide whether it is best to go forward or not. However, sometimes as highlighted in the case studies this type of arbitrary decisions will result in stakeholders seeking to influence the decisions through courts or even through direct action.

Significant benefits can be gained from the involvement of stakeholders. For radiation protection the most quoted are:

- Responds to shifts in societal attitudes to science, industry and government.
- Offers possibility of resolving tensions between economic and social concerns.
- Helps to prevent disputes and conflicts where it is deployed ex-ante.
- Helps to resolve disputes and conflicts where it is deployed ex-post.
- Increases the substantive quality and sustainability of decisions.
- Builds trust in institutions.
- Educates and informs the public.

To realise these benefits it has to be appreciated different stakeholders have different perspectives, perceptions, beliefs, interests and values. Having clear aims and objectives from the outset will assist in planning a dialogue process without conflict. Also it should be made clear who is responsible for making the final decision. In order to arrive at this point the roles of the regulators and stakeholders, should be well defined. To measure success, evaluation criteria must be developed to evaluate the process with the stakeholders that will be participating.

Even in the most inclusive and transparent stakeholder involvement programmes, there can be conflict between the equal opportunity to participate and influence both programme and outcomes for anyone who affected by the decision, and competent participation, i.e. construction of the most valid, considering both societal and technical aspects. To ensure this seen as an opportunity and a mutual learning process the programme has to be initiated early on, and efforts must be made to build trust and consensus among the stakeholders.

Once the *"optimum solution under the circumstances"* the involvement of local stakeholders must continue with the aim, of demonstrating to all parties the compliance with the objectives of the programme.

As the case studies have shown decision making is not always successful, even with the help of stakeholder involvement, but more than often stakeholder relations and legitimacy of radiation protection professionals can be improved through stakeholder involvement. This is an arduous path to take, but if the field of radiation protection is to involve the stakeholders in future decision making it is the only way to proceed.

To make this process a little simpler, IRPA have published the Guiding Principles for Radiation Protection Professionals on Stakeholder Engagement. These guiding principles should provide a good basis for running any stakeholder involvement programmes in the field of radiation protection.

Decommissioning and waste management

Thierfeldt, Stefan
Brenk Systemplanung GmbH, Heider-Hof-Weg 23, 52080 Aachen, GERMANY

Abstract

Decommissioning of nuclear installations gives rise to large quantities of different types of radioactive material. Depending on its type, the overall mass of the controlled area of a large nuclear power plant has a mass of 100,000 to 400,000 Mg. The most important material streams are activated metals from the reactor pressure vessel and its components, activated concrete from the biological shield and the surrounding building structures, contaminated materials from systems, components and other structural elements, contaminated concrete from building structures, electrical installations, insulation material etc.

Decommissioning projects are in progress in a large number of countries around the world. In many countries, decommissioning has developed to be a mature industry. Techniques for dismantling and decontamination have been developed and are now available for all tasks and materials. This is also true for management of radioactive waste originating from decommissioning. Solidification, incineration, melting of metals, encapsulation and supercompaction are examples for techniques for treatment and conditioning of radioactive waste. The final disposal of radioactive waste from decommissioning is treated differently in various countries. Some countries use near-surface repositories for such wastes, which mainly consists of low-level waste, while others rely on deep geological repositories.

Only a small portion of the overall material from decommissioning has to be disposed of as radioactive waste. The vast majority of material can be cleared (that means released from radiological control). A thorough radiological characterisation is the prerequisite for clearance, for which, however, material from decommissioning of nuclear power plants has suitable properties. The radionuclides involved in material from nuclear power plants generally consist of a large portion of gamma emitters, so that the concept of nuclide vectors can be used. The measurements can be based on key nuclides like Co-60 and Cs-137, and the activity of nuclides that are not easy to measure can be derived from these values. Clearance procedures and clearance levels have been introduced by a large number of countries, making clearance are very important option in material management. Various measurement techniques are available for performing clearance.

Introduction

This paper addresses two topics that are closely related:

- decommissioning of nuclear installations and
- management of materials originating from decommissioning.

Decommissioning is the final phase in the lifecycle of nuclear installations after siting, design, construction, commissioning and operation. It is a complex process involving operations such as detailed surveys, decontamination and dismantling of plant, equipment and facilities, demolition of buildings and structures, site remediation, and the management of resulting waste and other materials. Decommissioning gives rise to a large amount of various types of material – a few 100,000 Mg for large NPP blocks – that can be treated and disposed of as radioactive waste or can be decontaminated and cleared (released) as non-radioactive material. This is the reason why the decommissioning phase of nuclear installations poses much larger challenges for the waste management than the operating phase.

This paper tries to address all aspects of this wide range of topics at least briefly: It first describes the decommissioning as a global task and as a process for a particular facility (restricting itself to nuclear power plants as the type of nuclear facilities from which the largest amounts of decommissioning waste arises), then lists the most important material streams originating from decommissioning and the related material quantities, and finally covers both management of radioactive waste (i.e. of material that has to be disposed of because of its activity) and clearance of material (i.e. the release of material that is either not contaminated above clearance levels or that complies with these levels after decontamination). As the topic is very wide, the information given in each section has to be necessarily succinct.

When analysing the development of decommissioning projects over the last two decades, it becomes clear that the vast majority of issues concerning techniques for decommissioning and dismantling, decontamination, waste management including treatment and packaging, measurement and characterisation, as well as clearance and release have been solved. Standard procedures and techniques are available off the shelf and can be deployed in all types of nuclear installations. Decommissioning has become a mature field of work. Nevertheless, each decommissioning projects needs its individual planning and adaptation of the techniques to its distinctive features. Waste management options that are available in a specific country will also influence the choice of techniques and procedures, even the choice of the decommissioning strategy. Therefore, both topics are closely interrelated, and this paper tries to highlight these interrelations.

Generally, it is assumed that the fuel elements would have been removed before start of decommissioning. There are, however, a number of projects where decommissioning has started with fresh and spent fuel on the site. In order to reasonably limit the scope, removal and storage of spent fuel is not dealt with in this paper. Likewise, operational waste that is still present at the beginning of decommissioning can usually be dealt with in the same way as during operation and is therefore also not included in this paper.

Decommissioning

Decommissioning of nuclear installations is not just the opposite of its construction. The aspects of radiation protection, management of partly highly activated and contaminated material and of large quantities of material for which the absence of contamination has to be verified, the necessity of remote operation in some areas where space might be tight and other features make decommissioning of nuclear installations a technically challenging and interesting field. In this chapter, decommissioning strategies that are viable for nuclear power plants and other nuclear installations are presented, followed by an overview of decommissioning projects and is decommissioning techniques.

Decommissioning strategies

There are two basic strategies that are widely used for decommissioning: immediate or early dismantling and deferred dismantling. A third strategy, entombment, leaves the facility and structures in place. This option, however, is rarely used. (IAEA, 2007)

Early Dismantling: Immediate or early dismantling is the strategy in which the equipment, structures, components and parts of a facility containing radioactive material are removed or decontaminated to a level that permits the facility to be released for unrestricted use (clearance) as soon as possible after permanent shutdown. In some cases, where unrestricted release is not feasible, the facility may be released from regulatory control with restrictions imposed by the regulatory body. The implementation of the decommissioning strategy begins shortly after permanent termination of operational activities for which the facility was intended, normally within a few years. Early dismantling involves the prompt removal and processing of all radioactive material from the facility for either long term storage or disposal. Non-radioactive structures may remain on-site. This is the preferred decommissioning strategy.

Deferred Dismantling: Deferred dismantling is the strategy in which the final dismantling of the facility is delayed and the facility is placed into long term storage where it is maintained in a safe condition. This strategy may involve some initial decontamination or dismantling, but a major part of the facility will remain for a certain time period in a caretaker mode. This time period might range from a few years to several decades, after which time the decommissioning process will be completed and the facility can be released from regulatory control. The deferred dismantling option is often used at multi-facility sites when one or more of the facilities are shut down while others continue to operate. This is especially true of facilities that share some common systems.

Entombment: Entombment is the strategy in which the radioactive contaminants are encased in a structurally long lasting material until the radioactivity decays to a level that permits release of the facility from regulatory control. The fact that radioactive material will remain on the site means that the facility will eventually become designated as a near surface waste disposal site and criteria for such a facility will need to be met.

Figure 1 shows an example for the early dismantling option, i.e. the transformation of a nuclear power plant site from the operational status to (nearly) green field conditions. Some buildings may be left in place, in this case buildings housing interim storage facilities that have to remain on site until the waste may be removed to a repository. The rest of the buildings of the controlled area as well as other have been cleared and removed.

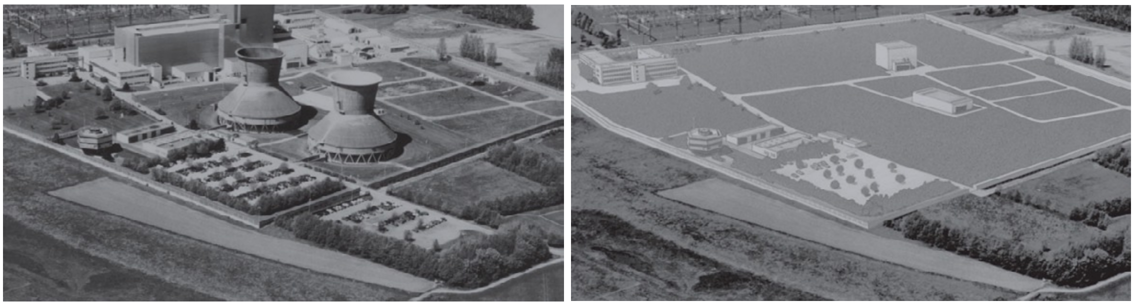

Figure 1. The site of NPP Würgassen (Germany). Left: before start of decommissioning (1995), right: after reaching green field conditions (artist's impression) (E.ON 2008).

Overview of Decommissioning projects

A large number of decommissioning projects exist worldwide. Table 1 gives an overview of shutdown power reactors in various countries that are under decommissioning (either early or deferred dismantling) or are awaiting decommissioning. There is an even larger number of research reactors that have also been permanently shut down or that are undergoing decommissioning. This overview makes it clear that decommissioning in many countries has become an industry handled by specialists rather than an experimental field that could be dealt with by the former operator of the facility alone.

Table 1. Shutdown reactors by country (IAEA 2010).

Country	Number of Units	Total MW(e)
Armenia	1	376
Belgium	1	10
Bulgaria	4	1632
Canada	3	478
France	12	3789
Germany	19	5879
Italy	4	1423
Japan	5	1618
Kazakhstan	1	52
Lithuania, Republic of	2	2370
Netherlands	1	55
Russian Federation	5	786
Slovak Republic	3	909
Spain	2	621
Sweden	3	1210
Ukraine	4	3515
United Kingdom	26	3301
United States of America	28	9764
Total	**124**	**37788**

There are a number of countries where a nuclear decommissioning industry has developed separately from the nuclear industry itself and where there is a good coexistence between operating nuclear installations and those undergoing decommissioning. As an example, Figure 2 shows an overview of NPPs in operation and undergoing decommissioning. The number of operating blocks and the number of blocks under decommissioning already equal each other.

Figure 2. Nuclear power plants in Germany in operation and undergoing decommissioning (Thierfeldt 2009).

Execution of decommissioning projects

Decommissioning projects are often implemented and executed using a phased approach. This means that the entire decommissioning project is structured into phases for which a license, permit or consent of the competent authority would be needed. The advantage of such an approach is that the next phase can be planned and the associated licensing procedure can be carried out while the previous phases are still in execution. Each phase can take advantage of experience gained in the previous phases. Figure 3 shows an example for decommissioning phases and their approximate duration (each phase divided into planning / licensing / implementation), while Figure 4 shows the corresponding illustration of the implementation of these phases for a boiling water reactor.

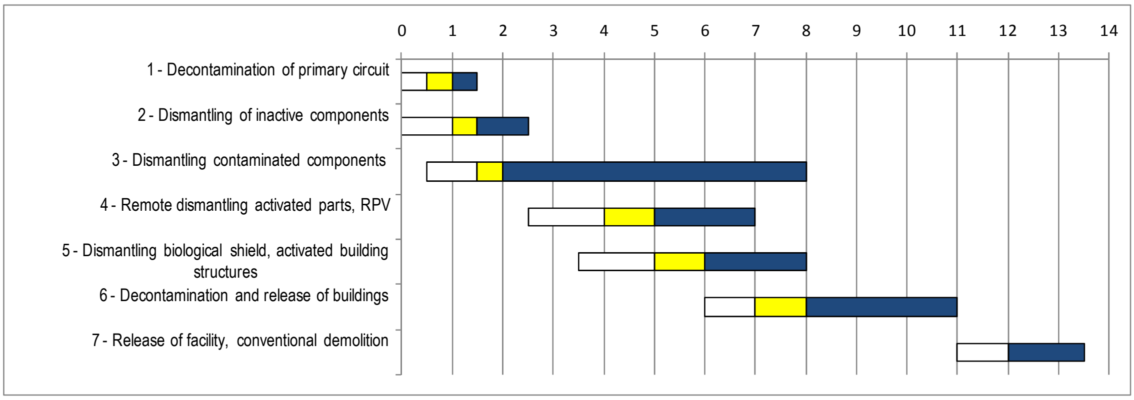

Figure 3. Example for decommissioning phases and their approximate duration for a large NPP.

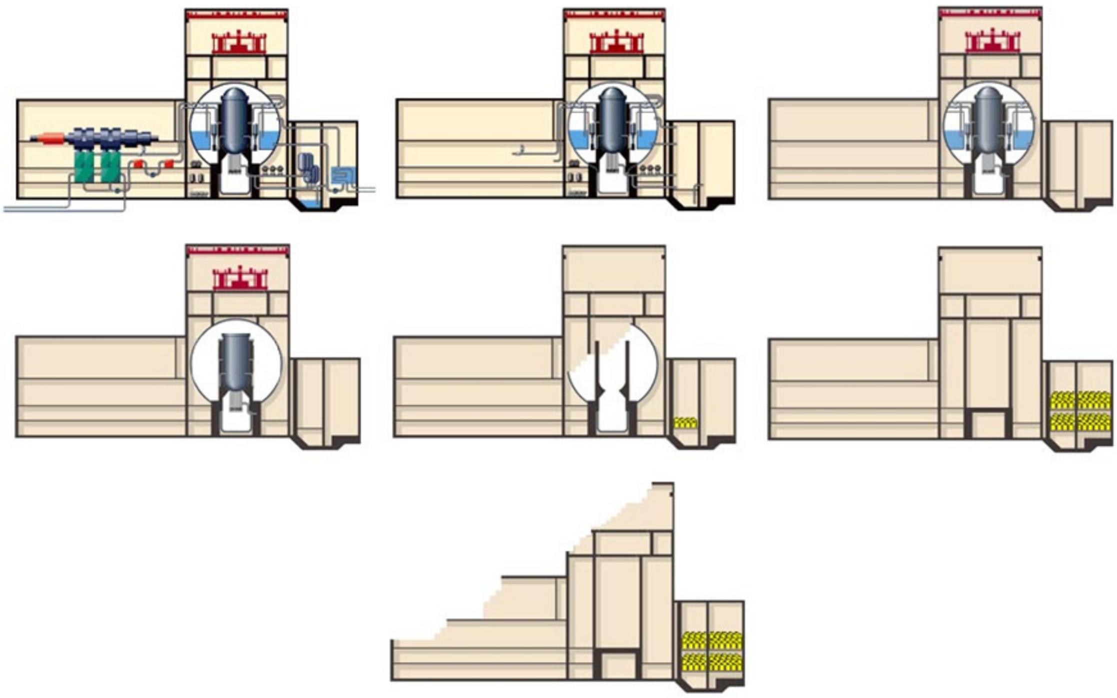

Figure 4. Illustration of decommissioning phases for a boiling water reactor (E.ON, 2008).

Decommissioning Techniques

For all the decommissioning strategies, the dismantling of external, unusable support systems and equipment will generally be performed using standard techniques. Much of this will be uncontaminated material that can be released from regulatory control and therefore needs to be segregated from contaminated material (see chapters on radioactive waste management and clearance).

There are differences in dismantling techniques between early and deferred dismantling. Higher dose rates resulting from high activation or contamination levels may require remote techniques for early dismantling of some facilities. High dose rates from activated components can generally be compensated by using additional shielding, e.g.

by working under water in the reactor spent fuel pool, and/or remotely operated techniques. For deferred dismantling, it is possible that some of the waste will have decayed to low levels and special techniques may not be needed during the dismantling phase. This will depend on the initial level of contamination of the specific structures, equipment or facilities to be decommissioned. It is desirable to plan for deferral periods if this will allow decay to low levels of contamination to simplify decommissioning. - Similar considerations apply to the entombment option: early preparation for entombment will require dealing with material with higher dose rates, while establishing entombment towards the end of a long deferral period will allow use of simpler techniques to prepare the facility as a near surface disposal site.

It can be reasonably assumed that most of the existing facility support equipment (e.g. lifting devices and bridges, utilities, water cleaning and filtration facilities, ventilation, sanitary facilities) will not be available after a prolonged deferred dismantling period without some type of refurbishment or replacement. This means that some advantages can be realised by selecting the immediate dismantling option in preference to deferred dismantling.

Decommissioning of facilities can be carried out with existing technology. There is no significant advantage in waiting for further progress in technology development, but in some particular cases (e.g. treatment/conditioning of special material such as graphite and the remote controlled tools needed for dismantling the reactor internals) some improvements may be expected and this could probably favour deferred dismantling in these particular cases. Nevertheless, there currently exists remote handling technology that allows the performance of this type of activity. (IAEA 2007).

Decommissioning techniques are generally divided into thermal techniques, mechanical techniques and other types. Dismantling and cutting techniques are available for metals, concrete, and all other purposes like cables, insulation etc. There is no single technique which could be used for all purposes. Thermal cutting techniques encompass various principles of heating and melting the material, like arc processes, in particular plasma arc processes, gas processes, laser beam processes, electro discharge machining and other processes, especially combinations of these techniques. An example is shown in Figure 5. Mechanical cutting techniques encompass grinding, various sawing techniques, shears, nibblers, milling cutters, diamond saws and diamond wire cutting etc., but also microwaves for concrete and hydraulic techniques. Examples are shown in Figure 6. A wider overview of decommissioning techniques can be found in (IAEA, 2008a).

Figure 5. Examples for thermal cutting techniques. Plasma cutting.

Materials arising from Decommissioning

This section deals with the various material types arising from decommissioning of nuclear installations. It can only present a short overview of the various material streams and their quantities, and it is necessary to restrict the overview to nuclear power plants, while research reactors and fuel cycle installations present different material compositions and waste streams. The largest part of all material streams will be going to clearance, while only a comparatively small portion will be disposed of as radioactive waste. Because of the completely different management and handling techniques for both parts, management of radioactive waste and clearance of material is dealt with in separate chapters.

Material types from decommissioning

The material types originating from decommissioning of light-water reactors are similar:

- activated and contaminated stainless steel from the reactor pressure vessel and its internals,
- contaminated stainless steel from the circuits, systems and components,
- carbon steel from components and structural elements,
- activated and contaminated concrete from the biological shield and adjacent concrete structures,
- contaminated concrete from building structures,
- electrical installations and cabling,
- insulation material,
- various other materials.

In gas-graphite reactors (GCR), there will also be activated and contaminated graphite.

Material quantities

It is clear that the material quantities that will arise from decommissioning depend on the size of the installation. There is, however, also a dependence on the type of the plant. In nuclear power plants with boiling water reactor (BWR), the secondary circuit and therefore the turbine hall and its components are part of the controlled area. The overall amount of material from BWRs is therefore larger than for a pressurised water reactor (PWR) of similar power rating. Furthermore, the specific type of construction also influences the material quantities. For example, PWRs of Russian type, VVER, have a higher amount of concrete than PWRs of a Western design, as VVERs do not have a full-pressure containment system like Western PWR, but a confinement system which consists of a large number of rooms by which overpressure could be gradually released in the case of an accident. This construction uses a higher amount of concrete per unit power.

Typical quantities of materials are provided in Table 2 for a 900 – 1300 MWe PWR and a 250 MWe GCR. The GCR has a higher mass per unit power than the PWR. In both cases the weight of the materials that are free of contamination and the weight of the building are not shown.

Table 2. Typical quantities of materials from decommissioning for a 900 – 1300 MWe PWR and a 250 MWe GCR (IAEA, 2008b).

Radioactive material	900 – 1300 MWe PWR	250 MWe GCR
activated / irradiated steel	650 Mg	3000 Mg
contaminated steel	3500 Mg	6000 Mg
graphite	-	2500 Mg
activated concrete	300 Mg	600 Mg
contaminated concrete	600 Mg	150 Mg

The weight of the building structures of the controlled area may amount to 200,000 Mg for large PWRs and 400,000 Mg for large BWRs. The structures include a few 10,000 Mg of reinforcement steel and other steel structures that are uncontaminated.

Activity levels and main contaminants

The activity levels, in particular the mass related activity (Bq/g) and the surface related activity (Bq/cm²), vary for the various material types, depending on the origin and history. Activated components of the reactor may reach specific activities of 10^9 Bq/g, the core region of the reactor pressure vessel may reach several 10^6 Bq/g, and activated concrete in the biological shield several 10^3 Bq/g. Surface contamination may range from some 10^5 Bq/cm² on highly contaminated areas down to a few Bq/cm² in less contaminated areas, nearing clearance levels. The main gamma emitting nuclides in LWR materials are Co-60 and Cs-137, causing the main part of the dose rate. Beta emitters like Fe-55, Ni-63 and Ni-59 as well as Sr-90 also contribute to the overall activity but not to the dose rate. Alpha emitters like Am-241 may be present in cases where (smaller or larger) fuel element defects have occurred during operation.

Management of Radioactive Waste

This chapter deals with the management of radioactive waste, while clearance of material is dealt with in the next chapter. First, a short overview of classification schemes for radioactive waste is given. Options for waste management and for decontamination are presented, followed by options for waste disposal.

Classification of radioactive waste

The main categories of decommissioning waste include:

(a) Low level radioactive waste;
(b) Intermediate level radioactive waste;
(c) High level radioactive waste;
(d) Hazardous, non-radioactive waste (chemicals, heavy metals, etc.);
(e) Non-radioactive and non-hazardous waste (cleared material that complies with clearance levels).

Each category of waste has its own unique concerns and specific management requirements.

The classification of radioactive waste is of particular importance when decommissioning nuclear facilities. The existence of guidelines for waste segregation and conditioning, in particular waste acceptance criteria for storage and disposal, can have a significant impact on the planning of decommissioning activities, particularly cost estimates and the selection of decontamination and dismantling activities.

A widely used classification system based on dose rates identifies waste as one of the following: low level waste (LLW), intermediate level waste (ILW), and high level waste (HLW). However, this system serves mainly to support waste handling and storage activities. Other countries may have different classification schemes, like e.g. Germany where the only distinction is made between heat-generating waste (spent fuel, vitrified waste from reprocessing) and waste with negligible heat generation (all other radioactive waste above clearance levels). For the long term management of decommissioning waste, it may, however, be more desirable to employ a classification based on the activity levels and half lives of the radionuclides contained in the waste, as defined by the IAEA. Figure 7 shows the IAEA waste classification scheme together with the German classification scheme.

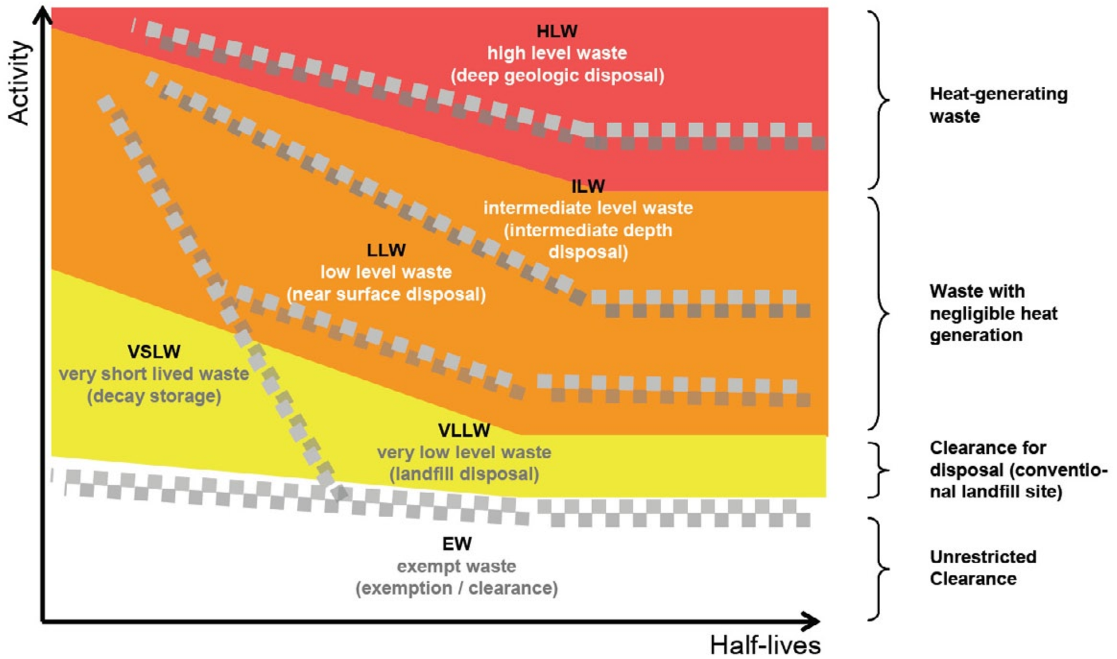

Figure 7. Waste classification according to IAEA and German classification scheme for comparison (German Government 2008).

Waste management options

Waste management starts with thorough characterisation of the material, taking into account the plant history including any incidents that might have led to contamination, activation calculations (for the reactor pressure vessel and the biological shield) and the results of a large number of samples and measurements. Characterisation of the plant is of paramount importance for a smooth implementation of decommissioning. It is, however, not possible to deal with this topic in this paper in any detail.

The basic options for waste management are depicted in Figure 8. In the process on the right starting with radioactive material the first decision is whether any treatment for reduction of activity (segregation of parts with higher and lower activity, decontamination) is technically and economically viable. If not, the material will end as radioactive waste and may need treatment and conditioning before being put into interim storage and eventually into final disposal. If treatment of the initial material is viable, the material has to be checked for compliance with release criteria (clearance levels). It may turn out that the material exceeds these values and has to be treated as radioactive waste, but in general it will be possible to bring the material to one of various release or clearance options (see next chapter). – The process for material for which contamination is only suspected is similar (branch on the left).

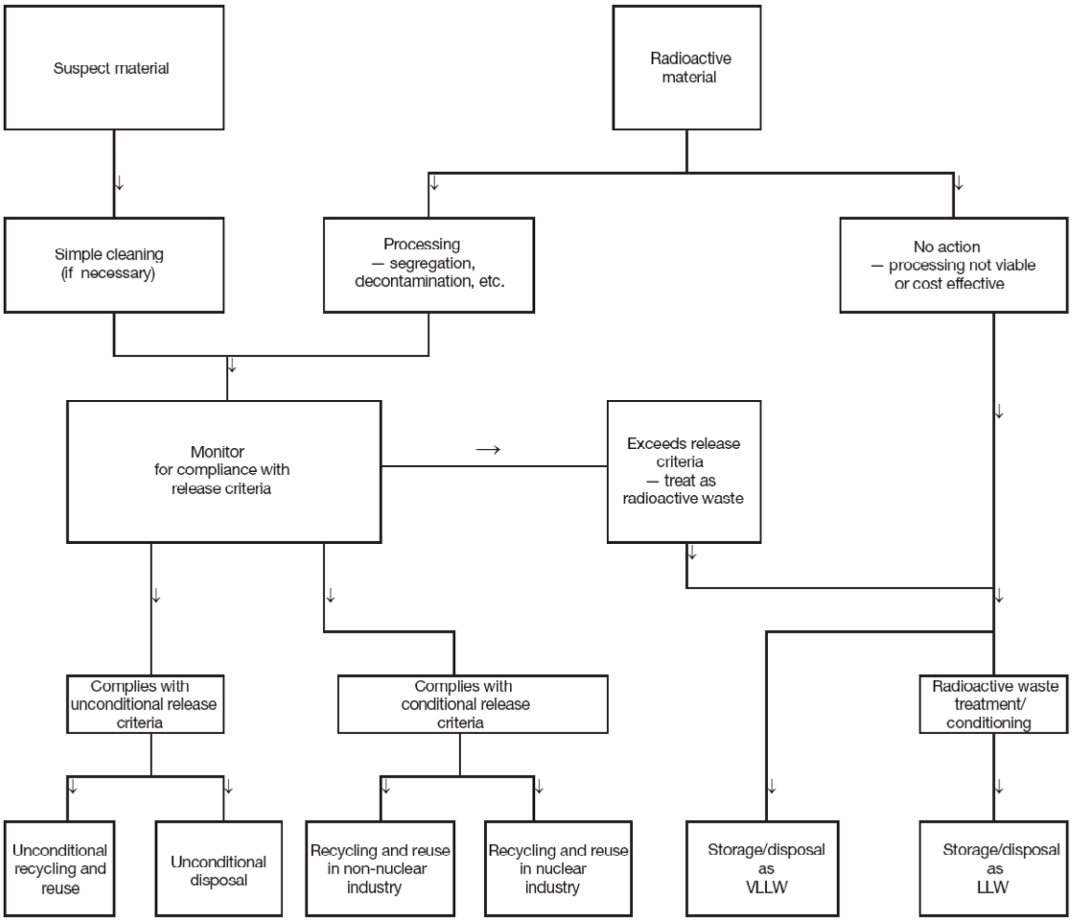

Figure 8. Management and disposition options for the segregation and characterisation of suspect and radioactive material (IAEA, 2008).

Decontamination

Decontamination techniques are based on the removal of surface contamination by mechanical, chemical or other procedures. Activation cannot be removed as it is a property of the entire volume of the material.

In many cases, light decontamination processes may be sufficient, like washing with water or a detergent, high-pressure water jetting or other commonly available processes. However, in many cases a fixed surface layer has to be removed, for which these techniques will not suffice. A widely used procedure for decontamination of metallic surfaces is grit blasting. Figure 9 shows an example of a grit blasting facility in a German nuclear power plant. The mobile facility is placed in the controlled area and forms part of the material management process. Metallic surfaces are monitored prior to and after blasting to verify the effect of the decontamination method and to decide whether the procedure has been effective so that the material complies with clearance levels. If necessary, the procedure has to be repeated. The steel grit is cleaned and reused until it is fully worn and then forms secondary waste (i.e. waste that arises from processes in addition to the primary waste from the material of the nuclear facility itself).

Figure 9. Left: loading of material into the grit blasting caisson. Right: the grit blasting container from the outside (E.ON, 2008).

Table 3. Overview of decontamination techniques for various purposes (IAEA, 2001).

OBJECTIVE/TASK	COMPONENT/SURFACE TO BE DECONTAMINATED	METHOD EMPLOYED
Decontamination before dismantling Reduction of occupational exposure	Pipeline system	Chemical Mechanical
	Pool/tank	Hydro-jet Blast Strippable coating
Decontamination after dismantling Recycle of contaminated metal Reduction of radioactive waste	Pipes, components	Electropolishing Chemical immersion Blast Ultrasonic wave Gel
Decontamination of building Unconditional release of building Reduction of radioactive concrete waste	Concrete surface	Mechanical: • Scabbler • Shaver • Drill and spalling • Steel grit blast Thermal stress: • Microwave irradiation • Flame scarfing

There are numerous other decontamination techniques like chemical baths using acids or bases in combination with electrolytic processes, called electropolishing. By removing a thin surface layer, the contamination is also removed. A rather comprehensive overview is given in Table 3.

Treatment and conditioning techniques

For management of RW from decommissioning, standard technologies can be used which have been applied already during the operational phase. Usually, the technology must be improved and upgraded to be able to manage the decommissioning RW, mainly because of the much larger quantities. The capacity of the RW management technology must be adapted accordingly. In addition, fragmentation and decontamination of solid RW and new measurement tasks usually requires purchasing of special technological equipment. (Thierfeldt, 2006)

The different NPP types produced different RW either from operation or decommissioning. The NPPs with WWER reactors are usually equipped with tanks with big capacities for storage of liquid or semi liquid RW from NPP operations (concentrates, sludges, ion exchangers). This RW must be treated before the decommissioning activities star. Treatment of such kinds of RW could be difficult from the view of meeting the acceptance criteria for disposal and a special methods and equipment must be developed.

There is a wide range of waste treatment and conditioning techniques of which only a few can be presented in the following.

- Solidification refers to a range of processes and which additives are added to a given batch of waste. The waste is then converted to a single, solid form. Before solidification, the waste may take a variety of forms, liquid, slurry, sludge or dried solid particles.
- Incineration may be used if the waste is burnable and does not contain significant amounts of hazardous substances for which the incineration plant is not suitable. The most important property of incineration is its large volume reduction.
- Melting of metals in a specialised licensed facility will transform surface contamination into volume activity, a kind of decontamination process, and will also result in size reduction. The molten metal can be poured into containers with other radioactive waste thus making effective use of any unused space.
- Encapsulation may be used for small, loose materials, e.g. by fixing the material with cement, polyethylene or other material, depending on the acceptance criteria of the interim storage facility and the repository.
- Supercompaction may be used as an effective process for volume reduction of metallic or other compressible waste. Figure 10 shows a volume reduction facility that can be set up in the controlled area of nuclear installations, forming part of the material management process.

Figure 10. Volume reduction of 200 l drums (FAKIR supercompaction facility, GNS).

Disposal options

The large field of disposal options that exist in various countries can only be briefly touched upon in this paper. Various countries like UK, France or USA prefer near-surface disposal of most wastes resulting from decommissioning. The waste is put into waste containers that are filled with concrete and is then emplaced into trenches lined with concrete which are finally covered in concrete, creating a monolithic waste structure. This waste form will remain stable until the activity will have decayed to levels that are below regulatory concern (several decades or a few hundred years). The amount of long-lived nuclides is usually limited in such repositories.

Other countries like Germany prefer deep geological disposal also for decommissioning waste. The characteristics of the waste containers and the mode of emplacement have been derived from operational and safety analysis of the repository. There are usually fewer restrictions on the activity content of the waste, as the isolation of the waste inside a deep geological repository is superior to a near-surface disposal site.

Waste management and selection of decommissioning strategy

Different aspects of waste generation and waste management can have an impact on the selection of a decommissioning strategy. Among the most important aspects are: the overall national waste management strategy, the amount of waste, the types and categories of waste (both radioactive and non-radioactive) and the facilities needed to process, handle, store and dispose of the waste. The absence of a waste management policy for any of these waste categories will introduce uncertainties in the decommissioning strategy selection process. If no disposal route exists for a particular waste category, the only option may be to store the waste on-site in regulated storage facilities.

Lack of a disposal facility is in itself insufficient reason for not performing immediate dismantling. The waste can be placed into an interim storage facility that will also require decommissioning eventually, once a final disposal scheme for the waste is decided upon. If the nuclear programme within a country is very limited and the type of facility to be decommissioned is amenable to entombment, then this may be the preferred option. As stated previously, an entombed facility has to be considered as a near surface waste disposal site and needs to meet the regulatory requirements for such a facility. This means, for example, that no or only limited amounts of long lived radionuclides are allowed in an entombed facility. If the country has not prepared the necessary infrastructure for a low level waste disposal facility, then entombment may not be feasible. However, the facility could be placed into a short deferred dismantling mode until such requirements can be put into place. (IAEA, 2007)

A country specific analysis of the influence of waste management techniques on decommissioning strategy selection among EU member states yielded three basic types of approaches (Thierfeldt, 2007):

- High influence on strategy selection: dismantling is postponed until a viable waste route becomes available, either in a prolonged form of early decommissioning which is drawn out over a suitably period of time or by choosing the deferred decommissioning option. Examples are NPP Barsebäck (Sweden), the four Italian nuclear power plants, in particular the NPP Latina and the NPP Vandellós 1 (Spain).
- Medium influence on strategy selection: dismantling is commenced although no repository is available. However, in order to manage the radioactive waste streams from decommissioning and to provide a storage even after dismantling of the nuclear installation will have been completed, an interim storage facility is created (e.g. in an existing building at the site which is converted into a storage facility or in a building newly constructed for this purpose). In some cases, the characteristics of this interim radwaste storage facility may have influence on the waste management options and the conditioning techniques, e.g. on the use of waste containers because of limited shielding provided by the waste building, on the mass of waste packages because of limited lifting equipment capacity etc. Examples are the NPPs Würgassen and Stade (Germany) and NPPs in the UK.
- Low or negligible influence on strategy selection: disposal routes for radioactive waste are available, either in the form of an existing repository or of centralised radwaste storage facilities, and consequently waste acceptance criteria are also established. In such a case, dismantling can commence without consideration to the creation of new waste disposal facilities or disposal routes. Examples are mainly decommissioning projects from countries with existing repositories like France

Clearance of Material

Clearance is of central importance for the material management in decommissioning projects. The topic is so broad that the analysis in this paper necessarily has to be very short. The vast majority of material from decommissioning of nuclear installations is either free of contamination (especially the large volumes of concrete from building demolition) or can be brought to sufficiently low levels by decontamination. If it can be demonstrated that the material, the buildings or the site of the facility complies with clearance levels, it can be released from regulatory control.

Clearance levels

Clearance is part of the EURATOM Basic Safety Standards (European Communities, 1996). Therefore, a number of countries have implemented clearance regulations with various degrees of complexity and using different clearance levels. The European Commission has also given guidance on clearance levels and the implementation of clearance for metal scrap, buildings, building rubble and unconditional clearance (European Commission, 1998, 2000a, 2000b). The IAEA has issued recommendations on unconditional clearance as well (IAEA, 2004). Table 4 shows a small comparison of values that are used or have been recommended for use in various countries. This table shows that there for some countries there are large differences for certain values which derive from the radiological models used. The values in many international studies that have been explicitly derived for unconditional clearance, however, are generally close together.

Table 4. Comparison of clearance levels for unconditional clearance for key radionuclides from studies and the regulatory framework of various countries and from international recommendations (values rounded to 1 significant digit; "-" means not analysed or no value given) (Thierfeldt, 2005).

Country/ Organis.	Regulatory framework/ study / recommendation	Clearance level in [Bq/g] for				
		Co 60	Cs 137	Sr 90	Am 241	H 3
Germany	Radiation Protection Ordinance Ann. III Tab. 1 Col. 5	0.1	0.5	2	0.05	1,000
Netherlands	report Timmermans et al. (recycling of steel)	100	100	10,000	100	1E7
Sweden	report Elert et al. (minimum of all clearance options for metals)	0.2	8	4	70	-
UK	report DETR	0.04	0.2	3	0.6	600
UK	Radioactive Substances Act	0.4	0.4	0.4	0.4	0.4
USA	report NUREG 1640	0.04	0.04	1	-	-
EU	RP 122 part 1	0.1	1	1	0.1	100
IAEA	Safety Guide RS-G-1.7	0.1	0.1	1	0.1	100
OECD/NEA	report of Task Group (additional surface specific CL apply)	0.2	0.7	94	50	-

A study on EU member states (Thierfeldt, 2006) showed that the existence of regulations for clearance will not necessarily depend on the size of the nuclear programme. Instead, most countries have implemented clearance regulations as soon as there is a substantial amount of material which need not be treated as radioactive waste and which has to be dealt with. A number of countries have followed one or more of the recommendations issued by the European Commission when implementing clearance in national regulations. While clearance regulations have been introduced in all countries except France, substantial differences pertain to the detailed design of these regulations, mainly the clearance options and the clearance levels which are in place. The comparison also reveals that the existence of a repository for radioactive waste is obviously not related to the implementation of clearance regulations in a particular country.

Measurement techniques for clearance

A large number of measurement techniques suitable for various clearance options is available which cannot be enumerated and outlined here. In cases where hard to measure radionuclides (alpha emitters, pure beta emitters etc.) form part of the nuclide vector and have to be taken into account, correlation with easy-to-measure nuclides are used. Usually a correlation between hard gamma emitters which have a high abundance in the nuclide vectors (e.g. ^{60}Co, ^{137}Cs), so-called key nuclides, is used. Correlation factors to other nuclides like ^{90}Sr, ^{241}Am etc. are determined from radiological measurements. The overall radionuclide contents of material can then be calculated from measuring the activity of the key nuclides and calculate the activities of the other nuclides via the correlation factors.

The applicability of direct measurements of gamma emitting nuclides as well as of the correlation method depends to a large extent on the percentage that these gamma emitting nuclides have in the nuclide vector. Because of the radioactive decay and because of the relatively short half-life of ^{60}Co (5.3 a) and the long half-lives of hard-to-measure nuclides (30 a for ^{90}Sr, 432 a for ^{241}Am), this percentage is continuously decreasing. Some installations, especially those with a high abundance of alpha emitting nuclides in the contamination, have taken this fact into account when determining the duration of the safe enclosure period. (Thierfeldt, 2006)

Examples for the three most important measurement techniques for material from NPPs are shown in the following figures. Figure 11 shows measurements with surface contamination monitors on metallic components, a technique which is indispensable for metallic material. These instruments are sensitive for beta and/or alpha radiation, so that the nuclide vector has to be known. Larger quantities (several 100 kg up to 1 Mg) of metallic material and bulk material like building rubble can be measured in bulk monitors of various sizes as shown in Figure 12. These facilities are sensitive for gross gamma radiation, so that the nuclide vector has to be known. Finally, building surface can be monitored using in-situ gamma spectrometry as shown in Figure 13. Here, the gamma emitting nuclides are measured individually.

Figure 11. Measurements with surface contamination monitors on metallic components (EON, 2008).

Figure 12. Measurements with a bulk monitor for large quantities of material (up to 1 Mg) (RADOS).

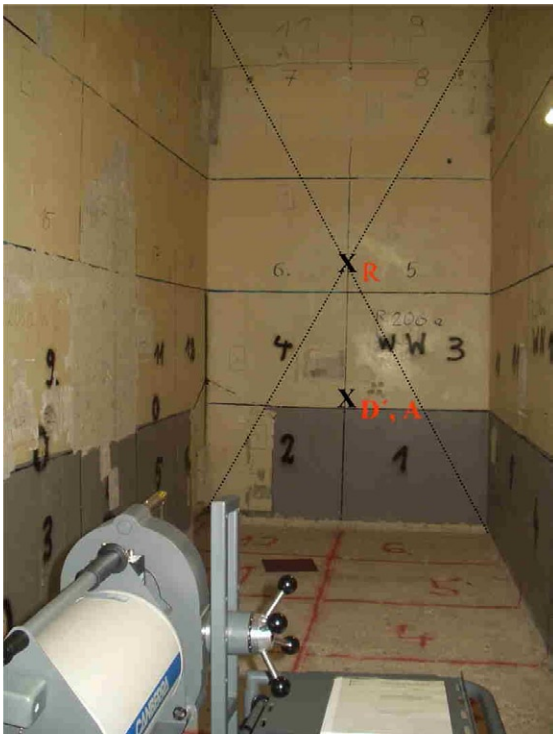

Figure 13. Measurement of a room with in situ gamma spectrometry (Naber, 2007).

In summary, the implementation of clearance or of an equivalent way of dealing with material with extremely low activity is a necessary prerequisite for carrying out active decommissioning. The recommendations on clearance issued by the European Commission (RP 89, 113, 122/I) or the use of similar clearance levels have proven to be viable. International harmonisation of clearance levels between European countries is a goal that has often been called for, but which has been achieved already to a large extent. The recommendations on clearance issued by the European Commission have played an important role as guidance. It is obviously not necessary to have exact harmonisation of the values of all clearance levels for all radionuclides, but to use clearance levels in the same order of magnitude for the most important radionuclides

Non-ionising radiation

Matthes, Rüdiger
Bundesamt für Strahlenschutz, GERMANY

Abstract
Technological development in modern societies cause an ever increasing exposure of people to non-ionising radiation in all situations of life. Examples include new technologies for diagnosis and treatment in medicine, wireless communication technologies at home and in the office, and high power devices for material processing in industry. The health implications of such exposures have been investigated quite intensively, but remain an issue of public concern. The relevant mechanisms and health effects are different throughout the non-ionising electromagnetic spectrum. Nerve excitation and tissue heating are well established examples. Cancer induction especially in children or from very long chronic exposure is still under investigation. The International Commission on Non-Ionizing Radiation Protection has issued guidance on limiting exposure to static, low, and high frequency electric and magnetic fields, that are regularly reviewed.

Introduction
This refresher course addresses the current scientific evidence of health related risks of exposures to static and low frequency (LF) electric and magnetic fields and high frequency (or radiofrequency (RF)) electromagnetic fields. It illuminates different aspects relevant for setting guidelines on limiting exposure. The following overview is based primarily on reviews conducted by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) (ICNIRP 2003, ICNIRP 2009a) and the World Health Organization (WHO 2006, WHO 2007).

Sources
Exposure to non-ionising radiation can result from both, natural and man made sources. Static electric fields occur naturally in the atmosphere. Beneath thunderclouds values of up to 3 kV m^{-1} can occur. High electric fields from man made sources are the result of either charge separation as a result of friction or the use of high voltages. Common examples are direct current (DC) power transmission that can produce static electric fields of up to 20 kV m^{-1}, rail systems using DC with fields of up to 300 V m^{-1} inside the train, and video display units that can create electric fields of around 10 - 20 kV m^{-1} at a distance of 30 cm. Local fields of up to 500 kV m^{-1} may be generated while walking on non conducting carpets.

The static geomagnetic field varies over the Earth's surface between about 35 - 70 µT. Magnetic flux densities of up to 2 mT have been reported inside electric trains and in developmental magnetic levitation systems. Workers are exposed to larger fields of up to around 60 mT from electrolytic reduction processes of alumina, and electric arc welding produces around 5 mT at 1 cm from the welding cables. Much larger magnetic fields are used in medical diagnosis. The static magnetic field of MRI scanners in routine clinical systems range from 0.2 - 3 T. In research applications, higher magnetic fields up to 9.4 T are used for whole body patient scanning. In terms of exposure, the magnetic flux density at the operator's console is typically about 0.5 mT, and higher. Strong fields are also produced in high-energy technologies such as thermonuclear reactors, magneto hydrodynamic systems and superconducting generators.

The dominant exposure to LF electric and magnetic fields is normally that associated with the generation, transmission and use of electricity at the power frequencies of 50 or 60 Hz. Maximum field strengths of up to several kV m^{-1} might be encountered at ground level below power lines operating at 100 kV or greater. Common sources are the various electrical appliances and tools used in industry and at home. The power frequency electric fields in conventional homes supplied with electricity range up to several hundred volts per metre. Power frequency magnetic fields in homes arise from the flow of current in electrical appliances and circuits both inside and outside the home, and from currents in conducting pipe work and the ground. The strongest LF magnetic fields in homes are usually those generated by electrical appliances. Transmission lines can produce maximum magnetic flux densities of up to a few tens of µT during peak demand, however mean levels are usually no more than a few µT. The magnetic fields encountered in electrified rail systems vary considerably because of the large variety of possible arrangements of power supply and traction. Operators in the vicinity of induction furnaces and equipment heaters may receive some of the highest exposure levels found in industry. Maximum flux densities of 1 - 60 mT have been reported. Incidental exposures to LF electric and magnetic fields can be incurred in a variety of occupational settings. Examples for typically magnetic flux densities that can occur are a few µT from underfloor heating, a few mT from tape erasers, a few mT from motorised equipment, several hundred µT from arc furnaces, and several mT from resistance welding.

At lower radio frequencies, below 30 MHz, the background electromagnetic radiation is mainly due to lightning discharges during thunderstorms. At high radio frequencies, above 30 MHz, the natural EM-fields originate from very broadband blackbody radiation from the warm earth and from extraterrestrial processes, mainly from the sun and the extraterrestrial microwave background radiation from the whole sky. The power density of the radiation component emitted by the warm surface of the ground at 300 K temperature (27 °C) is a few $mW \cdot m^{-2}$.

Man-made high frequency sources produce local field levels many orders of magnitude above the natural background. The antennas of broadcast stations are the most powerful continuous sources of high frequency electromagnetic energy intentionally radiated into free space. The cellular mobile telephone industry has undergone rapid growth resulting in a wide use of wireless communication devices in all parts of modern society today. The mobile phone networks consist of a system of adjoining 'cells', each with its own base station that sends and receives radio signals.

The base stations have power outputs ranging from tens of Watt in macrocells down to a fraction of a Watt in picocells. The exposure levels from these mobile telecommunications base stations are very low. Strong high frequency fields are encountered in medicine. Here high frequency fields are used for example for tissue heating (hyperthermia, diathermia), ablation, telemetry, and diagnostic purposes (MRI). High power electromagnetic sources are also used for material processing in industrial and domestic environments, for electronic article surveillance, for identification, and various RADAR applications. Microwave fields are also considered as carrier for wireless transport of electrical energy.

Mechanisms and effects

The three established physical mechanisms through which static magnetic fields interact with living matter are magnetic induction, magneto-mechanical, and electronic interactions. Magnetic induction originates through electrodynamic interactions with moving electrolytes. Static fields exert Lorentz forces on moving ionic charge carriers and thereby give rise to induced electric fields and currents. In accordance with Faraday's law of induction electric fields and currents within the body may also result from exposure to time varying magnetic fields, or from movement in a static magnetic field. The two types of mechanical effects that a static magnetic field can exert on biological objects are magneto-orientation and magneto-mechanical translation. In a static field, paramagnetic molecules experience a torque that orients them in a configuration that minimizes their free energy within the field. In the presence of gradients, static magnetic fields produce a net translational force on both diamagnetic and paramagnetic materials. Magnetic fields affect the recombination of radical pairs involved in an intermediate state of certain metabolic reactions.

Concerning magnetic field effects, different levels of biological organization at a cellular level have been investigated, including cell-free systems and various cell models using both bacteria and mammalian cells. Only a few in vitro studies on genotoxicity have been performed. Overall there is little convincing evidence from cellular and cell-free models for biologically harmful effects of exposure to static magnetic fields with flux densities up to several T. A large number of animal studies on the effects of static magnetic fields have been conducted (Saunders 2005). The most consistent responses seen in behavioural studies suggest that the movement of laboratory rodents in magnetic fields of about 4 T and higher may lead to aversive responses and conditioned avoidance. A well-established effect of exposure of animals to static magnetic fields greater than about 0.1 T is the induction of blood flow potentials in and around the heart and other major vessels of the central circulatory system. Exposures to static fields of up to 1 T have not been demonstrated to have an effect on foetal growth or postnatal development in mice. It is not possible to draw any conclusions from animal studies on possible genotoxic or carcinogenic effects of static magnetic fields. Detailed physiological studies in humans evaluating various physiological parameters including body (sublingual) temperature, respiratory rate, pulse rate, blood pressure, and finger oxygenation levels have not shown any pronounced effects of exposure to magnetic fields up to 8 T (Chakeres et al. 2003). Behavioural studies carried out on subjects situated in the proximity of MR systems with exposures up to 7 T have suggested that there may be a transient negative influence of exposure on eye-hand coordination and visual contrast sensitivity associated with head movement in the field (de Vocht et al. 2006, 2007a, 2007b). Overall, current information does not indicate any serious health effects resulting from the acute exposure of stationary humans to static magnetic fields up to 8 T. It should be noted, however, that such exposures can lead to potentially unpleasant sensory effects such as vertigo and transient decrements in the performance of some behavioural tasks during head or body movement. The few available epidemiological studies have mostly been conducted on workers exposed to moderate static magnetic fields of up to several tens of mT either working in aluminium smelters or chloralkali plants or as welders. Overall, the few available epidemiological studies on static magnetic fields have methodological limitations and leave a number of issues unresolved concerning the possibility of risk of cancer or other outcomes from long-term exposure. These studies do not indicate strong effects of static magnetic field exposure of the level of tens of mT on the various health outcomes studied, but they would not be able to detect small to moderate effects.

Time varying electric fields external to the body induce a surface charge on the body; this results in induced currents in the body, the distribution of which depends on exposure conditions, on the size and shape of the body, and on the body's position in the field. Surface charges may cause well-defined biological responses, ranging from perception to annoyance. The physical interaction of time-varying magnetic fields with the human body results in induced electric fields and circulating electric currents. Induced electric fields inside the body can be calculated by computational methods using anatomically and electrically realistic models of the body, which have a high degree of anatomical resolution. The responsiveness of electrically excitable nerve and muscle tissue to electric stimuli including those induced by exposure to LF electric and magnetic fields has been well established for many years. Myelinated nerve fibres of the peripheral nervous system have been stimulated by pulsed electric fields induced during volunteer exposure to the switched gradient magnetic fields of magnetic resonance (MR) systems. The most robustly established effect of electric fields below the threshold for direct nerve or muscle excitation is the induction of magnetic phosphenes, a perception of faint flickering light in the periphery of the visual field, in the retinas of volunteers exposed to LF magnetic fields. The retina as part of the CNS is regarded as an appropriate, albeit conservative model for induced electric field effects on CNS neuronal circuitry in general.

The experimental data available so far do not indicate that LF electric and/or magnetic fields affect the neuroendocrine system in a way that would have an adverse impact on human health. It has been hypothesized that exposure to LF fields is associated with several neurodegenerative diseases. For Parkinson's disease and multiple sclerosis the number of studies has been small and there is no evidence for an association between LF exposure and these diseases. For Alzheimer's disease and amyotrophic lateral sclerosis (ALS) more studies have been published. Overall, the evidence for the association between LF exposure and Alzheimer´s disease and ALS is inconclusive. Experimental studies of both short-term and long-term exposure indicate that hazardous cardiovascular effects associated with LF fields are unlikely to occur at exposure levels commonly encountered environmentally or occupationally.

Epidemiological studies have not shown an association between human adverse reproductive outcomes and maternal or paternal exposure to LF fields. There is limited evidence for an increased risk of miscarriage associated with maternal magnetic field exposure, but overall, the evidence for an association between LF fields and developmental and reproductive effects is very weak. A considerable number of epidemiological studies, carried out particularly during the 1980s and 90s, indicated that long term exposure to weak LF magnetic fields, orders of magnitude below the recommended limits, might be associated with childhood leukaemia. In contrast to the epidemiological evidence of an association between childhood leukaemia and prolonged exposure to power frequency magnetic fields, the animal cancer data, particularly those from large-scale lifetime studies, are almost universally negative.

Exposure to electromagnetic fields at frequencies above about 100 kHz can lead to significant absorption of energy and temperature increases. In general, exposure to a uniform (plane-wave) electromagnetic field results in a highly non-uniform deposition and distribution of energy within the body, which must be assessed by dosimetric measurement and calculation. As regards absorption of energy by the human body, electromagnetic fields can be divided into four ranges:

- frequencies from about 100 kHz to less than about 20 MHz, at which absorption in the trunk decreases rapidly with decreasing frequency, and significant absorption may occur in the neck and legs;
- frequencies in the range from about 20 MHz to 300 MHz, at which relatively high absorption can occur in the whole body, and to even higher values if partial body (e.g., head) resonances are considered;
- frequencies in the range from about 300 MHz to several GHz, at which significant local, non uniform absorption occurs; and
- frequencies above about 10 GHz, at which energy absorption occurs primarily at the body surface.

There are several theoretical hypotheses describing potential non-thermal mechanisms for biological effects from low level exposure. Some have been tested experimentally, but so far there has been no compelling evidence that they might plausibly account for any significant health effect.

Over the last 30 years there have been many in vitro studies on potential cellular effects of high frequency electromagnetic exposure. These studies gave insight into the basic mechanisms by which effects might be induced in more complex animal or human organisms. Interpretation of the experimental results is, however, limited by anomalous cell behaviour generated by the culture conditions and other factors which limit the extrapolation to humans. The studies conducted so far have not provided consistent evidence of biological effects under non-thermal electromagnetic exposure conditions. More recently, studies have been carried out using powerful high-throughput screening techniques capable of examining changes in the expression of very large numbers of genes. Such studies often showed a limited number of alterations where some genes were up- and others down-regulated. These advances in molecular studies are promising, but not yet decisive in risk evaluation.

Animal studies further support the conclusion that the most consistent and reproducible responses to acute high frequency exposure result from the induced heating. These studies established that, in general, an increase in body temperature elicits several cardiovascular changes including increased blood flow to the skin, increasing skin thermal conductance, and increased cardiac output, primarily due to an increase in heart rate, in order to maintain arterial pressure within the normal range. Deficits in learned behaviours, particularly the disruption of ongoing operant behaviours, occur mainly when core temperatures are increased by about 1°C or more. Similar rises in body temperature also result in significantly enhanced plasma corticosterone or cortisol levels in rodents and primates and transient changes in immune function and hematology, generally consistent with the acute responses to non-specific stressors. In addition, high frequency radiation can cause increased embryo and foetal losses, increased incidence of foetal malformations and anomalies, reduced foetal weight at term and impair male fertility at exposure levels that are sufficiently high to cause a significant increase in temperature. High frequency induced cataract also remains a well-established thermal effect of exposure in anaesthetised rabbits. However, primates appear less susceptible to cataract induction, and opacities have not been observed following either acute or prolonged exposures. The results of recent carcinogenicity studies in animals are rather consistent and indicate that carcinogenic effects are not likely at specific power absorption rates (SAR) of up to 4 W kg^{-1} averaged over the whole body, even for long-term exposure. To date, there is no consistent evidence of relevant effects at non-thermal exposure levels in animals.

The most consistent effects of acute exposure of human subjects to electromagnetic fields are the thermoregulatory responses to the induced heating. Volunteer studies indicate that exposed subjects can accommodate whole body heat loads of up to several 4 W kg^{-1} with minimal changes in core temperature. Increased skin blood flow and profuse localized sweating minimise skin temperature rises in response to high local peak SAR. Most volunteer studies have investigated the effects of electromagnetic exposures characteristic of mobile phone use, usually to the head, on a number of physiological parameters including brain electrical activity and blood flow, cognition, and more generally on the endocrine and cardiovascular systems. Some evidence suggests that such exposure may affect the spontaneous EEG in volunteers, but results overall are variable and inconsistent. The small changes seen in brain electrical activity and possibly in regional cerebral blood flow may not have any functional significance. Despite the large number of studies concerned with the issue, no consistent effects of electromagnetic fields on cognitive performance have been found so far. There is no robust evidence of any effect of mobile phone type radiation on children or adolescents. A wide range of subjective symptoms including headaches and migraine, fatigue, and skin itches have been attributed to various electromagnetic sources both at home and at work. However, the evidence from double-blind provocation studies suggests that the reported symptoms are not causally related to EMF exposure.

Results of epidemiological studies to date give no consistent or convincing evidence of a causal relation between electromagnetic exposure and any adverse health effect. On the other hand, these studies have too many deficiencies to rule out an association. A key concern across all studies is the quality of assessment of electromagnetic exposure, including the question of whether such exposure was present at all. Another general concern in mobile phone studies is that the time periods that have been examined to date are necessarily short. The implication is that if a longer time period is required for a health effect to occur, the effect could not be detected in these studies. Another gap in the research is children. No study population to date has included children, with the exception of studies of people living near radio and TV antennas.

Recommendations

ICNIRP is currently in the process of reviewing and revising its guidance concerning the limitation of exposure in the whole non-ionising radiation range. Guidelines on static magnetic fields have recently been published, revised guidelines on LF fields (1Hz – 100 kHz) have already undergone broad consultation and guidelines on radiofrequency fields (up to 300 GHz) will be reviewed synchronously to the health risk assessment process of the World Health Organization.

The exposure guidelines developed by ICNIRP are intended to protect against the adverse health effects of NIR exposure. Because adverse consequences of NIR exposure can vary across the entire range from trivial to life threatening, a balanced judgement is required before deciding on exposure guidance. Annoyance or discomfort may not be pathological per se but, if substantiated, can affect the physical and mental well being of a person and the resultant effect is considered to be a potential health hazard. ICNIRP seeks to define what is meant by adverse effects in its specific scientific reviews and guidelines. Examples are provided in Table 1.

Table 1. Relevant mechanisms of interaction, adverse effects, and biologically effective physical quantities used in different parts of the electromagnetic field spectrum.

field type	mechanism, interaction	adverse effect	effective quantity
static electric field	surface electric charge	annoyance of surface effects, shock	external electric field strength
static magnetic field	magnetic induction	annoyance of sensory effects, cardiovascular and CNS effects	external magnetic flux density
LF electric field	surface electric charge; induction of electric fields	annoyance of surface effects, shock; stimulation of PNS and CNS	external electric field strength; internal electric field strength
LF magnetic fields	induction of electric fields	stimulation of PNS and CNS	internal electric field strength
RF electromagnetic field	induction of electric fields; absorption of energy within the body; surface absorption of energy; thermo-acoustic wave propagation.	excessive heating, electric shock and burn; excessive surface heating; annoyance from microwave hearing effect	Specific energy absorption rate; Power density; Specific energy absorption

In general, separate guidance is given for occupational exposures and exposure of the general public. The limits for occupational exposure in the ICNIRP guidelines apply to those individuals who are exposed as a result of performing their regular or assigned job activities.

For static magnetic fields ICNIRP recommended that occupational exposure of the head and trunk should not exceed a spatial peak magnetic flux density of 2 T, to prevent vertigo, nausea and other potentially annoying sensations (ICNIRP 2009b). For work applications for which exposures above 2 T are deemed necessary, exposure up to 8 T can be permitted if the environment is controlled and appropriate work practices are implemented to control movement-induced effects. When restricted to the limbs, maximum exposures of up to 8 T are acceptable. Exposure of the general public should not exceed 400 mT (any part of the body). However, because of potential indirect adverse effects practical policies need to be implemented to prevent inadvertent harmful exposure of people with implanted electronic medical devices and implants containing ferromagnetic materials, and injuries due to flying ferromagnetic objects, and these considerations can lead to much lower restriction levels. The limits recommended for occupational and general public exposures to static magnetic fields are summarized in Table 2.

Table 2. Limits of exposure[a] to static magnetic fields.

Exposure characteristics	Magnetic flux density
Occupational	
Exposure of head and of trunk	2 T
Exposure of limbs	8 T
General public	
Exposure of any part of the body	400 mT

[a] ICNIRP recommends that these limits should be viewed operationally as spatial peak exposure limits.

Concerning time varying electric and magnetic fields, ICNIRP (ICNIRP 1998) recommended two classes of guidance: Basic restrictions that are based directly on established health effects. Depending upon the frequency of the field, the physical quantities used to specify these restrictions are internal electric field strength (E), current density (J), specific energy absorption rate (SAR), and power density (S). Reference levels are provided for practical exposure assessment purposes to determine whether the basic restrictions are likely to be exceeded. The derived quantities are electric field strength (E), magnetic field strength (H), magnetic flux density (B), power density (S), and currents flowing through the limbs (I).

For exposure to LF electric and magnetic fields, basic restrictions are provided on current density to prevent effects on nervous system functions. In the frequency range from a few Hz to 1 kHz, for levels of induced current density above 100 mA m^{-2}, the thresholds for acute changes in central nervous system excitability and other acute effects such as reversal of the visually evoked potential are exceeded. In view of safety considerations, occupational exposure should be limited to fields that induce current densities less than 10 mA m^{-2}. For the general public an additional factor of 5 is applied. ICNIRP is currently revising its guidance on limiting exposure to LF electric and magnetic fields. Different modifications with respect to the 1998 guidelines are under consideration. Protection from effects on central and peripheral nervous system are discussed. Field effects caused in the retina are considered a model for effects in the brain. With regard to the basic restriction, the induced electric field seems to be closer related to the biological effects and thus might replace the induced current density in future recommendations. In deriving reference levels, the most recent advances in numerical dosimetry will have to be considered.

For exposure to high frequency electromagnetic fields, the 1998 guidelines have been reconfirmed recently (ICNIRP 2009c). It is the opinion of ICNIRP that the scientific literature published since the 1998 guidelines has provided no evidence of any adverse effects below the basic restrictions and does not necessitate an immediate revision of its guidance on limiting exposure to high frequency electromagnetic fields. The biological basis of such guidance remains the avoidance of adverse effects such as "work stoppage" caused by mild whole body heat stress and/or tissue damage caused by excessive localized heating. there has been considerable advance in dosimetric investigations in terms of precision and resolution (Lin 2007). A special concern was raised with regard to numerical computations using anatomical models of human bodies which might influence the derivation of reference levels from the basic restrictions. Some published studies showed that in the frequency ranges of body resonance (~100 MHz) and from 1 to 4 GHz for bodies shorter than 1.3 m in height (corresponding approximately to children aged 8 y or younger) at the recommended reference level the induced SARs could be up to 40% higher than the current basic restriction under worst-case conditions. However, this is considered negligible compared with the large reduction factor of 50 (5,000%) for the general public. The basic restrictions recommended for occupational and general public exposures to high frequency electromagnetic fields are summarized in Table 3.

Table 3. Limits of exposure to high frequency electromagnetic fields.

Exposure characteristics	Frequency range	Current density mAm^{-2}	Whole body average SAR W kg^{-1}	Localised SAR (head/trunk) W kg^{-1}	Localised SAR (limbs) W kg^{-1}
Occupational					
	100 kHz-10 MHz	f/100	0,4	10	20
	10 MHz-10 GHz		0,4	10	20
General public					
	100 kHz-10 MHz	f/500	0,08	2	4
	10 MHz-10 GHz		0,08	2	4

Basic restrictions for frequencies between 10 and 300 GHz limit power density to 50 W m^{-2} (occupational exposure) and 10 W m^{-2} (general public).

International Commission on Radiological Protection (ICRP)

Abstract
In 2007, after almost a decade of development and worldwide, open consultation, the International Commission on Radiological Protection (ICRP) published its latest fundamental recommendations describing the overall system of radiological protection in the 2007 Recommendations of the International Commission on Radiological Protection. These replaced the 1990 Recommendations of ICRP published almost two decades earlier. Since then ICRP has focused primarily on developing publications that support or further elaborate elements of the system of radiological protection as described in the 2007 Recommendations. This paper describes these publications, as well as ongoing and planned future efforts with the same objective.

Introduction
The International Commission on Radiological Protection (ICRP) is an independent, international organization that advances for the public benefit the science of radiological protection, in particular by providing recommendations and guidance on all aspects of protection against ionizing radiation.

ICRP was established in 1928 by the International Society of Radiology (ISR) to respond to growing concerns about the effects of ionizing radiation being observed in the medical community. At the time it was called the International X-ray and Radium Protection Committee, but was restructured to better take account of uses of radiation outside the medical area and given its present name in 1950.

ICRP is a Registered Charity (a "not-for-profit organisation) in the United Kingdom, and has a Scientific Secretariat in Ottawa, Canada.

In preparing its recommendations, ICRP considers the fundamental principles and quantitative bases upon which appropriate radiation protection measures can be established, while leaving to the various national protection bodies the responsibility of formulating the specific advice, codes of practice, or regulations that are best suited to the needs of their individual countries.

ICRP offers its recommendations to regulatory and advisory agencies and provides advice the intended to be of help to management and professional staff with responsibilities for radiological protection. Although ICRP itself has no formal power to impose its recommendations, in fact legislation in most countries adheres closely to ICRP recommendations. In addition, the International Atomic Energy Agency (IAEA) International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources (commonly referred to as "the BSS") is based heavily on ICRP recommendations, and the International Labour Organisation (ILO) Convention 115, Radiation Protection Convention, General Observation 1992, refers specifically to the recommendations of ICRP. Effectively, ICRP recommendations form the basis of radiological protection practice, programmes, regulations, and international standards and guidance worldwide.

Originally, ICRP published its recommendations and advice as papers in various scientific journals in the fields of medicine and physics. Since 1959, ICRP has its own series of publications, since 1977 in the shape of a scientific journal, the Annals of the ICRP, which is published Elsevier Science.

ICRP has published well over one hundred publications on all aspects of radiological protection. Most address a particular area within radiological protection, but a handful of publications, the so-called fundamental recommendations, each describe the overall system of radiological protection. The system of radiological protection has been developed by ICRP based on (i) the current understanding of the science of radiation exposures and effects and (ii) value judgements. These value judgements take into account societal expectations, ethics, and experience gained in application of the system.

The 1990 Recommendations of ICRP form the basis of the current IAEA BSS, and are also the foundation of most radiological protection practices, programmes and regulations worldwide. The 2007 Recommendations recently replaced the 1990 Recommendations. They are the result of nearly a decade of development and several major worldwide public consultations. They update, consolidate, and develop additional guidance on the control of exposure from radiation sources issued since 1990, and they reflect a more up-to-date understanding of the science behind radiological protection and evolving societal expectations.

The 2007 Recommendations of ICRP

Although a complete review of the 2007 Recommendations (ICRP *Publication 103*) is beyond the scope of this paper, it is important to recall that all exposures are divided among three categories of exposure and three exposure situations.

Three categories of exposure described in the system of radiological protection are: occupational exposures, public exposures, and medical exposures of patients (and comforters, carers, and volunteers in research).

The system of radiological protection also recognises three types of exposure situations, intended to cover the entire range of exposure situations. Planned exposure situations involve the planned introduction and operation of sources. Emergency exposure situations are unexpected situations such as those that may occur during the operation of a planned situation, or from a malicious act, requiring urgent attention. Existing exposure situations are situations that already exist when a decision on control has to be taken, such as those caused by natural background radiation. These exposure situations replace the previous categorisation into practices and interventions, although in most cases planned exposure situations are analogous to circumstances in which one is undertaking a practice, and emergency and existing exposure situations are similar to situations requiring an intervention.

For more information on the 2007 Recommendations of ICRP the reader is referred to another paper prepared for this congress by the same author titled "ICRP 103 and Beyond".

Publications since the 2007 Recommendations of ICRP

At the time of writing this paper, ICRP has released seven ICRP publications (formally ten issues) of the Annals of the ICRP, and two additional publications are in press. These are listed in Table 1. In addition, a report titled "Reference Data for the Validation of Doses from Cosmic-Radiation Exposure of Aircraft Crew", jointly prepared by the International Commission on Radiation Units and Measurements (ICRU) and ICRP, is in press and will be published as an ICRU report by Oxford University Press.

Table 1. ICRP Publication to Date since the 2007 Recommendations of ICRP.

ICRP Publication	Title	Ann. ICRP Volume and Issue
104	Scope of Radiological Protection Control Measures	37 (5)
105	Radiological Protection in Medicine	37 (6)
106	Radiation Dose to Patients from Radiopharmaceuticals	38 (1-2)
107	Nuclear Decay Data for Dosimetric Calculations	38 (3)
108	Environmental Protection - the Concept and Use of Reference Animals and Plants	38 (4-6)
109	Application of the Commission's Recommendations for the Protection of People in Emergency Exposure Situations *	39 (1)
110	Adult Reference Computational Phantoms	39 (2)
In press	Application of the Commission's Recommendations to the Protection of People Living in Long Term Contaminated Areas after a Nuclear Accident or a Radiation Emergency	
In press	Avoidance of Unintended Exposure in Radiotherapy with New Technologies	

* ICRP *Publication 109* also includes the article "The History of ICRP and the Evolution of its Policies" by Clarke and Valentin.

These publications support and further elaborate elements of the system of radiological protection as described in the 2007 Recommendations, and most fall into one of two broad categories: those that elaborate on specific exposure categories (occupational, public and medical) or situations (planned, existing, and emergency), and those that provide detailed technical information necessary for the implementation of the system of radiological protection.

Two that do not fit neatly into this categorisation are ICRP *Publication 104* and ICRP *Publication 108*. They are overarching documents which consider, in principle, all exposure categories and situations.

Recent ICRP Publications Elaborating on Specific Exposure Categories and Situations

One of the first publications following the 2007 Recommendations was ICRP *Publication 105* on Radiological Protection in Medicine. This publication describes the application of the system of radiological protection for medical exposures, an exposure category quite different from occupational and public exposures by virtue of the fact that most of the time, most of the benefit and the detriment apply to a single individual: the patient. In the other two exposure categories, typically one group receives most of the detriment (e.g. the workers in a facility), while another group receives most of the benefit (e.g. the public at large receiving electrical power).

Two publications each examine one of the three exposure situations: ICRP *Publication 109* examines emergency exposure situations, and the ICRP publication in press "Application of the Commission's Recommendations to the Protection of People Living in Long Term Contaminated Areas after a Nuclear Accident or a Radiation Emergency" examines the system of radiological protection as applied to existing exposure situations.

These three publications elaborate upon the system of radiological protection as applied in most circumstances. The first covers medical exposures which occur, by definition, only within planned exposure situations. The second covers occupational and public exposures in emergency situations. The third covers public exposures in existing exposure situations, which ICRP considers as the only valid exposure category in that exposure situation. The exposures not within the scope of these three documents are occupational and public exposures in planned exposure situations.

As well, the ICRP Publication in press "Avoidance of Unintended Exposure in Radiotherapy with New Technologies" further elaborates on aspects of radiological protection with respect to medical exposures, focusing specifically on the use of certain new radiotherapy technologies.

Recent ICRP Publications Providing Supporting Information

Within this category is a recent publication specific to radiological protection in medicine. ICRP *Publication 106* is the third amendment to ICRP *Publication 53*, Radiation Dose to Patients from Radiopharmaceuticals. This is part of ongoing work to provide up-to-date biokinetic and dosimetric models for radiopharmaceuticals along with tabulated results giving absorbed doses to the various organs over time per unit activity administered.

Also within this category are two recent publications related to the calculation of protection quantities. Although the concepts of effective and equivalent dose have not changed in the 2007 Recommendations of ICRP, the methods and some of the parameters used to calculate these protection quantities have been updated. Revised radiation and tissue weighting factors were published in the 2007 Recommendations. In addition, the 2007 Recommendations specified that doses should now be calculated using voxel (volume element) phantoms. ICRP *Publication 110* provides the first of these voxel phantoms: those for the reference adult male and female. ICRP *Publication 107* provides updated nuclear decay data for dosimetric calculations, replacing ICRP *Publication 38*, Radionuclide Transformations: Energy and Intensity of Emissions. These publications are necessary steps towards developing dose conversion coefficients compatible with the full implementation of the 2007 Recommendations.

ICRP *Publication 104*: Scope of Radiological Protection Control Measures

In principle the system of radiological protection applies to all exposures to ionizing radiation. However, in practice the measures undertaken to control these exposures must be limited based on practical considerations. ICRP *Publication 104* discusses the scope of radiological protection control measures, and describes certain tools (e.g. exemption, exclusion and clearance) that can be used to manage the scope.

ICRP *Publication 108*: Environmental Protection – the Concept and Use of Reference Animals and Plants

In the past, ICRP concerned itself with the environment primarily with regard to the transfer of radionuclides through it because this directly affects the radiological protection of human beings. In the 1990 Recommendations ICRP stated that "the standard of environmental control needed to protect man ... will ensure that other species are not put at risk. Occasionally, individual members of non-human species might be harmed, but not to the extent of endangering whole species or creating imbalance between species."

However, in its 2007 Recommendations, ICRP acknowledges that that it is now necessary to demonstrate, directly and explicitly, that the environment is being protected. Therefore, it is necessary to develop a clearer framework to assess the relationships between exposure and dose, and between dose and effect, and the consequences of such effects, for non-human species, on a common scientific basis.

To this end, ICRP *Publication 108* sets out some high-level ambitions with regard to environmental protection. To aid in demonstrating whether these ambitions are being achieved, and help optimise the level of effort that might be expended on environmental protection, and ICRP has developed a set of Reference Animals and Plants (RAPs) and derived consideration reference levels (DCRLs). ICRP does not propose the application of dose limits to Reference Animals and Plants.

Current Initiatives and Future Work

The current plan of work for ICRP includes initiatives in several areas. Of significant interest is work on elaborating on the application of the system of radiological protection for radon. ICRP is also continuing efforts to: examine emerging scientific results on radiation effects and how they may impact the system of radiological protection; support calculation of protection quantities (effective and equivalent dose) in accordance with the 2007 Recommendations; and further elaborate on the system of radiological protection in medicine, other specific circumstances, and with respect to protection of the environment.

Radon

In November 2009 ICRP issued a Statement on Radon. The intention is to publish this Statement in the Annals of the ICRP with an accompanying report on assessment of lung cancer risk from radon, after undertaking a public consultation on the two documents together.

The statement reaffirms that, for planned exposure situations, any workers' exposure to radon incurred as a result of their work, however small, shall be considered as occupational exposure. Paragraph 178 of ICRP *Publication 103* defines occupational exposure is as all radiation exposure of workers incurred as a result of their work. It is noted the conventional definition of occupational exposure to any hazardous agent includes all exposures at work, regardless of their source. However, because of the ubiquity of radiation, the direct application of this definition to radiation would mean that all workers should be subject to a regime of radiological protection. Therefore the use of 'occupational exposures' is limited to radiation exposures incurred at work as a result of situations that can reasonably be regarded as being the responsibility of the operating management.

The statement, which will be supported by an accompanying report on assessment of lung cancer risk from radon, introduces a new recommended detriment-adjusted nominal risk coefficient for a population of all ages of 8×10^{-10} per Bq h m^{-3} for exposure to radon-222 gas in equilibrium with its progeny (i.e. 5×10^{-4} WLM^{-1}). The statement notes that this is consistent with other comprehensive estimates including that submitted to the United Nations General Assembly by UNSCEAR.

In addition, ICRP is working on a publication which will provide more specific recommendations for applying the system of radiological protection to radon exposure in various circumstances.

Radiation Effects

The system of radiological protection is based both on science (primarily what is known about the effects of radiation exposure) and value judgements. Therefore, a key component of the work of ICRP is staying current on the latest scientific findings on radiation effects, in particular to evaluate how they might influence the system of radiological protection. Work on assessing the lung cancer risk from radon has already been mentioned. This is only one part of an effort to review the state of knowledge of the health effects of exposure to alpha radiation. Two other groups within ICRP are also examining stem cell biology in relation to radiation effects, and tissue reactions and other non-cancer effects of radiation. The latter group is most interested in effects on the lens of the eye (where evidence seems to point to a threshold for radiation induced cataracts much lower than previously thought), and cardio-vascular effects (which are well documented at doses generally only important for patients undergoing radiation therapy, but for which there may be some emerging evidence of effects at doses approaching the upper end of the occupational dose limits).

Dose Calculation

As mentioned previously the system of radiological protection now recommends that effective and equivalent dose be calculated using more up-to-date radiation and tissue weighting factors, and using voxel (volume element) phantoms. In addition ICRP *Publication 107* provides new radionuclide transformation data, and there are relatively recent modifications to biokinetic models to be taken into account.

ICRP *Publication 110* provides the first voxel phantoms (for the reference adult male and female), but much work remains to develop similar voxel phantoms for paediatric, foetal, and pregnant female voxel phantoms. These phantoms, along with other factors, will then be used to calculate dose coefficients for external and internal exposure for workers and the public.

Radiological Protection in Medicine

When ICRP was created more than eighty years ago, the focus was on radiological protection of medical practitioners and researchers. Today ICRP still has a focus on radiological protection in medicine, and continues to provide recommendations on protection of practitioners, but radiological protection of patients has become a significant issue. Over the last decade this emphasis on radiological protection of patients has grown considerably given the rapid increases in worldwide patient doses from medical imaging.

Currently under way within ICRP are efforts related to the radiological protection of both patients and practitioners related to fluoroscopically guided procedures, including a specific report aimed at cardiologists. Another effort is related to radiological protection in paediatric diagnostic radiology.

ICRP is also working on recommendations on radiological protection education and training for healthcare staff and students, and recommendations that take into account consideration of the possibility of secondary cancers related to some modern radiotherapy techniques.

Further Elaboration of the System of radiological protection

Having broadly described on the system of radiological protection in ICRP *Publication 103*, and elaborated on some general circumstances of exposure in ICRP *Publication 105*, ICRP *Publication 109*, and the ICRP publication in press titled "Application of the Commission's Recommendations to the Protection of People Living in Long Term Contaminated Areas after a Nuclear Accident or a Radiation Emergency", ICRP is now planning a series of publications that further elaborate the system of radiological protection in more specific circumstances. These include reports that will focus on radiological protection related to: aircrew and space crew; naturally occurring radioactive materials; geologic waste disposal; deliberate exposure for security and legal requirements; and, the proper use of effective dose.

Radiological Protection of the Environment

As described previously ICRP *Publication 103* formally introduced explicit protection of the environment into the system of radiological protection, and ICRP *Publication 108* set out some high-level ambitions and a set of Reference Animals and Plants (RAPs) and derived consideration reference levels (DCRLs).

Current efforts in this area are focusing on a broader view of how the protection of humans and non-human biota are integrated into the system of radiological protection, and more specific recommendations on dosimetry for RAPs. The latter includes looking at questions related to radiation weighting factors for non-human biota, transfer values in environmental modelling.

Summary and Conclusion

The system of radiological protection described in the 2007 Recommendations (ICRP *Publication 103*) is an evolutionary change from that described in the 1990 Recommendations (ICRP *Publication 60*). This evolution is necessary in order for the system of radiological protection to remain current with respect to our evolving understanding of the relevant scientific findings, and also to continue to reflect current societal norms. For example, the revised radiation and tissue weighting factors reflect updated scientific knowledge, while a greater emphasis on environmental protection reflects a heightened social awareness of the importance of this area. As well, practical application of the system can point out areas for improvement.

However, as the system of radiological protection in general evolves so must the supporting recommendations and tools. As well, the recommendations must continue to take into account novel uses of radiation in medicine and other fields to help ensure an adequate level of safety under all circumstances.

In the five to ten years leading up to publication of the 2007 Recommendations much of the focus of ICRP was on development of this evolutionary update to the system of radiological protection. Barring revolutionary new findings that demand a rapid overhaul of the system, for the next decade or so ICRP will focus on refining and further elaborating the system of radiological protection as set out in 2007, always with an eye on emerging science, evolving social norms, and novel uses of radiation.

The Euratom Programme of Research and Training on Low Doses of Radiation

Jouve, André
European Commission, Directorate General for Research, Directorate J Energy (Euratom) Unit J2 Fission, Brussels, BELGIUM

Abstract
The Euratom programme of research and training on the risks associated with low doses of radiation will be closely aligned to priorities identified in the Strategic Research Agenda (SRA) of MELODI and the Transition Research Agenda (TRA) to be implemented through the project DoReMi funded as part of the 7th Euratom Framework Programme. These research agendas are aimed at integrating the European research effort on low dose, at opening this effort to the wider scientific community and at promoting and facilitating the sustainable integration of key research institutions in European Member States.

Introduction
The mandate of the European Commission to promote and support a programme of research and training in this field arises from Title II Chapter 1 of the Euratom Treaty. This Community programme also includes research on the harmful effects of ionising radiation. The aim of the Euratom Treaty is to promote the safe development of the peaceful use of nuclear energy. However, owing to the link with emission of ionising radiation and the exposure of workers and the public, this development cannot be sustainable without answering the legitimate questions of European citizens on the associated risks. In this regard, low and protracted exposures in the range of 0.1-1 Sv could be expected, but this range of exposures is even more likely to occur during the use of radiation for medical applications, in particular computed tomography. Low doses to normal tissues are also incurred during radiation therapy as a result of exposure to scattered radiation from the main field.

Strategic Research Agendas
The Euratom Framework Programme supported the work of the High Level and Expert Group (HLEG) in 2008 to set-up a Strategic Research Agenda (SRA) on low doses. This agenda promotes the sustainable integration of the research effort of organisations in European Member States, and the European Commission is contributing by providing Framework Programme financial support. This SRA will be the initial deliverable of the "Multidisciplinary European Low Dose Initiative" (MELODI) set up

by the HLEG. Composed so far of 9 European research organisations, MELODI is about to adopt a legal statute which will formalise its existence and allow its involvement in decision making on research strategies on low doses of radiation in Europe. Though it will be some time before the initiative becomes fully operational, this legal process is important to enable sustainability over the long term (20 years). Therefore, in the meantime, the European Commission supports research aimed at ensuring the Transition Research Agenda (TRA). The primary issues to be addressed by the TRA are the identification of priority proposals to be submitted following the Euratom Framework Programme calls in 2011 and 2012. In establishing the TRA, current and recent research findings will be evaluated in order to identify future priorities. This TRA is also, so far, being implemented through the 7th Euratom Framework Programme project DoReMi. More Euratom projects are expected to support the TRA in the future.

Challenge

The field of radiation protection and low dose in particular is a small world. Clear links are already established with other fields of research, especially the medical area. These links are beneficial for both Euratom and medical research. Indeed, through its long history of support to research in this field, which has led to a large number of excellent scientific publications, the Euratom programme contributes to advances in general understanding of the mechanisms of cancer induction and progression. This knowledge is now expanding to other health conditions such as cardiovascular disease. Similarly, the medical sector brings to the table its invaluable cohorts of exposed patients as part of imaging or radiotherapy protocols; these exposures are increasingly well recorded and contain reliable biological parameters. However, more efforts are needed to expand the synergy with other research fields. In particular, more and more knowledge is expected to be gained from the identification of gene expression, protein synthesis and their feedback on the gene expression, which are among the effects observed after exposure to ionising radiation. At low doses of radiation, the statistical power of epidemiology becomes less evident and needs to be substantiated by the observation of identified biochemical processes. Most of the other disciplines in the health sector are using similar approaches and similar tools. It is therefore time to carefully identify the synergies that can help Euratom to make the significant breakthroughs needed in the quantification of the risks arising from low doses of radiation and to open the radiation protection community to the wider scientific community.

In doing so, Euratom will attract new talents to radiation protection and this will also contribute to fulfilling the mandate from article 4 or the Euratom Treaty to develop training in this field. In this regard, Euratom research projects are not intended as a means to finance fellowships per se, rather they offer the possibility to engage graduate researchers in the research activities covered by a Euratom grant. The European Commission recommends that at least 5% of the overall budget of research projects is dedicated to such training activities.

Opening to the wider scientific community is also supported through large research projects such as DoReMi, which is a 6-year project with a total budget of €21M (of which €13M is from the Euratom programme). A significant part of this budget is foreseen for imbedded calls for proposals open to scientific teams which are not yet part of the project consortium. Such a provision is expected to give flexibility to the research, which is likely to need competences that may not necessarily be available among the teams at the origin of the project, in order to address specific issues in the strategic agenda. This also demonstrates that large projects such as DoReMi, which are crucial in terms integration of research, visibility, optimisation of management resources and follow-up, are also making funding available to a wider community than is represented simply by the actual project consortium.

Conclusions

The SRA of MELODI and the TRA of DoReMi will provide crucial orientations for the Euratom programme of research and training on low doses of radiation. This approach is in line with the overall strategy of the Euratom Framework Programme in the area of fission and radiation protection, which is also becoming more closely aligned with the two other SRAs, one drawn up for research in nuclear safety and technology by the Sustainable Nuclear Energy Technology Platform (SNE-TP) and the other being established by the Implementing Geological Disposal Technology Platform (IGD-TP). With this strategy, the European Commission relies on the key nuclear research and industrial organisations in Europe to establish strategic priorities and ways of collaborating to implement agreed agendas. This in turn commits Member States' national research funding and thereby contributes to the joint programming with the Community in priority areas, such as energy research. The success of this strategy relies on the endorsement by the key players of a common vision for the future, their commitment to realising this vision through an agreed strategic research agenda, and the openness towards the wider scientific community and other socio-political stakeholders.
